Principles and Practice of
Geriatric Medicine

Fourth Edition

Volume 2

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

In memory of my wife, Norma Mary, for her enduring support and encouragement and to my children, Aidan, Anne, Sarah, Helen and Damian for graciously accepting the limitations of my time.

- M.S. John Pathy

In loving memory of my parents, to whom I owe so much, and to my wife, Caroline, for her unflinching support throughout these last two years during the preparation of this textbook.

- Alan J. Sinclair

To all my older friends and patients who have taught me geriatrics, to my wife Pat and my children Robert, Sue and Jacqueline who have supported me throughout my career and to my grandchildren Amanda, Conor, Katelyn, Nicole and Paige who are my eternal joy and my hope for the future of elder care.

- John E. Morley

Preface

"I offer no apology for the publication of this volume. The subject is one of the highest importance, and yet it has been strangely overlooked during the last half-century by the physicians of all countries."

-George Edward Day
(1815–1872)

George Day's introduction to his textbook *Disease of Advanced Life*, published in 1848, regrettably remains appropriate for textbooks published over 150 years later. Modern physicians can still fail to recognize the differences in disease presentation and management between middle-aged and older adults. It is our hope that this Fourth Edition of "Principles and Practice of Geriatric Medicine" will help increase the awareness of geriatric principles and improve the treatment of older individuals. John Pathy's original vision for the first edition was to provide, in a single volume, a comprehensive reference source for all those involved in the medicine of old age. We have endeavored to adhere to this vision, but inevitably the size of the textbook has grown. While in any text of this size some overlap with general texts of medicine will occur, the emphasis is on those assessments and disorders that are particularly of relevance to older persons.

Over the seven years since the last edition of this text was published, there have been dramatic advances in our understanding of the pathophysiology of disease as it interacts with the physiological processes of aging. There has been a continuing validation of assessment tools for older persons and the development of some new ones. Large-scale studies of the efficacy of various geriatric systems such as Acute Care for the Elderly Units, Geriatric Evaluation and Management Units, and Home Care Systems have been carried out. All of these have demonstrated the value and cost-effectiveness of the geriatric specialist approach to managing older people. In comparison, most studies assessing Coronary Care Units and Intensive Care Units have failed to come close to demonstrating the effectiveness that has been shown for geriatric units. Despite this, all major hospitals have highly expensive critical care units, while fewer have developed geriatric units. The last decade has also seen an increased awareness of the need to enhance the quality of long-term care. This increase in geriatric knowledge has been recognized by the addition of nearly 40 new chapters in this edition. In addition, many of the previous chapters have been totally rewritten to allow the recognition of the changes that have occurred in our understanding of the care of older persons.

Previous editions of this textbook were edited by a single person, John Pathy. With the rapid increase in geriatric knowledge and John's desire for the Fourth Edition to reflect the input of other academic minds, he has added two new editors to share the burden with him, namely, Alan Sinclair and John Morley. This has allowed a more even distribution of the editing tasks, though John Pathy has continued to carry the lion's share. In recognition of the globalization of the world, in general, and geriatrics, in particular, one of the new editors, John Morley, is from the United States, while Alan Sinclair draws on his European experiences. In addition, a major effort has been made at the end of the text to recognize the differences (as well as the similarities) of geriatrics as it is practiced around the world. The enormous good fortune the editors had in recruiting a stellar class of contributors from around the world has, we hope, allowed this text to be truly representative of a global view of geriatric medicine. From the beginning, John Pathy has made this a goal of his text, and the editors feel that this edition has truly achieved an international view of old-age medicine as originally developed by Marjorie Warren and her colleagues in the United Kingdom.

The general outline of the text still follows that of the first edition. The first sections provide a general perspective of old age, the processes of aging, and social and community perspectives. The chapter on preventive medicine now focuses on issues of particular importance to older persons. In Part III "Medicine in Old Age", the section "Eating Disorders and Nutritional Health" has been increased to recognize the increased importance and understanding of nutrition in old age. Chapters on frailty, sarcopenia, palliative care, and women's health have been added to recognize the increasing importance of these issues in older persons. The final part on "Health Care Systems" focuses first on the emergence of continuous quality improvement, geriatric systems and evidence-based medicine as the foundation of high-quality geriatric medicine. The development of novel education systems is discussed. Finally, unique aspects of geriatric care around the world are examined.

In an attempt to improve the readability of the text, we have asked the authors to make liberal use of tables and figures, and key points have been added at the end of each chapter. References have been limited, and at the beginning of the reference list, authors identify a few key references to allow for further reading. The new editors have tried to keep the easy reading style of the previous editions, but, as can be

imagined, this has been a difficult task as we have increased the number of contributors from around the world.

Overall, we hope our readers enjoy and learn from this textbook; for the three of us, it has been a true labor of love. We particularly would like to thank our contributors for the excellent job they have done. We would also like to thank Layla Paggetti from John Wiley & Sons for her tireless efforts in making sure this book came to fruition. Finally, we would like to thank our families for their forbearance. This book is dedicated to all those who care for older persons.

M.S. John Pathy, Alan J. Sinclair, John E. Morley
December 2005

Preface to the Third Edition

With an increasingly aging population in both the industrialized and developing world, the health care needs of older people can no longer be dismissed by society.

A national provision for geriatric medical services was initially a British phenomenon that was later adopted by other European nations. On the other hand, the USA has long been at the forefront of much gerontological research. During the past decade, however, clinical practice and teaching in geriatric medicine has also moved forward at a phenomenal pace. The balance in this new edition reflects and emphasizes these changes.

Those familiar with the previous editions will note that this edition has been published as a two volume set. This has been necessitated by the addition of 27 new chapters and the reorganization of and increase in the number of clinical chapters. The original objective of providing an authoritative text on the medicine of old age has been maintained thanks to the distinguished panel of nearly 200 international contributors.

It is with deepest regret that I record the deaths of Professor Verna Wright and Professor Frank Benson.

Dr John Morris, Dr Arup Banergee and Dr Brian Williams have generously provided editorial advice on the gastroenterology, haematology and cardiology sections respectively.

The sustained support of Michael Osuch and Lewis Derrick of John Wiley & Sons is gratefully acknowledged.

It is hoped that these two volumes will encourage and inform all those whose clinical practice brings them into contact with elderly patients.

Preface to the Second Edition

In this new edition my priority was not only to revise and update, but to reorganize and restructure to make the information as accessible and useful to the reader as possible. The result is that not only have we included some 45 distinguished new contributors, and indeed several entirely new topics, but about 50% of the book has been rewritten almost from scratch, with the remainder heavily revised and updated, and the entire content radically reorganized into what I believe is a more practical and logical format. New subjects now considered to be at the forefront of practice, and some published here for the first time, are covered, and I am delighted to welcome the following group of new authors:

Professor D. Armstrong, Dr C.A. Bar, Dr W.H. Barker, Dr A.J. Bayer, Professor M. Bergman, Dr E.T. Bloom, Dr D.G. Clements, Dr K.J. Collins, Dr I.G. Finlay, Dr P. Finucane, Dr C. Freer, Dr S.R. Gambert, Professor A.M. Gelb, Ms J.E. Griffiths, Dr J.T. Hartford, Ms A.E. Helfand, Dr S.J. James, Mr D.F. Jessett, Dr R.A. Kane, Professor H. Katsunuma, Professor H. Kesteloot, Dr J. Lubinski, Dr L.M. Luxon, Professor W.J. Maclennan, Dr S.S. McCachren, Professor J.F. Macias-Nunez, Dr S.E. Mathers, Dr K. Morgan, Dr J.G. O'Brien, Dr M.E. Piper, Dr J. Powell, Ms H.G. Prince, Dr T. Pullar, Dr D.S. Rosenthal, Dr H.R. Silberman, Dr I.C. Stewart, Dr R. Strong, Professor M. Swash, Professor C.G. Swift, Professor W.A. Wallace, Dr M.F. Wilkins, Dr W.G. Wood, Dr A.M. Woods, Professor V. Wright.

It is with deepest regret, however, that I must record the death of three contributors:

Professor A.N. Exton-Smith, Dr R.A. Griffiths and Sir Alan Parks.

I express my sincere appreciation to Dr A.J. Bayer for his invaluable assistance with some of the chapters, to my secretary, Mrs Shirley Green, for her meticulous typing, checking of references and collating material, and to the Department of Medical Illustration, University of Wales College of Medicine, for undertaking the additional illustrations for the revised chapter on rehabilitation in the elderly. It is a pleasure to acknowledge the high standard of general editorial services provided by Dr Lewis Derrick, Desk Editor, and the continuing support of Mrs Verity Waite, Publishing Editor in Medicine, John Wiley & Sons.

Preface to the First Edition

In some parts of the world, notably Europe, North America and Japan, the impact of an expanding elderly population resulting from an era of unprecedented reduction in the diseases of early life has already had a dramatic effect on the epidemiology of disease. Within the foreseeable future no nation will escape a similar increase in the number of its elderly citizens with similar changes in the disease profile of its society. In the developed industrial nations Governments and medical schools, recognizing this phenomenon, are increasingly encouraging teaching and research in the medicine of later life. The objective of this textbook, written by authors of international repute, is to provide in a single volume a comprehensive reference source for all who are involved in the medicine of old age. Some overlap with textbooks of general medicine is inevitable but appropriate emphasis and attention is given to those disorders which are of particular relevance to the elderly.

Whilst this is primarily a clinical textbook, an account is given of the fundamental changes associated with aging which are so inextricably interlinked with diseases that their study is essential to our understanding and management of elderly sick and disabled people.

Equally important for those treating and caring for the old is an understanding of the influence, for good or ill, of the social environment within which the elderly have to function and its effect on their health.

Knowledge of programmes aimed at the promotion and maintenance of health, early detection of its impending breakdown and the organization and provision of services for health care are additional essential components of a complete account of the medicine of old age.

The early chapters of the book provide a general perspective of old age and the process of aging. Preventive aspects together with accounts of nutrition and sleep in the elderly and the interpretation of biochemical data in older patients, precede the main clinical section which occupies the greater part of the text. The later chapters cover rehabilitation, the management of the dying patient and aspects of the delivery of health care.

I acknowledge with gratitude the willing help of my colleagues, Dr Deirdre Hine and Dr D. Gwyn Seymour who read through much of the text and provided valuable criticisms and suggestions; and to my secretaries Mrs Lorraine Spriggs who did much of the typing and the arduous task of checking references, and Mrs Sylvia Bevan. I am indebted to Dr Ralph Marshall and his team in the Department of Medical Illustration at the University Hospital of Wales for preparing a number of figures and photographs.

Historical Perspectives

Michael J. Denham

Wellcome Trust Centre for the History of Medicine at UCL, London, UK

INTRODUCTION

The broad subject of old age has attracted the attention of writers and philosophers for many centuries. It contains the interrelated topics of the theories of aging, of how to increase longevity, and the medical management of sick elderly people. Initially, the first two themes attracted most attention. It was not until the twentieth century that literature relating to medical care came to the fore. This chapter concentrates on the twentieth-century developments in medical care of the elderly (geriatric medicine), mainly from a British perspective since much of the pioneering work was carried out in the United Kingdom.

THE EARLIER WRITERS ON OLD AGE

Early writers such as Hippocrates, Cicero, Galen, Roger Bacon, and Francis Bacon discussed old age in general terms pointing to features such as skin changes, reduction in physical strength, and deteriorating memory, sight, and hearing. None were sure of the cause(s) of old age. Theories ranged from incorrect diet, loss of heat to loss of moisture. Although the basis of growing old was unclear, several philosophers thought that a healthy old age could be promoted by keeping active, eating sensibly, and exercising regularly.

Later, British writers of the eighteenth and nineteenth centuries, such as Sir John Floyer, Sir John Hill, Sir Anthony Carlisle, Professor George Day, and Sir John Sinclair, wrote about old age and how life might be prolonged, but devoted limited attention to medical management of disease in older people. They generally considered it impossible to turn an elderly man into a young person, but agreed that much could be done to make later life healthy. Lifestyle was important. They recommended wise eating of easily digestible foods taken at regular intervals, exercising regularly, ensuring good sleep, keeping clean, wearing warm clothing, and avoiding constipation. In 1863, Dr Daniel Maclachlan, medical superintendent at the Royal Hospital Chelsea, criticized the lack of English literature relating to old age and pointed out that precise diagnosis could be difficult in older people because several diseases could exist simultaneously. In 1882, the English translation of Jean Martin Charcot's *Clinical Lectures of the Diseases of Old Age* was published, which described an extensive range of subjects including the overt signs of old age, rheumatism, gout, arthritis, fever and its feeble response in older people, respiratory infections, cerebral hemorrhage, and cerebral softening. However, his contribution to treatment and management was limited. The early twentieth-century English writers such as Sir Henry Weber, Dr Robert Saundby, G. Stanley Hall and Sir Humphry Rolleston continued to describe old age, but again medical management received little attention. Maurice Ernest's writing in 1938 pointed out that until the nineteenth century only superficial knowledge existed of how the body worked.

THE BIRTH OF MODERN GERIATRIC MEDICINE

Modern geriatric medicine commenced in the United States. Although American writers in the nineteenth century, such as Dr Benjamin Rush, had published on the subject of old age, the real impetus for advance came later when a young medical student, Ignatz Nascher (1863–1944), an immigrant to America from Vienna, was taken to an almshouse to see some interesting cases. An old woman hobbled up to the medical teacher with a complaint. The class was told that she was suffering from old age and that nothing can be done for her. This remark impressed him so strongly that after qualification he took up the study of the diseases of old age. His lifetime work on the subject resulted in his becoming known as the "father of geriatric medicine". His publication of *Geriatrics* in 1916 was followed by others including Dr Malford Thewlis, who published the first edition of his book, *Geriatrics,* in 1919; Dr Edmund Cowdry's whose *Problems of Aging* appeared in 1939; and

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Dr Alfred Worcester who published a series of lectures in 1940 called *The Care of the Aged, the Dying, and the Dead.* Dr Nathaniel Shock, in 1951, published the first edition of his classification of geriatrics and gerontology but pointed to the scarcity of material. In 1942 the American Geriatrics Society was formed with a membership of physicians, while in 1945 the Gerontological Society of America was created with a multidisciplinary membership. Each of the societies produced its own journal in 1946. Unfortunately, this momentum for change was not sustained, partly because physicians saw little attraction in the subject. Interest was not reignited until the 1960s when Medicare and Medicaid were introduced.

Thus it was that leadership and instruction in modern geriatric medicine in the postwar era passed to the United Kingdom (UK), where the achievements of a handful of pioneers were becoming known.

BRITISH DEVELOPMENTS

Health care in the United Kingdom goes back to that provided by the monasteries until they were dissolved in 1536. After the dissolution many of the aged and infirm, who could not be managed at home with the help of family members, were left uncared for. The Poor Law Relief Act of 1601 attempted to remedy these problems. Parishes levied a rate on all occupiers of property to provide work for the unemployed and accommodation for the lame, old, and blind. Workhouses were built for these purposes, but were made as unpleasant as possible to discourage people from entering them. Infirmaries were established to look after sick inmates of the workhouses. Outdoor relief was available for the poor but this was curtailed in 1832.

Hospitals did not become central to health care until the nineteenth–twentieth centuries, by which time two different types of hospitals were evolving: the voluntary hospitals and the workhouse/municipal infirmaries (Abel-Smith, 1964). Voluntary hospitals, some of which dated back to the tenth century, were financed from endowments, subscriptions, fees, and fund raising. They had a high reputation with good nursing and medical staff, and acted as a base for clinical teaching of medical students. They were reluctant to admit the chronic sick fearing that their beds could become blocked because these patients were slower in improving and there could be social problems preventing their discharge. An important consequence was that medical students rarely saw them and, therefore, were not taught about the diseases of old age or how to manage the mixture of medical and social problems they would meet after qualification.

Workhouse infirmaries were funded by local rates. They gradually became long-stay institutions for the chronic sick. Examples of unsatisfactory conditions and poor care in workhouses and infirmaries surfaced in the 1860s and resulted in visits by the *Lancet* commissioners and the inspectors of the Poor Law Board. The 1869 report of the *Lancet* Sanitary Commission was damning, stating "The fate of the "infirm" inmates of crowded workhouses is lamentable in the extreme; they lead a life which would be like that of a vegetable, were it not that it preserves the doubtful privilege of sensibility to pain and mental misery" (Anonymous, 1869).

In 1929 the Local Government Act came into force, which aimed to correct the existing bipartite system of health care of "one part for the pauper and the other part for the nonpauper". However, Charles Webster concluded that health services between the two world wars were ramshackle and uncoordinated, with hostility between sections of the service, increasingly chaotic funding, and with a hospital service which was unevenly distributed and limited in rural areas (Webster, 1993).

Further reform came in 1948 with the creation of the National Health Service (NHS) which rearranged British health care into a tripartite system. First, there was the hospital service which was formed by the nationalization of 1143 voluntary and 1545 municipal hospitals. It became the dominant partner in the Service. Second, there were the general practitioner and the ophthalmic, pharmaceutical, and dental services. The third arm, which was managed by the local authorities, included health centers, health visitors, and ambulance services. Their immensely valuable home help and meals-on-wheel services did not really "take off" until some years later. Importantly, health care for all became free of charge.

Voluntary and charitable organizations made important contributions to the care of the older person and research into old age. In 1943 the Nuffield Foundation was created, one of whose objectives was the care of the aged and the poor. This support led to the formation of the National Corporation for the Care of Old People in 1947. The Foundation also stimulated major research into the causes of old age (Gerontology). These moves to assist older people became increasingly important as the proportion of older people in the population steadily increased. In 1841, the over-65-year-old people comprised 4.5% of the population, which rose to 4.7% in 1901, 7.8% by 1921, 9.6% by 1931 and reached 10.5% in 1947.

AN OVERVIEW OF EARLY GERIATRIC MEDICINE IN THE UNITED KINGDOM

Modern geriatric medicine in the United Kingdom dates from 1926 when Dr Marjory Warren was appointed to the West Middlesex Hospital, where her interests were initially surgical. However, in 1935 the Hospital took over control of the adjacent old Poor Law institution and Warren was put in charge of 874 patients. The situation she found was described in the first of her many articles on the modern treatment of the chronic sick (Warren, 1943). At about the same time, three other British doctors were also keen to improve the medical care of the elderly: Dr Eric Brooke, Mr Lionel Cosin, and Dr Trevor Howell. Like her, they, too, applied classification, diagnosis, and treatment to their elderly patients, which had been previously missing. After the war, a further wave of

enthusiasts, such as Lord Amulree, Drs John Agate, Charles Andrews, Ferguson Anderson (later Professor), Bill Davison, Hugo Droller, Norman Exton-Smith (later Professor), Tom Wilson, and Lyn Woodford-Williams, began to make their mark with many publications.

These newly appointed postwar consultants in geriatric medicine had to embark on a steep learning curve. In the early days, they had the responsibility for very large numbers of inpatients, sometimes many hundreds, who were often kept in bed for no discernable medical reason, which could ultimately lead to a totally bedridden state. Generally there was a massive waiting list for admission, often precipitated by the death or illness of the carer or the person's inability to prepare meals for him/herself. These new consultants learnt that illness and the presentation of disease in the older person differed from that of younger people, that more time was required to recover, that prescribing drug therapy required great care, that extensive teamwork was needed for successful rehabilitation, and that local social service support was usually essential to provide alternative accommodation or domiciliary support services. They had to provide a service although they lacked adequate resources and staffs, had poor ward accommodation, inadequate investigative/treatment facilities, and were not always based on the main hospital site. They had to fight antagonism and resistance from their fellow consultants and some hospital management committees. One chairman of such a committee refused a consultant geriatrician the use of empty beds in general medical wards: "Over my dead body", he said. When he died the geriatrician got the beds. Another consultant had to fight for proper washing facilities in the wards and for curtains to be placed around the beds of elderly patients. Yet others had to struggle to get heating installed in the wards and repairs made to the leaking ward roofs.

Important studies of the elderly living at home or in residential homes appeared shortly after the war. Dr Joseph Sheldon, a general physician, published *The Social Medicine of Old Age* in 1948, which was the result of his research into the health of the elderly living in the community in Wolverhampton. In 1955, Professor William Hobson and Dr John Pemberton published *The Health of the Elderly at Home,* which was a study of older people living at home in Sheffield. In 1962, Professor Peter Townsend published *The Last Refuge*, a seminal study of old people living in residential homes.

The British Ministry of Health, which was created in 1919, and its medical officers supported the newly emerging style of medical care of the sick elderly patient with official circulars, memoranda, meetings, and documents. These highlighted its firm belief in modern management of elderly patients and the drive to establish a geriatric unit in every health district. The ministry organized surveys of hospitals in England and Wales, which were to be the basis of the forthcoming NHS. The reports, published in 1945, were generally very critical of services and accommodation for the chronic sick. "The worst and oldest buildings were set aside for the chronic sick" (Jones *et al.*, 1945). "The buildings are old, dark, devoid of modern sanitary conveniences, death traps in the case of "fire", and unfit for the nursing of the chronic sick" (Bevers *et al.*, 1945). "The first essential is that every patient should be thoroughly examined and treated with a view to restoring a maximum degree of activity" (Gray and Topping, 1945). Later, Lord Amulree and Dr Edwin Sturdee, both medical officers of the Ministry, presented a paper on the care of the chronic sick to the Parliamentary Medical Committee in 1946 (Amulree and Sturdee, 1946). In it they stated, "not only is the problem of the treatment of the chronic sick not being met, but also most people do not realize there is a problem". In 1957, Dr Christopher Boucher, a Principal Medical Officer at the Ministry, published the result of an important survey of services available to the chronic sick and elderly (Boucher, 1957). However, the ministry realized that it could not force change, but could only use persuasion to improve proper medical services for older people (Godber, 1991). Perhaps this was why that, even in 1978, 42 health districts in England still lacked geriatric beds in general hospitals.

The British Medical Association played its part in planning the medical care of older people with a series of very specific reports. A coordinated geriatric service was recommended to the newly created Regional Health Authorities, supported by a wide range of domiciliary services, which would be needed by the infirm elderly to enable them to stay at home for as long as possible (British Medical Association, 1947, 1948, 1955).

However, commentators looked back to the old Poor Law and the new NHS with mixed feelings (Webster 1988, 1991; Thane 1993, 2000). They pointed out that while the old Poor Law system had given a coordinated personal service to its clients, the tripartite structure of the NHS service led to lack of cooperation and coordination between the arms of the service. Chronic and mental services received a smaller share of capital and revenue, and clear guidelines for the treatment of old people were lacking. The political will to produce a nationwide effective geriatric service was lacking. On the other hand, the new service did provide the less well off with forms of care to which previously they had only limited entrée, and the elderly now had access to consultant services.

THE EARLY PIONEERS IN GERIATRIC MEDICINE

In 1935, *Dr Marjory Winsome Warren*, CBE, MB (1897–1960), was placed in charge of 874 patients from the adjacent Public Assistance Institution. These included 16 maternity patients and about 144 "mental observation" patients, who were subsequently transferred to their appropriate departments. She assessed and examined the remainder. She described the situation as follows:

> Having lost all hope of recovery, with the knowledge that independence has gone, and with a feeling of helplessness and frustration, the patient rapidly loses morale and self respect and develops an apathetic. . .temperament, which leads to laziness and faulty habits, with or without incontinence. Lack of interest in the surroundings,

confinement to bed. . .soon produces pressure sores. . .inevitable loss of muscle tone make for a completely bedridden state. . .[leading to] disuse atrophy of the lower limbs, with postural deformities, stiffness of joints, and contractures. . .in this miserable state, dull, apathetic, helpless, and hopeless, life lingers on, sometimes for years.

(Warren, 1946)

She criticized the medical profession: "It is surprising that [it] has been so long awakening to its responsibilities towards the chronic sick and aged, and that the country at large should have been content to do so little for this section of the community" (Warren, 1946).

She recognized the importance of the environment in helping patients recover. She improved ward lighting, arranged repainting of the wards from the previous drab color to cream, replaced old-fashioned beds, provided modern bedside lockers, bed tables, and headphones, as well as bright red top blankets, light colored bedspreads, and patterned screen curtains. Wards were equipped with handrails attached to the walls, and suitable armchairs provided. Floors were no longer highly polished and steps were avoided. Special chairs and walking sticks and frames were provided for arthritic and heart patients. Some equipment she designed herself is still used today. She was the first British geriatrician to publish admission, death, and discharge data. By 1948, Warren reported that the general medical staff acknowledged that their "chronic" elderly patients actually did better in the geriatric unit than in their own wards.

Mr Lionel Zelick Cosin, FRCS (1910–1993), came from a surgical background to the care of the elderly chronic sick (Cosin, 1991). At the outbreak of war, he was drafted to Orsett Lodge Hospital in Essex, which had been upgraded to an Emergency Medical Service Hospital in 1939. He became responsible for 300 chronic sick patients in addition to his surgical commitments. He found that they were fed and kept clean but no other treatment was given. When ordinary admissions restarted in 1944, he admitted elderly women with fractured femurs, successfully operated on them, gave them rehabilitation, and discharged them home.

In 1950, he was invited to establish a geriatric unit at Cowley Road Hospital in Oxford, where he became its first clinical director and established the first day hospital in the United Kingdom. He classified, diagnosed, and treated his elderly patients. He reorganized inpatient accommodation, creating an acute geriatric ward for investigation, treatment, and physiotherapy as well as a long-stay annex ward for the permanently bedfast, long-stay wards for the frail ambulant, and "residential home" type of accommodation for the more robust patients. These methods resulted in the average length of stay falling from 286 days to 51 days. The proportion remaining in hospital longer than 180 days declined from 20 to 7%. Admissions increased from 200 a year to 1200 through the same number of beds. The average age of the patients increased from 68 to 75 years. Approximately 10% of his patients became permanent bedfast (Cosin, 1956).

Dr Eric Barrington Brooke, FRCP (1896–1957), became the first medical superintendent of newly built, 800 bedded, St Helier Hospital in Carshalton. The building was hit several times by enemy bombs, his superintendent's house was destroyed by a flying bomb in 1944, and he was severely wounded and lost an eye but he returned to duty in due course. In 1953, he was appointed consultant physician to the Southampton group of hospitals.

His approach to his long waiting list for admissions was different from others because he had few hospital beds. He devised a scheme of managing patients at home with a domiciliary "inpatient service" supplemented by increased use of the outpatient department. The process began with a home visit made by a member of the hospital-based geriatric team. These revealed that only one in three of the patients on the list required admission on a short-term basis for investigation and treatment, terminal care, or to provide holiday relief for caring relatives. Where appropriate, he arranged for a coordinated home-based service with district nurses, home helps, domiciliary occupational therapists, a laundry service, and the Red Cross library. The local Women's Voluntary Service set up a hot "meals-on-wheels" domiciliary service. He viewed the general practitioner as the key member of the whole support scheme.

Dr Trevor Henry Howell, FRCP Ed. (1909–1988), first encountered elderly patients when he was a general practitioner before the war. What puzzled him was what represented "normal" for age and what represented disease. After his war service, he established a geriatric research unit at Battersea Hospital in London before becoming medical superintendent at Queen's Hospital, Croydon. He kept meticulous records of his patients, which formed the basis of over 300 papers and four books that he wrote. He kept a handwritten record of every book he read, every patient he saw, and every postmortem held on his patients. Like his colleagues, he firmly supported teaching medical students. He and Sturdee were the driving force behind the creation in 1948 of the Medical Society for the Care of the Elderly, which later became the British Geriatrics Society. Howell was its secretary for many years.

THE SECOND WAVE OF GERIATRICIANS

These were led by *Lord Amulree*, KBE, MD, FRCP (1900–1983), who, prior to his appointment as geriatric physician to University College Hospital and St Pancras Hospital in London in 1949, had worked at the Ministry of Health on aspects of care of the older person. This had brought him in touch with all the early pioneers. His appointment in geriatric medicine was, for a long time, the only one at a London teaching hospital. He and his staff classified, diagnosed, and treated elderly inpatients. Assessment visits were made to old people who were on the waiting list for admission. This ensured either appropriate placement of patients in hospital or that the necessary home support was arranged to enable the person to continue to stay at home. The result was a considerable shortening in the average inpatient length of stay, increased patient/bed turnover, and a reduced the waiting list.

Amulree was unique amongst geriatricians in having a "wide-angled" view of the care of elderly people. This resulted from his experience as a clinician, as a medical officer of the Ministry of Health and a Liberal peer in the House of Lords, where he spoke on matters relevant to the care of the elderly. He wrote extensively and his work included one of the first comprehensive articles on care of the elderly (Amulree, 1951). He is possibly best remembered for his maxim "Adding Life to Years", as well as his stature, wisdom, and willingness to help colleagues. He was President of the British Geriatrics Society for 25 years. When all his achievements are taken into account, there is a case for calling him "the father of British geriatric medicine".

Professor Norman Exton-Smith, CBE, FRCP (1920–1990), was based at the Withington Hospital in London, before moving to University College Hospital and St Pancras Hospital when Lord Amulree retired. Like others he made detailed assessment of his clinical management of sick elderly people. His style of medical management of inpatient care increased patient turnover and reduced their length of stay. He adapted progressive patient care to fit the needs of geriatric medicine. He led and/or encouraged research work, imbuing enthusiasm in his research team, registrars, and colleagues. He established a research unit at St Pancras Hospital and supported work in subjects such as thermoregulation, control of the autonomic nervous system, falls, osteoporosis, osteomalacia, fractures of the femur, nursing of the elderly patient, pressure sores, nutrition of the older person, meals on wheels, terminal care, predicting mortality, and cognitive assessment. He wrote many papers, a substantive textbook on geriatric medicine, and coauthored several books.

Exton-Smith considered the components of an effective geriatric department that included having a sufficient number of beds, both in total and in the District General Hospital; practicing progressive patient care; having adequate medical and nurse staffing; consulting with other consultant colleagues; making home visits; having a day hospital; and having good coordination with primary care and local authority services to produce a successful planned discharge. He thought that approximately half to two-thirds of all geriatric beds should be in the main hospital where the main diagnostic and treatment facilities were based, while the remainder should be in smaller units near the patients' home.

Professor Sir William Ferguson Anderson, OBE, FRCP (Glasgow, Edinburgh, and London), (1914–2001), was a strong advocate on behalf of older people. In 1965, he was appointed David Cargill Professor of Geriatric Medicine in the University of Glasgow. He firmly believed in the speciality as an academic discipline and the need to teach medical students about old age. He took geriatric medicine into the community, notably in Rutherglen, where he established health centers for the elderly. He wrote extensively, and his textbook *Practical Management of the Elderly* went into five editions. He lectured in many countries spreading the message of the achievements of British geriatric medicine, was a visiting professor to many countries, a major advisor to several medical charities for the elderly, and a superb charismatic ambassador for the speciality.

GERIATRIC MEDICINE IN THE HOSPITAL

Home visits were considered essential in the early days of the speciality. They were initiated by the geriatrician to assess patients on the waiting lists from a medical and social point of view, to gauge priority for admission, to ensure that right patients were admitted to the right bed, to reduce misplacement of elderly patients in inappropriate wards or local authority accommodation and help some patients remain at home with local authority domiciliary support. Knowledge gained at visits was often useful when planning discharge, and often assisted rapport with both patient and relatives. These visits revealed that the true list was often substantially shorter than the "paper" list because some patients had died, moved, recovered, or had been admitted elsewhere since being placed on the list. As waiting lists decreased, so the need for home visits began to disappear. However, domiciliary visits, made by the consultants at the request of the general practitioner, continued.

Progressive patient care was widely practiced throughout the United Kingdom. It was a concept first developed in America in an attempt to overcome a shortage of skilled nurses. It involved moving patients from ward to ward, or sometimes within wards, as they improved or required further treatment. Most were admitted first to the initial treatment ward. From there patients could be discharged home, or moved to the continuation care wards, where they would be divided further into two groups: continued rehabilitation or continued nursing care. From those wards the patients could be discharged, moved to a halfway house to await a place in a welfare home, or returned home. The disadvantage of the system was that beds were not always used to maximum efficiency and nursing continuity was lost as patients moved from ward to ward. On the other hand, it was argued that it helped patients' morale to be moved on as they improved.

A *consultative service* provided by geriatricians to consultant colleagues was another important feature of the new style geriatric service. An excellent example of such collaboration, involving the general and geriatric physicians, resulted in a reduction in mean and median durations of stay in general medical wards (Burley *et al.*, 1979). The mean stay for females over 65 years in general wards was reduced from 25 to 16 days and for the over 85s from 50 to 19 days. These changes were not due to increased transfers to the geriatric wards. Collaboration was particularly important for the orthopedic surgeons to assist the rehabilitation of elderly women after operations for a fractured neck of the femur. A thriving example, which achieved wide recognition, was created in Hastings by Dr Robert Irvine and Mr Michael Devas.

Day hospitals were one of the major innovations in modern geriatric medicine and are viewed by many geriatricians as an essential part of their service. These facilities provided rehabilitation, physical maintenance, follow-up care after discharge from hospital, and allowed minor medical procedures to be undertaken without the need for inpatient admission. The Department of Health and Social Services recommended 2 places/1000 for those over 65 years with the usual size of

a day hospital being 20–40 places per day (Department of Health and Social Security, 1971). They are generally open 5 days a week and require one session of consultant time, two sessions of junior doctor time, ten whole-time equivalent nurses and a rehabilitation team to provide a service for 30-day patients.

Transport has been a major limiting factor in day hospital efficiency. One psychogeriatrician with a large rural area thought patients spent almost as long in the ambulance as at the hospital and wondered if a new form of psychiatric day care should be created called *transport therapy*: "the patient is jogged along the countryside for several hours. . .the hospital became irrelevant and to travel happily becomes more important than to arrive. Meals can be taken at a friendly transport cafe, always provided there is a greater-than-average provision of functioning lavatories" (Arie, 1975). Other delays can result from the considerable time taken to use the tail lift to "load" patients into the ambulance, and the diversion of day hospital ambulance to other duties.

The efficiency and effectiveness of day hospitals has been much debated with criticism targeted at inadequate audit of their function, poor working policies and insufficient consultant input. Unfortunately, reliable data is difficult to obtain. Simple attendance rates are difficult to assess, since they depend on the size of the unit, the availability of transport, public holidays, and staff shortages. Properly designed trials are bedeviled by methodological limitations of the studies. Patients usually attend for different reasons and the number attending individual day hospitals may be small. Day units have different roles in different localities, and there can be difficulties in defining the control groups. The Royal College of Physicians of London reviewed 13 research studies including 6 randomized controlled trials, only two of which were based in the United Kingdom (Research Unit of the Royal College of Physicians, 1994). Unfortunately, they tended to give contradictory results depending on the nature of the treatment received by the control groups.

Long-stay care, for those geriatric patients who fail to recover, has its own special requirements (*A Better Home Life*, 1996). The pace of life is slower but the patients need to be kept as mentally and physically active as possible to prevent institutionalization. Different nursing skills are required. The accommodation needs to be designed to take account of the fact that it is likely to be the patient's home for several years and, therefore, it needs to be appropriately designed. Within the last 20 years or so, much of the long-stay care, which used to be part of the NHS, has been transferred into the private/voluntary sector.

GERIATRIC MEDICINE IN THE COMMUNITY

General practitioners have a pivotal role in elderly care. They provide free medical service for all those on their list of patients and act as first line of referral when the person becomes ill. They can obtain medical support from the geriatric service or the local social service department. Regular review of their patients over the age of 75 years has been promoted.

However, older people may not consult their general practitioner about their symptoms because they may feel that little could be done for them. Case-finding programs, which involve a search for untreated disability, have been revealing. Programs in Scotland found that general practitioners were largely aware of the major disorders affecting the elderly at home but were much less aware of minor disorders such as problems with sight, hearing, and care of toenails, which can have a major impact on quality of life and for which treatment can produce benefit (Williamson *et al.*, 1964). Another major Scottish innovation was the creation of successful health centers to provide a "walk-in" medical assessment and treatment for elderly people (Anderson and Cowan, 1955).

An effective social service department is an essential component of any geriatric service, since it can provide an extensive range of domiciliary care, such as home helps, meals on wheels, occupational therapy, appliances, and visits from the local social worker. Many provide residential homes for those who cannot manage at home even with maximum support and day centers for those who require diversional activities. The local social service departments liaise with voluntary organizations such as Age Concern, old people's clubs, and church organizations. However, many of these services were inadequate in the early days of the NHS and took time to develop.

TEACHING GERIATRIC MEDICINE

The teaching of medical students about the medical care of sick elderly people had long been recommended, but it was not until 1949 that Lord Amulree was appointed to University College Hospital, a London teaching hospital. Further advance had to wait until 1965 when Sir Ferguson Anderson became the first UK Professor of Geriatric Medicine. After this, progress was slow but by 1998 almost all the London teaching hospitals had a professorial chair in the speciality, and increasing numbers of chairs in geriatric medicine have been made in the country as a whole. These academic departments were usually based on an active geriatric unit with good community links. The curricula vary but could include biological and sociological gerontology as well as clinical geriatric medicine. Postgraduate research courses leading to the degrees of M.Sc. and Ph.D. have been set up. Some universities have a cluster of associated chairs, as the University of Manchester with two chairs in geriatric medicine, one each in cognitive gerontology, old-age psychiatry, gerodontology, biological gerontology, and social gerontology.

However, research of attitudes of medical students toward the elderly has shown that they tend to lose their initial

interest and empathy for older people as they train and qualify. A survey of their attitudes before qualification showed that they had empathy for, and a "bedside interest in", the elderly, which disappeared after graduation when the doctors considered their career prospects (Gale and Livesley, 1974). Parkhouse and McLaughlin (1976) found that no doctor, who had graduated in 1974, wished to enter geriatric medicine. Lambert *et al.* (1996) showed that little had changed in a review of career preferences among newly qualified doctors: preferences for geriatric medicine remained very low at 0.9%, well below general medicine and surgery, although above genetics. Factors blamed included the prejudice of medical teachers against geriatric medicine; poor image/role of the geriatrician, and mediocre working conditions. As a result, recruitment of medical staff into the speciality was poor. The Royal College of Physicians responded in 1972 and 1977 with a range of recommendations, including integration of geriatric medicine with general medicine, appointment of consultant physicians with a special interest in geriatric medicine, and rotation of junior training posts between the two specialties (Royal College of Physicians of London, 1972, 1977). The College also introduced the Diploma of Geriatric Medicine in 1986 to encourage general practitioners to gain interest in the care of older people.

ACHIEVEMENTS OF GERIATRIC MEDICINE

As the new style treatment methods were applied to the previously neglected chronic sick, clear evidence emerged of its effectiveness, particularly in hospitals. Official health data sources, such as Hospital In Patient Enquiry (HIPE) data collection, the Office of Health Economics, and Health and Personal Social Services Statistics for England, showed that the number of deaths and discharges of elderly people, and patient turnover from geriatric wards, steadily increased while the average and median lengths of stay decreased. In 1980, the Chief Medical Officer for England and Wales was able to report "the average length of stay for patients in hospital departments of geriatric medicine is steadily diminishing – more so than in any other hospital speciality. Only 10% remain in hospital for more than 6 months; the median length of stay is only 21.7 days" (Department of Health and Social Security, 1980). Progress was such that in 1984 the Nuffield Provincial Hospital Trust was able to comment "It [geriatric medicine] has established its expertise and has had notable success in developing and raising the standards of services for the old" (Batchelor, 1984). Concomitant with these developments, individual geriatricians began to create differing styles of practice: while some did not take emergency admissions, others took increasing numbers of acutely ill patients, and still others reintegrated with general medicine, taking part in unselected acute medical take and joint ward rounds with their general physician colleagues.

GERONTOLOGY: THE SCIENCE OF THE AGING PROCESS

Interest in gerontology in the United Kingdom was stimulated by the support of charitable foundations and the enthusiasm of a few individuals. The Nuffield Foundation created a medical and biological Research Committee, which gave grants to Howell for his research, to Dr Alex Comfort to work with Sir Peter Medawar at Birmingham and later at University College London, and to Professor Sir Frederick Bartlett at the University of Cambridge to establish a research unit to investigate the psychological aspects of aging. The Nuffield and the Ciba Foundations supported Vladimir Korenchevsky (1880–1959), a Russian biologist, who had studied under Pavlov and Metchnikoff. His enthusiasm for the science of aging culminated in his becoming director of the Oxford Gerontological Institute. He was a driving force behind the creation of the International Association of Gerontology (IAG). The Ciba Foundation supported the IAG, which held its first meeting in 1950 in Liege, Belgium. The first meeting of the clinical section of the IAG was held in Sunderland in the United Kingdom in 1958 and was chaired by Dr Oscar Olbrich. A later meeting was held in Manchester in 1974, which was organized by Professor Brocklehurst. The Ciba Foundation maintained its interest in old age by establishing a series of special colloquia in London, which were attended by many international experts on aging, and supported the British Society for the Research in Ageing, which was founded by Korenchevsky.

PROBLEM AREAS

The birth of geriatric medicine in the United Kingdom was hampered by the indifference of the medical profession to elderly patients for many reasons. The care of the aged and infirm lacked the dramatic appeal of acute illness in the young. Physicians questioned why elderly people should be put through extensive rehabilitation when they had only a few years to live. Complete recovery was rarely possible and the result was often disproportionate to the effort required. Chronic sick patients were often accommodated in poorly equipped and staffed hospitals. General physicians feared "bed blocking" if they admitted elderly patients, appeared uninterested in deciding what was normal or abnormal in this age-group, in learning what treatment could achieve, were displeased at the diversion of resources from general medicine to geriatric medicine, and were unenthusiastic about the considerable social/nonmedical components of geriatric medicine. Geriatricians were viewed as "second-rate" physicians.

Another concern was the quality of care given to the elderly in hospital. This culminated in the publication in 1967 of *Sans Everything: a Case to Answer,* which alleged inappropriate care in hospitals for the elderly and mentally ill. Official investigations found that the complaints were inaccurate, vague, lacking in substance, misinterpretations,

or overemotional (Martin, 1984). Following yet another allegation of improper care in a unit for the mentally subnormal in 1967, the Secretary of state for Health created the Hospital Advisory Service (HAS) in 1969, which was to act as his "eyes and ears". It was to be responsible only to him and was to be independent of the Department of Health. Visits to hospitals for the elderly and mentally ill started in 1970 and were carried out by teams of "in-post" professionals: consultant geriatricians or psychiatrists, senior nurses, paramedical staff, administrators, and later social workers. It is best considered as a form of "peer review". Later its remit was extended to cover community services, at which time it was renamed the Health Advisory Service.

The development of specialist service for the elderly mentally ill lagged behind that of the physically ill. Not infrequently, these patients were inappropriately admitted to geriatric wards, where staff had limited experience in managing them. Sometimes they were admitted to large general mental hospitals where the general psychiatrists did not welcome them. The ministry was aware of the problems presented by these patients and published advisory documents (e.g. Ministry of Health, 1950; Department of Health and Social Security, 1972). Eventually, guidelines were introduced to ensure admission to an appropriate ward: assessment by a multidisciplinary team was recommended. Joint assessment units with input from the local authority, psychiatrists, and the geriatrician were set up, although they tended to silt up owing to the failure to move the patients on to suitable ward or accommodation. Psychogeriatric day hospitals were opened, which provided a useful community function. Local authority residential homes were encouraged to take more mentally ill patients. However, it was not until the 1970s that consultant psychogeriatricians were appointed.

Another source of debate was the term *geriatrics* and its allied words. The word *gerocomy,* attributed to Galen, was used for the medical care of the elderly and was adapted to *geroncology* for their sociological aspects. In 1903, Metchnikoff invented the word *gerontology* for the biological study of the aging process. Nascher is generally credited with coining the word *geriatrics* (Nascher, 1916). "The term was... derived from the Greek, *geron*, old man and *iatrikos*, medical treatment. The etymological construction is faulty but euphony and mnemonic expediency were considered of more importance than correct grammatical construction". Howell pointed out at least one author who had confused *gerontology* (the science of old age) and *geriatrics* (the care of the aged). The word *gerontology* has been attacked as a barbarous misspelling and the word *geratology,* the study of old age, has been suggested instead. The founders of the Medical Society for the Care of the Elderly did not use the word *geriatrics* since it was, in 1940s, almost unknown. Many UK hospital geriatric units, aware of the public's perception of *geriatrics* as being apparently synonymous with *senility*, now call themselves "Department for the Medical Care of the Elderly" or "Care of the Elderly Department".

KEY POINTS

- In spite of interest in old age, enlightened medical treatment of the elderly sick patient did not start until the twentieth century.
- Classification of patients and modern treatment methods showed that the majority of those admitted to elderly care wards could be discharged.
- Community studies found unreported minor illness in older people, which could have a major impact on the quality of life if left untreated.
- University authorities were slow to implement the education of medical students about the medical and social aspects of illness in the older person.
- Powerful charitable foundations supported research into the causes of aging.

A Biological Perspective on Aging

Thomas B.L. Kirkwood

University of Newcastle, Newcastle-upon-Tyne, UK

INTRODUCTION

The biological perspective on aging is important for what it tells us about why and how the body becomes progressively more vulnerable to disability and disease as we grow older. Although there is significant variability in how aging affects individuals, certain underlying processes appear to follow a fairly common course. Furthermore, humans share features of aging with a wide range of other animal species. Thus, research that is being done on factors that influence aging in these species may throw light on at least some aspects of human senescence.

WHY AGING OCCURS

One of the questions of greatest interest for biological gerontologists is the nature of the genetic contribution to longevity. How do genes act on the aging process? How did the relevant genes evolve?

It is clear on several grounds that aging and longevity are influenced by genes (Finch and Tanzi, 1997). Firstly, the life spans of human monozygotic twin pairs are statistically more similar than life spans of dizygotic twins, pointing clearly to a role for genetics. Secondly, there are significant differences in life span between different genetically inbred strains of any given laboratory animal, such as the mouse. Third, studies of simple organisms like fruit flies, nematode worms, and yeast have identified gene mutations that affect duration of life. However, although genes influence longevity, it has also been shown that genes account for only about 25% of the variance in human life span (Finch and Tanzi, 1997; Cournil and Kirkwood, 2001).

The nature of the genetic contribution to the aging process has received much attention, both from the perspective of evolutionary theory and through experimentation. The evolutionary angle is valuable because it can tell us a great deal about the kinds of genes that are likely to underlie the aging process (Kirkwood and Austad, 2000). Although it is widely supposed that aging evolved as some kind of evolutionary necessity – to clear older generations out of the way as a form of inbuilt population control – there is in fact scant evidence that aging plays such a role in nature, or that such an evolutionary pressure could have worked. The reason is simple: animals in nature die young. Only rarely do they survive long enough to reveal significant aging. Out of a population of newborn wild mice, for example, nine out of ten of them will be dead before 10 months even though half of the same animals reared in captivity would still be alive at 2 years (Austad, 1997). Thus, aging in mice is seen only in protected environments, and a similar statement would have applied to primitive human populations, before the advent of civilization.

The fact that aging is rarely seen in natural animal populations speaks tellingly against any suggestion that aging evolved as a genetically programmed means to limit population size and avoid overcrowding. Instead of being programmed to die, organisms are genetically programmed to survive. However, in spite of a formidable array of survival mechanisms, most species appear not to be programmed well enough to last indefinitely. The key to understanding why this should be so, and what governs how long a survival period should be catered for, comes from looking once more at the data from survival patterns in wild populations. If 90% of wild mice are dead by 10 months, any investment in programming for survival much beyond this point can benefit at most 10% of the population. This immediately suggests that there will be little evolutionary advantage in programming long-term survival capacity into a mouse. The argument is further strengthened when we observe that nearly all of the survival mechanisms required by the mouse to combat intrinsic deterioration (DNA damage, protein oxidation, etc.) require metabolic resources. Metabolic resources are scarce, as is evidenced by the fact that the major cause of mortality for wild mice is cold, due to insufficient energy to maintain body temperature. From a Darwinian point of view, the mouse will benefit more from investing any spare

resource into thermogenesis or reproduction than into better DNA repair capacity that it needs.

This concept, with its explicit focus on evolution of optimal levels of cell maintenance, is termed *the disposable soma theory* (Kirkwood, 1977, 1997). In essence, the investments in durability and maintenance of somatic (nonreproductive) tissues are predicted to be sufficient to keep the body in good repair through the normal expectation of life in the wild environment, with some measure of reserve capacity. Thus, it makes sense that mice (with 90% mortality by 10 months) have intrinsic life spans of around 3 years, while humans (who probably experienced something like 90% mortality by age 50 in our ancestral environment) have intrinsic life spans limited to about 100 years. The distinction between somatic and reproductive tissues is important because the reproductive cell lineage, or germ line, must be maintained at a level that preserves viability across the generations, whereas the soma needs only to support the survival of a single generation. As far as is known, all species that have a clear distinction between soma and germ line undergo somatic senescence, while animals that do not show senescence, such as the freshwater Hydra, have germ cells distributed throughout their structure.

The above argument clearly identifies the level of extrinsic mortality as the principal driver in the evolution of longevity. If the level of extrinsic mortality is high, the average survival period is short and there is little selection for a high level of maintenance. Any spare resources should go instead towards reproduction. Consequently, the organism is not long-lived even in a protected environment. Conversely, if the level of extrinsic mortality is low, selection is likely to direct a higher investment in building and maintaining a durable soma. Studies comparing the biochemistry of cellular repair among long- and short-lived species bear this prediction out. Cells from long-lived organisms exhibit greater capacity to repair molecular damage and withstand biochemical stresses than cells from short-lived species (Kapahi *et al.*, 1999; Ogburn *et al.*, 2001).

The disposable soma theory provides a bridge between understanding not only why aging occurs but also how aging is caused in molecular and cellular terms. It thus extended earlier considerations by Medawar (1952), who suggested that because organisms die young there is little force of selection to oppose the accumulation within the genome of mutations with late-acting deleterious effects, and by Williams (1957) who suggested that genes with beneficial effects would be favored by selection even if these genes had adverse effects at later ages. This is known as *the theory of antagonistic pleiotropy*, the term pleiotropy meaning that the same gene can have different effects in different circumstances.

By combining the insights from the mutation accumulation, antagonistic pleiotropy, and disposable soma theories, evolutionary biology has established a solid basis to explain why aging occurs. The four cornerstones of this basis are: (i) there are no specific genes for aging; (ii) genes of particular importance for aging and longevity are those governing durability and maintenance of the soma; (iii) there may exist other genetically determined trade-offs between benefits to young organisms and their viability at older ages; and (iv) there may exist a variety of gene mutations with late deleterious effects that contribute to the senescent phenotype. It is clear that multiple genes probably contribute to the aging phenotype and a major challenge is therefore to identify how many of each category exist, and which are the most important.

HOW AGING AFFECTS TISSUES

The evolutionary explanation of aging, as summarized above, leads to a number of clear predictions about the nature of the underlying mechanisms that lead eventually to age-related frailty, disability, and disease (and eventually to increasing mortality). In its essence, aging is neither more nor less than the progressive accumulation through life of a variety of random molecular defects that build up within cells and tissues. These defects start arising very early in life, probably even *in utero*, but in the early years both the fraction of affected cells and the average burden of damage per affected cell are low. However, over time, the faults increase, resulting eventually in age-related functional impairment of tissues and organs.

This view of the aging process makes clear the life-course nature of the underlying mechanisms. Aging is a continuous process, starting early and developing gradually, instead of being a distinct phase that begins in middle to late life. The view also helps us reexamine the sometimes controversial relationship between "normal aging" and age-related disease. In an extreme version of this view, the term "normal aging" is reserved for individuals in whom identifiable pathology is absent, whereas specific age-related diseases, such as Alzheimer's disease, are seen as distinct entities. An obvious difficulty that arises, however, when any attempt is made to draw a line between normal aging and age-related disease is that as a cohort ages, the fraction of individuals who can be said to be aging "normally" declines to very low levels. Whether the word "normal" can usefully be applied to such an atypical subset is debatable.

In a clinical context, it often makes sense to try and draw a distinction between normal aging and disease, since this may have implications for treatment. However, if our aim is to understand the mechanisms responsible for age-related conditions, such a distinction can obscure what is really going on and impede progress toward developing novel interventions that are targeted at "upstream" processes.

The majority of chronic, degenerative conditions, such as dementia, osteoporosis, and osteoarthritis, involve the progressive accumulation of specific types of cellular and molecular lesions. Since the aging process, as we have seen, is caused by the general accumulation of such lesions, there may be a much greater overlap between the causative pathways leading to normal aging and age-related diseases than has hitherto been recognized. In the case of osteoporosis, for example, progressive bone loss from the late 20s onwards

is the norm. Whether an individual reaches a critically low bone density, making him or her highly susceptible to fracture is governed by how much bone mass they had to start with and by their individual rate of bone loss. The process that leads eventually to osteoporosis is thus entirely "normal", but what distinguishes whether or not this process results in an overtly pathological outcome is a range of moderating factors. In the case of Alzheimer's disease, most people above age 70 have extensive cortical amyloid plaques and neurofibrillary tangles (the so-called "hallmarks" of classic Alzheimer's disease) even though they may show no evidence of major cognitive decline (Esiri *et al.*, 2001). In this instance, what determines whether or not the diagnosis of Alzheimer's disease is called for may be not so much the presence of lesions as which specific targets are affected.

MECHANISMS OF CELLULAR DAMAGE

Aging is highly complex, involving multiple mechanisms at different levels. Much recent evidence suggests that an important theme linking several different kinds of damage is the action of reactive oxygen species (ROS; also known as "free radicals") which are produced as by-products of the body's essential use of oxygen to produce cellular energy (Martin *et al.*, 1996; von Zglinicki *et al.*, 2001). Of particular significance are the contributions of ROS-induced damage to cellular DNA through (1) damage to the chromosomal DNA of the cell nucleus resulting in impaired gene function, (2) damage to telomeres – the protective DNA structures that appear to "cap" the ends of chromosomes (analogous to the plastic tips of shoelaces), and (3) damage to the DNA that exists within the cell's energy-generating organelles, the mitochondria, resulting in impaired energy production.

DNA Damage and Repair

Damage to DNA is particularly likely to play a role in the life-long accumulation of molecular damage within cells, since damage to DNA can readily result in permanent alteration of the cell's DNA sequence. Cells are subject to mutation all the time, both through errors that may become fixed when cells divide and as a result of ROS-induced damage which can occur at any time. Numerous studies have reported age-related increases in somatic mutation and other forms of DNA damage, and have suggested that an important determinant of the rate of aging at the cell and molecular level is the capacity for DNA repair (Promislow, 1994; Burkle *et al.*, 2002).

Although DNA damage may take many forms, it is estimated that oxidative damage is among the most important, accounting for large numbers of oxidative hits per cell per day. A key player in the immediate cellular response to ROS-induced DNA damage is the enzyme poly(ADP-ribose) polymerase (PARP). Grube and Bürkle (1992) discovered a strong, positive correlation of PARP activity with the species life span, cells from long-lived species having higher levels of PARP activity than cells from short-lived species. In a similar vein, it was found that human centenarians, who have often maintained remarkably good general health, have a significantly greater poly(ADP-ribosyl)ation capacity than the general population (Muiras *et al.*, 1998).

Telomeres

In many human somatic tissues a decline in cellular division capacity with age appears to be linked to the fact that the telomeres, which protect the ends of chromosomes, get progressively shorter as cells divide (Kim *et al.*, 2002). This is due to the absence of the enzyme telomerase, which is normally expressed only in germ cells (in testis and ovary) and in certain adult stem cells. Some have suggested that in dividing somatic cells, telomeres act as an intrinsic "division counter", perhaps to protect us against runaway cell division as happens in cancer but causing aging as the price for this protection (Campisi, 1997). Erosion of telomere length below a critical length appears to trigger activation of the same kinds of cell cycle checkpoint, especially the p53/p21/pRb system, as are involved in the more general cellular response to DNA damage.

While the loss of telomeric DNA is often attributed mainly to the so-called "end-replication" problem – the inability of the normal DNA-copying machinery to copy right to the very end of the strand in the absence of telomerase – it has been found that stress, especially oxidative stress, has an even bigger effect on the rate of telomere loss (von Zglinicki, 2002). Telomere shortening is greatly accelerated (or slowed) in cells with increased (or reduced) levels of stress. The clinical relevance of understanding telomere maintenance and its interaction with stress is considerable. A growing body of evidence suggests that telomere length is linked with aging and mortality (e.g. Cawthon *et al.*, 2003). Not only do telomeres shorten with normal aging in several tissues (e.g. lymphocytes, vascular endothelial cells, kidney, liver), but also their reduction is more marked in certain disease states. For example, there appears to be a 100-fold higher incidence of vascular dementia in people with prematurely short telomeres (von Zglinicki *et al.*, 2000). Viewed together with the observation that oxidative stress accelerates telomere loss, the intriguing possibility arises that prematurely short telomeres *in vivo* are an indicator of previous exposure to stress and may therefore serve as a prognostic indicator for disease conditions in which oxidative stress plays a causative role (von Zglinicki, 2002).

Mitochondria

An important connection between oxidative stress and aging is suggested by the accumulation of mitochondrial DNA (mtDNA) deletions and point mutations with age (Wallace, 1992). Mitochondria are intracellular organelles, each carrying its own small DNA genome, which are responsible for

generating cellular energy. As a by-product of energy generation, mitochondria are also the major source of ROS within the cell, and they are therefore both responsible for, and a major target of, oxidative stress. Any age-related increase in mutation of mtDNA is likely to contribute to a progressive decline in the cell and tissue capacity for energy production. Age-related increases in frequency of cytochrome c oxidase (COX)-deficient cells have been reported in human muscle (Müller-Höcker, 1989; Müller-Höcker *et al.*, 1993; Brierley *et al.*, 1998) and brain (Cottrell *et al.*, 2000), associated with increased frequency of mutated mtDNA.

Until recently, the evidence for age-related accumulation of mtDNA mutations came mainly from tissues such as brain and muscle where cell division in the adult, if it occurs at all, is rare. This led to the idea that accumulation of mtDNA mutation was driven mainly by the dynamics of mitochondrial multiplication and turnover within nondividing cells (Kowald and Kirkwood, 2000). However, recent work has revealed a strongly age-dependent accumulation of mtDNA mutations in human gut epithelium, which has the highest cell division rate of any tissue in the body (Taylor *et al.*, 2003). Thus, it appears that mtDNA mutation accumulation may be a widespread phenomenon.

Proteins

So far, we have concentrated on damage to DNA. However, damage can also affect any of the macromolecules that make up the cell, as well as those that form extracellular structures such as cartilage and bone. In particular, damage to protein molecules occurs to a considerable extent, and accumulation of faulty proteins contributes to important age-related disorders such as cataract, Parkinson's disease, and Alzheimer's disease. In some ways, the accumulation of defective proteins is harder to explain than the accumulation of DNA damage, since individual protein molecules are subject to a continual cycle of synthesis and breakdown. Thus, damage to any individual protein molecule should be cleared as soon as that molecule is degraded. The exceptions occur when the defective protein molecules become resistant to breakdown, for example, because they form aggregates large enough to withstand the normal removal systems. It is the buildup of such aggregates that is commonly linked with cell and tissue pathology.

Interactions between Mechanisms

We have so far considered a number of distinct mechanisms that can contribute to cellular aging. For each of these, there is evidence supporting the hypothesis that it is indeed an agent of senescence. However, the extent of the contribution to senescence almost invariably appears too small for the mechanism to be a sufficient explanation of age-related degeneration. The obvious solution to this "conundrum" is that cellular aging is multicausal and that the various mechanisms all play their part. For example, a buildup of mtDNA mutations will lead to a decline in the cell's energy production, and this will reduce the capacity to carry out energy-dependent protein clearance. In recent years, novel methods based on computer modeling of interactions and synergism between different aging mechanisms have begun to build a better integrated picture of how cells breakdown with age (Kirkwood *et al.*, 2003).

METABOLIC FACTORS INFLUENCING AGING

Numerous opportunities exist to test the evolutionary prediction that in safe environments (those with low extrinsic mortality) aging will evolve to be retarded, whereas aging should evolve to be more rapid in hazardous environments. Field observations comparing a mainland population of opossums subject to significant predation by mammals, with an island population not subject to mammalian predation, found the predicted slower aging in the island population (Austad, 1993). What is interesting from the metabolic perspective is to understand how these ecologically driven effects are mediated at the level of cellular and molecular mechanisms.

The disposable soma theory predicts that the proportional effort devoted to cellular maintenance and repair processes will vary directly with longevity. For instance, the long-lived rodent species *Peromyscus leucopus* exhibits lower generation of ROS, higher cellular concentrations of some antioxidant enzymes, and overall lower levels of protein oxidative damage than the shorter-lived species *Mus musculus* (Sohal *et al.*, 1993). A direct relation between species longevity and rate of mitochondrial ROS production in captive mammals has also been found (Ku *et al.*, 1993; Barja and Herrero, 2000), as has a similar relationship between mammals and similar-sized but much longer-lived birds (Herrero and Barja, 1999). Markers of glycoxidation, the nonenzymatic modification of reducing sugars, are also found to accumulate more slowly in long-lived, as opposed to short-lived, mammals (Sell *et al.*, 1996).

Of particular significance in terms of metabolic factors influencing aging rates has been the discovery that insulin signaling pathways appear to have effects on aging that may be strongly conserved across the species range (Gems and Partridge, 2001). Insulin signaling regulates responses to varying nutrient levels and so the discovery of the major role for these pathways in aging fits well with the central concept of the disposable soma theory, namely, that aging results from and is controlled by the metabolic allocation of the organism's metabolic resources to maintenance and repair.

One of the clearest examples of how metabolic signaling affects aging and longevity comes from a study on genes of the insulin signaling pathway in *Caenorhabditis elegans* (Murphy *et al.*, 2003). When threatened with overcrowding, which the larval worm detects by the increasing concentration of a pheromone, it diverts its development from the normal succession of larval molts into a long-lived, dispersal

form called *the dauer larva* (Larsen *et al.*, 1995). Dauers show increased resistance to stress and can survive very much longer than the normal form, reverting to complete their development into adults should more favorable conditions be detected. An insulin/IGF-1-like gene, *daf-2*, heads the gene regulatory pathway that controls the switch into the dauer form, and mutations in *daf-2* produce animals that develop into adults with substantially increased lifespans (Kenyon *et al.*, 1993). In common with other members of the evolutionarily conserved insulin/IGF1 signaling pathway, *daf-2* also regulates lipid metabolism and reproduction. The *daf-2* gene product exerts its effects by influencing "downstream" gene expression, in particular via the actions of another gene belonging to the dauer-formation gene family, *daf-16*, which it inhibits (Kimura *et al.*, 1997).

It was shown by Murphy *et al.* (2003) that more than 300 genes appeared to have their expression levels altered by *daf-16* regulation. This large number suggests that, as predicted by the evolutionary theory, many genes are involved in determining longevity. The genes modulated by *daf-16* turned out to be a heterogeneous group although several broad categories could be discerned. The first category comprised a variety of stress-response genes, including players like antioxidant enzymes. A second group of genes encoded antimicrobial proteins, which are important for survival in this organism because its death is commonly caused by proliferation of bacteria in the gut. A miscellaneous third group included genes involved in protein turnover, which is an important cellular maintenance system. Thus, the metabolic regulation of the rate of aging in *C. elegans* is mediated through genetic effects on a diverse array of survival mechanisms, exactly as the disposable soma theory predicted.

By this point, it will be seen that, from a range of studies at the genetic, cellular, and molecular levels, both in humans and a variety of other organisms, a picture is clearly emerging of the main elements of the biological science of human aging (Figure 1). These elements are the result of the relentless role of biochemical *stresses*, such as exposure to ROS, driving a gradual but progressive accumulation of *damage* to cells, tissues, and organs. The process is not entirely passive, since the rate of accumulation is strongly resisted by maintenance and repair processes, which are controlled by *genes*. Furthermore, the regulation of these genes may, at least in some organisms, be influenced by metabolic factors, for example, responding to levels of nutrition. This picture is one that readily accommodates the role of at least five major elements contributing to the individuality of the human aging process: genes, nutrition, lifestyle (e.g. exercise), environment, and chance. The recognition of this interplay of factors is likely to be crucial for integrating biological, clinical, and social gerontology. For example, environment is often defined by social factors such as housing, transport, and income. Poor environments may adversely affect an individual's opportunities to do the optimal things for healthy aging in terms of nutrition, lifestyle, and so on. In particular, a poor environment can reinforce a tendency for the older person to suffer social isolation, which in turn can exacerbate psychological and physical deterioration. On the positive side, the understanding that we now have of the biological science of human aging supports the idea that the aging process is much more malleable than has hitherto been recognized. This opens the way to a range of interventions that may improve health in old age and extend quality life.

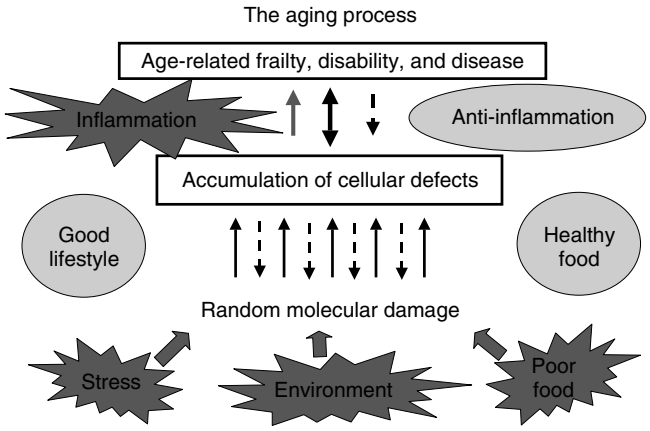

Figure 1 The aging process is driven by a life-long accumulation of molecular damage, resulting in gradual increase in the fraction of cells carrying defects. After sufficient time has passed, the increasing levels of these defects interfere with both the performance and functional reserves of tissues and organs, resulting in age-related frailty, disability, and disease. Stress, adverse environment, and poor nutrition can increase the rate at which molecular damage arises. Molecular damage is partially countered by cellular maintenance and repair systems (dashed arrows). Accumulation of cellular damage can cause inflammation, which can exacerbate the development of overt age-related frailty, disability, and disease. This may be countered by anti-inflammatory factors (dotted arrow)

KEY POINTS

- There is no biological program specifically to cause aging.
- The body is programmed for survival but our survival mechanisms, which evolved to cater for the typical longevity of our evolutionary ancestors, are insufficient to prevent damage from accumulating.
- Aging is caused by the life-long accumulation of subtle molecular and cellular faults, a process that probably begins *in utero*.
- Multiple mechanisms contribute to the buildup of damage that causes aging, and there are multiple maintenance and repair systems working to combat this buildup of damage. It is the genetic setting of these maintenance and repair systems that explains the genetic contribution to human longevity (which explains about 25% of the variation in human life span).
- The rate at which damage accumulates, and thus the aging process itself, is malleable through the actions of factors such as nutrition, lifestyle, and environment.

INTRODUCTION

Protozoa floating in the Cambrian sea many billion years ago could have been the first cell-like living organisms on earth resembling today's *Amoeba*. From such unicellular organisms, it took billions of years for the evolution of a wide variety of multicellular organisms. One necessary condition for the survival of these organisms, including Protozoa, is that each one must be able to maintain its identity by discriminating itself from many others in the same environment. It is interesting to note that this ability to discriminate "self" from "non-self" is the basic function of the immune system. Leukocytes in higher vertebrates as mammals are quite similar to Cambrian Protozoa in terms of appearance and function and constitute a major component of the immune system. In a broad sense, they can be categorized into granulocytes, macrophage (monocytes), and lymphocytes.

Animals are equipped with three types of defense systems against invading pathogenic microbes. One is a physical barrier composed of skin and mucosal surface of gastrointestinal and respiratory tract. This barrier is reinforced by humoral substances containing lysozymes or acid. Second is a natural (innate) immune system composed of granulocytes, macrophages, dendritic cells, and natural killer (NK) cells. Granulocytes and macrophages can nonspecifically ingest and kill microbes by lytic enzymes in lysozymes. NK cells can nonspecifically kill tumor cells and virus-infected cells. The importance of granulocytes is illustrated by the fact that people suffering from drug-induced hypo- or agranulocytosis occasionally die within a week after the onset of the disease. Third is an acquired (specific) immune system. Its major component is lymphocytes, but many of their functions are helped by macrophages, dendritic cells, and NK cells. Unlike natural immune system, killing of microbes by acquired immune system is specific to a certain type of microbe (a specific antigen); therefore, there are countless numbers of clones of lymphocytes corresponding to the countless numbers of antigens in the environment and each clone of lymphocytes can specifically react to a corresponding antigen, resulting in proliferation of specific effector cells or production of specific antibody. Moreover, the immune reaction retains memory analogous to that of the nervous system, and the sequence of generation of effector cells and antibody production occurs very quickly upon subsequent infections by the same microbes. However, immunological functions are known to decline with age in many mammals, including humans (Makinodan and Kay, 1980; Hirokawa, 1992; Linton and Dorshkind, 2004), and the decline occurs more in the acquired immune system than in the natural immune system. It is of clinical importance that with a decrease of immunologic vigor, the incidence of various age-associated diseases such as infections, cancers, and vascular diseases increases. Table 1(a) shows causes of death observed in 3000 autopsy cases in geriatric institutions in Geneva, Switzerland (Mac Gee, 1993). The most prevalent fatal condition was bronchopneumonia. The same observation was also seen in Tokyo Metropolitan Geriatric Hospital, Japan (Table 1b). Infections such as bronchopneumonia compose almost 40% of the direct causes of death in autopsy cases over 60 years of age, although a variety of antibiotics are available. The occurrence of severe acute respiratory syndrome (SARS) in the winter of 2003 clearly indicated the immune deficient state of the elderly. Fatality rate increased with age in SARS (Hong Kong, China), occurring in more than 50% in people 65 years and over (Table 1c). These results suggest that elderly people whose immune functions are at an exceptionally high level can live longer and become centenarians. They also underscore the importance of age-related decline of immune functions. Regarding infection, there is a hypothesis that chronic antigenic stimulation could lead to an increasing prevalence of senescent, dysfunctional T cells, and therefore contributes to more general alterations in the immune system (Pawelec *et al.*, 2004).

A related serious problem of our society is acquired immune deficiency syndrome (AIDS), and AIDS is due

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

Table 1a Causes of death in a hospitalized geriatric population: An autopsy study of 3000 patients

Bronchopneumonia	42.9%
Malignant neoplasms	28.1%
Pulmonary thromboembolism	21.2%
Acute myocardial infarction	19.6%
Urinary tract infection	12.3%
Acute cerebrovascular disease	6.5%
Internal hemorrhage	5.5%
Congestive cardiac failure	3.3%

The data, based on 3000 consecutive autopsies (1758 females/1242 males: mean age 80.3 years) performed from 1972 to 1992 in Geneva Geriatric Instutitions (Mac Gee W).

Table 1b Major causes of death in autopsy cases of elderly persons at Tokyo Metropolitan Geriatric Hospital

	People over 60 years (%)	People over 70 years (%)
Infections	39.2	27.6
Vascular diseases in brain and heart	29.7	43.1
Malignancies	18.7	22.4
Others	12.4%	6.9%

The data, based on 923 autopsy cases (570 females/353 males) over 60 years of age.

Table 1c Fatality rate of SARS increased with age in Hong Kong

Age	Fatality rate (%)
24 years and under	0
25–44 years	6
45–64 years	15
65 years and over	52
Total	14–15

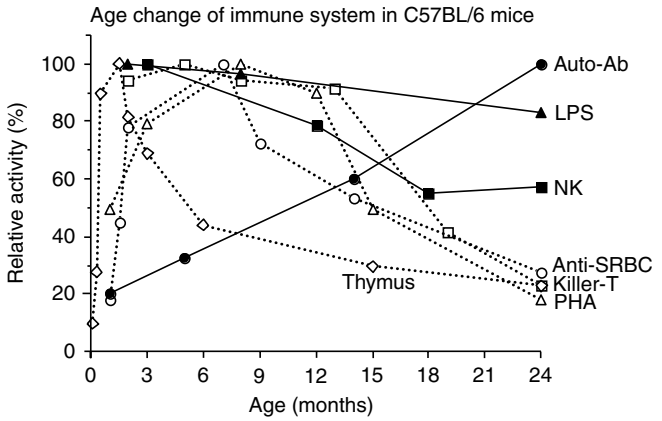

Figure 1 Age-related changes in the immune functions of C57BL/6 mice. Age-related decline is seen in three kinds of T cell-dependent immune functions: mitogenic response of spleen cells to phytohemagglutinin (PHA, closed triangle), cytolytic T cell activity (killer T, open squares), and anti-SRBC antibody response (anti-SRBC, open circles). Thymic involution (open diamonds) precedes the decline of these T cell-dependent immune functions. Proliferative activity of B cells (LPS, closed triangles) declines very slightly with age. Activity of natural killer (NK) cells (closed squares) declines moderately. Production of autoantibody (auto-Ab, closed circles) increases with age (Reprinted from Archives of Gerontology and Geriatrics, **19**: 171, Hirokawa *et al.*, Copyright 1994, with permission from Elsevier)

to insufficiency of $CD4^+$ helper T cells caused by HIV infection. With most elderly people, a much wider range of nonspecific immunological deficiency occurs. This chapter will outline how the immune functions decline with age in humans and animal models.

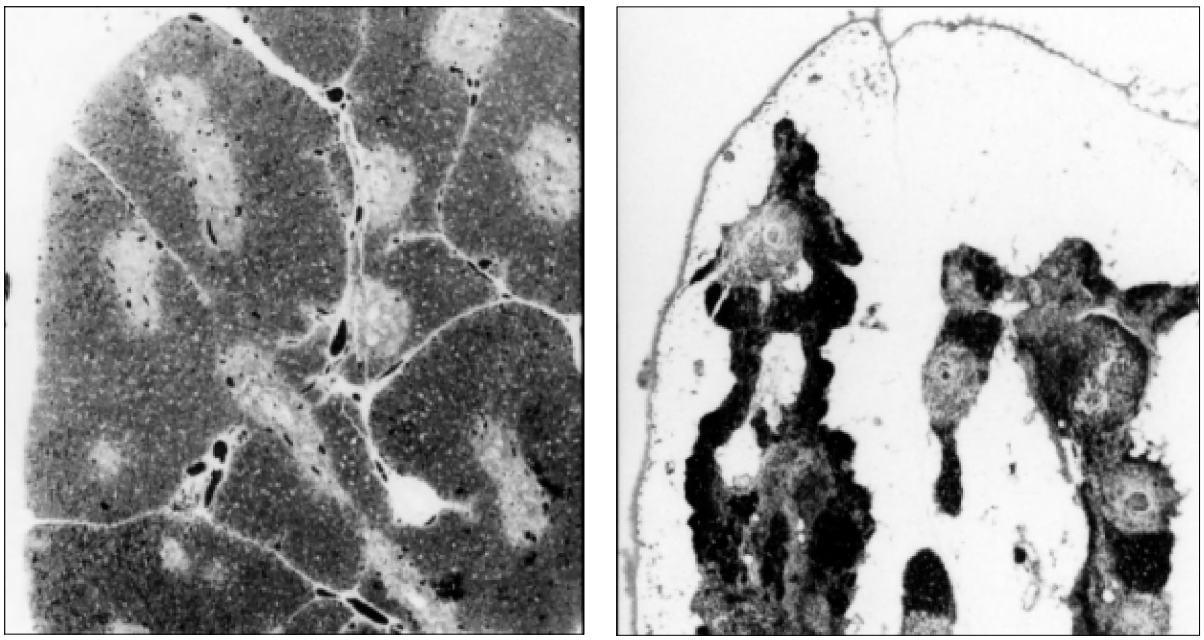
SENESCENCE OF IMMUNE SYSTEM

1. *T cell-dependent immune system is most susceptible to aging*

The natural immune system is already functioning at the time of birth and does not show a pronounced age-related change during the course of life in healthy individuals. On the other hand, the acquired immune system is immature and does not function well in the early stage after birth. Its activity develops quickly by exposure to innumerable antigens, including microbes in the environment, peaks at puberty, and starts to gradually decline thereafter. Studies in several long-lived mouse strains and humans performed in several laboratories, including ours (Makinodan and Kay, 1980; Hirokawa, 1992; Linton and Dorshkind, 2004; Deng *et al.*, 2004), indicate that: (a) decline primarily occurs in T cell-dependent immune functions such as T cell-dependent antibody formation, cytolytic T cell activity, T cell proliferative response to various mitogens and tuberculin skin test; (b) all these changes are preceded by thymic involution; (c) activity of NK cells also declines with age, but the magnitude of the decline is less than that of T cells; (d) there is a marginal decline in B cell mitogenic response to lipopolysaccharide (Figure 1); and (e) transition of pro-B cells into pre-B cells and migration of newly made B cells to the spleen from bone marrow are reduced in old individuals. Considering the fact that T cells are mainly produced in the thymus, a causal relationship appears to exist between thymic involution and subsequent age-related decline in T cell functions. Physiologically, the major reason why T cells are more susceptible to aging than other immune cells is that the recruitment of T cells is quite limited, as the thymic capacity to provide T cells to peripheral lymphoid tissues declines quickly after puberty. The situation is quite different in B cells, dendritic cells, and macrophages, which are constantly replenished by the bone marrow throughout life.

2. *Lymphoid and hemopoietic tissues*

As cells composing the acquired immune system are mainly located in lymphoid tissues, we will see how lymphoid tissues change with age.



(a) (b)

Figure 2 Histology of the thymus from newborn (a) and 28-years-old male (b) The thymus from newborn maintains the basic structure of thymus, composed of cortex and medulla. By contrast, the thymus from a young adult male is composed of a large amount of fatty tissue and fragments of thymic tissues

(a) Thymus
The Thymus is the key organ for the development of T cells. Thymic involution is generally known to occur after puberty. However, an early sign of involution such as fatty infiltration could be observed as early as 5 years of age, and the number of thymic epithelial cells starts to decline shortly after birth. Normal thymic architecture of cortex and medulla, as seen in the newborn stage, completely disappears in the thymus of people over 20 years of age due to extensive fatty infiltration (Figure 2). In a normal mouse strain (mean life span about 2 years), the thymic size peaks at 4–6 weeks and gradually declines, but without fatty infiltration. As will be seen in the later section, the thymic capacity to provide T cells to the periphery is high in the newborn stage and quickly declines thereafter. Nevertheless, Douek *et al.* (1998) reported that thymocytes were still proliferating in the thymus of human adults and newly generated T cells were being exported to peripheral lymphoid tissues. From a structural viewpoint, thymic fragments of human adults are composed of cortical and medullary portions and they provide T cells to the periphery, although very low in number (Shiraishi *et al.*, 2003) and less functional. This will be discussed later.

(b) Spleen
Splenic weight decreases in elderly people, but unlike the thymus, the onset of the decrease is at about the seventh decade, far later than that of thymus. It is composed of red pulp and white pulp. The latter portion occupies about 20% of total spleen and is mainly responsible for immune reactions. Germinal centers are well developed in white pulp of the young spleen, but rarely seen in that of the old spleen (Figure 3).

(c) Lymph node
The size of the lymph node is most prominent in the first decade in humans, as with the case of the thymus. Thereafter, lymph nodes are less conspicuous or not palpable in healthy individuals. Lymph nodes become swollen at the time of infection, but the magnitude of swelling is less prominent in elderly people than in the young. As is seen in the spleen, there is a profound reduction of the germinal center reaction in the lymphoid tissues of the aged. As the germinal center is necessary for generation of high affinity antibodies, the absence of germinal center is considered a cause for the compromised humoral responses in aging (Zheng *et al.*, 1997).

(d) Mucosal lymphoid tissue
The intestine contains a considerable amount of lymphoid tissue, produces a large amount of immunoglobulin (Ig) A, and plays a major role in the protection against infectious diseases of the intestinal tract. There are accumulating data showing that deficits are found in the intestinal mucosal immune responses of elderly humans and old animals (Schmucker, 2002). Nasal-associated lymphoid tissue is important for the protection of respiratory infections, and its function is also impaired with the advancement of age. It is important to note that the production of IgA antibody in nasal mucosa is efficiently enhanced by local administration of antigen, not by systemic injection of antigen

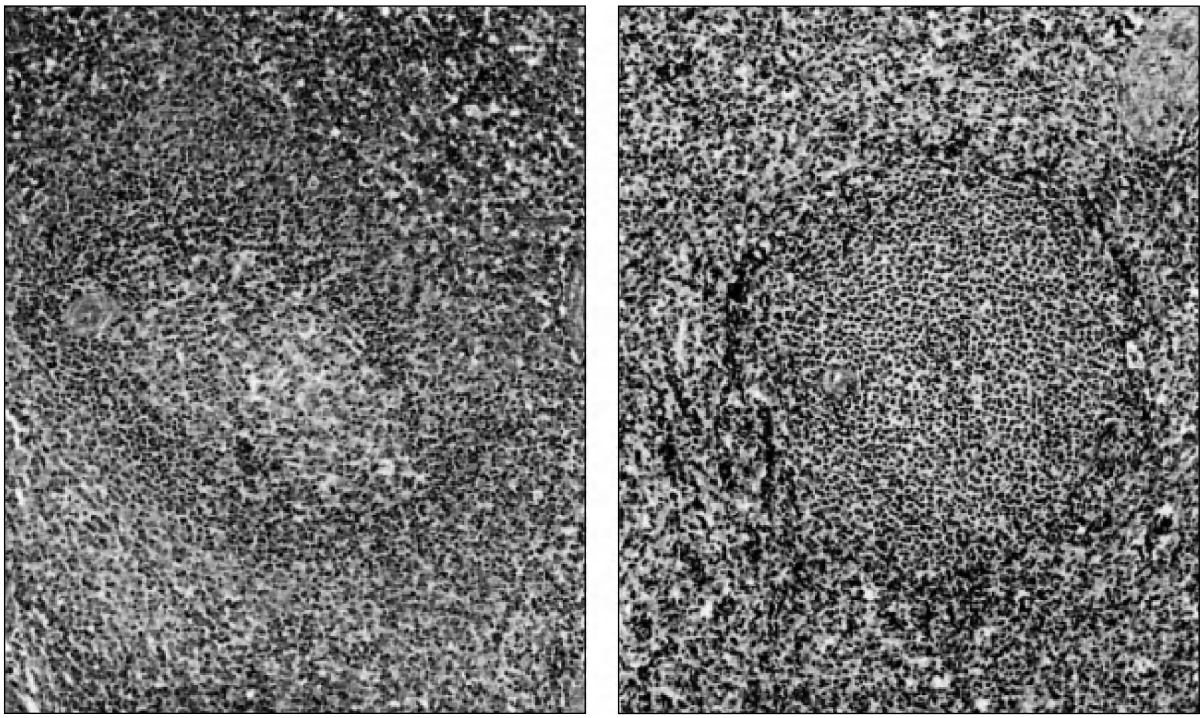


Figure 3 Histology of white pulp of spleen from 36-year-old male (a) and 83-year-old male (b). Formation of germinal center is observed in (a), but not in (b)

Table 2 Concentration of IgA antibody in the nasal mucosa is efficiently increased by intranasal immunization of antigen, not by other routes

Immunization route	in → in		iv → ip	
Age of mice	3 m	18 m	3 m	18 m
Ig A levels in nasal mucosa	172 ± 17	54 ± 20	2 ± 0.8	2 ± 0.8
Ig G levels in serum	30364 ± 2370	11230 ± 4584	162481 ± 14322	111903 ± 7488

Levels of antibodies, ng/mouse.
in, intranasal immunization; iv, intravenous immunization; ip, intraperitoneal immunization.
in → in, antigen was first intranasally given and a booster 3 weeks later by the same route;
iv → ip, antigen was first intravenously given and a booster 3 weeks later by ip.
Antigen; Influenza virus vaccine (A/PR/8/34) mixed with cholera toxin B.
Asanuma *et al.* (2001).

(Table 2). Thus, efficient protection against influenza could be accomplished by intranasal local administration of vaccine.

(e) Bone marrow

The Bone marrow is a primary source of hematopoietic and lymphoid cells. An apparent age-related decrease of red bone marrow is observed in humans and rats, but not in mice. Proliferative activity assessed by Ki-67-positive cells was high in the middle-aged group and declined slightly in the elderly group. Apoptosis was relatively low in the young and middle-aged group, but significantly increased in the elderly group (Figure 4). These data suggest that hypocellularity in the bone marrow of elderly people could be ascribed partly to the increase in apoptosis and decrease of proliferative capacity. Interestingly, plasma cells, or IgA, and IgG containing cells increase in human bone marrow, with a concomitant increase of these immunoglobulins in serum. In aged mice, bone marrow, and not spleen, becomes the major site of immunoglobulin production.

3. *Serum immunoglobulins*

Despite age-related atrophy of lymphoid tissues, such as spleen, lymphoid tissues, and thymus, the level of serum IgA and IgG gradually increases with age, but that of IgM does not change. Increased level of serum immunoglobulin is consistent with an increase in immunoglobulin synthesizing plasma cells in lymphoid tissues and bone marrow, and with a decrease in the rate of degradation. Although serum immunoglobulin level increases with age, immunoglobulins

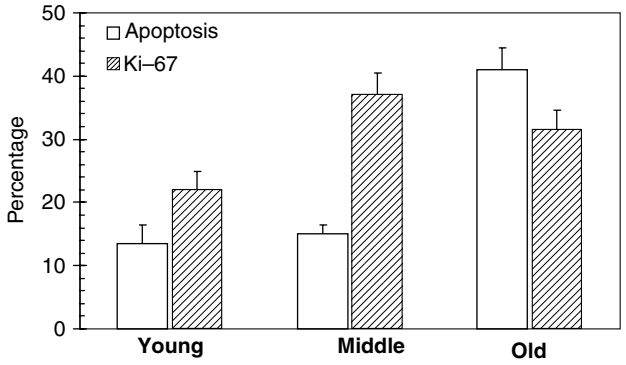

Figure 4 The percentage of apoptotic cells and proliferating cells in human bone marrow of 3 different age-groups. The percentage of apoptotic cells was determined by the terminal deoxynucleotidyl transferase-mediated dUTP nick end-labeling (TUNEL) method. The Ki-67^+ cells indicate cells in the proliferating phase. Vertical bars indicate SEM. Young, subjects less than 20 years old. Middle, subjects between 50 and 59 years old. Old, subjects between 80 and 100 years old

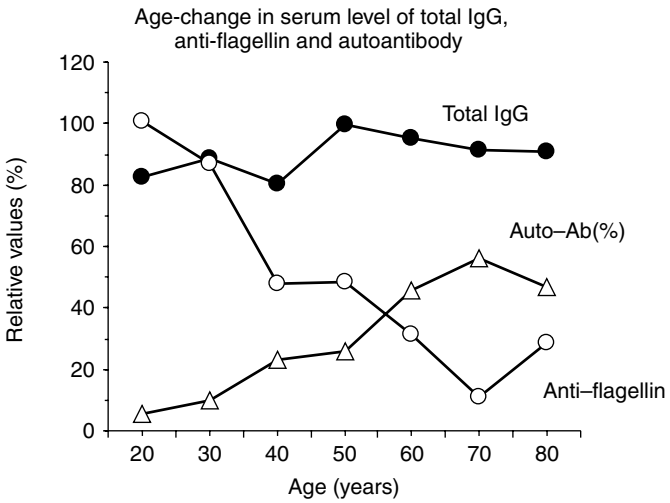

Figure 5 Age-related changes of total IgG (closed circles), relative values of anti-Flagellin (open circles) and incidence of autoantibody (auto-Ab, open triangles) in human serum (the highest level, 100%). Modified from Rowley *et al.* (1968) and Suzuki *et al.* (1984)

produced in old mice are less protective because of their low titer and affinity. The production of specific antibodies decreases with age with an increased production of autoantibodies (Figure 5), which will be discussed later. Interestingly, frequency of benign monoclonal gammopathy increases with age.

CELLS OF THE IMMUNE SYSTEM

Much information is available regarding cells in the peripheral blood, but little about cells making up the microenvironment of various lymphoid tissues, except for thymus, whose role in the aging of immune system will be discussed in the next section. Absolute number of lymphocytes, T cells, and B cells generally declines with age in association with altered composition of their subsets (Utsuyama *et al.*, 1992; Cossarizza *et al.*, 1996; Fagnoni *et al.*, 2000). It should be stressed that the decline starts during childhood or after puberty (Utsuyama *et al.*, 1992). This section will present an overview of changes of various immune cells at the cellular level.

1. *Hematopoietic stem cells (HSCs)*

The number of hematopoietic stem cells (HSCs) in the bone marrow does not change greatly with age, when assessed by the number of colonies formed in the spleen of lethally irradiated mice (CFU-s). However, when the number of cells per colony is counted, the cell counts in colonies derived from young bone marrow are apparently higher than those from old bone marrow, indicating that proliferative activity of old bone marrow cells declines with age (Albright and Makinodan, 1976). A recent review paper relates age-related functional activity of HSCs with age-related decline in replicative activity of HSCs in both murine models and human, and concludes that age-related functional decline in adult tissue HSCs limits longevity in mammals (Geiger and Van Zant, 2002). The ability of HSCs to differentiate into mature B cells also declines, and IL-7 plays an important role in the expansion of B cell precursors in bone marrow. An apparent decrease in the number of IL-7 responsive $B220^+$ B cell precursors was observed in old mice when compared with young mice (Jonsson and Phillips, 1993). Progenitors of T cells also decrease with age, when assessed by the ability of bone marrow from young and old donors to repopulate the thymus and spleen of lethally irradiated mice. However, alteration of the thymic microenvironment is much more responsible for the thymic involution than alteration of progenitors of T cells, as the size of thymus restored by bone marrow transplantation is apparently smaller in Y $\rightarrow$ O than in O $\rightarrow$ Y bone marrow chimera (Table 3).

2. *T cells*

T cells play a pivotal role in the acquired immune system and are most profoundly affected by aging. The magnitude of decrease in T cell functions *in vivo* between young and old individuals is sometimes more than 10-fold, and generally greater than the decrease observed in B cells or NK cells. Age-related changes of T cells can be ascribed to the following three types: (a) quantitative change, (b) a change in the proportion of T cell subsets, (c) a qualitative change, such as proliferative response and cytokine production.

(a) Quantitative change

The number of T cells in human peripheral blood is high in infants and young adults before 20 years of age, and a significant decrease is observed between the second and third decade. The number stays at almost the same level through the sixth decade and declines after the seventh decade (Table 4) (Figure 6) (Utsuyama *et al.*, 1992). Such a decline in T cell numbers appears to be associated with the acceleration of thymic involution. Some investigators have proposed that the thymus plays

Table 3 Comparison of regeneration of thymus, splenic T cells, and their subset among four combinations of bone marrow chimera mice constructed between young and old mice

Types of radiation bone marrow chimeras (donors → recipients)	Thymic weight (mg)	Splenic T cells ($\times 10^6$)	CD4:CD8 (ratio)	Naïve T: memory T (ratio)
Y → Y	43.9	21.1	6.5	0.91
O → Y	44.4	24.3	6.1	0.33
Y → O	14.2	9.9	8.9	0.16
O → O	13.6	8.4	7.9	0.13

Numbers indicate levels 8 weeks after the construction of bone marrow chimera mice: bone marrow cells from donor mice were grafted to sublethally irradiated mice.
Y, Young mice; O, Old mice.

Table 4 Age-related changes in cells in peripheral blood

Age	WBC	Lymphocytes	T cells	CD4/8 ratio	B cells	NK cells	Monocytes
1–19	6.8 ± 0.5	2.7 ± 0.4	1.7 ± 0.2	1.56 ± 0.09	0.27 ± 0.06	0.38 ± 0.05	0.33 ± 0.04
20–29	6.3 ± 0.3	2.2 ± 0.2	1.4 ± 0.1	1.67 ± 0.10	0.16 ± 0.02	0.38 ± 0.06	0.18 ± 0.02
30–39	6.6 ± 0.4	2.2 ± 0.2	1.3 ± 0.1	1.56 ± 0.10	0.15 ± 0.02	0.38 ± 0.06	0.23 ± 0.03
40–49	7.0 ± 0.6	2.3 ± 0.2	1.4 ± 0.1	2.31 ± 0.21	0.15 ± 0.02	0.42 ± 0.05	0.22 ± 0.02
50–59	6.6 ± 0.4	2.5 ± 0.2	1.5 ± 0.1	1.98 ± 0.13	0.16 ± 0.02	0.42 ± 0.05	0.23 ± 0.02
60–69	6.5 ± 0.4	2.2 ± 0.2	1.3 ± 0.1	2.49 ± 0.25	0.17 ± 0.03	0.52 ± 0.05	0.31 ± 0.03
70–79	5.8 ± 0.4	2.0 ± 0.2	1.1 ± 0.1	2.91 ± 0.70	0.13 ± 0.02	0.57 ± 0.12	0.39 ± 0.04
80–89	6.1 ± 0.3	1.8 ± 0.1	1.1 ± 0.1	2.13 ± 0.18	0.11 ± 0.01	0.45 ± 0.04	0.29 ± 0.02
90–	6.1 ± 0.4	1.7 ± 0.2	0.9 ± 0.1	2.21 ± 0.39	0.08 ± 0.02	0.41 ± 0.06	0.41 ± 0.06

Values $\times 10^3$ indicate cell counts per mm^3 in the peripheral blood, except for CD4/8 ratio.
Cell counts of WBC (white blood cells), lymphocytes, and monocytes were obtained by routine blood cell count. Cell counts of T cells, B cells, and NK (natural killer) cells were obtained by flow cytometric method.

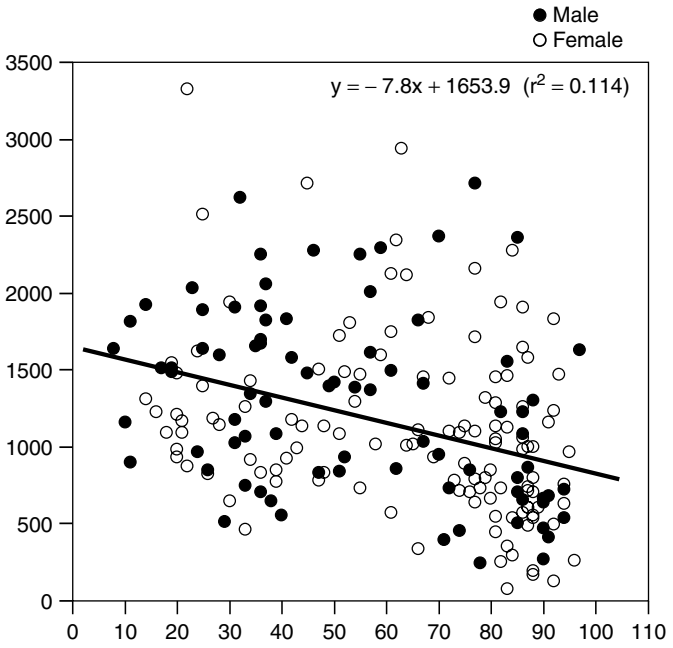

Figure 6 Number of T cells (per mm^3) in peripheral blood of male (closed circles) and female (open circles), ranging in age from 6 to 97 years. The line indicates regression

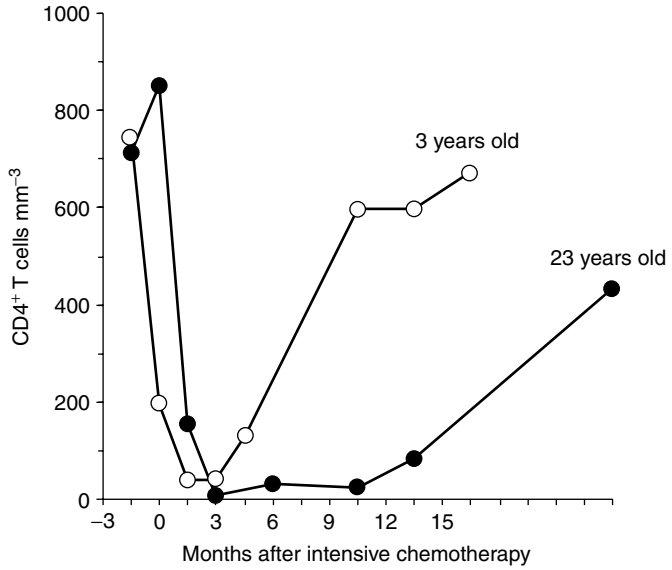

Figure 7 Regeneration of $CD4^+$ T cells in peripheral blood in patients following intensive chemotherapy. Number of $CD4^+$ T cells drastically declined after chemotherapy. In a 3-year-old patient, the number recovered nearly to the previous level in 9 months. In a 23-year-old patient, however, recovery of the number of $CD4^+$ Ta cells was significantly delayed. Modified from Mackall *et al.* (1995)

a time-keeper's role or acts as an 'aging clock'. The level of T cell numbers is easily influenced by exogenous factors, such as infection and stress, and the individual variation increases with advancing age. In this regard, the most important point is that the recovery in the T cell number after exposure to stress or drug treatment is reduced in old individuals as compared with younger ones (Mackall *et al.*, 1995; (Figure 7)).

(b) Change in T cell subsets

$CD4^+$:$CD8^+$ T cell ratio In long-lived C57BL/6 mice, the percentage of splenic T cells gradually increases after birth, peaks at around 3 months of age, stays at a constant level until 12 months of age, and then gradually declines thereafter. The number of $CD4^+$ T cells stays relatively constant in the adult and senescent stages, while that of $CD8^+$ T cells gradually declines with age. Thus, the ratio of $CD4^+$:$CD8^+$ T cell subset rises after 3 months of age. Of clinical importance is that a similar age change is observed in human peripheral blood. Thus, the ratio of $CD4^+$/$CD8^+$ T cells is low in infants and young adults, increases in middle-aged people, and again decreases in old people over 80 years of age (Table 4) (Utsuyama *et al.*, 1992). In a Swedish longitudinal Octogenarians (OCTO)-immune study, a combination of decreased $CD4^+$:$CD8^+$ T cell ratio and poor T cell proliferation was associated with higher mortality in a subgroup of very old Swedish individuals (Wikby *et al.*, 1998). In this respect, it is interesting to note that the number of $CD8^+$ T cells carrying receptors for viral epitope (cytomegalovirus (CMV) or Epstein–Barr virus (EBV)) increases with age in some cohorts (Ouyang *et al.*, 2002), which could contribute to the decrease of $CD4^+$:$CD8^+$ T cell ratio.

Naïve and memory helper T cell subsets Human $CD4^+$ and $CD8^+$ T cells can be divided into two subsets based on the expression of two markers: CD45RA and CD45RO that seem to differentiate the so-called naïve and memory T cells. At birth, most of the T cells are of naïve type and the number decreases thereafter with reciprocal increase in the number of memory type T cells (Cossarizza *et al.*, 1996). Figure 8 shows age-related changes of naïve and memory T cells in human and C57BL/6 mice (Utsuyama *et al.*, 1992). In mouse T cells, $CD4^+$ $CD45RB^{high}CD44^{low}$ and $CD4^+$ $CD45RB^{low}$ $CD44^{high}$ are referred to as *naïve* and *memory T cells*, respectively (Mossmann and Coffman, 1987). The age-related reciprocal change in the ratio between naïve and memory T cell subsets in mice (Figure 8b) is much more clear-cut than in humans (Figure 8a). In young mice, naïve and memory T cells are almost comparable to the proinflammatory Th1 and anti-inflammatory Th2 T cell ratio, in terms of cytokine production. However, the situation changes in old mice; that is, naïve T cells produce more IL-4 than IL-2 and memory T cells produce more IL-2 than IL-4.

Other T cell subsets CD28 is a costimulatory molecule that is required for optimal activation and proliferation by antigenic stimulation of T cells. T cells expressing CD28 decrease with age *in vivo*, and progressive loss of CD28 is observed in long-term T cell culture (Effros *et al.*, 1994). Thus, expansion of $CD28^-$ T cells may be one of the hallmarks of immunosenescence. CD95 is a surface molecule mediating apoptotic signal and plays an important role in immunological regulation. T cells expressing CD95 decrease with age, especially within the $CD8^+$ T cell subset (Fagnoni *et al.*, 2000).

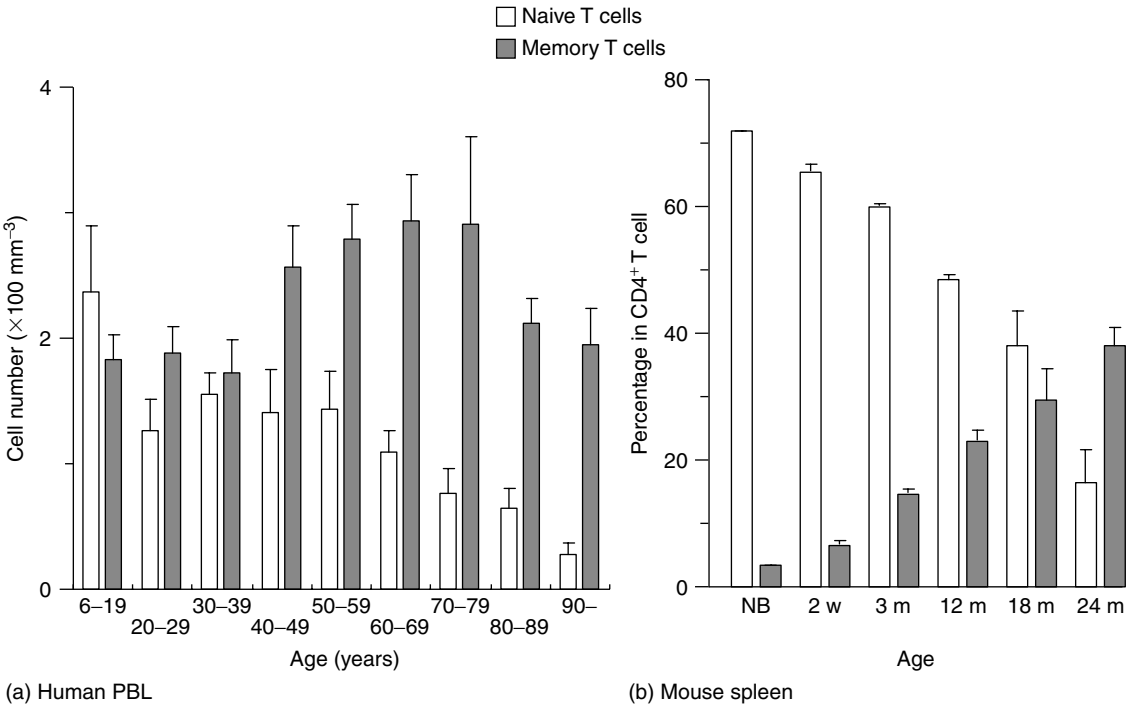

Figure 8 Age-related decrease of naïve T cells (open columns) is seen with a concomitant increase of memory T cells (cross-hatched columns) in human peripheral blood (a) and mouse spleen (b). After Utsuyama *et al.* (1992) (Reprinted from Mechanisms of Age and Development, vol 63, Utsuyama M *et al.*, pp 57–66, Copyright 1992, with permission from Elsevier)

Naturally arising $CD25^+CD4^+$ regulatory T cells contribute to the maintenance of immunologic self-tolerance and negative control of various immune responses (Sakaguchi, 2004). Suppressive activity of human $CD4^+$ $CD25^+$ T cells is reported to decline with age (Tsaknaridis *et al.*, 2003).

(c) Qualitative change

Qualitative changes in T cells are observed by their ability to proliferate and produce various cytokines following antigenic or mitogenic stimulation (Douziech *et al.*, 2002; Utsuyama *et al.*, 1993). Antigenic stimulation is received by the T cell antigen receptor (TCR), and the signal is transmitted through CD3 molecules to activate various signal transduction molecules, eventually giving rise to proliferation and cytokine production. Aging definitely influences signal transduction and cytokine production, which will be discussed later. T cells from aged humans appear to be more sensitive to TNF-α-induced apoptosis (Salvioli *et al.*, 2003).

3. *B cells*

B cells play an important role in the production of antibody. Quantitatively, the number of B cells in human peripheral blood decreases with age (Table 4) (Utsuyama *et al.*, 1992; Huppert *et al.*, 1998). Antibody forming capacity is known to decrease with age in humans and animals, and the decline is due to insufficiency of helper T cells, intrinsic changes in B cells, or both. For example, immunization with tetanus toxoid (TT) results in a significant increase in serum titers in young adults for up to 1 year, but the serum TT titers falls off to baseline by 6 months in old adults (Burns *et al.*, 1993). Stem cells in the bone marrow differentiate to pro-B cells, then to pre-B cells, and finally to B cells with sIgM. It is well known that frequencies of pre-B cells are diminished in aged mice. Age-related decrease was also observed in the number of both pro-B cells and very early B-lineage progenitors in mouse bone marrow (Miller and Allman, 2003).

Qualitatively, various age changes appear to occur in B cells. An intrinsic molecular change may occur in the aging B cells, as utilization of VH and VL genes in antibodies to a bacterial epitope (e.g. phosphorylcholine hapten) differs between young and old mice. Old mice express less diversified antibody repertoires, possibly as a consequence of reduction in the number of antibody precursors and increased peripheral selection that may be responsible for the progressive establishment of immunodeficiency.

4. *NK cells*

NK cells are a critical component of the innate immune response against various infections and tumors. The number of NK cells increases with age in humans after a certain point in old age, but contrarily, it decreases in mice (Utsuyama *et al.*, 1992; Mariani *et al.*, 1994). Despite discrepancy in the number of NK cells between humans and mice, the killer cell activity declines both in humans and mice (Mariani *et al.*, 1994). Proliferation of purified NK cells from healthy elderly donors in response to IL-2 is decreased as compared to those from young donors (Borrego *et al.*, 1999).

5. *NKT cells*

NKT cells represent a unique subset of T cells sharing some characteristics with NK cells and are found at high frequency in the liver. The number of liver NKT cells decreases in old humans and mice (DelaRosa *et al.*, 2002; Tsukahara *et al.*, 1997), in association with impaired cytotoxicity and cytokine production. It is interesting to note that liver NKT cells bearing TCR$\alpha\beta$ decrease in number with age, but those bearing TCR$\gamma\delta$ are functionally increased in very old mice (Mocchegiani and Malavolta, 2004).

6. *Macrophages*

Macrophages are one of the prototype cells of the innate immune system. Conflicting results are reported on functions of macrophages and monocytes. Phagocytosis and lysosomal enzyme activity do not change with age; however, the ability of macrophages to present antigen declines with aging. Lectin-induced proliferation of T cells is inhibited by prostaglandin (PG) E2, hydrogen peroxide (H_2O_2), and transforming growth factor (TGF) $\beta 2$, which are produced by macrophages. The inhibitory effect is significantly greater when macrophages are derived from aged rats. The production of H_2O_2 and nitric oxide (NO) in peritoneal macrophages is reduced in old mice when compared to that of young mice (Ding *et al.*, 1994). Antitumor activity of peritoneal macrophages declines with age, together with the reduced capacity to produce IL-1 and NO. Adherence of macrophages to fibronectin (FN) and type 1 collagen increases during aging, and this may be related to atherogenesis of the aorta during aging. Age-related increases in the number of monocyte/macrophage/osteoclast precursor cells could explain the increased resorptive activity seen in the elderly. Tumor necrosis factor (TNF) production by alveolar macrophages and spleen cells in response to a Streptococcus-derived factor (OK-4323) increases with age in mice (Han *et al.*, 1995). Both splenic and activated peritoneal macrophages from aged mice express significantly lower levels of all Toll-like receptors (TLRs). Secretion of IL-6 and TNF-α is decreased when stimulated with known ligands for TLRs (Renshaw *et al.*, 2002). Lipopolysaccharide (LPS) stimulated macrophages from aged animals have significantly higher levels of the inducible cycloxygenase 2 enzyme, leading to increased production of PGE_2, which is known to inhibit T cell function (Hayek *et al.*, 1997), as mentioned above.

7. *Granulocytes*

Granulocytes are a major component of natural immunity and operate as the front line of defense against various infectious agents. In healthy subjects, most functions of granulocytes do not change or even increase compared with young control. However, age-related impairment or alteration of various magnitude was detected including phagocytosis, intracellular killing, chemotaxis, proliferative response to GM-CSF, expression of CD16, production of superoxide

anion, mobilization of intracellular free calcium, apoptosis, and antibody-dependent cell-mediated cytotoxicity (ADCC) activity (Seres *et al.*, 1993; Fulop *et al.*, 1997; Schroeder and Rink, 2003; Plackett *et al.*, 2004).

8. *Antigen presenting cells (APC)*

Macrophages, B cells, and dendritic cells play an important role in presenting antigen to T cells. In senescent accelerated mice (SAMP1), B cells and dendritic cells express low level of Major Histocompatibility Complex MHC-II and intercellular adhesion molecule 1 (ICAM-1) and show a decrease in antigen presenting cells (APC) function. A decrease is also observed in accessory function of human monocytes, which is essential for T cells to proliferate in response to phytohemagglutinin (PHA) stimulation. The type of MHC should be the same between APC and T cells; however, T cells from aged, but not young, humans can be stimulated with influenza vaccine presented by allogeneic APC (Schwab *et al.*, 1992). Dendritic cells (DC) are "professional" APC, for they are most efficient in presenting antigens to T cells. Since maturation of DC subsets is suppressed by IL-10, age-related increase of IL-10 could negatively influence the maturation of DC in the elderly (Uyemura *et al.*, 2002). The number of DC is decreased in skin (Langerhans' cells) of aged mice and peripheral blood of elderly people (Shodell and Siegal, 2003).

9. *Extrathymic T cells*

It is established that T cells of various types could be developed outside of the thymus, although the number is smaller than those derived from the thymus. T cells of extrathymic origin have either $\alpha\beta$ or $\gamma\delta$ type TCR, and are found in the liver and within epithelial cells of the digestive tract. With the age-related decline of thymic function to provide T cells to the periphery, extrathymic T cells generally increase in number. They probably play a role in the local defense against pathogenic microbes as well as in the maintenance of mucosal epithelium.

ROLE OF THYMUS IN AGING OF THE IMMUNE SYSTEM

The immunological function of the thymus was first revealed by the famous brief report of Miller (Miller, 1961), indicating that neonatal but not adult thymectomy brought about immune deficiency in mice. This suggests that the thymus starts to lose its function to provide T cells to the periphery shortly after the birth. Table 5 summarizes the rate of decline in various thymic functions in long-lived mice: (a) immigration of pre-T cells into the thymus; (b) proliferative activity of thymocytes; (c) emigration of T cells to the spleen; (d) the thymic function to provide helper T cells; and (e) killer T cells (Hirokawa *et al.*, 1994). The results clearly indicate that most thymic functions decline very rapidly; that is, within 4 weeks after birth. In this respect,

Table 5 Age-related changes in thymic function in mice

Experiments	1d	1 w	2 w	4 w	17 m	24 m
Experiment 1						
Immigration of pre-T cells Into thymus	100	NT	NT	7	3	3
Experiment 2						
1. Rate of proliferation of thymocytes	100	45	15	NT	17	NT
2. Rate of emigration of T cells to spleen	100	25	15	NT	1	NT
Experiment 3						
1. Rate of proliferation of thymocytes	100	73	71	85	NT	65
2. Activity of helper T cells	100	62	41	40	NT	10
3. Activity of killer T cells	100	125	55	25	3	0.5

The numbers are percentages as compared with the value at 1-day-old mice (100%) and average of 3 mice. NT, not tested; d, days; w, weeks; m, months. Experiment 1: Bone marrow cells from young B10.Thy-1.1 mice were injected i.v. into congeneic C57BL/6.Thy-1.2 mice at various ages from day 1 to 24 months old, and the number of donor-type thymocytes was counted 4 weeks later. Experiment 2: Bone marrow cells from young B10.Thy-1.1 mice were directly injected into thymus of congeneic C57BL/6 mice at various ages from day 1 to 24 months old, and the numbers of donor-type T cells in thymus (1) and spleen (2) were counted 4 weeks later. Experiment 3: Thymus from C57BL/6 mice at various ages from 1 day to 24 months old was implanted into congenic nude mice at 6 weeks of age. Twelve weeks later, number of thymocytes (1), activity of helper T cells (2), and killer T cells (3) in spleen were assessed.

repopulation of $CD4^+$ T cells after their elimination with anti-CD4 antibody (GK1.5) is 5 times less in aged than in young mice, and there is no repopulation in thymectomized mice (Rice and Bucy, 1995). In humans, Mackall *et al.* (1995) reported that regeneration of $CD4^+$ T cells after intensive chemotherapy was seen within 6 months in a 3-year-old infant, but was significantly retarded in a young adult 23 years of age (Figure 7). Such thymic changes, which start in the early phase of life, could be determined by assessing age-related changes occurring in either pre-T cells in the bone marrow or the thymic microenvironment, or both. To address this issue, four combinations of bone marrow chimeric mice were constructed by transplantation of bone marrow cells from young (3 months old) or old (24 months old) donors into young or old irradiated recipient mice ($Y \rightarrow Y$, $Y \rightarrow O$, $O \rightarrow Y$, $O \rightarrow O$). It was shown that the thymic weight was almost comparable for those chimeric mice when the recipients are young, regardless of the age of bone marrow donors, but was distinctly reduced when the recipients are old, regardless of the age of bone marrow donors. In other words, the magnitude of *in vivo* proliferative capacity of the thymocytes was mainly dependent upon the age of thymic microenvironment (Table 3). In the experiment of intrathymic injection of bone marrow cells in mice, it was shown that the rate of emigration of T cells from the thymus greatly decreased between birth and 1 month of age (Table 5) (Hirokawa *et al.*, 1988). These findings, taken together, indicate that the

age-related alteration of thymic microenvironment is more responsible for the physiologic impairment in generating new T cells than that caused by intrinsic changes in progenitors (pre-T cells) in bone marrow (Hirokawa *et al.*, 1988).

As already described in the preceding sections, the impairment of T cell functions in the aged individuals is partly ascribed to a change in composition of T cell subsets. Such age-related change in T cell subsets can also be due to alteration in the ability of thymus to provide T cells to the periphery. It was shown that the thymus of young mice, as compared with that of old mice, produces more $CD4^+$ than $CD8^+$ splenic T cells. In case of $CD4^+$ T cell subsets, the thymus of young mice produces more naïve T cells than memory T cells, while the thymus of old mice does the opposite (Table 3). These findings are consistent with the facts that $CD8^+$ T cells are more susceptible to aging than $CD4^+$ T cells, and naïve T cells decrease with age as memory T cells increase (Utsuyama *et al.*, 1992).

CAUSES OF AGE-RELATED DECLINE IN THYMIC FUNCTION

Physiological thymic involution is considered to be under the control of both extrathymic and intrathymic factors. Since thymic involution is accelerated after puberty, sex hormone could be a possible candidate influencing thymic function. In practice, thymic involution can be delayed or reversed by castration regardless of age. Thymic hypoplasia with T cell-dependent immunodeficiencies was observed in congenitally hypopituitary Snell dwarf mice (Dorshkind *et al.*, 2003) and in rats that had undergone hypophysectomy. Conversely, thymic hyperplasia could be induced in rats by the destruction of the anterior portion of hypothalamus (AHTL, Anterior Hypothalamus Lesioning) (Utsuyama *et al.*, 1997a). AHTL gives rise to decreased secretion of somatostatin (SST) and relative increase in growth hormone releasing hormone (GHRH) in the hypothalamus. This leads to increased secretion of growth hormone (GH), causing thymic hyperplasia. As compared with young adult, high level of GH (>10 folds) is detected in the serum of newborn mice or rats, or rats treated with AHTL. In other words, size and function of thymus are partly dependent on the serum level of GH, which, in turn, is regulated by the balance between SST and GHRH in the hypothalamus (Figure 9) (Hirokawa *et al.*, 2001).

Regarding intrathymic factors influencing thymic size, most important is the thymic microenvironment composed mainly of epithelial cells. As shown in the experiment of bone marrow chimeras constructed with tissues from young and old donor mice (Table 3), the age of thymic microenvironment is crucial for the magnitude of thymopoiesis. Thus, it is important to search for genes or factors that are expressed at high level in the newborn stage and progressively decline thereafter. It has been recently reported that stromal cells expressing Notch ligand Delta-like-1 acquire the capacity to induce the differentiation of hematopoietic progenitors into CD4 CD8 double- and single-positive T cells (Schmitt

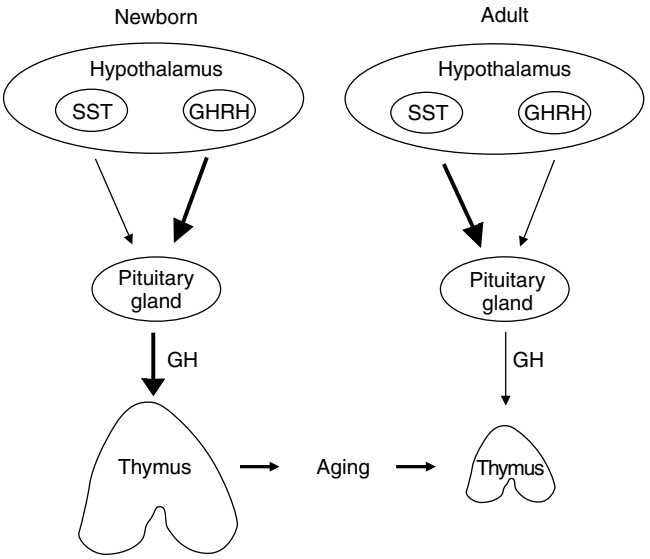

Figure 9 Control of thymic function by hypothalamus-pituitary axis. In newborn animals, positive signal of growth hormone releasing hormone (GHRH) is superior to negative signal of somatostatin (SST) in hypothalamus, leading to high secretion of growth hormone (GH). In young adult animals, negative signal (SST) exceeds positive one (GHRH) leading to a decrease in secretion of GH. A decrease in the serum level of GH in the young adult gives rise to thymic involution

and Zuniga-Pflucker, 2002). A decline in IL-7 production is another factor that is responsible for thymic involution (Andrew and Aspinall, 2002). The mRNA expression of Notch ligand Delta-like-1 and IL-7 is very high at birth and quickly declines thereafter (Hirokawa and Utsuyama, 2004). In addition, there are many other genes that are expressed at high level in the thymic stromal cells at birth and quickly decline thereafter (Hirokawa and Utsuyama, 2004). Many of them seem to participate in the process of physiological thymic involution.

CYTOKINE PRODUCTION

Among many cytokines, two types of cytokines, Th1 and Th2, are recognized. Th1 types are IL-2, IFNγ, and TNFβ, mainly responsible for cell-mediated immunity and suppressing antibody formation. Th2 types are IL-4, IL-5, IL-6, IL-10, and IL-13, responsible for antibody formation and suppressing cell-mediated immunity. It is generally accepted that production of Th1 type cytokines decreases with age, with a reciprocal increase of Th2 type cytokines, although there are some conflicting reports (Deng *et al.*, 2004; Glaser *et al.*, 2001; Neuber *et al.*, 2003). For instance, production of IL-2 and INFγ was reported to decline with age (Deng *et al.*, 2004), and such a decline is considered to be responsible for the impaired proliferation of old T cells upon antigenic stimulation. In contrast, production of IL-4, IL-5, IL-6, and 1L-10 by T cells increases with age (Castle *et al.*, 1997; Neuber *et al.*, 2003). Although INFγ belongs

to Th1 type cytokines, there are many reports indicating age-related increase in production of IFNγ or number of IFNγ^+ cells (Castle *et al.*, 1997; Neuber *et al.*, 2003; McNerlan *et al.*, 2002; Pietschmann *et al.*, 2003). The decrease in Th1 cytokines could explain a decrease in delayed type response to tuberculosis in the elderly, and increased production of Th2 cytokines would be consistent with increased frequency of autoimmune phenomena in the elderly population. IFNγ has a double edge effect in the immune system: one is antiviral effect and the other is suppressive effect on T cell function. With respect to the latter, production of TNF-α (Han *et al.*, 1995) and TGF-β also increases with age. These cytokines are known to contribute to age-related decline in immune functions. In any event, age-related change in the composition of T cell subsets is associated with an altered balance in cytokine production, and, together, they contribute to the impaired immune response capacity of old individuals.

SIGNAL TRANSDUCTION

Cells of the immune system are generally activated by stimuli such as antigens or cytokines through various receptors on the membrane. The stimulation through a receptor induces a cascade of intracellular signal transduction eventually reaching the nuclei and leading to DNA replication or generation of mRNA of some proteins.

Important receptors of T cells are TCR, costimulatory receptors, and cytokine receptors. The level of TCR expression does not change with age or, at best, only slightly (Fulop *et al.*, 1999). TCR/CD3 complex on T cells are internalized after mitogenic stimulation and reexpressed in certain interval. The level of reexpression is significantly retarded in T cells from old, as compared with young mice (Wakikawa *et al.*, 1997). CD28 is an important costimulatory receptor and the expression is known to decrease in humans (Effros *et al.*, 1994). Information is limited about the age-related change in the expression level of cytokine receptors. The expression level of IL-2R is decreased in the elderly. An increase of IL-2R after mitogenic stimulation is retarded in T cells from old mice.

Intracellular signal transduction is apparently different between cells derived from young and old individuals (Pawelec *et al.*, 2001). Pantel and Miller (Pantel and Miller, 1992) reported that quantitative and qualitative changes were observed in the pattern of protein phosphorylation between young and old T cells stimulated with mitogens. The activity of phospholipase C (PLC) acts on the phosphatidy-4,5 bisphosphate (PIP2) for liberation of inositoltrisphosphate (IP3) and diacylglycerol (DAG). The amount of PLC and PIP2 proteins extracted from T cells are comparable between young and old mice. However, phosphorylation of PLC was significantly impaired in old T cells as compared with young ones, when assessed *in vivo* after stimulation with anti-CD3 antibody (Utsuyama *et al.*, 1993). Phosphorylation of PLC is dependent upon protein tyrosine kinase (PTK) associated with CD3 molecules. Our laboratory found that

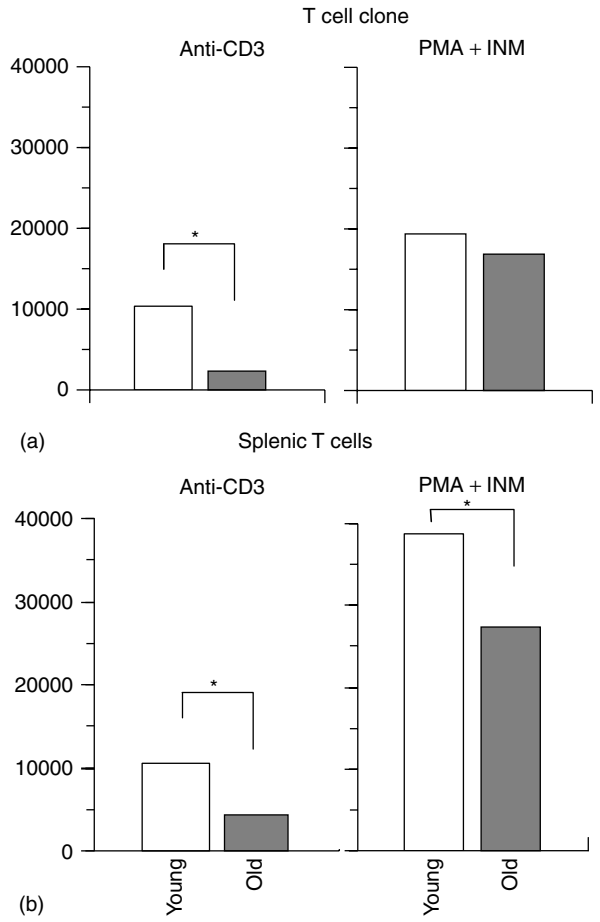

Figure 10 The proliferative response of T cell clones and splenic T cells after stimulation with anti-CD3mAb or PMA + INM. (a): [^{3}H]thymidine uptake of T cell clones established from young and old mice after stimulation with anti-CD3mAb or PMA + INM. (b): [^{3}H]thymidine uptake of splenic T cells prepared from young and old mice after stimulation with anti-CD3mAb or PMA + INM. *indicates a significant difference between young and old mice ($P < 0.001$). anti-CD3mAb: anti-CD3 monoclonal antibody (2.5μg/ml). PMA: phorbol myristate acetate (100 ng ml^{-1}). INM: ionomycin (20 ng ml^{-1})

phosphorylation of PTK such as lck, fyn, and ZAP-70 is impaired in old T cells as compared with young ones (Utsuyama *et al.*, 1997b). These findings collectively suggested that the decline in the proliferative response of old T cells could be partly ascribed to the impairment of intracellular signal transduction. Impaired phosphorylation of PTK and PLCγ1 in an old T cell clone is associated with LPS messengers and low influx of Ca^{2+}. An old T cell clone can be fully activated to the level of a young one by stimulation with phorbol myristate acetate (PMA) plus ionomycin (INM) that bypass receptor activation and directly stimulate Protein kinase C (PKC) and induce influx of Ca^{2+} (Utsuyama *et al.*, 1997b). However, when using splenic cells freshly prepared from young and old mice, the proliferative response of T cells of old mice to PMA plus INM is still lower than that of the young one (Figure 10) (Utsuyama *et al.*, 1997b). These results indicate that age changes of signal transduction

appear to be present in multiple sites within cells. The Jak-Stat pathway is one of the main signal routes under the IL-2R of T cells and is altered with age (Pawelec *et al.*, 2001). An age-related increase is observed in proportion of CD3ζ chains, associated with a FC-epsilon R instead of forming the usual ζ/ζ-homodimer in mice (Tamura *et al.*, 2000). In humans, T cells showed selective reduction in an isoform of PKC. Such a change in molecules may affect T cell function.

As regards B cells, a decreased sensitivity to the growth-promoting effects of IL-4 may be one of the mechanisms underlying defective specific antibody synthesis in aging. Such an age-related change of B cells might be related to decreased activity of PTK/PKC in human. A significant decrease of IP3 formation in granulocytes from elderly subjects was also reported.

These results suggest that alterations in signal transduction pathways occur with age in probably all cells of the immune system.

NEUROENDOCRINE-IMMUNE NETWORK

The immune system is closely related with the neuroendocrine system. Thymic involution accelerates in association with rise of sex steroids after puberty. In fact, restoration of thymic mass as well as certain immune functions is observed in the aged animals after gonadectomy. An increase of thymulin section is detected in aging rats by administration of growth hormone and thyroxine. Autonomic nerves may have influence on thymic function. An age-related decrease in noradrenergic nerves (Bellinger *et al.*, 1992) as well as dopamine-D1 like receptors (Ricci *et al.*, 1995) in the thymus may be responsible for reduced thymic mass with age. The hypothalamus plays an important role in the control of both endocrine functions and autonomic nerves; therefore, it also could be a control center regulating the rate of immunological aging. Inducing a lesion in the anterior portion of hypothalamus brings about either atrophy or hypertrophy of the thymus, depending upon the specific area of destruction (Utsuyama *et al.*, 1997a). As mentioned in the previous section, thymic function and size are partly under the control of hypothalamus (Hirokawa *et al.*, 2001). Lymphocytes can produce various hormones and neurotransmitters and express receptors for them. Figure 11 shows the expression of receptors for hormones and neurotransmitter in lymphocytes, revealed by RT-PCR. Changes of the expression level with age are variable; that is, an increase, or a decrease, or

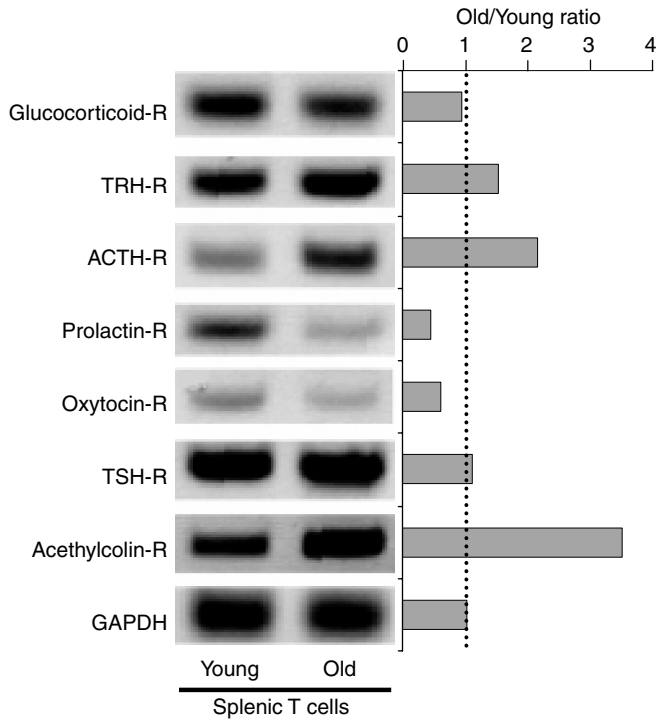

Figure 11 mRNA expression of various receptors (R) to hormones and neurotransmitters of T cells from young and old mice. Columns indicate ratio of old: young. mRNA expression of TRH-R, ACTH-R, and Acetylcholine-R are shown to increase with age

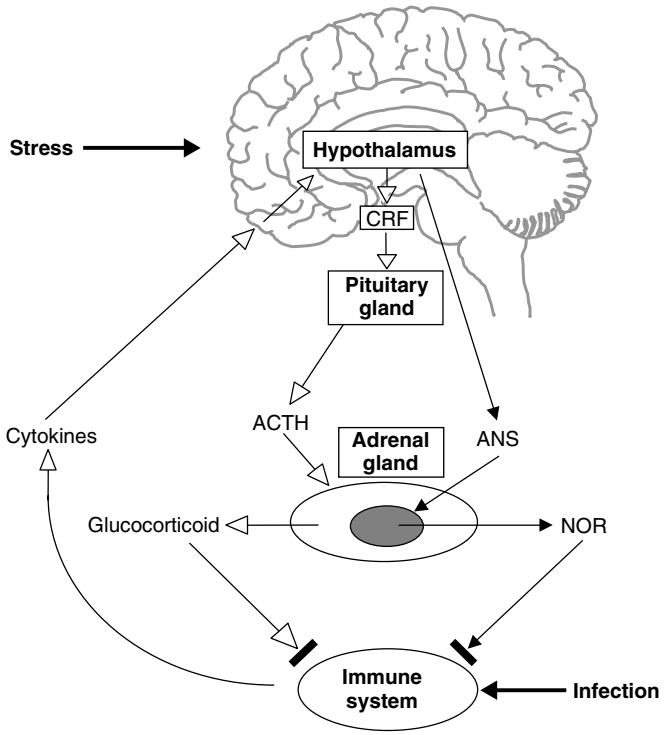

Figure 12 Stress-induced activation model of the neuroendocrine-immune network. Various types of stress from the external environment are received by the nervous system, and some signals eventually stimulate the hypothalamus to secrete Corticotropin releasing factor (CRF). CRF then stimulates the pituitary gland to secrete ACTH, which, in turn, stimulates the adrenal cortex to secrete glucocorticoid. At the same time, other stress-induced signals trigger the hypothalamus to stimulate the autonomic nervous system (ANS), eventually leading to the secretion of noradrenalin (NOR) by the adrenal medulla. Both glucocorticoid and NOR also suppress immune functions. Independently, infection stimulates the immune system to produce various types of cytokines, most of which enter the brain and stimulate the hypothalamus that eventually results in the secretion of both glucocorticoid and NOR

no change. Furthermore, cells of the nervous system can produce various cytokines and cytokine receptors. Age-related changes were reported in the levels of cytokines and their receptors in normal or pathological conditions (Utsuyama and Hirokawa, 2002; Godbout and Johnson, 2004). Another possible center for regulating immunological aging is the pineal gland, which produces melatonin for circadian rhythm. It is interesting to note that grafting of pineal gland in aged mice produces a remarkable restoration of thymic structure and cellularity. There is a growing belief that direct innervation or hardwiring of peripheral immune effector sites monitors and modulates immune homeostasis, together with the cytokine network (Downing and Miyan, 2000). More physiological studies *in vivo* are needed to further understand the significance of the neuroendocrine-immune network in aging. The data thus obtained would be helpful in understanding various diseases that are associated with immune dysfunction in the elderly population. As seen in Figure 12, the neuroendocrine-immune network acts as an integral system to combat various types of stress, including infection. As the network's function declines with age, its capacity to cope with stress declines. Thus, one physiologic characteristic of aging is the decrease in physiologic capacity of the neuroendocrine-immune network to cope with stress from the external environment.

IMMUNE RISK PHENOTYPES

As already mentioned, elderly people with elevated level of immune functions can live longer and become centenarians. Thus, the level of immune functions may predict the life span of individuals. In this respect, the longitudinal study in Baltimore (Shock *et al.*, 1984) suggests that the number of lymphocytes in the peripheral blood appeared to be a simple predictor of mortality; that is, individuals with a significant drop in the number of lymphocytes show higher rate of mortality within the next couple of years. In similar longitudinal studies of OCTO and Nonagenarian (NONA) on naturally aging population in Sweden, the concept of immune risk phenotype (IRP) was presented (Ferguson *et al.*, 1995). Parameters included in the high IRP phenotype were high CD8, low CD4, and poor T cell proliferative response that could predict two-year mortality of persons 80 years of age or older (Ferguson *et al.*, 1995). Further studies are required for the confirmation of the concept of IRP that would be helpful in understanding the importance of immune functions in morbidity and mortality of the elderly.

AUTOIMMUNE PHENOMENA INCREASING WITH AGE

Some autoimmune diseases are known to occur in young adults rather than in the elderly. For example, systemic lupus erythematosus (SLE) is an autoimmune disease that generally occurs in young females over 20 years of age. From the viewpoint of T cell immunity, however, people over 20 years of age are already in the early phase of the age-related decline of immune functions. As peak incidence of SLE, rheumatoid arthritis, and Hashimoto's thyroiditis are observed at the third, fifth, and sixth decade respectively (Figure 13), one could speculate that autoimmune diseases occur in the people whose immune functions are in the declining phase. These autoimmune diseases occur in a limited number of persons with distinct genetic background, as well as other factors such as aging of the immune system. It is important to

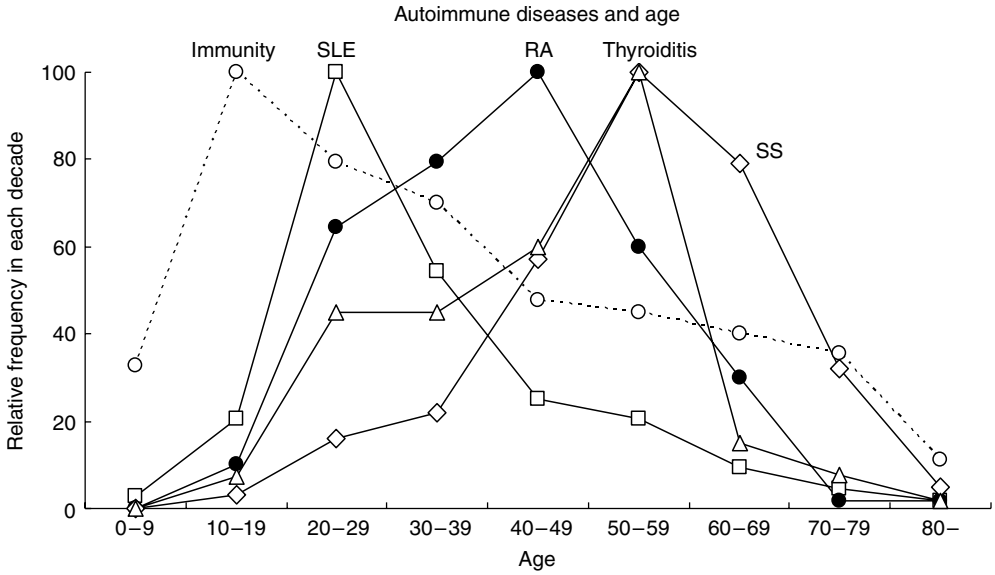

Figure 13 Age-related change of immune response and incidence of four autoimmune diseases in humans. SLE: systemic lupus erythematosus. RA: rheumatoid arthritis. Thyroiditis: Hashimoto's thyroiditis. SS: Sjögren's syndrome. Ordinate indicates relative values or frequencies, as compared with the peak level

note that autoimmune phenomena occur in most of the aged people, and they are called *age-associated autoimmune phenomena* rather than autoimmune disease, as they are generally not associated with clinical manifestations. On the other hand, the range of autoimmune disease is expanding. For instance, atherosclerosis might be an autoimmune disease due to an immune reaction against heat shock protein 60 (Wick, 2000).

Age-associated autoimmune phenomena are composed of two types of autoimmunity: one is the production of autoantibody and the other the generation of autoreactive T cells.

1. *Autoantibodies*

Accumulating data show that various kinds of autoantibodies are detectable in the sera of the elderly individuals. Both the frequency and the concentration of autoantibodies also increase with age and with a concomitant decrease of normal immune functions (Figures 1 and 5).

2. *Auto-reactive T cells*

It is very common to find focal lesions of lymphocytic infiltration in many organs of elderly autopsy cases, and most of these lymphocytes are revealed to be $CD4^+$ T cells when examined immunohistologically. The composition of the infiltrating lymphocytes in these lesions of submandibular glands was quite similar to those seen in Sjogren's disease. Focal lesions of T cell infiltration were also found in the thyroid, adrenal glands, liver, and kidney of the elderly autopsy cases as well as in aging mice. The incidence of focal T cell infiltration apparently increases with advancement in age, although the onset, incidence, and severity are different, depending on tissues and organs. In NFS/sld mouse, an animal model of human Sjogren's syndrome, α fodrin, a cytoskeletal protein, was identified as an autoantigen causing autoimmune disease (Haneji *et al.*, 1997). Interestingly, the lesion in NFS/sld mouse starts to appear as early as 1 month of age and becomes more pronounced and aggravated with age, and similar lesions develop in other sites (Kobayashi *et al.*, 2004).

RESTORATION OF IMMUNE FUNCTIONS

The development of methods to restore impaired immune functions of elderly people is urgently needed (Hirokawa and Utsuyama, 2002). Most of the methods reported are still at the level of animal models. Broadly speaking, there are two ways for immunological restoration: one is activation or functional enhancement of existing immune cells in individuals, and the other is transplantation or infusion of active or functional immune cells from young donors.

1. *Enhancement of immune cell functions*

(a) Caloric restriction

The effects of caloric restriction (CR) in rodents are pronounced in terms of elongation of life span and restoration of immunological functions (MaCay *et al.*, 1935). There has been accumulating evidence that similar observations are found not only in rodents but also in many other animal species, and CR influences various physiological systems, including the immune system (Longo and Finch, 2003; Heilbronn and Ravussin 2003; Pahlavani, 2004). Two important outcomes of CR are reduction of oxidative stress and improved glucoregulation. Studies are now ongoing to see the effect of CR on various physiological parameters in monkeys (Roth *et al.*, 2002), and they suggest several beneficial effects. Although data are limited, CR in humans could bring about similar physiological changes resembling those of rodents and monkeys. Thus, for example, there is a study reporting that long-term calorie restriction is highly effective in reducing the risk of atherosclerosis in humans (Fontana *et al.*, 2004). Animals under CR have decreased fat mass and alterations in insulin/insulin-like growth factor 1 (IGF-1). Mice with a fat-specific insulin receptor knockout (FIRKO) have reduced fat mass and show an increase in mean life span, although intake of calorie is normal (Blüher *et al.*, 2003).

(b) Antioxidants

Harman (Harman, 1969) hypothesized that degenerative changes associated with aging could be produced by the accumulation of deleterious side reactions of free radicals produced during cellular metabolism. Free radicals or reactive oxygen species (ROS) are harmful to immune cells, gradually attenuating their activities with increase in age. For instance, oxidative inactivation of CD45 protein tyrosine phosphatase may contribute to T lymphocyte dysfunction in the elderly (Rider *et al.*, 2003). Thus, vitamin E and other dietary antioxidants may play an important role in reducing ROS-initiated decline of immune functions with age. In animal models, vitamin E supplementation has been shown to increase immunological function and enhance survival against infection (Adolfsson *et al.*, 2001). Dietary supplementation with thioproline, a free radical scavenger, can significantly increase phagocytosis, NK activity, and proliferative response of lymphocytes in old mice (De La Fuente *et al.*, 2002). In humans, restoration of immune functions has been observed in some, but not all individuals (Ravaglia *et al.*, 2000; Gardner *et al.*, 2000). It is interesting to note that age-related physiological zinc deficiency induces deleterious changes in thymus structure and function, which can be partially corrected by a mild oral zinc supplementation (Mocchegiani and Muzzioli, 2000).

(c) Endocrine hormones

Age-related changes in the production of several hormones may be closely related with immunosenescence (Arlt *et al.*, 2002). Sex steroid hormones are inhibitory for lymphoid cells. Therefore, their withdrawal generally gives rise to enhanced immunological functions, as already described in gonadectomy. In contrast,

pituitary hormones, such as growth hormone and thyroid stimulating hormone, are stimulatory for the thymus and T cells. Concentration of dehyroepiandrosteron (DHEA) declines with age in humans. *In vivo* treatment of old rats with DHEA results in the restoration of age-associated defects in the protein kinase C signal transduction pathway with enhancement of mitogenic response of spleen cells (Corsini *et al.*, 2002). Melatonin is a hormone secreted by the pineal gland, and it plays an important role in the regulation of circadian rhythm. Melatonin was shown to act as a free radical scavenger; therefore, it could chemically correct immunodeficiencies of the elderly (Pierpaloi *et al.*, 1994). However, data reported on its effect on immunity are conflicting; some are positive (Atre and Blumenthal, 1998) and others are negative (Pahlavani *et al.*, 2002).

(d) Thymic peptides
Peptides isolated from the thymus are thymosin, thymic humoral factor (THF), thymopoietin, and FTS or thymulin, and they used to be called *thymic hormones*, but not any more. It is now generally accepted that they are not directly involved in T cell differentiation. Both successful and unsuccessful restoration of T cell function by thymic peptides, based on *in vivo* and *in vitro* experiments, have been reported by many investigators.

2. *Grafting of cells and tissues*

In animal experiments, transfusion of T and B cells from young mice into old mice did not give rise to a significant effect, probably due to inhibitory effects of preexisting cells in old individuals (Makinodan and Kay, 1980). In humans, the treatment of AIDS patients by transfusion of autologous T cells, expanded *ex vivo* in large scale, has been successful; that is, T cells were expanded 100–1000-fold by *ex vivo* culture for 2 weeks with recombinant interleukin-2 and immobilized monoclonal antibody to CD3 (Shimizu *et al.*, 2000). This model of large scale *ex vivo* expansion of T cells could be applied for the restoration of immune functions of the elderly.

The level of immune functions of aged mice can be restored to a level approaching that of young adult mice by grafting both newborn thymus and bone marrow cells of young donor animals (Hirokawa and Utsuyama, 2002). The results suggest that intrinsic cellular change of the immune system is more responsible for immune deficiencies of aged individuals than the environmental or structural tissue change, including connective tissues and humoral factors. Table 6 shows relative levels of anti-SRBC antibody response in eight combinations of chimeras, constructed by young or old recipients, young or old bone marrow cells, and newborn or old thymus. The relative magnitude of antibody response is always high or medium, regardless of the age of recipients and bone marrow cell donors. Thymic stromal tissues, rather than bone marrow cells, are important for restoration of the T cell-dependent immune system. In practice, aged mice treated with multiple newborn thymus grafting can survive significantly longer than control mice (Hirokawa and Utsuyama, 2002). For human application, MHC type should be the same or very close between donors and recipients. Therefore, a new method needs to be developed for the reconstruction of the thymic microenvironment using appropriate cells and genes of the individual (Hirokawa and Utsuyama, 2004).

Table 6 Eight combinations of chimeras constructed by young/old recipients, young/old bone marrow, and newborn/old thymus

Recipients	Bone marrow	Thymus	anti-SRBC antibody response
Young	Young	Newborn	High
Young	Young	Old	Low
Young	Old	Newborn	High
Young	Old	Old	Low
Old	Young	Newborn	High
Old	Young	Old	Low
Old	Old	Newborn	Medium
Old	Old	Old	Low

Young (2 months) and old (23 months) C57BL/6 male mice were irradiated (8.5Gy) and transplanted with bone marrow cells (5×10^5) from young (3 months) or old (24 months) C57BL/6 male mice. One month later, thymus from newborn or old (24 months) mice was transplanted under kidney capsule of recipient mice. One month after the last treatment, anti-SRBC antibody response was assessed.

CONCLUDING REMARKS

The immune system not only functions as the body's defense system against infections from the external environment but also as the body's regulatory system, maintaining homeostasis of the internal environment. In the latter case, the immune system operates together with the endocrine and nervous systems using many common mediators among themselves. In other words, the neuroendocrine-immune network combats various kinds of stresses from the outer environment, and its age-related decline in functional capacity is causally related to the increase in occurrence of various age-associated diseases and decline in quality of life (QOL) in the elderly population. Thus, the restoration of immune capacity is necessary not only for protection against infection but also for the improvement of QOL in the elderly.

Age-related functional decline is observed in many kinds of cells and tissues composing the immune system, but the most pronounced decline occurs in those involved in T cell-dependent immune functions that are due mainly to thymic involution starting in the early phase of life. Accordingly, the restoration of T cell-dependent immune functions is becoming an important issue in combating infectious diseases and improving the QOL of the elderly population. Various methods to restore T cell-dependent immune functions in the frail elderly population are now under investigation in many laboratories. Among them, the reconstruction of thymic microenvironment using modern tissue and gene technology appears to be one of the most exciting and challenging tasks.

KEY POINTS

- Infection, a major cause of death in the elderly population, is primarily due to age-related decline in T cell-dependent immune functions.
- Age-related decline of T cell-dependent immune functions, caused by thymic involution that occurs early in life, is manifested quantitatively by a decrease in the number of T cells and a shift in the proportion of T cell subsets, and qualitatively by changes in proliferative activity and cytokine production that are caused by alteration of molecules involved in intracellular signal transduction.
- The immune system collaborates with the neuroendocrine system, and the neuroendocrine-immune network combats various kinds of environmental stress, including infections.
- Age-related decline in immune functions is causally related to increase in occurrence of various age-associated diseases, including infections, autoimmune diseases, and autoimmune phenomena against internal antigens, and, as a consequence, to decrease in quality of life (QOL).
- Restoration of impaired immunological functions in the elderly is an urgent need, and therefore, various restorative methods are discussed, including caloric restriction, antioxidant dietary supplements, hormone supplement, and grafting of limiting immune cells and tissues.

Physiology of Aging

Rafi Kevorkian

Saint Louis University, St Louis, MO, USA

THE HUMAN BODY EVOLVING, CHANGING, AND AGING

In the last century, we have seen a near doubling of life expectancy in humans. Modern medicine has left us with a vast knowledge of information toward the aging process. A multitude of changes have been known to occur consistently in humans. This chapter will examine and focus on these changes. The organ systems will be highlighted with a brief synopsis of each and how they age. The aging process affects all organ systems and, as such, understanding these changes will allow us to better understand the functional impact they have on the aged individual.

A multitude of changes occur in each organ. These changes are irrespective of diseases modifying aging. The rate of age-related decline in organ function varies greatly. Aging has been defined as a failure to maintain homeostasis under conditions of physiological stress. All species show aging. Within a normal cell, oxidative stress (free radical theory of aging) chronically leads to changes in gene expression. This leads to alteration in the phenotype and aging of tissue. In a different model, "wear and tear" (somatic mutation, error catastrophe, protein glycosylation) of cells leads to necrosis or apoptosis. This leads to an increase in cell turnover causing an alteration in the phenotype leading to an aged cell. Senescence is defined as the permanent exit from the cell cycle of cells that would normally be able to undertake division. This may also lead to aging because it leads to a decline in the growth potential of cell populations, which have undergone turnover. These cells display biochemical features that are distinct from their growing counterparts. The expression of some genes (intrinsic mutagenesis, programmed death) goes up, while others go down or are unaffected. Olovnikov proposed that cells might count divisions through the progressive shortening of chromosome ends (telomeres). Telomerases are enzymes that prevent shortening of telomeres. The consequence of this is that a small amount of terminal DNA is not replicated with repeated cell divisions. This may contribute to senescence. It has been shown by Zglinicki that mild oxidative stress may increase the rate of telomere shortening. DNA helicases unwind damaged DNA to allow for repair. Organisms that have greater resistance to DNA damage have conferred longevity (Von Zglinki *et al.*, 2000). The neuroendocrine theory of aging stresses the need to regulate the biological clock to maintain homeostasis. The hypothalamo–pituitary–adrenal axis acts as the master regulator to adjust to the physiological needs of the organism during stress. The neuroendocrine-immuno theory of aging stresses the relation of the endocrine system as it regulates the immune system to fight off infection. As the immune system wanes, the organism becomes susceptible to death due to higher chance for infection. Aging then would result from a "decreasing ability to survive stress". Thus, a multitude of factors can lead to aging.

AGING OF ORGANS

Aging of the Skin

The skin is the largest organ of the body. It has many important functions. It functions as a mechanical barrier, regulates temperature, initiates immunological functions, communicates external stimuli to the body, and protects against the effects of ultraviolet light. The skin is composed of three major layers. The outermost layer is the epidermis, followed by the dermis, which leads to the hypodermis. In the epidermis, a multitude of cells exist such as keratinocytes, melanocytes, Langerhans cells, and Merkel cells. The basement membrane separates the epidermis from the dermis. The dermis is composed of connective tissue, consisting mainly of collagen fibers, and elastin. The fibroblasts are the major cell type. The hypodermis is composed of the adipocytes, as well as the intravascular bundle. The typical signs of aging include wrinkling and sagging of the skin. Extrinsic aging is more prominent in the hands, neck, and the face and is attributed to sun exposure (Gilchrest, 1989).

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Intrinsically aged skin is thin, pale, and finely wrinkled. Histological staining shows flattening of the dermo-epidermal junction. This form of aging is felt to be secondary to superoxide free radical formation. Aged skin demonstrates a reduced keratinocyte proliferative capacity. The number of epidermal cell layers remains unaltered during aging (Table 1). A decrease in melanocytes contributes to the paling of the skin.

The dermo-epidermal junction flattens with age due to the retraction of the epidermal papillae (Table 2). This leads to a skin structural unit, which is less resistant to shear forces than younger skin is. Skin thickness tends to decrease after the seventh decade (de Rigal *et al.*, 1989). Within aging skin, increased vasoconstrictor responses and decreases in both vasodilators and vasoprotective agents have been demonstrated. Atrophy and hypertrophy of the subcutaneous tissue are common in aged individuals.

The repair of physical damage is an essential day-to-day function of skin. Alteration in wound healing may lead to chronic ulceration and nonhealing. The dysfunction of dendritic cells leads to the formation of skin neoplasms. The decrease in the protective effect of the skin leads to further loss of protection from UV light. Sunlight is also felt to lead to the generation of oxygen radicals leading to aging. It has been shown *in vitro* that Keratinocytes and dermal fibroblasts from habitual sun exposed sites have shorter life spans (Glichrest, 1979; Gilchrest, 1980; Gilchrest *et al.*, 1983).

In summary, the skin is the major barrier for our body to protect us within the environment (Table 3). As the aging process ensues, cellular functions are altered leading to problems with wound healing, immunosurveillance, temperature regulation, and general barrier functions.

Table 1 General effects of aging on the cell types resident within the skin

Cell type	Effect of aging
Keratinocytes	↓ proliferation, ↓ differentiation
Melanocytes	↓ density, ↓ proliferation, ↓ biochemical activity
Epidermal lymphocytes	↓ antigen presentation, ↓ response to activating factors
Fibroblasts	↓ proliferation, ↓ ECM production, ↑ ECM turnover
Endothelial cells	↓ proliferation, ↓ response to vasodilators
Inflammatory cells	↓ proliferation, ↓ response to mitogens

ECM, extracellular matrix

Table 2 General effects of aging on the function of individual components of the skin

Skin structure	General effects of aging
Epidermis	Little change in overall structure and function
Basement membrane	Flattening (loss of rete ridges)
Dermis	↓ thickness, ↑ stiffness
Vasculature	↓ number of blood vessels, ↓ blood flow
Sebaceous glands	↓ secretion of sebum in women
Hypodermis	↓ or ↑ dependent on body location
Hair	Graying, hair loss
Nails	↓ growth and change in appearance

Table 3 Summary of age-associated changes in skin function

Skin function	General effects of aging
Wound healing	
a. Inflammatory response	Dysfunctional and protracted
b. Re-epithelialization	Slowed and sometimes inhibited
c. Dermal repair	Impaired granulation tissue formation
d. Angiogensis	Reduced
Immunoregulation	Dysfunctional and impaired leading to neoplasm
Thermoregulation	Impaired ability to perceive the cold, decreased sweat response
Barrier function	Decreased with respect to UV protection

Skeletal Muscle Aging

Skeletal muscle comprises 40–50% of the human body. It is composed of muscle tissue, nerve tissue, blood vessels, and connective tissue. Myoblasts are precursor cells, which fuse together forming bundles of muscle fibers. There are two types of individual muscle fibers: type I or slow twitch and type II or fast twitch. Type two has two components: type A are called *fast-oxidative fibers*, and type B are known as *fast-glycolytic fibers*. There are several types of muscle contractions: shortening contractions, isometric contractions, and lengthening contractions. Skeletal muscles have developed adaptive responses to the generation of reactive oxygen species to protect themselves from oxidative damage.

These age-related changes in muscle mass are termed *sarcopenia* (*see* **Chapter 80, Sarcopenia and Sarcopenic-Obesity**). This leads to an age-related decrease in muscle strength and power. The basal metabolic rate of muscle decreases by 4% per year after the age of 50. The synthesis of myosin heavy chains declines with age, whereas the sarcoplasmic protein pool is unchanged (Balagopal *et al.*, 1997; Rooyackers *et al.*, 1996; Welle *et al.*, 1993; Short *et al.*, 1999). The regenerative potential of skeletal muscle, and overall muscle mass, declines with age. Several cytokines (Cannon, 1998), including Interleukin-1, tumor necrosis factor (TNF), Interleukin-15, ciliary neurotrophic factor, as well as growth hormone and insulin-like growth factor-I (IGF-I) (Welle, 1998) have strong influence on the balance between muscle protein synthesis and breakdown. Glucocorticoids have catabolic effects, reducing protein synthesis and stimulating protein degradation in muscle. In older rats, muscle wasting occurred more rapidly and the recovery of muscle mass was impaired (Dardevet *et al.*, 1995). Testosterone declines with age in men and a concomitant change in body composition occurs with a lower percentage of muscle mass and a redistribution of body fat (Baumgartner *et al.*, 1995). Thyroid hormone (T3) acts on nuclear receptor proteins, which, in skeletal muscle cells, regulate the gene expression of myofibrillar protein isoforms (Yu *et al.*, 1999). As circulating T3 levels decrease with aging, there is an associated fiber shift from fast to slow (Sonntag, 1987). Insulin-mediated skeletal muscle cell glucose uptake declines with advancing age (Paolisso *et al.*, 1995; Ferrannin *et al.*, 1996).

Table 4 Summary of changes in muscle

Age-related changes of muscle
Reduction in muscle mass (30–40%)
Decreased myosin heavy chain synthesis
Decrease in force
Infiltration of fat into muscle tissue
Increased fatigability
Decrease in basal metabolic rate
Decreased innervations
Increased number of myofibril per motor unit
Loss or reduced proliferation of satellite cells

During senescence, there is a loss of motor neurons and muscle fibers. The loss of motor neurons is of primary importance because it is likely to be the main reason for loss of muscle fibers. Electrophysiological studies have demonstrated a reduced number of motor units in old muscle (Dohert and Brown, 1993). The size of the average motor unit increases with age. The loss of strength does not result from failure of the central nervous system to activate motor nerves. However, a reduced rate of firing of motor nerves during maximal voluntary contraction in older subjects may limit the maximal force production in some muscles (Kamen *et al.*, 1995). During a sustained contraction, central fatigue may be more common in older adults than in younger persons. Age-related fiber atrophy generally is restricted to type II fibers, at least in the muscles of the leg. This selective atrophy is important functionally because type II fibers can generate more power than type I fibers. It is unclear whether there is impairment in the release of calcium affecting the rate of relaxation and contraction. Welle *et al.* have shown that older human muscle has reduced expression of several mRNA's encoding proteins involved in mitochondrial electron transport and ATP synthesis (Welle *et al.*, 2000). An accumulation of DNA deletions is seen in mitochondria of skeletal muscle with age (De flora *et al.*, 1996).

In summary, a multitude of changes occur with skeletal muscle and aging, affecting size, strength, endurance, and functionality in the elderly (Table 4).

The Aging Eye

Multiple population-based studies have shown a significant increase in the prevalence of impaired vision with advancing age (Tielsh *et al.*, 1990; Klaver *et al.*, 1998; Klein *et al.*, 1991; Attebo *et al.*, 1996). As such, visual impairment is negatively associated with the independence and functional status of elderly people (Wang *et al.*, 1999; Klein *et al.*, 1998). In addition, impaired vision may negatively affect cognitive functions among the elderly (Uhlmann *et al.*, 1991; Lin denberger and Baltes, 1994). The eye suffers age-related disease and is affected by many systemic illnesses (*see* **Chapter 103, Disorders of the Eye**). The eye consists of the retina, lens, cornea, and a neurovasculature.

The lens is a transparent, avascular tissue contained within a capsule. The lens cells divide, but are not shed. As a result, the lens continues to grow throughout life. It has defense mechanisms from reducing compounds that can cause damage. Aggregation of proteins are thought to be responsible for the yellowing of the lens as well as the increase in light scattering. Glutathione, a key-protecting molecule in the lens, tends to decrease with aging. Crystallins are proteins that provide the high refractive index of the lens. Alterations in structure and increased aggregation of these proteins are noted with aging. Cataract formation increases with aging. A multitude of enzymes have lowered activity in a cataract.

Table 5 Changes in vision with aging

Vision
Impaired dark adaptation
Yellowing of lens
Inability to focus on near items (presbyopia)
Decreased contrast sensitivity
Decreased lacrimation
Minimal decrease in static acuity
Profound decrease in dynamic acuity (moving target)

The retina is the light-responsive part of the eye. It is highly vascular unlike the lens, and it has 6 neural cell types organized in 10 layers. The photoreceptor cells (rods and cones), and the retinal pigment epithelium (RPE) are most affected with aging. Photoreceptor density decreases with aging. There is also loss of ganglion cells and RPE. Lipofuscin is a protein that is formed through many mechanisms. Its accumulation can cause cell death in cell culture (Davies *et al.*, 2001; Shamsi and boulton, 2001). Age-related macular degeneration (AMD) is the major cause of nonpreventable blindness in Western countries. Prevalence increases with aging. The molecular pathway leading to AMD has not been elucidated yet. There are also age-related changes to the sclera where it is thinner, yellower, and less elastic. Light scattering appears to increase through the cornea with aging. The vitreous body tends to liquefy with age, and collagen fibers concentrate.

In summary, a multitude of changes occur with aging affecting the functionality and cognitive capabilities of elders (Table 5).

The Aging Cardiovascular System

Aging is associated with complex and diversified changes of cardiovascular structure and function. Changes occur at the structural/functional levels, as well as the molecular/cellular level. The heart becomes slightly hypertrophic and hyperesponsive to sympathetic (but not parasympathetic) stimuli, so that the exercise induced increases in heart rate and myocardial contractility are blunted in older hearts. The aorta and major elastic arteries become elongated and stiffer, with increased pulse wave velocity, evidence of endothelial dysfunction, and biochemical patterns resembling atherosclerosis. The arterial baroreflex is altered in aging, with the baroreceptor of the heart showing greater impairment than the baroreceptor control of peripheral vascular resistance. No

Table 6 Effects of normal aging on the cardiovascular system

Structural/functional level
Systolic function
1. No change in maximum capacity of the coronary flow bed
2. Moderate left ventricular hypertrophy
3. Maintenance of ability to generate wall tension
4. Decreased velocity of myocardial shortening
5. Increased myocardial stiffness
6. Prolonged duration of (systolic) contraction
7. Increased left ventricular cavity diameter
8. No change in stroke volumes, heart rate, cardiac output, or ejection fraction at rest
9. Greater use of the Frank–Starling mechanism
10. Decline in maximum heart rate and maximum oxygen uptake with exercise
11. Increased ventricular stiffness
12. Decreased ventricular relaxation
Diastolic function
1. Delayed relaxation
2. Diastolic peak filling rate deceases with age
3. Decreased peak velocity of early filling while atrial fraction increase with age
4. Ratio of early peak to atrial peak (E/A ratio) flow velocity decrease with age
Arterial function
1. Increased arterial stiffness
2. Decreased endothelial function
3. Increased blood pressure
Molecular/cellular level
1. Increased catecholamine levels
2. Decrease in β-adrenoceptor-mediated responses
3. Preservation of β-adrenoceptor number/density but decreased sensitivity
4. Maintenance of peak amplitude of force generation
5. Increased duration of the myoplasmic calcium transient during excitation-contraction coupling (in rats)
6. Prolongation of the ventricular transmembrane action potential (in rats)
7. Cell dropout and compensatory cellular hypertrophy

conclusive evidence has been shown that alterations in afferent, central neural, efferent, and effector organ portions of the reflex arch are altered with aging. Reflexes arising from cardiopulmonary vagal afferents are blunted in aged individuals.

In summary, a multitude of changes occur in the aged heart (Table 6). It is important to clarify that all these changes in cardiovascular function do not imply failure of the system, and in the absence of overt cardiovascular disease, do not result in symptoms.

The Aging Immune System

The function of the immune system declines with age (Table 7). This leads to an increased frequency of infections, increased prevalence of neoplasms, and autoimmune disorders. Thymic involution is a hallmark of aging although there are thymic independent pathways for the development of the immune system. Response to vaccines is also decreased. The ability of hematopoetic stem cells to replicate decrease with aging (Geiger and Van Zant, 2002).

There is an age-dependent alteration to antigen presenting cells. Certain cytokines increase with aging such as: (1) interferon γ, (2) TGF-β, (3) TNF, (4) IL-6, and (5) IL-1, which can lead to dysregulation of hematopoiesis. Most tests of T-cell function is depressed in elderly individuals (Thoman and Weigle, 1989). They tend to secrete less IL-2 after being stimulated by antigen presenting cells. Several studies have suggested a positive association between good T-cell function *in vitro* and individual longevity (Roberts-Thomson *et al.*, 1974; Murasko *et al.*, 1988; Wayne *et al.*, 1990), and between absolute lymphocyte counts and longevity (Bender *et al.*, 1986). A high proportion of centenarians have relatively well preserved immune functions compared to the less elderly (Franceschi *et al.*, 1995).

Monocytes have also been shown to have decreased function with aging (Table 8, 9). Natural killer cells have been shown not to have altered function with aging (Kutza *et al.*, 1991).

Table 7 Changes in immune system function

Immune system
1. Decreased cell-mediated immunity
2. Lower affinity antibody production
3. Increased autoantibodies
4. Decreased delayed-type hypersensitivity
5. Decreased cell proliferative response to mitogens
6. Atrophy of thymus and loss of thymic hormones
7. Increased interleukin IL-6
8. Decreased IL-2 and IL-2 responsiveness
9. Decreased production of B cells by bone marrow
10. Accumulation of memory T cells (CD-45)
11. Impaired macrophage function
12. Facilitated production of anti-idiotype antibodies

Table 8 Changes in T cells with age

Decreased	Increased
Number of reactive T cells	Number of memory cells
Number of mitogen-responsive cells	T-cell help for nonspecific-antibody production
Proliferative response	
Expression of early activation genes	
Sensitivity to activating signals	
Cytotoxic cell target	
T-cell help for specific antibody production	
Help for generation of cytotoxic cells	

Table 9 B cell changes with aging

B cells
↓ surface MHC class II molecule expression
↓ proportion of cells capable of clonal expansion
↓ number of bone marrow precursors
↓ number of T cell-dependent antibody-forming cells
↓ potency
↓ antibody efficacy

MHC, major compatibility complex

In summary, a multitude of changes occur in the immune system that affects function and survival in the elderly.

The Aging Pulmonary System

The aging lung mimics closely changes in lung tissue that are associated with disease process such as emphysema. There is stiffening of the chest wall, loss of respiratory muscle strength, a decrease in intervertebral spaces and a decrease in elastic recoil of the lung tissue. These changes result in age-related declines in the lung volumes and flow rates affecting the forced expiratory volume (FEV1) and the forced vital capacity (FVC) (Johnson and Dempsey, 1991). The PaO_2 decreases progressively and linearly, falling from approximately 95 Torr at age 20 to about 75 torr at age 70 (Sorbini *et al.*, 1968). The alveolar dead space increases while the pulmonary diffusing capacity decreases progressively and linearly with age, falling approximately 20% over the course of adult life. The ventilatory responses to both hypoxia and hypercapnia have also been shown to decrease with age.

The ability to exercise, as indicated by the maximal oxygen uptake (Vo_2 max) also decreases linearly and progressively, falling about 35% between the ages of 20 and 70. The alveolar ducts also enlarge resulting in decreased surface area.

In summary, a multitude of changes occur in the lung with aging that affect the exercise potential of the aged (Table 10).

The Aging Nervous System

The nervous system is composed of a multitude of cells, and layers which control many aspects of function such as memory, speech, verbal, and visual function, as well as sensory and motor functions. There is great variation between individuals (Table 11).

Both normal senescent age-related changes and late onset diseases of the brain produce decline in performance. The number of contacts and the total surface area of the synapses decrease significantly and their average synaptic size increases at a different extent according to the brain area taken into account. Pre- and postsynaptic elements thicken with age, while vesicle size decreases (Table 12). There is failure of the chemical transmission process with aging (Agnati *et al.*, 1990).

The regulation of calcium influx is essential to presynaptic and postsynaptic events. Tannaka *et al.* (1996) showed that reduced calcium influx with aging might cause the reduced acetylcholine release by aged synapses. Brain aging is also associated with oxidative damage and low energy metabolism (Cotman and Su, 1990), and nitric oxide has cytotoxic action on neurons (Nomura, 1996). Adrenal glucocorticoids have been shown to accelerate age-related damage in the hippocampus, because of their ability to compromise energy metabolism and make neurons more vulnerable to glutamate excitoxicity (Maines *et al.*, 1998).

Autonomic dysfunction increases with aging. Age-associated changes have been reported in some, but not all regions of the autonomic nervous system. There is greater age-related changes in the sympathetic system than in the parasympathetic system.

Table 10 Changes with aging of the lung

Pulmonary system
1. Decreased FEV1 and FVC
2. Increased residual volume
3. Cough less effective
4. Ciliary action less effective
5. Ventilation–perfusion mismatching causes PaO_2 to decrease with age
6. Trachea and central airways increase in diameter
7. Decreased lung mass
8. Decreased respiratory muscle strength
9. Diffusion of carbon monoxide decreased
10. Maximal inspiratory and expiratory pressures decrease
11. Chest wall stiffens

Table 11 Changes in the aging nervous system

Central nervous system
1. Small decrease in brain mass
2. Decreased brain flow and impaired autoregulation of perfusion
3. Proliferation of astrocytes
4. Decreased density of dendritic connections
5. Increased numbers of scattered senile plaques and neurofibrillary tangles
6. Decreased myelin and total brain lipid
7. Altered neurotransmitters including dopamine and serotonin
8. Nonrandom loss of neurons to modest extent
9. Increased monoamine oxidase activity
10. Decrease in hippocampal glucocorticoids receptors
11. Slowed central processing and reaction time (Belli and Wilber, 2001)

Table 12 Age-related changes in the pre- and postsynaptic markers of the striatal dopamine synapse (Agnati *et al.*, 1990)

Presynaptic markers	
Tyrosine hyrdroxylase - IR	↓
TH-activity	↓
Dopamine	→ / ↓
DA turnover	→ / ↑
Cold stress-induced DA turnover increase	↓
Reserpine-induced DA turnover increase	↓
DA turnover increase induced by training in reaction time	↓
Postsynaptic markers	
D1 receptor levels	↓ / →
D2 receptor levels	↓
D1 receptor turnover	↓
D2 receptor turnover	↓
Adenylate cyclase activity	↓
cAMP-induced phosphorylation	↓
DA/cholecystokinin receptor interaction	↓
D2 denervation supersensitivity	↓

TH, tyrosine hyrdroxylase; DA, dopamine; IR, immunoreactive.

Table 13 Age-related changes in the Peripheral Nervous System

Peripheral nervous system
1. Loss of spinal motor neurons
2. Decreased vibratory sensation, especially in feet
3. Decreased thermal sensitivity
4. Decreased sensory nerve action potential amplitude
5. Decreased size of large myelinated fibers
6. Increased heterogeneity of axon myelin sheaths

In summary, the aging nervous system has many features that affect individuals in a wide variety of ways (Table 13).

The Aging Skeleton

Almost everyone loses bone with aging (Table 14). Women have acceleration of bone loss with onset of menopause. Men lose bone more slowly, and lose cortical bone only as they lose tissue in general, not preferentially, as is the case in women. Both men and women lose trabecular and cortical bone. Osteoporosis is a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue. This increases the susceptibility to fracture. Remodeling of both cortical and trabecular bone takes place through sequences of activation, resorption (by osteoclasts), and formation (by osteoblasts). A multitude of hormones regulate bone remodeling; (a) calcitriol, (b) parathyroid hormone (PTH), (c) sex steroids, (d) calcitonin, (e) Insulin-like growth factors (IGF-1, IGF-2). Vitamin D and PTH maintain serum calcium. Serum calcium levels do not change with age, but the way in which they are maintained changes dramatically.

With increasing age, serum calcium levels are increasingly maintained by resorption of calcium from bone rather than resorption from the diet. The decreased sensitivity of the parathyroids to calcium, decreased responsiveness of the kidney to PTH, and decreased responsiveness of the intestine to $1,25(OH)_2D$ all work together to increase serum PTH levels with age. Calcium supplementation is effective in lowering PTH levels and reducing bone loss in the elderly (Dawson-Hughes *et al.*, 1990)

The Aging Gastrointestinal Tract

The digestive tract maintains much of its normal physiological function during the aging process. There are a number of physiological changes that occur with aging that have the potential to influence drug deposition and metabolism, and may influence gastrointestinal (GI) function.

Table 14 Changes in calcium homeostasis with age

Parameter	Age-related change
Serum calcium	No change
Intestinal calcium absorption	↓
Serum parathyroid hormone	↑
Serum $1,25(OH)_2D$	↓ or no change
Resorption of calcium from bone	↑
Net calcium balance	↓

Table 15 Changes of aging in the GI tract

System	Change
General	Reduced total body mass Reduced basal metabolic rate Reduced proportion of body fat
Gastrointestinal	Increased gastric acid production Reduced gastric emptying rate Reduced gut motility Reduced gut blood flow Reduced absorption surface Decrease in gut-associated lymphoid tissue
Hepatic–biliary	Reduced liver mass Reduced liver blood flow Reduced albumin synthesis Impaired clearance of drugs that require phase I metabolism

Pharyngoesophageal function changes with age, but the clinical significance is unclear. In elderly individuals, a decrease in the number of myenteric ganglion cells per unit area along with a thickening of the smooth muscle layer has been described. In a study by Sonies (1992), age had no effect on peristaltic velocity, basal lower esophageal sphincter (LES) pressures, or frequency of "abnormal" double and triple peaked waveforms. Moore *et al.* (1983) and Horowitz *et al.* (1984) have both shown that gastric emptying is reduced in the elderly. Goldschmiedt *et al.* (1991) showed that gastric acid levels are increased with aging. The incidence of peptic ulcer disease is known to increase with age. Gastroduodenal mucosal prostaglandin levels have been shown to decline in aging (Cryer *et al.*, 1992). Changes in small bowel motor patterns are described with aging. This includes relatively minor effects on small bowel manometric patterns with decreased frequency of contractions after eating, reduction in the frequency of the migrating motor complex, and reduced frequency of propagated clustered contractions (Anuras and Sutherland, 1984). The physiologic and clinical consequences of these changes are uncertain. The absorption of nutrients by the intestinal tract depends on a multitude of factors. Highly lipid soluble compounds such as vitamin A show increased absorption whereas vitamin D is decreased. Fat absorption is decreased whereas cholesterol is increased. Carbohydrate absorption has been shown to decrease in rats. Numerous studies have assessed sigmoid functioning and colonic transit, and there is little evidence of any alteration in these measures in older adults (Orr and Chen, 2002).

In summary, physiologic changes of the GI tract are primarily preserved although changes do occur that have clinical consequences (Table 15).

The Aging Kidney

The aging kidney maintains its ability to regulate body fluid homeostasis under general conditions (Table 16). It becomes progressively limited in its ability to respond to stresses.

Table 16 Changes in the renal system with aging

Renal system
1. Decreased creatinine clearance and GFR 10 ml/decade (Hoolensberg *et al.*, 1974)
2. Decrease of 25% in renal mass
3. Decrease in sodium and potassium excretion and conservation
4. Decreased concentrating and diluting capacity
5. Decreased serum renin and aldosterone
6. Accentuated ADH release in response to dehydration
7. Decreased nitric oxide production
8. Increased dependence of renal prostaglandins to maintain perfusion
9. Decreased vitamin D activation
10. Impaired secretion of acid load

GFR, glomelular filtration rate; ADH, antidiuretic hormone.

Table 17 Morphologic changes in aged kidneys

Morphologic changes	Reduced size and weight Relative cortical atrophy
Vascular changes	Hyalinosis of arterial walls
Glomerular changes	Increased number of sclerosed glomeruli Hypertrophy of the remnant glomeruli Increased thickness of basal membrane Mesangial matrix expansion Irregular fusion of foot processes
Tubular changes	Reduction in the number of tubules Atrophy of the tubular epithelium Increased thickness of basal membrane
Interstitial changes	Interstitial fibrosis

These changes result from anatomic changes as well as from alterations in tubular cell function and responsiveness to hormonal and hemodynamic factors.

The loss of renal mass is mainly due to progressive atrophy of the renal cortex, with relative sparing of the medulla. By age 80, between 10 and 30% of the glomeruli are completely sclerosed. The glomeruli of the outer cortex are affected the most (Table 17).

There are also functional changes in aged kidneys. Renal blood flow decreases about 10% per decade after a peak in young adulthood, and the renal plasma flow is reduced by 50%.

The cause of age-related changes in the kidney remain unknown (Viig and Wie, 1995). One hypothesis, the hyperfiltration theory due to reduced nephron mass, proposes that a kidney with reduced number of glomeruli, has increased capillary blood flow through each Glomerular bed and a corresponding high intracapillary pressure (Neuringer, 1993). This high pressure results in local endothelial damage, platelet aggregation, and thrombin production. This leads to the release of growth factors from platelets such as (1) platelet-derived growth factor, (2) epidermal growth factor, (3) fibroblast growth factor, and (4) tumor necrosis factor α (Neuringer, 1993; Hostetter *et al.*, 1981; Brenner, 1985). These factors increase fibroblast collagen production and mesangial cell sclerosis (Wardle, 1992). Angiotensin II secretion is then increased due to the disruption of vascular hemodynamics. As glomeruli become sclerosed, the amount of blood flow to each remaining nephron increases, further potentiating the damage. The other hypothesis describes an imbalance between synthesis and degradation of matrix proteins leading to glomerulosclerosis. There is limited data for this hypothesis.

In summary, a multitude of functional and morphologic changes occur in the aged that affect homeostasis (Table 18).

The Aging of the Endocrine System

Aging is associated with hormonal changes. Aging is associated with anatomic changes of the endocrine glands as a result of programmed cell death, autoimmune destruction of the gland, or neoplastic transformation of glandular tissue. Age-related changes could also occur in hormonal secretion secondary to physiologic changes due to circadian and seasonal rhythm, or in frequency or height of hormonal pulses. Other changes with aging include (1) altered bioactivity of hormones, (2) altered transport of hormones to binding receptor sites, (3) altered hormone–receptor interactions, or (4) postreceptor changes. Aging is associated with alterations in plasma membrane properties and intrinsic changes in cellular enzyme activity, and changes in calcium mobilization and gene expression. Aging is associated with important structural changes (Table 19).

Changes in hormone secretion are noted with aging. They are related to altered endocrine cell physiology than cellular

Table 18 Functional changes in aged kidneys

Renal blood flow	Decreased Relative increase of medullary blood flow
Glomerulus	Decreased glomelular filtration rate Increased filtration fraction Increased permeability to macromolecules
Tubule	Impaired ability for sodium and potassium handling Deranged tubular transport Impaired concentration and dilution Impaired acidification
Other	Decreased synthesis of rennin Decreased 1-α-hydroxylase activity

Table 19 Anatomic changes of endocrine glands with aging

Endocrine gland	Structural changes
Pituitary	Increased occurrence of adenomas and empty sellae, proportional decrease in eosinophil cells, increased nonparenchymal cells
Thyroid	Lymphocytic and plasma cell infiltration, fibrosis, and increased nodularity
Parathyroid	Increase in oxyphil cells, large oxyphil nodules
Adrenal glands	Fibrotic changes in cortex, accumulation of lipofuscin, mitochondrial fragmentation, increased adenomas and vascular hemorrhage, cellular depletion of zona reticularis
Testis	Germ cell arrest, thinning of germinal epithelium
Ovary	Depletion of oocytes, papilomatous outgrowths, sclerosis of medulla
Pancreas	Loss of compact structure of islet cells, amyloid deposition

Table 20 Age-related changes in the degradation of hormones

Increased	Decreased	Probably no change
Epinephrine	Aldosterone	FSH, LH
PTH	Testosterone	GnRH in rats
Cortisol	Dihydrotestosterone	ACTH
	Estradiol	AVP
	Noradrenaline	Glucagon
	Insulin	Calcitriol
	GH	T4, T3
		TSH

FSH, follicle stimulating hormone; LH, luteinizing hormone; PTH, parathyroid hormone; GnRH, gonadotropin-releasing hormone; ACTH, adenocorticotropic hormone; AVP, arginine vasopressin; GH, growth hormone; TSH, thyroid stimulating hormone.

depletion. Age-related changes in the pituitary gland are attributed to altered pulsatile pattern of hormone secretion. Desynchronization of various biological rhythms occurs with aging. Glandular sensitivity to secretagogs are also affected with some glands having reduced, increased, inhibited, or no alteration in response. Finally, clearance of hormones is also altered with aging.

In summary, a multitude of changes occur in the aged endocrine glands affecting homeostasis greatly (Table 20).

Aging of Other Systems

A multitude of changes occur in other systems of the body (Table 21). The dysregulation of these systems affect homeostasis in a multitude of ways.

In summary, the aged body, complex yet intricate, adaptive yet reactive, has shown a resolute progression and preservation of function. Although many changes occur leading to decreased reserves, the successful aging process that some seniors possess proves the will of humanity to strive for longevity.

Table 21 Changes of organ systems with aging

System	Change
Hematopoeisis	Decreased bone marrow reserves in response to high demand
Temperature	Impaired shivering
Regulation	Decreased cutaneous vasoconstriction and vasodilatation
	Increased core temperature to start sweating
Smell	Detection decreased by 50%
Thirst	Decreased thirst drive
Balance	Reduced number of organ of Corti hair cells
	Increased threshold vestibular responses
Audition	Bilateral loss of high-frequency tones
	Central processing deficit
Adipose	Decrease in expression and activity of lipoprotein lipase
	Decreased leptin levels in females and increased in males
Genitourinary	Incomplete bladder emptying and increased residuals
	Reduced intensity for orgasm for men and women
	Prolonged refractory period for erections for men

KEY POINTS

- A multitude of theories have been proposed to explain how the body ages.
- Cytokines play a major role in the aging process.
- Modulation of cytokines can slow the aging process.
- The aging of certain organ systems compound the aging affects of other organs.
- The rate of decline among organs varies greatly.

Aging of the Brain

Charles Mobbs

Mount Sinai School of Medicine, New York, NY, USA

In a single review, it is obviously impossible to comprehensively address the neurobiology of aging. One book on the subject (Hof and Mobbs, 2001) is almost 1000 pages long but is still not comprehensive. Numerous reviews examining various specific aspects of brain aging have also been published (Grady and Craik, 2000; Toescu *et al.*, 2000; Barnes, 2001; Brandt, 2001; Farkas and Luiten, 2001; Mattson *et al.*, 2001; Finch, 2003). Therefore, the present review focuses on two major functions, motor systems and cognitive systems, that are most susceptible to age-related pathologies.

MOTOR SYSTEMS

Motor functions are among the most vulnerable to age-related disease. These impairments in humans may be associated with the development of several age-related diseases of motor systems (including Huntington's disease and Parkinson's disease) superimposed on universal but gradual impairments in neuromuscular functions, especially due largely to decrease in muscle mass. The incidence of each disease peaks at a characteristic age (for Huntington's disease around age 40, for Parkinson's disease around age 70), then begins to decline, but the relative contribution of the universal age-related declines in neuromuscular function continues to increase with age. As the incidence of disease increases, the contribution of disease to individual variation in motor function also increases, and to the extent that risk of disease is primarily genetic, genotype contributes substantially to phenotype during this time. However, as the incidence of motor diseases decreases (after about age 70) there is also a decline in the relative contribution of motor disease genes to age-related impairments in motor function.

Huntington's Disease

Huntingtons' disease is an autosomal dominant neurodegenerative disease associated with profound movement disorders whose age-specific incidence peaks around the age of 40 (Greenamyre and Shoulson, 1994). Monozygotic twins are essentially 100% concordant in the development of Huntington's disease, demonstrating the primary contribution of genotype to the risk of developing Huntington's disease (Sudarsky *et al.*, 1983). Huntington's disease is caused by a variable expansion of a CAG repeat producing a polyglutamine stretch in the gene product, huntingtin (Lunkes *et al.*, 1998). Using this genetic marker, Kremer *et al.*, (1994) demonstrated that by late middle age the concordance between genotype and Huntington's phenotype is essentially 100%.

Nevertheless, at relatively young ages (under 20), there is little concordance between genotype and Huntington's phenotype, since at these young ages only about 10% of individuals who express CAG repeats in the huntingtin gene exhibit Huntington's phenotype. Therefore, with respect to incidence, Huntington's disease represents an extreme coupling between genotype and age-related phenotype, in which the coupling increases from very low (below the age of 20, where a great majority of individuals bearing the CAG repeat do not exhibit the Huntington phenotype) to essentially 100% concordance by age 70 (at which age almost every individual who bears the CAG repeat would have developed the disease). By the same token, however, the relative contribution of the CAG repeat to phenotypic variation in the whole population increases with age as the incidence of the disease peaks at about 40 years of age, but then begins to decline as the incidence of Huntington's disease decreases.

Parkinson's Disease

Parkinson's disease is about 10-fold more prevalent than Huntington's disease, and the incidence rate of Parkinson's disease peaks later than that of Huntington's disease, at about 75 years of age, after which incidence rate begins

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

to decline (Martilla, 1987). In contrast to the perfect concordance for Huntington's disease in identical twins, several studies have failed to observe any concordance for Parkinson's disease in identical twins (Lilienfeld, 1994). This observation demonstrates a much lower overall contribution of genotype to Parkinson's phenotype than for Huntington's phenotype. On the other hand, several families have been studied where Parkinson's disease follows an autosomal dominant pattern of inheritance (Golbe *et al.*, 1996), and in several different families this led to the identification of an allele of α-synuclein as the genetic basis of the disease in these families. (Polymeropoulos *et al.*, 1997). In another group of families where Parkinson's disease is inherited in an autosomal recessive pattern, mutations in the gene coding for parkin account for the appearance of the Parkinson's phenotype (Hattori *et al.*, 1998; Kitada *et al.*, 1998). Nevertheless, mutations in α-synuclein and parkin only account for a small subset of all cases of familial Parkinson's disease (Vaughan *et al.*, 1998), and thus, of an even smaller subset of all cases of Parkinson's disease.

These observations demonstrate that the coupling of genotype to phenotype is much lower, and the genetic basis much more complex in Parkinson's disease, than in Huntington's disease. On the other hand, Parkinson's disease is not only much more common than Huntington's disease, it is a much more heterogeneous syndrome, and thus plausibly involves a more heterogeneous set of pathophysiological processes. Thus, for those forms of Parkinson's disease for which a single gene defect has been defined, the coupling between genotype and phenotype behaves as it does in Huntington's. Thus, within kindreds in whom α-synuclein mutations are common, at young ages, there is no concordance between mutations in α-synuclein and Parkinson's phenotype, whereas by age 70, there is a very high concordance between genotype and phenotype. On the other hand, in the population as a whole, this relationship is less evident since α-synuclein mutations only account for a small proportion of all cases of Parkinson's disease, in contrast to Huntington's disease, where all cases are accounted for by mutations in a single gene.

It should be noted that the incidence rate of familial forms of Parkinson's disease peaks earlier than nonfamilial forms than in sporadic or nonfamilial forms. Thus, mutations in parkin lead to juvenile-onset Parkinson's disease, whose incidence peaks at around 20 years of age and the incidence of Parkinson's disease due to mutations in α-synuclein peaks at around 50 years of age. In contrast, the incidence rate of Parkinson's disease in the population as a whole peaks around 70 years. Since twin studies indicated that genotype makes little contribution to the late-onset (and most common) form of the disease, taken together, these data imply that the contribution of genotype to Parkinson's phenotype increases with age until about age 50, then begins to decline, such that, by age 70 and over, there is little contribution of genotype to phenotype (Langston, 1998).

Nonpathological Age-related Changes in Motor Function

For age-related diseases, the effect of genotype generally increases with age until about age 70 (in humans), then begins to decline as the incidence of age-related diseases declines. However, as the incidence of disease decreases in later life, relative contribution of disease to the variance in age-related phenotype also begins to decline. Thus, a major question is the extent to which genotype accounts for nondisease phenotype during aging. While it might be assumed that the effect of life-long environmental effects would increasingly dominate genetic effects, there is little evidence to support this as a general phenomenon. For example, twin studies have indicated that although psychomotor speed declines with age, the effect of genotype and possibly early environment continues to dominate this phenotype during aging (at least until age 67), whereas in contrast, effects of exercise were minimal (Simonen *et al.*, 1998).

COGNITIVE FUNCTION

Although genetic effects on motor diseases increase with age before they decrease, it might be hypothesized that cognitive functions are more likely to reflect cumulative experience during aging, and thus the contribution of genotype might be less for cognitive functions. However, as described below, effects of genotype are probably at least as great on cognitive functions during aging as for motor functions.

Alzheimer's Disease

Twin studies have demonstrated a much greater significant genetic contribution to the risk of developing Alzheimer's disease than for Parkinson's disease, with most studies indicating that about 50% of the variance in vulnerability to Alzheimer's disease is genetic (Pedersen *et al.*, 2004). Conclusions from twin studies have been corroborated by family studies. For example, offspring whose parents had both been diagnosed with Alzheimer's disease had a 47% chance of developing Alzheimer's disease by age 65, far higher than the risk of the general population at that age (Bird *et al.*, 1993). Similarly, analysis of 70 families with evidence of the hereditary forms of Alzheimer's disease indicated that offspring whose parents had Alzheimer's disease had a lifetime risk of developing the disease (by age 87) of 64% (compared to a risk of less than 10% in the general population by that age). Interestingly, the risk for offspring in families with early-onset Alzheimer's disease was only 53%, compared to 86% for offspring in families with late-onset Alzheimer's disease (Farrer *et al.*, 1990). Thus, at least within these families, there is evidence of increased penetrance of genotype during aging. On the other hand, the incidence rate of Alzheimer's disease appears to decrease

after age 90 (Lautenschlager *et al.*, 1996). Because of the relatively small number of individuals alive at these very advanced ages, it is not yet known if the effect of genotype on the risk of Alzheimer's disease may decline after age 90.

Allelic variations in several specific genes (presenilin 1, presenilin 2, β-amyloid precursor, and Apolipoprotein E (ApoE)) have been implicated in the etiology of Alzheimer's disease (Cruts and Van Broeckhoven, 1998). How aging influences the penetrance of these genes is of great interest. Campion *et al.*, (1999) addressed this question in a study which examined the genetic basis of early-onset autosomal dominant Alzheimer's disease in the whole population of a single city in France. In this study, early-onset autosomal dominant Alzheimer's disease was defined by the occurrence of Alzheimer's disease before the age of 61 in three generations of a family. Thirty-four such families were observed in the city examined, with a population of almost 5 00 000. In 56% of such families, allelic variations in presenilin 1 were observed, and in 15% of such families, allelic variations of the β-amyloid precursor were observed. In contrast, in nine families which did not exhibit an early-onset form of the Alzheimer's disease, such allelic variations were not observed. These data suggest that the penetrance of presenilin 1 and β-amyloid precursor mutations reaches 100% at relatively young ages (around age 60). However, since the incidence of Alzheimer's disease before the age of 60 is less than 5% of the incidence at age 80–90, this demonstrates that the coupling between presenilin 1 (or β-amyloid precursor) and Alzheimer's disease phenotype peaks at around age 60, then returns to being negligible by age 80. In contrast to the (eventual) complete penetrance of the presenilin and β-amyloid alleles, alleles of the ApoE gene are never completely penetrant, but nevertheless account for a much larger proportion (possibly 20%) of cases of Alzheimer's disease (Slooter *et al.*, 1998). Nevertheless, the effect of ApoE genotype peaks at around age 70, then declines (but is significant even at 90 years of age) (Farrer *et al.*, 1997; Slooter *et al.*, 1998). Thus, taken together, the evidence indicates that the coupling between genotype and Alzheimer's disease phenotype peaks at about 70 years of age, then, as with other age-related diseases, the role of genotype begins to decline.

Nonpathological Age-related Impairments in Cognitive Functions

Several studies have examined the effects of aging and genotype on performance in standardized intelligence tests (Swan *et al.*, 1992; Plomin *et al.*, 1994; Finkel *et al.*, 1995; McClearn *et al.*, 1997; Emery *et al.*, 1998; Finkel *et al.*, 1998). For example, Plomin *et al.*, (1994), as part of the Swedish Adoption/Twin Study of Aging examined cognitive functions in 112 pairs of twins (both monozygotic and dizygotic) reared apart and in 111 matched pairs of twins reared together. The age of the twins was 64.1 ± 7.5 (mean $\pm$ SD) years. At this age, the average heritability of general cognitive function (a composite of spatial, verbal, memory, and speed of processing performances, after removal of effects of age and gender) was 80%. In a review of studies from both the Swedish Adoption/Twin Study of Aging and the Minnesota Twin Study of Adult Development and Aging, Finkel *et al.*, (1995) concluded that both sets of studies suggested that heritability of general cognitive function is about 80% throughout adulthood (though this estimate is higher than has been observed in other studies), but evidence suggested a possible decrease in heritability after age 70. A further analysis of the Swedish Twin study appeared to corroborate this result, since in Swedish twins over the age of 80, heritability of general cognitive function was estimated to be about 62% (McClearn *et al.*, 1997). Although direct comparisons are not conclusive, other studies have suggested that heritability of general cognitive function increases from about 50% in childhood and adolescence to about 80% in adulthood (McCartney *et al.*, 1990; MaGue *et al.*, 1993). Although aging influences the heritability of general cognitive function, the effect of age on cognitive function itself is more specific to certain subsystems. In general, functions reflecting knowledge improve with age, whereas functions reflecting speed of processing and memory are impaired with age. Thus, aspects of cognition reflected by the Wechsler subscales of Information, Vocabulary, and Comprehension are relatively unimpaired or even improve with age in nondemented individuals, whereas cognitive functions reflected by the subscales of Block Design, Picture Arrangement, and Digit Symbol, tend to deteriorate robustly with age (Botwinick, 1978). Interestingly, the heritability of general cognitive function during aging is greater than the heritability of any of the functions reflected by subscales, which has been interpreted to indicate that the "nature of the genetic influence in the cognitive domain appears to be more general than specific" (Plomin *et al.*, 1994). Thus, in contrast to the effect of age on the heritability of general cognitive function, heritability on memory function alone appears to be stable with age (Finkel and McGue, 1998).

Since cognitive function is defined by experience, it may seem surprising that heritability of cognitive function can increase with age at all (although decreasing after the age of 70). One resolution of this apparent paradox is that the influence of experience may greatly depend on genotype; that is, the effect of experience may be enhanced by genotype. For example, in a twin study examining the effect of genotype on the acquisition of a motor skill, Fox *et al.*, (1996) reported that while genotype influenced the initial performance of the skill, the effect of genotype on the enhancement of the skill by practice was even greater. These investigators concluded that "the effect of practice is to decrease the effect of environmental variation (previous learning) and increase the relative strength of genetic influences on motor performance". Similarly, it seems plausible that genotype may influence the cumulative effect of experience on general cognitive functions. On the other hand, after the age of 70, it appears that these genetic effects have reached their peak, and the effects of unique experiences come to dominate.

KEY POINTS

- Pathological and nonpathological age-related impairments are quantitatively and qualitatively distinct: pathological impairments involve substantial neuronal loss, whereas, nonpathological impairments do not involve such loss.
- Pathological impairments in motor functions include Parkinson's disease and Huntington's disease, the former entailing very little genetic effects while the latter is almost entirely genetic.
- Nonpathological impairments in motor functions include loss of muscle mass.
- About half the vulnerability to Alzheimer's disease is due to genetic effects.
- The importance of heredity in determining age-related impairments increases with age until about age 70, after which environmental influences become increasingly important.

Psychological Aspects of Aging

Peggy A. Szwabo

Saint Louis University School of Medicine, St Louis, MO, USA

INTRODUCTION

This chapter will address how adults psychologically adapt as they age. Psychological theories of adult development have been extensively written about in the scientific literature. Several approaches addressing life stage perspective will be presented as it relates to mental vitality in late life.

Psychology is the study of behavior and the facts and factors that influence behavior. Psychology of aging studies behavior that is organized or disorganized as the adult ages, that is, how the adult adapts or does not adapt to life stresses. These behaviors may be constant throughout life as the person experiences tasks and challenges.

Generally, psychology is viewed as a broad field encompassing personality development, intelligence, memory, motivation, neuropsychological changes, creativity, and sensory and motor functioning. Important for the aging person are information processing, cognition, life satisfaction, and personal control. As with all fields, psychology of aging interrelates with the biological and social aspects of aging. Psychological processes are constantly intertwined with biological, social, and environmental factors. Understanding the psychology of aging helps the practitioner assess the person's ability to adapt to change, understand, and cope with aging, illness, and loss. Furthermore, understanding the older adult's previous or lack of coping and adaptive skills, the practitioner may be able to predict and understand potential problems.

Successful psychological aging is dependent upon mental vitality. Mental vitality can be described as psychological or intellectual energy. That is, given life's choices, how does the aging adult face the challenge? What is the individual's mental vigor to cope with changing biopsychosocial changes? What has been their history of adapting and coping throughout life? Studies have found that ill health is related to problems with cognition, learning, and motivation, thus challenging the elder's ability to cope (Havighurst, 1968; Botwinick, 1977). As Kermis (l986) so aptly put, aging is the greatest challenge.

Mental vitality encompasses present life-style choices, as well as one's history of choices. These choices include reducing stress, establishing rest and relaxation, challenging the mind, cultivating satisfying relationships and activities, and avoiding known risk factors such as smoking, poor nutrition, weight problems, and excessive alcohol consumption. Equally important are the attitudes and beliefs that the older adult has about aging that reflect how successfully one ages. A mentally vigorous older adult with a positive attitude will be able to better cope with life's challenges and make informed choices. While cognitive deficits have been extensively written about, it is the positive changes and adaptive abilities that may be more important in daily living skills.

LIFE STAGE PERSPECTIVE

In this chapter, the focus will be on the emphasis of mental vitality as a life stage approach. This developmental-stage theory emphasizes integration of life experiences. The developmental theorists attempt to describe human development as a sequence of stages or steps. Developmental-stage models hold that changes in the adult personality are results of interaction of the social and biological environment. How the individual interacts with others and integrates that interaction into his/her personality is determined by the developmental tasks that the person performs. These tasks are markers of the individual's movement through the life cycle. Each task combines some aspects of the person's biological, psychological, and social functioning. Developmental tasks combine the drive toward growth of the person with the demands, constraints, and opportunities of the social environment. These tasks occur for all people in approximately the same sequence, which may overlap each other without a particular onset or termination. Failure and delay in resolving these tasks may affect how successful one will be in resolving future tasks, adjustment, and overall mental health. All of these tasks act to move the individual toward optimal psychological function and personal integrity if they are

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

successfully accomplished. Erikson (1963), the most familiar of the developmental-stage theorists, applied his approach to the aged. In his eight stages of development, the person has a conflict with two possible outcomes, adaptive or maladaptive solutions. If an early stage is resolved with a low degree of adaptation, resolving later stages will be more difficult. Erikson's last two stages directly apply to adults and aging adults. These two stages are broad and cover many years, resulting in other theorists defining more definitive age-specific conflicts.

Havighurst and Peck postulated theories that have particular significance for the elderly. Both authors elaborate on Erikson's psychosocial tasks with consideration of tasks of the older adult (Havighurst, 1968; 1972; Peck, l968; Erikson, l963). Havighurst (1968) describes the six tasks of old age as follows:

1. adjusting to declining physical strength and health;
2. adjusting to retirement and its reduced income;
3. adjusting to changes in the health of one's spouse or partner;
4. establishing an explicit affiliation with one's age group;
5. adopting and adapting social roles in a flexible way;
6. establishing satisfactory physical living arrangements.

Aging adults experience a variety of physical, social, and psychological losses. These losses can affect mobility both physically and socially, resulting in increasing isolation. There is a chance that the environment will continue to diminish unless the individual takes action. Havighurst's (1968) focus is on reorganizing functions and expectations. For example, older adults who do not accept their changing physical and health limitations and adapt may become maladjusted. Partner roles may change if one partner becomes ill. The partner who nurtured may need nurturing care; the healthy partner may have to assume new roles of banker, handyman, and decision maker. Old age is a time of almost constant change. Older adults who do not adapt or adjust flexibly may find themselves increasingly stressed and maladjusted. According to Havighurst (1968), the continued refining roles and expectations to meet environmental demands accomplish the maintenance of identity.

Peck's (1968) tasks are summarized into three areas of conflict. The first is ego differentiation versus work-role preoccupation, and finding a way to identify and appreciate self without the job or one's career as the marker of success. This includes satisfaction with retirement and children leaving home. The task is to find new ways, activities, and passions to define one's self. The second is body transcendence versus body preoccupation, which is understanding the changes in the body and illnesses without being preoccupied with symptoms or illness concerns. The question is, can one live successfully despite age-related changes and disease states? Many older adults cope with illness and live successful lives despite pain or infirmity. Others are preoccupied with their illness, by constantly talking about their symptoms, medication requests, and frequent doctor appointments or "shopping". Lastly, the third area of conflict is ego transcendence versus ego preoccupation. This process is the coming to terms with the reality of death, putting closure on the past, ensuring the welfare of children and others, and leaving a legacy. There is a need to share one's wisdom, knowledge, and experience. Conversely, if maladaptive, there is a tendency to treat the world as if it will end with their death. This person may not make wills or plans for the future, or for anything that would go on after their death (Peck, 1968).

In summary, the personality is constantly changing in response to the individual's adaptation throughout life. Life challenges can occur at any time in the life cycle, but older people are more likely to have to confront more challenges simultaneously. Losses, physical and functional changes, and cultural expectations stress older adults when their psychological reserves are low and their social supports are diminishing (Kermis, 1986).

WHAT DO WE KNOW?

Aging is not uniform or static. There is differentiation among the aging commonly divided into four groupings of the young-old (60–70 years of age), the old (71–74 years of age), the old-old (75–84 years of age), and the frail-old (85 years of age and over) (Neugarten, 1977; Neugarten, 1979; Riley and Suzman, 1985). Each grouping has different tasks, abilities, and issues. For example, the 60–70-year-old groups may still be employed and more active. They may be dealing with retirement, considering housing options, developing leisure activities, and relationship issues. The 71–74-year-old group may be adjusting to retirement, loss or changes in work-role identity, income changes, friends moving or ill, widowhood, and readjusting time management. Neugarten (1974, 1979) noted that chronic illness and role losses were more characteristic of those over the age of 75. She, further, contended that the 55–74-year olds are more like the middle-aged with fairly good health and as active as they wish.

Riley and Suzman (1985) further divided the old-old into the old-old and the frail-old. The old-old group may have more medical conditions, more medications on board, and may require more support services either by family or agencies or both. There are more losses, more issues with dependency and those related to assisted living situations. For couples, one partner may need more care and placement, resulting in the couple being separated.

As a group, the frail elderly is growing the fastest, with estimates of over 3 million in the United States (Aging Demographics, NIA, 2004). Worldwide, the World Health Organization (WHO) estimates 4 million elders over the age of 85 (Aging Demographics, AAHSA, 2004). This group is primarily female, widowed, and more likely to face declining functional ability without a spousal caregiver. The old-old and particularly the frail-old group experience more physiological changes, more comorbid medical conditions, more

frailties, higher rates of dementia, and loss of connectedness. Connectedness is the desire to feel connected to others, their homes, and community. This sense of connectedness is threatened when there are limitations in functioning, necessitating moves to a more secure and assisted living environment, removing the elder form the security of their neighborhood, their home (Kropf, 1992).

Overall, the frail elder is more likely to be in a supported living setting with more health problems, is more dependent upon others to meet their daily needs, and generally takes longer to recover from acute illnesses (Blazer, 1980; Beckett and Schneider, 1992). Many of this population, primarily women, may outlive their financial and health care resources (Beckett and Schneider, 1992; Mercer and Garner, 1989).

With each group, there may be a wide range of health or illness states varying from healthy, chronic but stable, acute, and acute superimposed with chronic illnesses. Rather than relying totally on age categories alone, it is also important to address health status, adaptive abilities, and social characteristics.

AGE-RELATED PSYCHOLOGICAL CHANGES

Intelligence

Intelligence is composed of crystallized and fluid intelligence. Crystallized intelligence is the ability to apply past learning to new situations. Crystallized intelligence increases with age, experience and knowledge. Examples of crystallized intelligence are problem-solving activities, mechanical skills, word meanings, and understanding social relationships. Fluid intelligence is the ability to improve organization of information and to generate new hypotheses. Fluid intelligence decreases with age. Fluid intelligence consists of reasoning and abstraction, relationships between objects, acquiring new ideas, and adapting to change.

IQ increases until the 20s, then levels off and generally remains stable throughout the life cycle. With aging, there is decreased speed on timed tests. Poor health represents an adverse factor in the older adult's performance. If given more time, the older adult is as accurate as a younger adult is. In general, older adults perform better on everyday practical tasks over laboratory-based tests. Performance on Wechler Adult Intelligence Scale (WAIS) demonstrates that older adults have an increase in verbal skills, while there is a decrease in tests of performance. Results show that intelligence is stable until the 70 s, when there is a decrease in performance countered by an increase in verbal skills (Botwinick, 1977). These verbal skills reflect the knowledge and skills acquired over a lifetime.

Aging does influence intellectual functioning. Changes in motor skills and slower decision-making time affect reaction time. Performance is also affected by changes in cerebral cortex functioning and cardiovascular deterioration. When decision making, older adults have been found to sacrifice speed for accuracy and to reject quick, simplistic solutions to problems, preferring to work slowly and to examine issues from a variety of perspectives before responding. Older persons are more likely to make errors of omission rather than errors of commission, which suggests cautiousness, deliberateness, and anxiety (Poon, 1985). As a compensatory strategy and to avoid embarrassment, many older persons avoid unfamiliar activities and places. This cautiousness may be mistaken for resistance or obstreperousness.

A word of caution is advised to many older adults who do not have the advantage of many years of formal education as compared to younger persons and have been many years away from the classroom environment (Botwinick, 1977). Deliberateness, slower response time, and time away from traditional school activities impact tests of intellectual abilities.

Clinicians need to clearly evaluate the impact of physical infirmities, compensatory skills, and the older adult's social environment before coming to any conclusions regarding intellectual decline. The impact of the living situation, lack of stimulation, and isolation may constrain intellectual functioning and should not be ignored (Botwinick, 1977). If healthy and fit, the older adult's response time is no different from that of less healthy younger people.

MEMORY

The capacity to learn continues throughout life. Optimal learning involves reading or following instructions on how to organize information, finding tasks meaningful and rewarding, and being able to link visual memory with auditory information. There are three phases of information processing – encoding, storage, and retrieval. With aging, more time and effort is required to encode information. Sensory changes can reduce memory efficiency. Because sensory memory lasts less than a second and with aging sensory changes, the older adult is less able to encode as well. Short-term memory lasts a few seconds and declines with age.

Recall involves search and retrieval of information from storage. Recognition requires matching information in storage with information obtained in the environment. Recognition abilities remain stable over time (Poon, 1985). All ages do well in recognition tasks, but recall diminishes over time. It is easier for older adults to do tasks of recognition than recall information.

Long-term memory includes storage of information, a fact learned earlier in life, and day-to-day experiences, and is relatively permanent. Long-term memory increases from age 20 to 50 and then is constant into the 70s. Older adults require more time to encode new information. This encoding process is affected not only by sensory losses but also by changes in the environment, such as moves and deaths. These events contribute to memory deficits.

Many older adults adapt fairly well, and deficits may not be evident until a traumatic event occurs or is uncovered by a skilled clinician. Using compensatory strategies to augment

memory, such as use of calendars and notes and taking time and practicing new material, is indicated. Structure and familiarity also help in improving memory and retention. With slowed recall and physical decline, there is a slower response, which can be misconstrued as more significant memory deficits or resistance.

In summary, older adults do retain well-practiced and adaptive skills. Less-practiced tasks and recall requiring a timed response declines.

SENSORY

The nervous system is important in receiving, processing, and storing information. The senses provide contact to the environment. Changes or decline in senses affects one's participation in their environment and their quality of life. Losses or changes in vision, hearing, taste, smell, and touch influence the individual's functioning, activities, stimuli response, and perceptions. Sensory losses can produce alterations in behavior, independence, confidence, and self-esteem. On the other hand, assumptions are made that sensory-impaired elders are senile, stubborn, or manipulative. Careful assessment of sensory loss is indicated before assumptions can be made concerning self-care and adaptive capabilities. Glasses and hearing aides help compensate for sensory losses and allow more independence.

CREATIVITY

Even though creativity is generally not considered a component of psychological functioning, it is an area that is a part of mental vitality and quality of life. There have been many debates that creativity is limited to a few and it declines with age (Adams-Price, 1998). Research shows that creative thinking is a universal ability that helps adults manage satisfying lives. Creativity is a complex of traits, skills, and capacities, including the ability to work independently, curiosity, unconventional thinking, openness to experience, and tolerance of ambiguity (Adams-Price, 1998; Generations, 1991). Cognitive psychologists define creativity as a mental process like imagination and intuition. The newer definition is particularly apropos to the older adult. It is the integration of cognitive processes, knowledge, thinking style, personality, motivation, and environment over a lifetime. Creativity is a way to address and resolve dissatisfactions, improve quality of life, and can be a response to limits and an uncertain future (Generations, 1991; Adams-Price, 1998). Older adults do appear to experience a decrease in divergent thinking, the ability to generate novel ideas, but this is a qualitative change in the creative process. In contrast, there is an increase in crystallized intelligence and integrative or convergent thinking (Sasser-Coen, 1993). Later life may afford more time for reflection, life review, and creative pursuits aimed at the development of one's life story and the filling in of gaps and discontinuities. This creative process, which is similar to Butler's (1963) *Life Review*, is a positive therapeutic process. Adams-Price (1998) concludes that late-life creativity reflects aspects of late-life thinking: synthesis, reflection, and wisdom.

IMPLICATIONS FOR PRACTICE

Aging is an adaptive challenge. Mental vitality is the vigor needed to meet this task. As clinicians, continual evaluation of the older person's understanding of the implication of age-related changes and losses is required. Identifying coping skills and adaptive strategies is paramount as well to an effective relationship and treatment planning. To incorporate the aforementioned psychological changes into practice, recommendations are outlined.

1. Face-to-face education should occur, presenting the information in small increments and supplemented with one-page practical handouts to carry home.
2. Helpful teaching techniques include teaching time, with practice and episodic spot checks to reinforce or to correct, and phone number and contact person to call if they have questions or concerns.
3. Allow time to complete forms in a setting conducive to writing.
4. Printed materials need to be in larger boldface type and simplified to adjust for sensory changes. The guidelines of the Americans with Disabilities Act recommend that print be at least 18-point font. Signs should be in large print or symbols with contrasting background of eggshell, matte, or nonglare paper for easier reading and to clarify directions (ADA, 1990).
5. Observe accessibility and visibility issues in the physical environment. Are the directions and locations easy to follow? Lighting should be 100 to 300 lux to ensure adequate vision and easy reading (ADA, 1990).
6. Encourage the older person to take notes or write their concerns before their appointment.
7. If necessary or beneficial, suggest that the older person bring someone to assist or take notes.
8. Encourage the older adult's participation in the treatment planning.
9. Allow the older person the opportunity to present concerns, fears, or objections to the plan.
10. Allow time to process information and study their options.
11. Ask how they are coping and what coping strategies they use. For example, "How do you handle this?" "You have a lot to deal with," "How are you holding up?" or "What helps you?"
12. Encourage innovative or creative solutions. Ask how they would solve.
13. Referral to support group, if exists, for their medical condition.

14. Referral to geriatric/gerontology professional for counseling and environmental options.

CONCLUSION

Not all cognitive changes are negative. The positive cognitive changes include greater experience-based knowledge, increased accuracy, better judgment concerning their abilities, and generally an improved ability to handle familiar tasks as compared to their younger counterparts.

Aging presents psychological and cognitive challenges requiring mental vitality to adapt. An older person who ages "successfully" has been able to use their accumulated knowledge and wisdom to accomplish most day-to-day living activities well. Rigidity and exaggerated and maladaptive behaviors may represent psychological and neurological problems and are not normal aging, and a referral to a specialist is warranted. As with any treatment planning, the older adult's problems may be obvious but treatment interventions are based upon what the person can do.

KEY POINTS

- Mental vitality or energy is needed for older adults to cope with life changes.
- Intelligence changes with age. Older persons have increased verbal skills and they demonstrate slowed performance skills. Life-long experience and knowledge is reflected in verbal skills.
- Older adults tend to be more cautious in decision-making activities, pondering their options before responding. This deliberateness should not be mistaken for resistance.
- Memory changes with age. Long-term memory remains fairly constant. It is easier to do tasks of recognition over recall activities.
- Illness, social, and environmental changes affect learning, memory, and creativity. These changes need to be incorporated in treatment planning.
- Creativity is a positive therapeutic process that encourages reflection and development of the older adult's life story.

Neurochemistry of Aging

Alan M. Palmer[1] ***and*** **Paul T. Francis**[2]

[1] *Pharmidex, London, UK, and* [2] *King's College London, London, UK*

Based in part on the chapter 'Neurochemistry' by Alan M. Palmer and Steven T. DeKosky, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

INTRODUCTION

The world's population is getting older. During the first 50 years of this millennium, the worldwide population aged over 65 years is projected to increase from 6.9% of the total population to 15.9%, which constitutes an extra billion people (Table 1). This is attributable to a combination of a progressive increase in life expectancy (Table 1) and elevated fertility in many countries during the two decades after World War II (i.e. the "Baby Boom" effect; Figure 1) (*see also* **Chapter 9, The Demography of Aging**). This growing number of older adults increases demands on the public health system and on medical and social services, particularly for chronic neurological diseases such as stroke, Alzheimer's disease (AD), and Parkinson's disease (*see* **Chapter 9, The Demography of Aging**). Such disorders affect older adults disproportionately and contribute to disability, diminish quality of life, and increased healthcare costs. Thus, stroke afflicts 30% of persons aged over 65 years (fatally in 10%), and its incidence doubles during successive decades. AD affects 10% of the population aged over 65 years and is rising to 49% of those aged 80 years or more, and Parkinson's disease affects 1% of persons aged 60 or older and 2.6% of those over the age of 85 years (Palmer and DeKosky, 1998). Both age-associated neurological deficits and the increased risk to ischemic stroke and neurodegenerative disease with advancing age can be attributed to neurobiological deterioration. In many cases, the changes in degenerative diseases are qualitatively the same, but quantitatively more severe, than those of normal aging.

Aging itself causes more modest changes in overall function. Thus, there is a mild slowing of both motor speed and reaction time and a decline of complex cognitive skills, particularly memory. Memory is a complex function, encompassing the encoding, storage, and retrieval of diverse types of information. There are multiple memory systems in the brain. For example, there are dissociable systems underlying such memory functions as new learning of verbal information, acquisition of a procedural skill, and retrieval of semantic knowledge from long-term storage. Age does not affect all domains of cognition equally. For some functions, such as speed of visual-motor processing, slight decline often can be detected as people enter their 40s and 50s. However, for most cognitive abilities, no measurable decline is evident until age 65 or older. For example, the average expected number of words recalled from a 15-word list after a 30-minute delay is approximately 10 for people aged 55–65, nine for those aged 66–70, and eight for those up to age 85. These changes, while noticeable, are not disabling. Furthermore, some aspects of cognition, such as an individual's general fund of information, can actually continue to improve throughout their lifetime. There is considerable current interest in distinguishing age-related changes in cognition from "mild cognitive impairment" (MCI) (*see also* **Chapter 94, Mild Cognitive Impairment**), which may be a prodrome of various forms of dementia (Figure 2). Noncognitive changes in behavior are also important in aging since there is often an increase in psychiatric symptoms, including major depression, and a profound disruption of the sleep-wake cycle (*see* **Chapter 63, Sleep Disorders in Elderly People**; **Chapter 98, Geriatric Psychiatry** and **Chapter 100, Depression in Late Life: Etiology, Diagnosis and Treatment**).

This chapter will consider the neurochemical pathology of aging and, where appropriate, relate this to the changes associated with stroke, vascular dementia, AD, and Parkinson's disease (*see also* **Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly**; **Chapter 71, Acute Stroke**; **Chapter 92, Cellular Changes in Alzheimer's Disease** and **Chapter 95, Vascular Dementia**).

THE AGING BRAIN

Brain weight and volume decrease with age. On average, the brain loses 5–10% of its weight between the ages of 20 and 90. In the older brain, tissue loss is most obvious on the surface and is seen as shrinkage of the brain gyri and sulci, which reflects a loss of neurons – from 10 to 60% – in different cortical areas. Neuronal loss is particularly evident in the hippocampus, but is also seen in the cerebellum, locus ceruleus, nucleus basalis of Meynert and the raphe nucleus. Besides neuronal loss, there also appears to be diminished dendritic arborization with age, although the number of synapses appears not to decline with age, which contrasts with AD, where there is clear evidence of synapse loss (Palmer and DeKosky, 1998) (*see also* **Chapter 8, Neuropathology of Aging** and **Chapter 5, Aging of the Brain**).

NEUROCHEMICAL CHANGES IN THE AGING BRAIN

Cholinergic Neurons

The cholinergic hypothesis of memory posits that the deterioration in cognitive function associated with age or AD is attributable to decreased cholinergic neurotransmission. The major success of this hypothesis is that it has led to the rational development of new medicines, principally acetylcholinesterase (AChE) inhibitors which inhibit ACh catabolism, together with numerous other cholinomimetics that are currently undergoing clinical development (Palmer, 2002; Wilkinson *et al.*, 2004). Although the first AChE inhibitors (e.g. tacrine) were associated with significant side effects and short plasma half-lives, second-generation compounds (e.g. donepezil, rivastigmine, and galantamine) have superior safety and efficacy profiles. Other cholinomimetic approaches to therapy include selective muscarinic M_1 receptor agonists, M_2 receptor antagonists, and nicotinic receptor agonists. Despite the apparent clinical utility of cholinomimetic approaches to the treatment of cognitive dysfunction, the evidence to support this hypothesis does have a number of shortcomings. In addition, recent data suggest a greater role of cholinergic neurons in mediating some of the noncognitive behavioral symptoms associated with AD (Francis *et al.*, 1999). The utility of AChE inhibitors in the treatment of MCI is currently under investigation, but clear efficacy has not yet been established.

Dopaminergic Neurons

There is a steady decline in dopaminergic cells in the substantia nigra with age in humans. The number of dopaminergic neurons in each substantia nigra declines from 400 000 at birth to 250 000 at age 60. In Parkinson's disease, cell counts range from 60 000 to 120 000. Dopaminergic cells in the substantia nigra innervate the neostriatum and corresponding changes in the concentration of dopamine in the neostriatum have also been observed (Table 2). It has been

Table 2 Summary of neurochemical changes in aging

Neuron type	Cortex	Hippocampus	Striatum
Cholinergic	Reduced in most studies	No change in most studies	Reduced in most studies
Noradrenergic	No change in most studies	No change in most studies	No change
Serotonergic	No change in some studies but reductions in others	No change	No change in most studies
Dopaminergic	No change	No change	Reduced in most studies
GABAergic	Reduced in all studies	Reduced in all studies	Reduced in one study
EAAergic	No change	No change	No change

The table is largely derived from Palmer and DeKosky (1998).

suggested that Parkinson's disease is related to a combination of environmentally induced subclinical damage to the substantia nigra pars compacta and the age-related loss of additional nigra neurons. Essential to this hypothesis is the existence of deteriorated function of the nigrostriatal pathway with advancing age. However, the hypothesis that Parkinson's disease is simply the additive effects of aging and cumulative neurotoxicity has been challenged by data indicating that the pattern of striatal cell loss in normal aging differs substantially from the pattern typically observed in Parkinson's disease. Nonetheless, before frank Parkinsonian symptoms emerge it is necessary that there is more than an 85% loss of dopamine from the striatum. The age-related loss of dopamine from the striatum therefore contributes to emergence of symptoms in Parkinson's disease and to the shuffling gait and stooped posture often seen in the very elderly. Age-related changes in dopaminergic neurons were largely restricted to the neostriatum since neither the cerebral cortex nor the hippocampus displayed marked age-related changes (Palmer and DeKosky, 1998).

The age-associated loss of nigrostriatal neurons may also underlie the striking increase in choreic symptoms seen midlife in patients with Huntington's disease. In addition to changes in dopamine (DA), a number of studies have consistently demonstrated elevation in the activity of the DA catabolic enzyme monoamine oxidase-B (MAO-B). This may serve to reduce synaptic concentration of DA with age and this will exacerbate the functional consequences of age-related loss of DA neurons. In contrast to MAO-B, the activity of MAO-A is relatively spared in Parkinson's (Palmer and DeKosky, 1998). Dopamine receptors have not yet been extensively studied in the aging human brain, but evidence indicates increased binding to D-1 receptors and reduced binding to D-2 receptors in the neostriatum. This age-related loss of D-2 receptors with age has been suggested to underlie the increasing incidence and severity of tardive dyskinesia with aging (Palmer and DeKosky, 1998).

Noradrenergic Neurons

Marked loss of locus ceruleus neurons has been reported, as a function of age, from approximately 19 000 cells in youth to about 10 000 cells for people in their ninth decade (Palmer and DeKosky, 1998). In contrast to morphometric studies, neurochemical studies have indicated a general sparing of noradrenergic indices in aging, with the possible exception of the hippocampus (Table 2). This is probably a reflection of the assessment in neurochemical studies of only transmitter and metabolite concentration and the postmortem instability, which in turn leads to increased variability, in these markers (Palmer and DeKosky, 1998). This is supported by studies of experimental animals, where postmortem influence is small and pronounced age-related reductions in noradrenergic activity have been reported, particularly in hypothalamic regions (Palmer and DeKosky, 1998). Noradrenaline is catabolized largely by MAO-A; about one-third is catabolized by MAO-B. Therefore, noradrenergic function may also be affected by the age-related increase in MAO activity, albeit to a lesser extent than dopamine. The two general types of adrenergic receptors, α and β, have been further subdivided into $\alpha 1$ and $\alpha 2$ and $\beta 1$ and $\beta 2$. $\beta 2$ receptors have been found to decline with age in the cerebral cortex whereas, $\beta 1$ receptors were unaffected (Palmer and DeKosky, 1998). Disturbances of the noradrenergic system are considered to play a role in depressive illness, so age-associated changes may contribute to the increased incidence in depression in the elderly.

Reduced concentration of noradrenaline (NA) have generally been reported in postmortem AD brain together with marked atrophy and cell loss from the locus ceruleus. This has been corroborated by data obtained from tissue removed antemortem where both the concentration of noradrenaline was reduced in both temporal and frontal cortex. In addition, high affinity uptake of [^{3}H]noradrenaline was reduced in the temporal cortex (Palmer, 1996).

Evidence suggests that these changes may contribute to some of the noncognitive changes in behavior associated with AD (Palmer, 2002).

Serotonergic Neurons

There are reports indicating loss of 5-hydroxytryptamine (serotonin, 5-HT) nerve terminals in the cerebral cortex but not in the hippocampus or neostriatum (Table 2). 5-HT is principally catabolized by the MAO-A and so is not likely to be affected by the age-related increase in MAO-B activity.

The 5-HT content in the neocortex from AD subjects has, in general, been found to be reduced. Neurofibrillary tangles and neuronal loss occur in the dorsal raphe nucleus, but it is unclear what proportion of cells are affected and whether the affected cells relate topographically to areas of pronounced neocortical damage (Palmer and DeKosky, 1998). Postmortem data indicating and serotonergic denervation has been corroborated by antemortem studies in which the release and uptake of 5-HT have been measured in addition to the

concentration of both 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) (Palmer, 1996).

Dysfunction of serotonergic (and noradrenergic) neurons probably relate more to noncognitive changes in behavior, such as aggression and depression that often accompany AD. In addition, the activity of serotonergic (and noradrenergic) neurons has been shown to closely reflect the state of behavioral arousal (maximal during periods of vigilance and absent during rapid-eye-movement sleep), so loss of these neurons may be responsible for the disturbance of sleep (and selective attention) associated with aging and AD (Palmer and DeKosky, 1998).

Cortical Interneurons

γ-Aminobutyric acid (GABA) constitutes a major inhibitory transmitter system in the cortex, accounting for as many as 30% of all cortical neurons. A number of markers of GABA metabolism have been examined in human brain and all have been shown to decline with aging (Table 2). A large number of peptides have been described in the cerebral cortex that are localized to neurons and are released upon depolarization. These are believed to play a role in slow chemical signaling. It appears that virtually all such peptides are colocalized with GABA in a GABAergic interneurons. Although neuropeptides have not been extensively examined in the aging human brain, it can be expected that they will change in concert with GABAergic neurons (Palmer and DeKosky, 1998).

In AD, reduced concentrations of both GABA and somatostatin-like immune reactivity have been reported. By contrast, studies of tissue obtained antemortem have indicated that the concentration of GABA and somatostatin-like immunoreactivity (SLIR), the potassium-evoked release of GABA and SLIR and glutamic acid decarboxylase (GAD) activity were unaltered in AD (Palmer, 1996). This suggests that GABAergic neurons are not affected until a relatively late stage of the disease. In such a case, it is likely that loss of cortical interneurons contributes to the final stages of the syndrome of dementia, but it is difficult to predict the consequences (if any) of the small losses associated with aging.

Excitatory Amino Acid–releasing Neurons

Pyramidal cells are the largest and most abundant neuron type in the cerebral cortex and play a key role in all aspects of higher mental and sensorimotor function. The neurotransmitter(s) associated with these neurons is considered to be an excitatory amino acid (EAA), principally L-glutamate and L-aspartate (Francis, 2003). Age-related loss of pyramidal neurons from the hippocampus and cortex have been demonstrated (Morrison and Hoff, 1997). Corresponding neurochemical data to support these changes is equivocal (Palmer and DeKosky, 1998). In experimental animals, EAA neurotransmission is, in at least a functional sense, preserved with normal aging since EAA uptake in cortex, hippocampus, and striatum and EAA release in cortex are preserved with age in a study using long-lived Fischer 344/Norwegian brown strain of rat aged 3, 12, 24, and 37 months (Palmer *et al.*, 1994). This corresponds with data from most other studies. The exceptions (Segovia *et al.*, 2001) may be attributable to comparisons between immature and mature animals since brain maturation may not be complete until 12 months. Thus "aging" changes may simply reflect changes occurring as a result of brain maturation rather than senescence. Other complicating factors include the common use of animals that do not achieve senescence (most inbred strains die before "old age" is achieved), along with the practice of comparing just two age points.

Tissue from the same animals used in Palmer *et al.* (1994) was used in a detailed study of the integrity of N-methyl-D-aspartate (NMDA) receptors. Both coagonist sites (for glutamate and glycine) were examined along with polyamine and zinc modulatory sites (Palmer, 2000). No age-related changes were observed, which largely corresponds with data from other studies (Segovia *et al.*, 2001), particularly if the caveats mentioned above are taken into account. Thus, it appears that both EAA terminals and NMDA receptors are preserved with aging; α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate receptors also appear to be unchanged with aging (Segovia *et al.*, 2001). However, there may be losses in distinct brain regions. This is supported by an immuonhistochemical study showing an age-related loss of human AMPA receptors from cholinergic neurons in the basal forebrain. What's more, since these alterations increase cation permeability, they may well contribute to the age-related loss of cholinergic neurons and contribute to the vulnerability of these neurons in AD (Ikonomovic *et al.*, 2000).

The relative preservation of EAA nerve terminals in aging contrast to the status of these neurons in AD (Francis, 2003). Some of the symptoms of AD, particularly aphasia, agnosia, and apraxia, are often similar to those associated with cortical disconnection syndromes (Pearson, 1996). This has led to the hypothesis that AD represents a global cortical disconnection syndrome in which each cortical region functions in isolation. Support has derived from correlations between the loss of pyramidal neurons from layers III and V of Alzheimer's patients with the severity of dementia and scores on five psychometric tests (Mann, 1996).

STRUCTURAL MARKERS OF BRAIN MEMBRANES

Markers of Neuronal Membrane and Connectivity

Neuron membrane–specific protein and lipid membrane markers have been utilized in human as well as experimental animal studies to quantify "axodendritic expanse", the amount of a neuronal (as opposed to glial) membrane present in a given volume of tissue (or expressed per mg wet weight

or per mg protein). Lipid sialoganglioside is enriched in neuronal membranes, and has been used as a neuronal marker. This relative stability is in contrast to the marked loss of gangliosides in AD, in which massive neuronal and axodendritic loss occurs (Palmer and DeKosky, 1998).

A more specific marker of neuronal connections is synaptophysin, a protein present at the synapse itself. Increases in synaptophysin occur in animal brains during the period of developmental synaptogenesis. In respect to normal aging, little data is available but studies in monkeys show no reduction. This may reflect the fact that synapses take up a small proportion of the neuropil or that synapse loss occurs at a similar rate to brain atrophy (Geinisman *et al.*, 1995). However, synaptophysin decreases in the target zone after lesion-induced denervation and increases with regeneration of synapses (Palmer and DeKosky, 1998). Therefore, as expected in AD, synaptophysin is decreased in areas of known synapse loss which are affected by the disease (cortex and hippocampus) but not in regions that are behaviorally or neuropathologically uninvolved, such as the cerebellum (Palmer and DeKosky, 1998). Actual synapse loss in AD compared to age equivalent controls has been shown in electron microscopic studies, which directly quantify synapses (Palmer and DeKosky, 1998). The severity of dementia of AD patients has been shown to correlate with synapse counts in biopsy tissue and synaptophysin concentration in postmortem tissue (Palmer and DeKosky, 1998).

White Matter

White matter represents axons, their insulating sheath, and the supporting cell. Age-related white matter changes are a frequent finding in CT/MRI of older subjects. The evidence points toward an association between white matter changes and cognitive impairment, with speed of mental processes, attention, concentration, executive functions, and visual spatial skills being the cognitive domains more commonly affected (Ferro and Madureira, 2002).

PROTEIN SYNTHESIS AND GENE EXPRESSION

Overall, the data suggest that there is a reduction in the capacity to synthesis proteins during aging, which is related to changes in the nucleus. Studies of the aging rodent brain indicate diminished rates of protein synthesis, but such studies have not been performed on the human brain, although the shrinkage of neurons and decreases in specific proteins (e.g. neurotransmitter receptor enzymes) may stem from such declines. In AD, the capacity for protein synthesis is reduced, which in pyramidal cells may be associated with the formation of neurofibrillary tangles. This, along with impaired cytoskeletal transport of proteins, will substantially disrupt normal function.

POSSIBLE CAUSES OF AGE-ASSOCIATED NEURODEGENERATION

The cause of age-associated neurodegeneration is not yet known. However, there are a number of mechanisms of neurodegeneration that may play a role in senescent brain dysfunction. These include the triumvirate of excitotoxicity, oxidative stress, and impaired energy metabolism, along with neurotrophic factors, and are considered below.

Excitotoxicity

The excitotoxic hypothesis of brain injury posits that elevated interstitial concentrations of EAAs cause cell death by overactivation of EAA receptors. EAAs could accumulate because of a disruption of energy metabolism leading to increased EAA release or impairment or reversal of EAA uptake (or a combination of both). Another possibility is that the number of EAA receptors or their selectivity for particular ions change and thus cause cell death. For example, loss of basal forebrain cholinergic neurons in AD may be linked to the numbers of calcium-permeable AMPA/kainate receptors present on such cells. By whatever mechanism a major consequence of these changes is depolarization of the postsynaptic membrane, which removes the depolarization block to the NMDA receptor channel complex, thus permitting a large influx of Ca^{2+} ions over the period that it is in the open state. Toxicity is then determined by both the magnitude and duration of the rise in cytosolic Ca^{2+} concentrations.

It is now well established that excitotoxic mechanism contribute to the neurodegenerative changes associated with stroke and motor neuron disease, while for AD the extent of such involvement remains to be established clearly. In aging, there is increased vulnerability of selected populations of neurons to excitotoxicity and oxidative stress. Environmental stress can also contribute to hippocampal cell death. These neurons have endogenous glucocorticoid receptors, which interact with glucocorticoids secreted from adrenal glands in response to stress reduce glucose uptake (Behl, 1998). This increases vulnerability to cell death and may provide the basis to stress-induced neurodegeneration, which has been observed in experimental animals. The hippocampus is particularly vulnerable to both age- and Alzheimer-associated degeneration and is selectively vulnerable to the effect of metabolic poisons (Palmer *et al.*, 1994).

Oxidative Stress

The brain is particularly vulnerable to free radical damage because of its high requirement for both energy and oxygen, along with particularly high concentrations of polyunsaturated fatty (which are major substrates for free radicals) acids and transition metals (which often catalyze radical-generating reactions). This situation is exacerbated by a lower antioxidant capacity than that in most other organs. Oxidative stress

occurs when pro-oxidant activity exceeds the capacity of the tissue's antioxidant capacity. Oxidative stress increases with age because of increased pro-oxidant activity rather than any diminution of antioxidant capacity (Palmer *et al.*, 1994). This elevated pro-oxidant activity causes oxidative damage to DNA, protein, and lipids in the brain, which leads to neuronal dysfunction and ultimately to neuron loss. Nerve terminals are particularly vulnerable because of the high number of mitochondria, which is the source of most free radicals. This is supported by age-related increases in a marker of DNA damage (8-hydroxydeoxyguanosine concentration) and elevated lipid peroxidation in synaptosomes (pinched off nerve endings). The oxidative polymerization of lipids leads to the formation of lipofuscin and increases in a linear fashion with age in humans. Its formation occurs as a result of free radical formation, so accumulation with age may reflect the cumulative consequence of free radical reaction over the lifespan. Lipofuscin has been shown to accumulate in both the cholinergic nucleus basalis of Meynert and the serotonergic raphe nucleus and may therefore be associated with the age-associated loss of these cells. Similarly, neuromelanin accumulation, also thought to occur in response to free radical reactions, increases with aging in the noradrenergic locus coeruleus and the dopaminergic substantia nigra, and there is good evidence for free radical involvement in the etiology of Parkinson's disease (Beal, 2003).

In addition to oxidative damage to DNA and lipids, there is also evidence for an age-related increase of oxidized protein (assessed by measuring the concentration of protein carbonyls) in brain tissue from both humans and experimental animals. The full significance of oxidative stress increasing with age is not yet clear, but the fact that damage to DNA, lipids, and proteins is also evident in AD and Parkinson's disease (Floyd, 1999) suggests that these age-related changes increase vulnerability to the pathogenic process associated with neurodegenerative diseases.

There is evidence of free radical damage to all classes of macromolecules (protein, DNA, RNA, lipids, and sugars) in brains of patients with AD, although great care must be taken to control for the effects of postmortem delay and brain acidosis occurring as a consequence of terminal coma. Taking this into account, there is evidence of damage to specific proteins such as the glial glutamate transporter GLT-1, glutamine synthase and β-actin as well as the lipids arachidonic acid and docosahexaenoic acid (Butterfield *et al.*, 2001). The oxidative damage to GLT-1 has been attributed to the action of an aldehydic product of lipid peroxidation, 4-Hydroxynonenal (Lauderback *et al.*, 2001). The functional consequences of this modification are as yet unknown but may explain the functional reduction in glutamate uptake seen in AD (Procter, 1996) in the presence of stable amounts of GLT-1 protein (Beckstrom *et al.*, 1999).

Reduced Energy Availability/Mitochondrial Function

There remains some uncertainty as to whether the cerebral metabolic rate as determined by positron emission tomography (PET) declines with aging but the most closely controlled studies indicate that at least some brain regions are affected. The complication is that brain atrophy as well as functional decline can both contribute to reductions. Only when studies using full coregistration of PET with MRI become more frequent will it be possible to resolve this issue. Cerebral metabolic rate for glucose and for oxygen and cerebral blood flow are all reduced in AD and the pattern of reductions tends to mirror neuropathology. Again the complication is atrophy and cell loss. However, evidence energy levels appear to be reduced in AD, probably because of impaired mitochondrial function (Beal, 1998; Francis *et al.*, 1993). The likely cause is not known, but it may be related to reductions in the activity of key enzymes in the Kreb's cycle. Thus, there have been consistent reports of reduced activity of pyruvate dehydrogenase α-ketoglutarate dehydrogenase and cytochrome oxidase (Blass, 2003). Other evidence points to the possibility of uncoupling of oxidative phosphorylation and oxidation (Francis *et al.*, 1993), which would reduce energy availability; it is also likely to increase free radical production.

Neurotrophic Factors

Over the past decade, there has been much interest in the possible role of neurotrophic factors in neurological disorders. In particular, nerve growth factor (NGF), the founding member of the neurotrophin family, has generated great interest in relation to AD. This interest is based on the observation that cholinergic basal forebrain are dependent upon NGF and its receptors for their survival. In fact, NGF transduces its effects by binding two classes of cell surface neurotrophin receptors: TrkA and p75, both of which are produced by cholinergic neurons. Recent findings indicate an early defect in NGF receptor expression in CBF neurons; therefore, treatments aimed at facilitating NGF actions may prove highly beneficial in counteracting the cholinergic dysfunction found in end-stage AD and attenuating the rate of degeneration of these cholinergic neurons (Lad *et al.*, 2003). There are no quantitative data on changes in NGF receptor density over the lifespan or in aging.

Amyloid (Aβ)

Aβ, a 40–42 amino acid peptide derived from amyloid precursor protein, is considered to play a central role in the pathophysiology of AD since it forms the core of senile plaques. In some cases, (autosomal dominant AD and Down's syndrome (*see* **Chapter 92, Cellular Changes in Alzheimer's Disease** and **Chapter 101, The Older Patient with Down's Syndrome**)) this occurs because of increased production of Aβ, whereas in sporadic AD it may be linked to altered Aβ processing or impaired clearance of Aβ. Both Aβ deposition and plaque formation increase with aging, although the mechanism is not yet clear, it may be linked to oxidative stress since amyloidoisis is blocked by antioxidants.

APPROACHES TO THERAPY

Aging is a highly complex multifactorial process characterized by the progressive loss of the ability of organs and cells to maintain normal function. Thus, there is no unitary neurochemistry of aging and age-associated brain dysfunction manifests in a variety of way and increases the likelihood of coincidence neurological disease. It is therefore unlikely that there will ever be a single pharmacotherapy for brain aging, but, rather, specific therapies will be used for particular symptoms, as is now being realized in neurological disorders such as AD (Palmer, 2002). Understanding the underlying neurochemistry thus provides an essential framework for rational therapy, which may be categorized as either neuroprotective or palliative (*see also* **Chapter 97, Treatment of Behavioral Disorders**).

Neuroprotective Therapy

Antiexcitotoxic Agents

Excitotoxicity clearly plays an important role in mediating neurodegenerative changes in stroke, severe hypoglycemia, severe epilepsy, and severe head injury. Although the involvement of excitotoxic mechanism in chronic brain injury is less clear-cut, evidence is emerging for a critical role in mediating the neurodegenerative changes associated with motor neuron disease and AIDS. Excitotoxicity coupled with oxidative stress may also be central to the neuropathology associated with the diseases of Huntington, Parkinson, and Alzheimer. Since most of these diseases are age-related, disease-induced changes are probably potentiated by the neurodegeneration associated with normal aging, which itself may be caused by excitotoxic injury, probably in conjunction with oxidative stress (Palmer *et al.*, 1994). Thus, there is great potential for drugs that block the cascade of destruction associated with excitotoxic injury. Preclinical studies have now established the utility of NMDA and AMPA/kainate receptor antagonists in the treatment of acute brain injury. However, none of these compounds showed clear efficacy in clinical trials (Dawson *et al.*, 2001). However, one well tolerated NMDA receptor antagonist (memantine) has recently been launched as a palliative for AD (Palmer and Stephenson, 2005). Whether it is also able to alter the course of this disease remains to be established (Tariot *et al.*, 2004).

Antioxidants

The proposed involvement of oxidative damage in aging has prompted studies to examine the neuroprotective efficacy of various antioxidants. However, the results so far are encouraging but variable (Floyd, 1999). The nitrone-based free radical trap PBN (α-phenyl-*N*-*tert*-butyl nitrone) has been investigated extensively. Chronic low-level administration to old experimental animals appears to reverse their age-enhanced susceptibility to stroke. In addition to its radical scavenging activity, it has also been shown to block inflammation-induced neurodegeneration, suggesting there that the senescent brain may be an enhanced neuroinflammatory state as well as at an increased level of oxidative stress (Floyd and Hensley, 2000).

Palliative Therapy

Of the behavioral changes seen in apparently normal elderly, relatively few have a significant impact on function. Those changes that affect function relate primarily to motor slowness, difficulty with complex cognitive complexity, visual and auditory alterations, depression, and sleep disturbance. The most successful example of palliative therapy is the use of levodopa to treat Parkinson's disease. The effect of levodopa on age-associated motor dysfunction is not yet clearly established. The age-associated impairments in cognitive function may well respond to therapies aimed and improving cognitive function in Alzheimer patients. Some of the symptoms of AD, particularly aphasia, agnosia, and apraxia, are often similar to those associated with cortical disconnection syndromes. Quantitative data on the distribution of senile plaques and neurofibrillary tangles further suggest that corticocortical projection fibers are selectively affected within association areas of the cortex. This has led to the hypothesis that AD represents a global cortical disconnection syndrome in which each cortical region functions in isolation. Support for this hypothesis has come from an antemortem study of AD, in which loss of the perikarya of pyramidal neurons from layers III and V of the midtemporal gyrus of Alzheimer's patients was found to correlate significantly with an assessment of the severity of dementia and scores on five psychometric tests (Mann, 1996). As pyramidal neurons use EAA as a neurotransmitter and receive prominent excitatory inputs, the cortical disconnection hypothesis of AD predicts that changes in EAA neurons and receptors make a substantial contribution to the progressive impairments of memory, personality, and intellect that characterize AD (Francis, 2003). Studies have demonstrated that the NMDA receptor antagonist Memantine improves global functioning and activities of daily living, cognitive function, and caregiver burden (Tariot *et al.*, 2004). Another approach is to target 5-HT_{1A} receptors, which in the cerebral cortex are entirely located on pyramidal cells. 5-HT_{1A} receptor antagonists have been shown to increase EAA release; it has been suggested that such compound will be effective in the treatment of AD (Schechter *et al.*, 2002). Cholinergic mechanisms have also been linked to memory dysfunction, although recent evidence suggests that the cholinergic system may play a greater role in attentional processing. There are a number of approaches to the treatment of the cholinergic deficit in AD, most of which have focused on ACh replacement with precursor (choline or lecithin) the AChE inhibitor physostigmine or the muscarinic agonist are coline. More recent studies have used M_2 muscarinic antagonists, M_1 muscarinic

agonists, nicotinic agonist, or improved AChE inhibitors (Palmer, 2003).

Again in AD, dysfunction of noradrenergic and serotonergic neurons probably relate more to noncognitive changes in behavior, such as aggression, depression, and sleep disturbances, that often accompany AD (Palmer and DeKosky, 1993; Procter, 1996). Thus, there is now a theoretical basis for treating subsets of elderly persons and patients with AD who display overt noncognitive changes in behavior with drugs that act upon noradrenergic and serotonergic systems (Palmer and DeKosky, 1998). Thus, for example, 20–30% of elderly persons with concurrent mental illness are depressed. Similarly, depression affects a similar proportion of Alzheimer patients and anti-antidepressant therapy appears to be effective, although there have been no double blind yet (Palmer and DeKosky, 1998).

CONCLUSIONS AND FUTURE DIRECTIONS

Neurochemical changes in the aging brain are varied and for many markers they are qualitatively the same, but quantitatively less severe than those occurring in neurodegenerative disease. Impairments in dopamine transmission probably contribute to the gait and movement disorders in the elderly and contribute to the age-associated increase in the prevalence of Parkinson's disease. Similarly, alterations in EAA and cholinergic transmission probably contribute to the impairments in cognition and attention seen in the elderly whereas the age-related decline in noradrenergic and serotonergic transmission are likely to contribute to the age-associated changes in noncognitive behavior, such as depression, aggression, and sleep disturbance. This lays the conceptual framework for palliative therapy for the behavioral abnormalities associated with old age. Similarly, the development of preventative therapy depends on a clear understanding of the mechanisms responsible for age-associated neurodegeneration. The most plausible mechanism at present is that it occurs as a result of oxidative stress, which causes damage to DNA, lipid, and protein, which contribute to cell dysfunction. If this is sufficient to impair the production of ATP (which is required for neurons to maintain their high level of activity), then the membrane potential will not be maintained. This inability to maintain neuronal membrane potential (because of diminished activity of the Na^+ /K^+ ATPase) eases the Mg^{2+} blockade of the NMDA receptor and facilitates activation by EAAs, leading to increase influx of Ca^{2+} and, if sustained at a high level, will lead to cell death.

Given the major implications of cognitive competency for personal independence and quality of life, together with growing evidence that how an individual lives in earlier stages of life affects cognitive aging, greater attention to memory and the aging brain is likely to have significant public health benefits. It is now clear that significant cognitive decline is not an inevitable consequence of advanced age. Furthermore, AD and related disorders, which in the past have been approached with a sense of therapeutic nihilism, are increasingly being seen as targets for active intervention. But what of "age-associated memory impairment"? New research that offers to attain the ancient goal of improving our cognitive ability raises an important issue – the use, by healthy people, since aging is not considered a disease. There is a long history of "cognitive enhancers" but the effectiveness of such supposed "nootropics" is far from clear (Rose, 2002). Although pharmaceutical companies race to provide treatments for memory loss in AD, there is much less enthusiasm to treat "age-associated memory impairment".

Long term, however, it is clear that there is likely to be an increased need for drugs to improve cognitive function in both the demented and nondemented elderly. With the projected growth in the elderly (Figure 1), there will be a corresponding decline in the number of working taxpayers relative to the number of older persons. This means that there is likely to be inadequate public resources and fewer adults available to provide informal care to older, less able family members and friends. Having drugs available to improve brain function (for both cognitive and noncognitive aspects) would clearly be a positive contribution. However, CNS drug discovery is associated with significant challenges (Palmer and Stephenson, 2005) and the pharmacotherapy of aging remains an embryonic science.

KEY POINTS

- The number of people in the world aged over 65 years is projected to increase sharply in the next 2–3 decades.
- Aging is associated with loss of brain cells, but this loss is much less pronounced than that seen in neurodegenerative disorders such as Alzheimer's dementia and Parkinson's disease.
- Aging is associated with modest changes in cognitive function and mild changes in noncognitive changes in behavior.
- Aging is a major risk factor for neurodegenerative diseases and psychiatric disorders such as depression.
- Our understanding of the neuronal basis of aging is becoming more sophisticated, but the pharmacotherapy aging remains an emerging science.

Neuropathology of Aging

Seth Love
University of Bristol, Bristol, UK

INTRODUCTION

The effects of age on the nervous system, and the nature of the association between senescence and senility have long exercised us and been subjected to detailed clinical, electrophysiological, biochemical, morphologic and molecular genetic study. This chapter includes a detailed description of the gross and microscopic alterations in the nervous system that occur with increasing age. Inevitably, this involves some consideration of the histological overlap between the alterations of "normal" aging and those due to degenerative neurological diseases, particularly Alzheimer's disease. The pathological findings in Alzheimer's disease and other neurological diseases are, however, described in more detail elsewhere in this book.

GROSS CHANGES

External Appearance

External examination is relatively insensitive to the effects of age on the adult brain but some changes are usually evident by about the 7th decade. The sulci are slightly wider and the gyri narrower than in younger individuals and there is often some thickening and opacity of the leptomeninges over the cerebral convexities, particularly toward the vertex. The dura mater may become firmly adherent to the skull vault.

Brain Weight

Several studies have documented an approximately inverse linear relationship between age and brain weight in later years. In a series of over 7000 autopsies, Peress *et al.* (1973) found that a decline in brain weight was evident from as early as 30 years of age and affected the supratentorial and infratentorial parts of the brain proportionately. Hartmann *et al.* (1994) calculated that the weight of the brain decreases from mean values of 1336 g in young adult males and 1198 g in young adult females by about 2.7 g per year in males and 2.2 g per year in females. Similar figures can be derived from data based on magnetic resonance imaging (MRI). In the MRI series of Coffey *et al.* (1992), the volume of the cerebral hemispheres was found to fall by an average of 0.23% per year in healthy adults; the reduction in volume was greater than average in the frontal lobes (0.55% per year), the temporal lobes (0.28% per year) and the amygdala-hippocampal complex (0.30% per year). Resnick *et al.* (2003) reported that the mean annual rates of tissue loss in adults aged between 59 and 85 years were 5.4, 2.4, and 3.1 ml per year for total brain, gray, and white volumes, respectively. Thus, although there is some shrinkage of gray matter, the greater part of the reduction in brain weight is due to atrophy of the white matter.

Ventricular Size

Not surprisingly, as brain weight declines, ventricular size tends to increase. The effects of aging on the volume of ventricular and sulcal cerebrospinal fluid (CSF) have been the subject of several CT and MRI studies. In an MRI study of 76 healthy adults, Coffey *et al.* (1992) found the volume of the lateral ventricles to increase by an average of 3.2% per year and of the third ventricle by 2.8% per year. Pfefferbaum *et al.* (1994) reported that the ventricular volume increased between 21 and 70 years by approximately 0.3 ml per year but the volume of sulcal CSF increased more rapidly, at 0.6 ml per year. Resnick *et al.* (2003) found mean ventricular volume to increase by 1.4 cm^3 per year over a 4-year period in his cohort of normal 59–85 year olds.

MICROSCOPIC CHANGES IN THE GRAY MATTER

Neuronal Loss and Neuronal Shrinkage in Cerebral Cortex and Hippocampus

There is marked regional variation in the pattern of neuronal loss in the central nervous system. Several studies have been made of the distribution and extent of neuronal loss in the neocortex. The earliest of these were based on relatively time-consuming manual counting methods and, of necessity therefore, included fewer cases and smaller samples of cortex than later studies in which counts were obtained by means of automated image-analyzers. Variations in the methodology and results of these studies were discussed in detail by Terry *et al.* (1987). Early studies (see Love, 1998) indicated a variable but substantial depletion of neurons from the cerebral cortex during adult life in many regions, amounting to 40–50%. In contrast, both Haug *et al.* (1984) and Terry *et al.* (1987) found no correlation between age and neuronal density in several regions of cerebral cortex, the "loss" of large neurons being largely attributable to shrinkage and associated, therefore, with an "increase" in the number of smaller neurons. Terry *et al.* (1987) suggested that the fully automated acquisition and analysis of some earlier morphometric data, with no manual editing of the digitized images, may have been inaccurate. It is worth noting that most of these investigators have found a two- to threefold variation between the numbers of neurons in any given region of cortex even in neurologically normal individuals of similar age, so that the relatively small early series should be interpreted with circumspection. Using stereological methods that avoid artifacts due to gray matter atrophy, processing, or sectioning, Pakkenberg *et al.* (2003) calculated that the number of neocortical neurons in women was 19.3 billion and in men, 22.8 billion, a difference of 16%. The number of neurons declined by less than 10% between 20 and 90 years. In summary, the evidence is of some, but only mild, loss of neurons from the neocortex of neurologically normal individuals during adult life, and shrinkage of many of the larger neurons that remain. The gender-related difference in the number of neocortical neurons probably exceeds the loss of neurons that is attributable to aging.

Several recent studies have shown that neuronal populations in the entorhinal cortex of cognitively normal subjects remain stable well into old age (Trillo and Gonzalo, 1992; Lippa *et al.*, 1992; Gómez-Isla *et al.*, 1996). This contrasts with findings in Alzheimer's disease, in which severe loss of neurons from laminae II and IV is an early manifestation (Lippa *et al.*, 1992; Gómez-Isla *et al.*, 1996).

Studies differ as to the extent and distribution of neuronal loss from the aging hippocampus. Miller *et al.* (1984) recorded a loss of neurons from the CA1 field, of approximately 3.6% per decade. Devaney and Johnson (1984) made a rather confusing study of neuronal density in the hippocampus. They counted dispersed cells in a hemocytometer and related their numbers to the weight of the whole of the hippocampus. The density of neurons as determined in this way increased slightly between 20 and 87 years but this is probably attributable to senescent shrinkage of the molecular layer of the dentate fascia and hippocampal white matter. Probably the most accurate quantification of neurons in different parts of the hippocampus has been that of West and colleagues (West, 1993; West *et al.*, 1994) employing modern stereological methods. They found an age-related decline in the numbers of neurons in the subiculum and hilus of the dentate gyrus, at about 0.7% per annum and 0.4% per annum respectively, but no significant change in the number of neurons in the CA1 field (which shows most marked loss of neurons in Alzheimer's disease). Although the number of CA1 neurons is probably well preserved during normal aging, Dickson *et al.* (1994) found hippocampal sclerosis, characterized by marked focal loss of neurons and gliosis predominantly involving the CA1 field, to be a surprisingly common finding in demented patients over 80 years of age, usually in the absence of other neurodegenerative diseases to account for the dementia.

Cholinergic and Peptidergic Input to Cerebral Cortex and Changes in the Nucleus Basalis of Meynert

Most investigators have found that there is only mild or no reduction in the number of neurons in the nucleus basalis of Meynert complex, which provides the cholinergic input to the cerebral cortex (Chui *et al.*, 1984; Mann *et al.*, 1984; Bigl *et al.*, 1987; Lowes-Hummel *et al.*, 1989). However, substantial age-related reductions, of 50% or more, were reported by McGeer *et al.* (1984) and de Lacalle *et al.* (1991). These last authors found the neuronal loss to be greatest in the posterior subdivision (64.5% by 90 years), where there was also 10% shrinkage of the remaining neurons. The loss from the intermediate subdivision was 42% and no significant change in the number of neurons occurred in the anterior subdivision, where the cell size actually increased by an average of 15%. According to Baloyannis *et al.* (1994), it is principally the small spiny GABA-ergic neurons in the nucleus basalis that decrease in number in normal aging, the large cholinergic neurons being spared. In keeping with this observation, the density of cholinergic fibers in the neocortex, entorhinal cortex, and amygdaloid complex declines only slightly in normal aging, compared with the dramatic loss in Alzheimer's disease (Geula and Mesulam, 1989; Benzing *et al.*, 1993; Emre *et al.*, 1993). The density of somatostatin-, neurotensin- and substance P-containing nerve fibers in the cerebral cortex, amygdaloid complex, and subcortical white matter seems to be preserved well into old age (Benzing *et al.*, 1993; Emre *et al.*, 1993; Ang and Shul, 1995).

Other Subcortical Nuclei

The numbers of neurons in many of the subcortical nuclei that have been studied are relatively stable throughout adulthood. The density of neurons in the striatum remains constant

(Pesce and Reale, 1987), although there is some shrinkage of the large, strongly calbindin-positive neurons (Selden *et al.*, 1994). No significant loss of neurons occurs from the supraoptic or paraventricular nuclei of the hypothalamus (Goudsmit *et al.*, 1990; Wierda *et al.*, 1991). There is loss of neurons from the suprachiasmatic nucleus, although less so than in Alzheimer's disease (Swaab *et al.*, 1993). Swaab *et al.* (1993) documented hypertrophy of neurons containing estrogen receptors in the infundibular/arcuate nucleus of the hypothalamus in postmenopausal women and speculated that this may be related to the development of hot flushes. Similar observations were made by Abel and Rance (2000).

With increasing age, there is a mild loss of pigmented neurons from the substantia nigra and locus ceruleus (Perry *et al.*, 1990; Fearnley and Lees, 1991). This loss is not related to coexistent Alzheimer-type or Lewy body pathology (Perry *et al.*, 1990; Love *et al.*, 1996) and has not been demonstrated in all series (Kubis *et al.*, 2000). In the substantia nigra, the fallout of neurons with age is largely confined to the medial ventral and dorsal tiers of the pars compacta, whereas Parkinson's disease affects the lateral ventral tier most severely (Fearnley and Lees, 1991). The number of neurons remains constant with age in the roof nuclei of the cerebellum (Heidary and Tomasch, 1969), the ventral cochlear nucleus (Konigsmark and Murphy, 1970), the nucleus of the facial nerve (van Busirk, 1945) and the inferior olivary complex (Moatamed, 1966). With aging, there is a significant decrease in the number of neurons in the vestibular nuclear complex (Tang *et al.*, 2001). Alvarez *et al.* (2000) found that aging does not affect the size of the complex, and that the neuronal loss affects the descending, medial and lateral vestibular nuclei but not the superior nucleus. Tomlinson *et al.* (1981) counted neurons in the locus ceruleus in brains from 25 neurologically normal adults and noted that the counts gradually declined after middle age. The number of cholinergic neurons in the pedunculopontine nucleus was reported to decrease with age between the third and tenth decades (Ransmayr *et al.*, 2000); however, four centenarians had neuronal cell counts comparable to those in much younger adults, leading the authors to speculate that centenarians may start out with greater numbers of neurons in the pedunculopontine nucleus or may experience slower loss of neurons with aging.

Dendritic Changes

There is accumulating evidence that the dendrites in several regions of the adult brain are capable of considerable growth and plasticity, resulting in expansion of the dendritic tree. This may be a compensatory response to loss of adjacent neurons. This phenomenon is best documented for dendrites in the molecular layer of the hippocampal dentate gyrus (Flood *et al.*, 1987; de Ruiter and Uylings, 1987) and in lamina II of the parahippocampal cortex (Buell and Coleman, 1979; Flood and Coleman, 1990). In contrast, the extent of the dendritic trees decreases in both of these regions in patients with Alzheimer's disease. Whereas the expansion of the dendritic tree in the parahippocampal cortex seems to continue well into old age, that in the molecular layer of the dentate gyrus peaks in middle age and subsequently regresses (Flood *et al.*, 1987). The dendritic trees of neurons in the subiculum (Flood, 1991) and the pyramidal cell layer of the hippocampus remain relatively constant during normal aging (Flood and Coleman, 1990; Hanks and Flood, 1991) but regress in Alzheimer's disease.

Outside of the hippocampus and parahippocampal gyrus, only relatively minor dendritic alterations have been observed in the cerebral cortex. Jacobs and Scheibel (1993) found that the number of dendritic segments in pyramidal cells in the superior temporal gyrus remained relatively stable with age although the length of the dendrites tended to decrease. A decrease in the number of basal dendrites with advancing age was noted by Nakamura *et al.* (1985) in pyramidal neurons in the motor cortex (Brodmann area 4).

Limited information is available concerning changes to dendrites in the subcortical nuclei. Arendt *et al.* (1994) found that the dendritic field of neurons in the nucleus basalis increased in size during normal aging. In contrast, the growth of dendrites that occurred in Alzheimer's disease tended to increase their density without enlarging the dendritic field. Significant loss of dendrites was observed in neurons in the substantia nigra of elderly subjects (Cruz-Sanchez *et al.*, 1995)

Synaptic Density

With increasing age, there is a mild decline in the density of synapses in the hippocampus and in parts of the cerebral neocortex, whether assessed by electron microscopy (Adams, 1987; Bertoni-Freddari *et al.*, 1990) or synaptophysin immunohistochemistry (Masliah *et al.*, 1993; Eastwood *et al.*, 1994). A possible exception is the postcentral (primary somatosensory) cortex, in which Adams (1987) found the density of synapses to remain constant. Masliah *et al.* (1993) calculated that the density of synaptic terminals in the frontal cortex of subjects over 60 years was approximately 20% below that of younger subjects. The loss synapses in the hippocampus and at least some regions of the neocortex is probably accompanied by an increase in the mean area of contact at each synapse (Adams, 1987; Bertoni-Freddari *et al.*, 1990).

Love *et al.* (2005) found that the concentration of synaptic proteins in the superior temporal cortex was related to the apolipoprotein E (*APOE*) genotype. In superior temporal cortex from normal brain, the concentration of the postsynaptic protein PSD95 (postsynaptic density-95) was significantly higher in cortex from people with than without an *APOE* $\varepsilon 2$ allele. In contrast, possession of the *APOE* $\varepsilon 4$ allele was associated with lower concentrations of two presynaptic proteins, synaptophysin and syntaxin. A positron emission tomographic investigation showed that people who possess an $\varepsilon 4$ allele have lower rates of cerebral glucose metabolism in the posterior cingulate, parietal, temporal, and prefrontal cortex (Reiman *et al.*, 2004), and in another study,

morphometry revealed that neurons in nucleus basalis of Meynert from people with $\varepsilon 4$ have smaller Golgi apparatus (Dubelaar *et al.*, 2004), another measure of metabolic activity. These *APOE*-related premorbid differences in synapses and metabolic activity may influence the capacity of the brain to respond to injury and may thereby account for the association between *APOE* and clinical outcome in a range of neurological diseases, such as head injury (Chiang *et al.*, 2003; Teasdale *et al.*, 1997), hemorrhagic stroke (McCarron *et al.*, 2003), and multiple sclerosis (Chapman *et al.*, 2001; Fazekas *et al.*, 2001).

Dystrophic Axons and Ubiquitinated Deposits

During normal aging, axons in certain parts of the central nervous system tend to undergo dystrophic changes: they develop focal argyrophilic swellings within which lysosomes, mitochondria, membranous bodies, and neurofilaments accumulate. Sites of predilection include the gracile and cuneate nuclei, the substantia nigra, the globus pallidus, and the anterior horns of the spinal cord. These dystrophic axons react strongly with antibodies to ubiquitin, which also label smaller, dotlike structures in the white matter and cerebral cortex. Ubiquitin is an 8-kDa polypeptide involved in the degradation of many abnormal or short-lived proteins. The density of the dotlike structures increases with age and they are particularly prominent after about 60 years (Dickson *et al.*, 1990). These small ubiquitinated bodies correspond to dystrophic neurites (Dickson *et al.*, 1990; Dickson *et al.*, 1992; Migheli *et al.*, 1992; Yasuhara *et al.*, 1994) and foci of granular degeneration of myelin sheaths in the white matter (Dickson *et al.*, 1990, 1992; Migheli *et al.*, 1992).

Lipofuscin

Lipofuscin, a pigment produced by oxidation of lipids and lipoproteins, accumulates with age in the form of irregularly shaped, brown cytoplasmic granules that are acid-fast, sudanophilic, and autofluorescent under ultraviolet light. Electron microscopy shows the granules to contain both highly electron-dense, and homogeneous, moderately electron-lucent material, aggregated together within a unit membrane. Lipofuscin accumulates to a varying extent in most neurons and glia (Wisniewski and Wen, 1988). Neurons of the inferior olivary nuclei tend to amass large amounts of lipofuscin from early adulthood. With increasing age, relatively large amounts of lipofuscin also accumulate in the dentate nucleus of the cerebellum, pyramidal neurons in the cerebral cortex and hippocampus, large neurons in the amygdala, thalamus and hypothalamus, and motor neurons in brain stem and spinal cord.

Hirano Bodies

Hirano bodies are brightly eosinophilic rod-shaped or oval cytoplasmic inclusions (Figure 1). They contain actin, actin-associated proteins, tau, low and middle molecular weight neurofilament subunits, and C-terminal β-amyloid precursor protein epitopes, and consist of a regular lattice of multiple layers of parallel 10–12-nm filaments, a 12-nm gap separating adjacent layers (Hirano, 1994). Filaments in one layer are transversely or diagonally orientated with respect to those in the adjacent layers. Hirano bodies are most numerous in the CA1 field of the hippocampus, particularly in the stratum lacunosum, but can occur elsewhere in the central nervous system (and are occasionally seen in Schwann cells in the peripheral nervous system). In the stratum lacunosum, their density increases until middle age and declines gradually thereafter. There is an increased density of Hirano bodies in the stratum lacunosum in chronic alcoholics (Laas and Hagel, 1994). In normal elderly subjects, Hirano bodies also occur in the stratum pyramidale, where their number continues to increase well into old age, but they are particularly numerous in this region in patients with Alzheimer's disease.

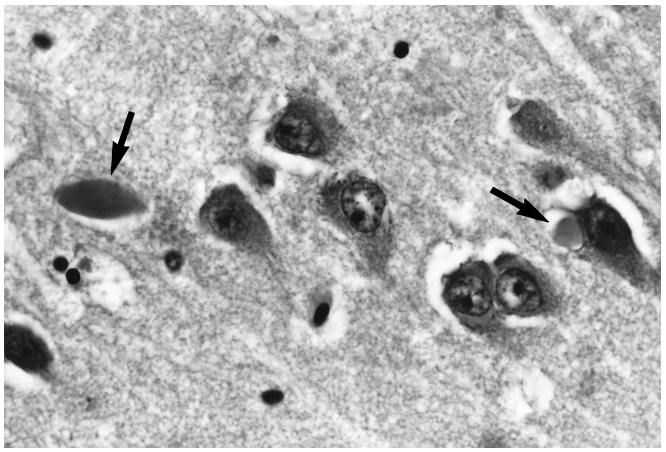

Figure 1 Hirano bodies (arrows) in the pyramidal cell layer of the hippocampus

Granulovacuolar Degeneration

The term "granulovacuolar degeneration" describes the accumulation of small, round, dense bodies, more or less in the center of clear vacuoles, in the neuronal cytoplasm (Figure 2). The dense bodies are ubiquitinated (Love *et al.*, 1988; Dickson *et al.*, 1993) and react with antibodies to some, but not all, epitopes of the microtubule-associated protein, tau (Dickson *et al.*, 1993). These data have been interpreted as suggesting that the dense bodies are a product of partial degradation of tau, which is the main constituent of neurofibrillary tangles. In the absence of Alzheimer's disease, granulovacuolar degeneration rarely occurs to any noticeable extent before the 7th decade but becomes increasingly prominent thereafter (Peress *et al.*, 1973; Xu *et al.*, 1992). Neurons in the CA1 field are most severely affected and, in descending order of severity, those in the prosubiculum, CA2, CA3, and CA4 fields less so (Xu *et al.*, 1992). In normal aging, granulovacuolar degeneration is virtually confined

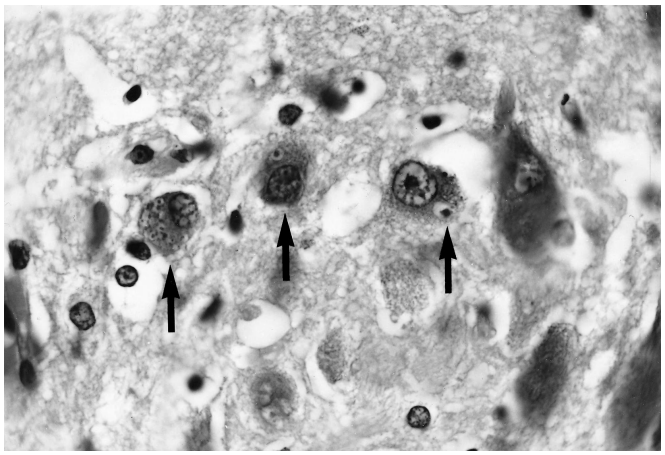

Figure 2 Granulovacuolar generation of several neurons (arrows) in the CA1 field of the hippocampus

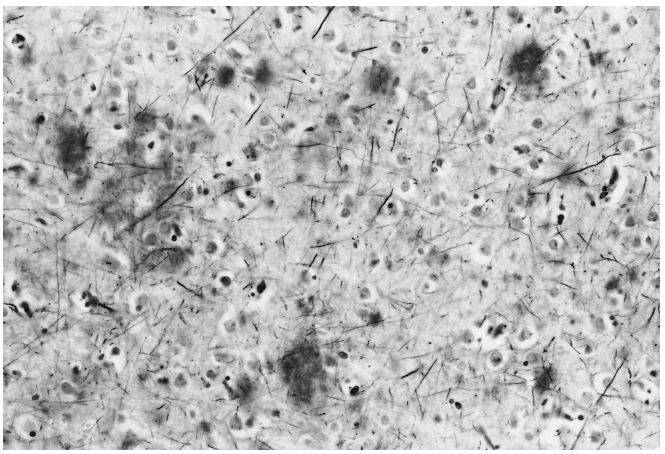
to the hippocampal formation. Granulovacuolar degeneration is more severe in patients with Alzheimer's disease and may involve other neurons in a wide range of subcortical nuclei in addition to those in the hippocampus (Xu *et al.*, 1992).

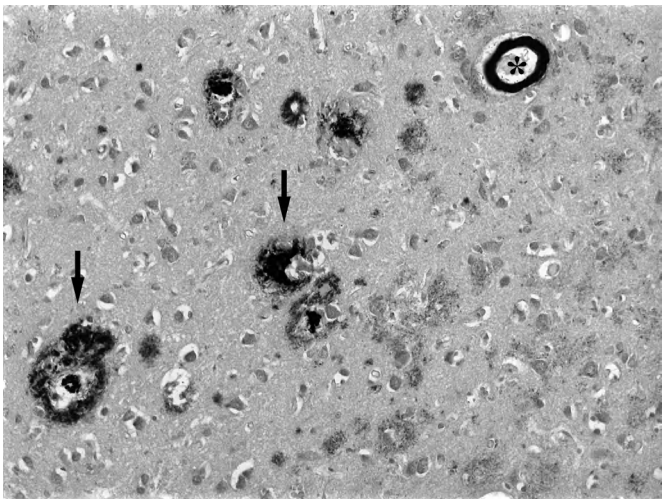
Plaques

The nature and composition of plaques are considered in detail in **Chapter 92, Cellular Changes in Alzheimer's Disease**. The plaques that develop during normal aging, after 55–60 years, are predominantly diffuse (nonneuritic) (Mann *et al.*, 1990; Crystal *et al.*, 1993). They consist largely of nonfibrillar extracellular Aβ peptide, predominantly Aβ_{1-42}. They are readily visualized by silver impregnation or immunohistochemistry for Aβ (Figure 3). Despite the absence or marked paucity of amyloid fibrils in these plaques, they are usually faintly autofluorescent under ultraviolet light in thioflavin-S preparations (although much less so than neuritic plaques).

The diffuse plaques of aging resemble those of Alzheimer's disease in both their chemical composition (see, for example, Fukumoto *et al.*, 1996) and widespread neocortical distribution. They are usually much less abundant than in Alzheimer's disease, but there is overlap in the density of diffuse plaques in patients and cognitively normal elderly people. In the latter group, the plaques rarely involve the striatum or cerebellum, which are often affected in Alzheimer's disease, but plaques can occur in the lateral inferior pulvinar and superior colliculus (Leuba *et al.*, 2001). Although diffuse plaques are a common finding in older age, their accumulation does not seem to be consistent or progressive (Crystal *et al.*, 1993; Mackenzie, 1994). Delaere *et al.* (1993) reported that Aβ deposits were a constant finding in the brains of the "oldest old", based on a study of 20 centenarians. However, even in very old subjects, diffuse plaques may be very scanty or even absent (e.g, Giannakopoulos *et al.*, 1993; Morris *et al.*, 1996).



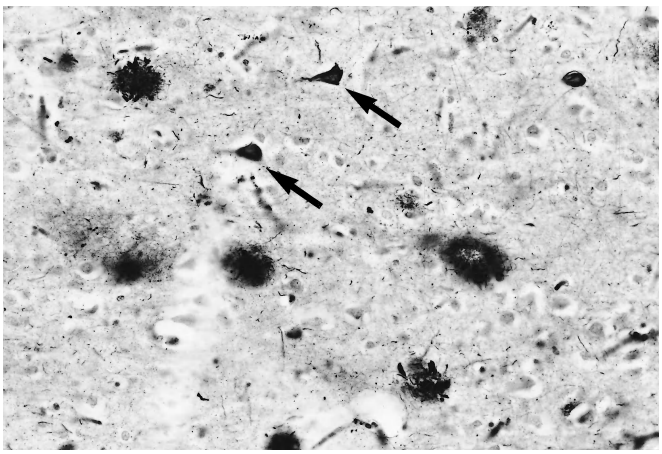
(a)



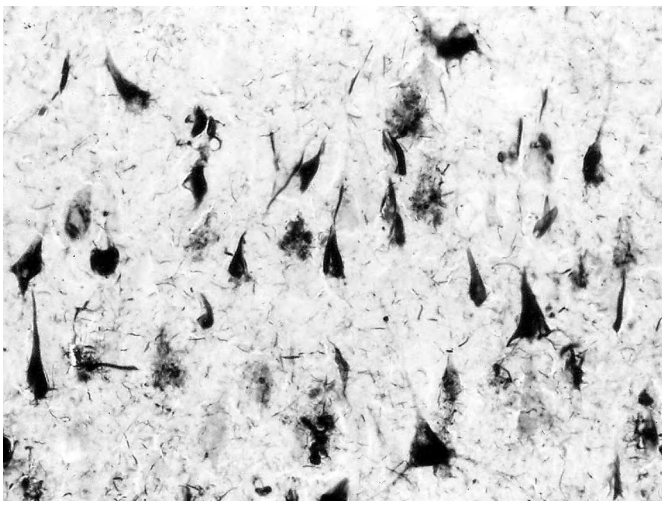
(b)

Figure 3 (a) Diffuse plaques in the superficial cortex (modified Bielschowsky silver impregnation). (b) Immunohistochemistry for Aβ reveals several diffuse plaques (toward right of figure) as well as some densely labeled neuritic plaques (arrows) and a blood vessel with changes of amyloid angiopathy (asterisk)

Neuritic plaques can also occur in cognitively normal elderly subjects, predominantly in the CA1 field, subiculum and entorhinal cortex, and also, in small numbers, in the neocortex. Neuritic plaques are usually much more numerous in the context of Alzheimer's disease (*see* **Chapter 92, Cellular Changes in Alzheimer's Disease**), but the distinction is not clear cut and reports differ as to the extent of overlap (Davis *et al.*, 1999; Leuba *et al.*, 2001; Neuropathology Group. MRC CFAS, 2001). Neuritic plaques contain extracellular Aβ in the form of amyloid fibrils, and irregularly swollen dystrophic neurites, which are strongly argyrophilic (Figure 4). Microglia and astrocyte processes may also be present. Within the dystrophic neurites are accumulations of lysosomes, degenerating mitochondria and membranous bodies. Some dystrophic neurites also contain paired helical filaments, composed of modified tau proteins (see *Neurofibrillary tangles* in following text). Neuritic



(a)



(b)

Figure 4 (a) Neuritic plaques and neurofibrillary tangles (arrows) in the temporal cortex (modified Bielschowsky silver impregnation). Note the swollen, darkly impregnated dystrophic neurites within the plaques (modified Bielschowsky silver impregnation). (b) Neurofibrillary tangles are strongly immunopositive for tau. In this section of hippocampus from a patient with Alzheimer's disease, the antibody also labels many neuropil threads, nerve cell processes that contain abnormal filaments similar to those in the tangles

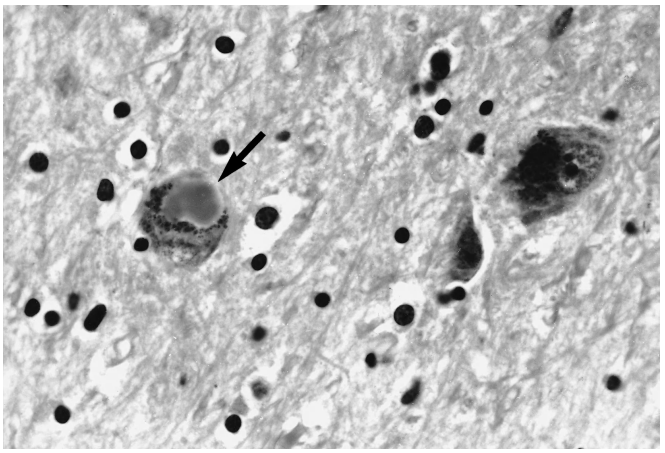
plaques in Alzheimer's disease probably include at least two, usually distinct, types of dystrophic neurite: those containing tau proteins and those that contain the synaptic protein, chromogranin A (Yasuhara *et al.*, 1994; Wang and Munoz, 1995). It has been reported that the tau-positive dystrophic neurites tend to be more elongated, less globular in shape, than those containing chromogranin A, but that the latter predominate in the neuritic plaques that may occur in cognitively normal subjects (Yasuhara *et al.*, 1994).

Neurofibrillary Tangles

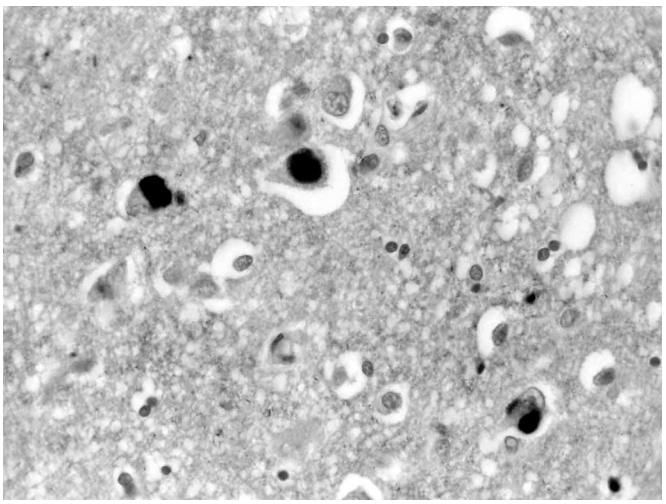
Neurofibrillary tangles consist of hyperphosphorylated tau proteins that are variably ubiquitinated and glycated (Brion *et al.*, 1985; Mori *et al.*, 1987; Love *et al.*, 1988; Yan *et al.*, 1995; Yen *et al.*, 1995). These form filaments measuring up to 10 nm in diameter, paired in right-handed helices with a period of approximately 80 nm and a maximum width of approximately 20 nm (Terry, 1963; Kidd, 1964; Ruben *et al.*, 1993). The filaments are aggregated together in the cytoplasm in looped or twisted skeins that are faintly basophilic, appear autofluorescent when stained with thioflavin-S and viewed under ultraviolet light, and can be impregnated with silver or immunostained for tau to facilitate their light microscopic detection (Figure 4). Although the frequency of neurofibrillary tangles tends to increase with age after 55–60 years (Tomlinson *et al.*, 1968; Peress *et al.*, 1973; Price *et al.*, 1991; Arriagada *et al.*, 1992; Hof *et al.*, 1995; Davis *et al.*, 1999), they are not a consistent feature of normal aging and are much more numerous and widely distributed in Alzheimer's disease and certain other neurological disorders (e.g. Wisniewski *et al.*, 1979; Love *et al.*, 1995; Spillantini *et al.*, 1999). When present in cognitively normal elderly individuals, tangles may be confined to the transentorhinal cortex or may also involve the subiculum and CA1 field of the hippocampus, lamina II and, to a lesser extent IV, of the entorhinal cortex (in the anterior part of the parahippocampal gyrus) and the anterior olfactory nucleus (Price *et al.*, 1991; Braak and Braak, 1991; Arriagada *et al.*, 1992; Hof *et al.*, 1995; Braak and Braak, 1996). In the absence of dementia, the neocortex and subcortical nuclei contain few, if any, neurofibrillary tangles (although in one study, some degree of neocortical neurofibrillary pathology was found in as many as one-third of nondemented elderly individuals (Neuropathology Group, MRC CFAS, 2001)). The involvement of different populations of neurons by neurofibrillary tangles seems to follow a consistent, predictable topographic sequence during "normal" aging that is indistinguishable from the earliest, presymptomatic stages of Alzheimer's disease (Braak and Braak, 1991; Arriagada *et al.*, 1992; Braak and Braak, 1996). It is arguable that the asymptomatic accumulation of neurofibrillary tangles in the transentorhinal cortex and limbic region should be regarded as a preclinical manifestation of Alzheimer's disease (for further discussion, see Braak and Braak (1996)).

Lewy Bodies

The structure and patterns of distribution of these neuronal inclusions are described in the context of Parkinson's disease and other Lewy body diseases in **Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly** and **Chapter 96, Other Dementias**. Lewy bodies are an incidental finding in the substantia nigra and locus ceruleus in a small proportion of neurologically normal adults. These Lewy bodies are of the classical (brain stem) type: usually roughly spherical, with an eosinophilic core surrounded by a paler "halo" (Figure 5). One or more Lewy bodies may be present in the cytoplasm of a single neuron. Electron microscopy shows the core to consist of amorphous, electron-dense material and the halo to comprise



(a)



(b)

Figure 5 (a) Incidental Lewy body (arrow) in the substantia nigra of an 84-year-old man who did not have clinical features of Parkinson's disease. (b) The principal constituent of the Lewy body is α-synuclein, here demonstrated immunohistochemically in Lewy bodies in the cerebral cortex

radiating filaments between which are scattered granules of lipofuscin and neuromelanin, mitochondria, dense-core vesicles, and other organelles (Forno, 1996). The principal constituent of the Lewy body is α-synuclein (Spillantini *et al.*, 1997; Wakabayashi *et al.*, 1997), a protein that is normally associated with presynaptic vesicles (Iwai *et al.*, 1995). Its functions are still unclear, but may include protection against oxidative stress, maintenance of the presynaptic vesicular pool, and a role in synaptic plasticity (Hashimoto *et al.*, 2002; Kaplan *et al.*, 2003; Murphy *et al.*, 2000). Other constituents of the Lewy body include phosphorylated neurofilament subunits (Hill *et al.*, 1991), ubiquitin (Love *et al.*, 1988), epitopes of complement proteins (Yamada *et al.*, 1992), multicatalytic proteinase (Masaki *et al.*, 1994), cyclin-dependent kinase 5 (Brion and Couck, 1995), and several other proteins (for review, see Pollanen *et al.*, 1993).

Lewy bodies occur in Parkinson's disease, dementia with Lewy bodies, and other Lewy body diseases (*see* **Chapter 96, Other Dementias** (Lewy Body etc.)). The prevalence of brain stem Lewy bodies is much lower in adults who do not have neurological disease. Perry *et al.* (1990) observed Lewy bodies in 2.3% of 131 subjects between 51 and 100 years who had been screened to exclude neurological or psychiatric disorders. In a series of 273 brains from non-Parkinsonian patients, Gibb and Lees (1988) found the prevalence to increase from 3.8 to 12.8% between the sixth and ninth decades. A lower age-specific prevalence was reported by Wakabayashi *et al.* (1993): an increase from 0.7% to 6.5% over the same age span. It has been suggested that incidental Lewy bodies are a manifestation of preclinical Parkinson's disease (Gibb and Lees, 1988; Wakabayashi *et al.*, 1993).

CENTRAL WHITE MATTER

As noted earlier (see *Brain weight*), with increasing age, the white matter declines in volume to a greater extent than does the gray matter, although the two processes are obviously related since the degeneration of a nerve cell is accompanied by the loss of its myelinated axon, and the latter usually occupies a greater volume than the cell body and dendrites. In a morphometric comparison of three groups of neurologically normal adults, $\leq$50 years, 51–70 years, and 71–93 years, Meier-Ruge *et al.* (1992) found a 16–20% loss of white matter volume in the elderly compared with the young adults and a 10–15% loss of myelinated fibers. In a stereological study of changes in cranial white matter between 18 and 93 years, males were found to have a total myelinated fiber length of 176 000 km at 20 years and 97 200 km at the age of 80 (Marner *et al.*, 2003). In females, the lengths were 149 000 km at 20 and 82 000 km at 80 years. These figures correspond to a decrease of 10% per decade, and a sex difference of 16%. The loss predominantly affects small caliber fibers. Other age-related changes in the white matter include a tendency for axons in some regions to form dystrophic swellings, and an accumulation of ubiquitinated dotlike structures (see *Dystrophic axons and ubiquitinated deposits*, explained previously).

In many neurologically normal, elderly subjects, scattered hyperintensities and more diffuse high signal regions are demonstrable in the cerebral white matter on T2-weighted MRI, particularly in the periventricular region. The histological correlates of these "lesions" are somewhat inconsistent. Some are probably infarcts; others are foci of rarefaction or gliosis, often perivascular. Correlations have been described with denudation of the ependymal lining of the lateral ventricles (Scheltens *et al.*, 1995) and perivenous collagenous thickening (Moody *et al.*, 1995). The substrate of some MRI hyperintensities may remain obscure despite careful histological examination (Grafton *et al.*, 1991).

SPINAL CORD AND NERVE ROOTS

The degenerative changes of the spinal column, such as cervical spondylosis and intervertebral disk disease which become increasingly frequent and pronounced with age, are often associated with degenerative changes in the spinal cord. These include anteroposterior flattening of the lower cervical cord and various degrees of loss of neurons from the anterior horn (Wang *et al.*, 1999). Degeneration of posterior column fibers, particularly in the cervical region, is common in the elderly (Ohnishi *et al.*, 1976), and often accompanied by large numbers of copora amylacea (see following text). A morphometric study by Low *et al.* (1977) of the intermediolateral column of the spinal cord in adults, revealed a progressive loss of preganglionic sympathetic neurons with age, amounting to about 8% per decade. A similar rate of attrition of myelinated fibers was noted in the T6–8 rami communicantes, containing the preganglionic sympathetic nerve fibers (Low and Dyck, 1978). The authors suggested that this loss may account for the tendency to postural hypotension in the elderly. It should be noted, however, that there are also alterations in the paravertebral and prevertebral sympathetic ganglia of elderly subjects (see *Sympathetic ganglia*, in the following text). The population of motor neurons in the lumbosacral spinal cord declines slightly with age. Tomlinson and Irving (1977) found that the decline occurred only after 60 years of age but Kawamura *et al.* (1977a) recorded a gradual loss of motor neurons in the L3–5 segments from early adulthood onwards. Not surprisingly, the latter authors also found that there was a corresponding age-related loss of myelinated fibers from the L3–5 anterior spinal nerve roots (Kawamura *et al.*, 1977b).

GLIOSIS

The number of astrocytes and the extent of associated gliosis have generally been thought to increase with age in most parts of the central nervous system. Beach *et al.* (1989) assessed the severity of gliosis at different ages by immunostaining sections for glial fibrillary acidic protein (GFAP). They found that gliosis increased with age in the cerebral cortex, white matter, and subcortical nuclei, but that its severity and distribution were very variable. Whereas the white matter of young adults showed an even pattern of GFAP immunoreactivity, that in the elderly tended to be uneven. Gliosis was accentuated around blood vessels. Terry *et al.* (1987) reported that the increase in the number of glia in the elderly was more pronounced in the frontal and temporal cortices than in the parietal cortex. In contrast to these older studies, more recent stereological analysis of neocortical cells by Pakkenberg *et al.* (2003) revealed no significant difference when the number of neocortical glia in six elderly individuals, of mean age 89.2 years, was compared with that in six young adults with a mean age of 26.2 years.

CORPORA AMYLACEA

Corpora amylacea are spherical inclusions, predominantly located in astrocyte processes, although they can also occur within axons. They are composed largely of sulphated polysaccharides (polyglucosans) and stain deeply with hematoxylin, periodic acid-Schiff and methyl violet. Minor constituents include ubiquitin, heat-shock proteins (Martin *et al.*, 1991; Cisse *et al.*, 1993), tau (Loeffler *et al.*, 1993; Singhrao *et al.*, 1993), certain complement proteins (Singhrao *et al.*, 1995), and oligodendrocyte proteins – myelin basic protein, proteolipid protein, galactocerebroside, and myelin oligodendrocyte protein (Singhrao *et al.*, 1994). On electron microscopy, corpora amylacea appear as densely packed 6–7-nm filaments that are not bounded by a unit membrane (Ramsay, 1965). Toward the center of the inclusions, the filaments may be admixed with amorphous granular material.

Corpora amylacea increase in number with normal aging, particularly in the subpial and subependymal regions of the brain (Figure 6), around blood vessels, and in the white matter of the spinal cord (Martin *et al.*, 1991), although not to the extent that they do in Alzheimer's disease and other neurodegenerative disorders. The subpial region of the inferomedial part of the temporal lobe is a site of predilection for accumulation of these bodies. Several hypotheses have been proposed to account for their formation and distribution. It was suggested by Tokutake *et al.* (1995) that they are involved in astrocytic absorption and accumulation of inorganic materials from the blood and cerebrospinal fluid, by Cisse and Schipper (1995) that they are a product of degeneration and autophagy of mitochondria, and by Singhrao *et al.* (1995) that they may shield immunogenic products of neuronal and oligodendroglial degeneration from lymphocytic recognition and autoimmune activation.

BLOOD VESSELS AND AMYLOID ANGIOPATHY

The development of atherosclerotic and hypertensive changes and their relationship to brain hemorrhages and infarcts

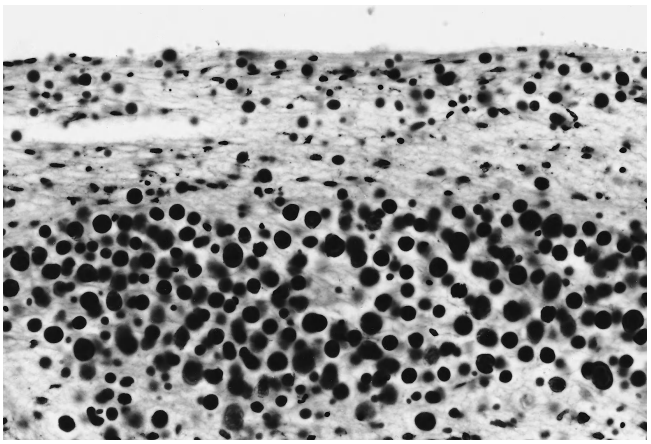


Figure 6 Numerous periventricular corpora amylacea in an 87 year old

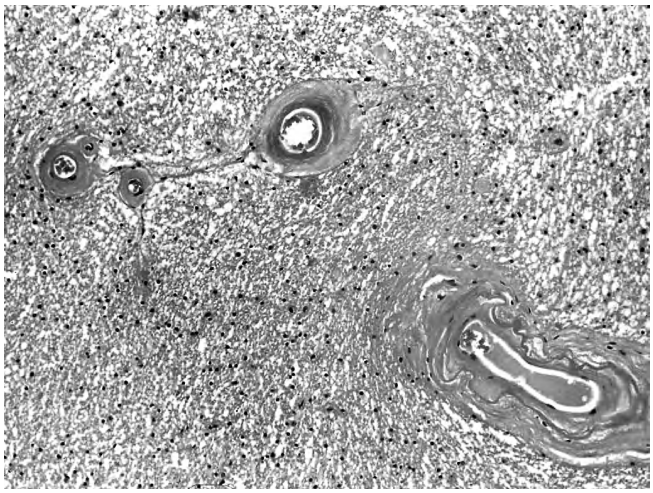
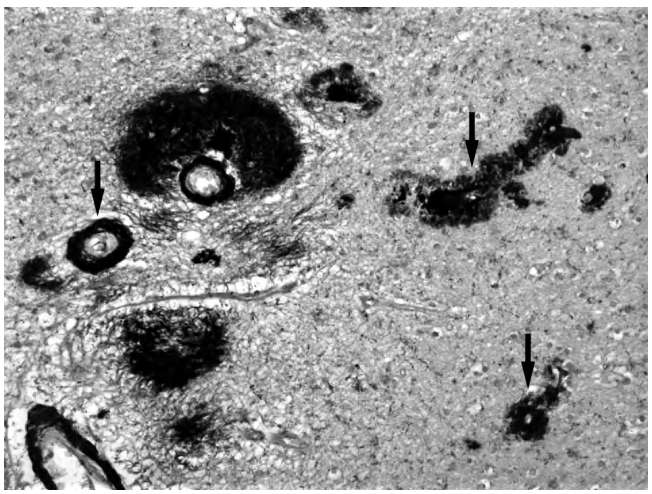


(a)



(b)

Figure 7 (a) Degenerative change affecting arteries and arterioles in the cerebral white matter. The tunical media and adventitia have been replaced by a thick layer of hyaline collagenous connective tissue. There is also some fibrous thickening of the intima. (b) Severe CAA, in which Aβ-immunopositive amyloid has replaced the tunica media and adventitia of several blood vessels in the cerebral cortex, and in some cases has also infiltrated the adjacent brain parenchyma. Note the narrowed lumen of some of the affected blood vessels (arrows)

are considered in **Chapter 71, Acute Stroke** and **Chapter 72, Secondary Stroke**. In the elderly, mild loss of smooth muscle cells, medial fibrosis, and hyaline change are very common in parenchymal blood vessels in the brain and spinal cord, particularly in the basal ganglia and cerebral white matter (Hauw *et al.*, 2002) (Figure 7a). Mineralization of vessel walls is also common, especially in the globus pallidus and deep cerebellar white matter. The smooth muscle degeneration and fibrosis are exacerbated in patients with hypertension (Masawa *et al.*, 1994). A mild degree of cerebral atheroma is also common, even in the absence of hypertension and other specific risk factors such as cigarette smoking and diabetes mellitus (*see* **Chapter 122, Type 2 Diabetes Mellitus in Senior Citizens**; **Chapter 48, Hypertension**). These changes decrease the compliance of cerebral blood vessels and probably contribute to an increased tendency to tortuosity or "corkscrewing" (Fang, 1976) and an enlargement of the perivascular spaces.

Many elderly people have patchy, segmental deposition of amyloid in the media and adventitia of blood vessels in the cerebral cortex and leptomeninges (Figures 3b and 7b). This abnormality is termed *cerebral amyloid angiopathy* (CAA), although it is not always confined to the cerebrum and may also involve the cerebellar cortex and leptomeninges, and rarely other parts of the central nervous system (CNS). CAA is present in about 30% of the normal elderly (Tomonaga, 1981; Esiri and Wilcock, 1986; Vinters and Gilbert, 1983; Love *et al.*, 2003), and over 90% of patients with Alzheimer's disease (Esiri and Wilcock, 1986; Ellis *et al.*, 1996; Premkumar *et al.*, 1996; Chalmers *et al.*, 2003), in whom the CAA tends to also be more severe – involving a greater proportion of blood vessels, over a greater part of their circumference, and sometimes extending into the adjacent brain parenchyma (so-called *dyshoric change*). In contrast to the predominance of Aβ_{1-42} in plaques, Aβ_{1-40} predominates in CAA although Aβ_{1-42} is also present. Sporadic Aβ-related CAA is very rare before 60 years, but thereafter increases in prevalence with age (Love *et al.*, 2003). The pathogenesis of CAA remains unclear. Some observations suggest that Aβ is deposited from interstitial fluid as it passes along perivascular drainage pathways toward the subarachnoid space (Weller *et al.*, 2000; Weller and Nicoll, 2003); degenerative vascular changes that impede the flow of fluid along these pathways may partly account for the increased prevalence of CAA with age. However, it is likely that multiple factors contribute to development of CAA (Love, 2004).

The deposition of amyloid progressively replaces, first the tunica media, and then the adventitia, with resulting loss of vascular compliance and contractility. In severe cases, the amyloid extends into the adjacent brain parenchyma (Figure 7b). CAA tends to narrow the lumen, because of thickening of the vessel wall, exacerbated in some cases by concentric separation of the amyloid-laden media and adventitia. Severe CAA may compromise the viability of affected blood vessels (Prior *et al.*, 1996). Not surprisingly, therefore, CAA carries a risk of focal hemorrhage or infarction (Okazaki *et al.*, 1979; Itoh *et al.*, 1993; Cadavid *et al.*, 2000). As would be expected from the distribution of the vascular amyloid, associated hemorrhages tend to be superficially situated within the brain parenchyma and to rupture into the subarachnoid space, or to occur primarily within the subarachnoid space (Okazaki *et al.*, 1979; Yamada *et al.*, 1993). CAA may also cause ischemic damage to the white matter, probably through a combination of luminal stenosis, thrombosis, loss of autoregulation, and vasospasm.

APOE genotype is linked to several aspects of CAA pathology. In Alzheimer's disease, the presence and severity of CAA are strongly associated with possession of *APOE* ε4 (Premkumar *et al.*, 1996; Chalmers *et al.*, 2003). In the absence of Alzheimer's disease, this association is weak or absent (Love *et al.*, 2003). In patients with CAA, possession

of *APOE* $\varepsilon 2$ is a risk factor for cerebral hemorrhage (Greenberg *et al.*, 1998; Nicoll *et al.*, 1997), probably because this allele is associated with the development of additional vasculopathic changes such as fibrinoid necrosis (Greenberg *et al.*, 1998; McCarron *et al.*, 1999). *APOE* $\varepsilon 4$ has been reported to be associated with cerebral hemorrhage in patients with CAA in some populations (Greenberg *et al.*, 1995) but not others (Itoh *et al.*, 1996; Nicoll *et al.*, 1997). However, interpretation of this latter association is complicated by the fact that possession of $\varepsilon 4$ is also associated with increased mortality after cerebral hemorrhage (McCarron *et al.*, 2003); series that are based largely on postmortem diagnosis of CAA-associated hemorrhage are therefore likely to be skewed toward the inclusion of $\varepsilon 4$-positive cases.

CHOROID PLEXUS

Intracellular accumulations of amyloid fibrils are a constant finding in choroid plexus epithelium in the elderly (Eriksson and Westermark, 1986). They are usually abundant in Alzheimer's disease (Miklossy *et al.*, 1998; Wen *et al.*, 1999). The fibrils form circular cytoplasmic inclusions (Figure 8) known as *Biondi rings* (Biondi, 1934; Eriksson and Westermark, 1990). Ependymal cells may also accumulate amyloid fibrils, but these take the form of slender wisps rather than rings. Ultrastructurally, Biondi rings consist of densely packed straight and paired helical filaments (Eriksson and Westermark, 1986; Miklossy *et al.*, 1998; Wen *et al.*, 1999). They are immunopositive for Aβ. Miklossy *et al.* (1998) found them also to react with antibodies to P component, ubiquitin, fibronectin and tau but not neurofilament proteins.

With age, the choroid plexus tends to undergo multifocal mineralization, in the form of roughly spherical, concentrically laminated deposits known as *psammoma bodies* (Figure 9). These usually form in the fibrovascular cores of the papillae. Kwak *et al.* (1988) found that the age-specific prevalence of choroid plexus mineralization in CT brain scans increased from 0 below 10 years, through 5.9% between 10 and 14 years, 17.4% between 15 and 19 years, 51.5% between 30 and 39 years, to 74.4% in patients over 80 years in age.

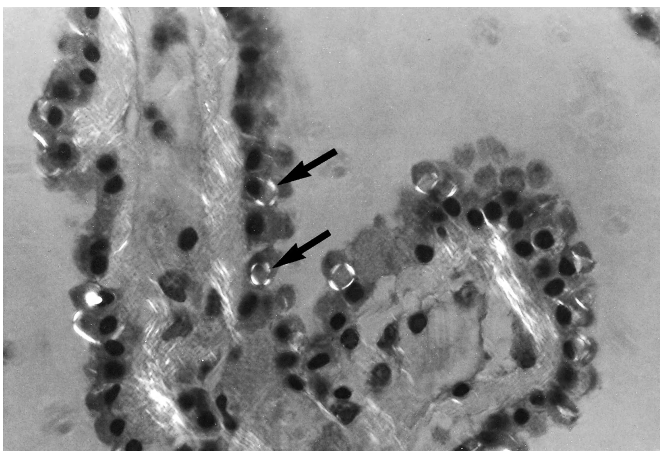


Figure 8 Several birefringent Biondi rings (arrows) in the choroid plexus of an 84 year old

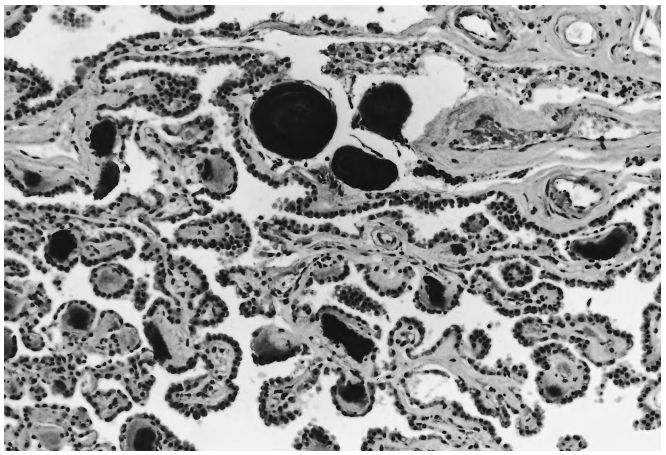

Figure 9 Darkly stained psammoma bodies in the choroid plexus

PINEAL

During adolescence and early adulthood, the pineal may undergo cystic expansion. On review of MRI scans of 6023 subjects, Sawamura *et al.* (1995) found that pineal cysts were more common in women, in whom the prevalence was greatest (5.8%) between the ages of 21 and 30 years. The finding of cysts is less common in subsequent decades, reported figures for their overall prevalence ranging from 1.3% (Sawamura *et al.*, 1995) to 2.4% (Golzarian *et al.*, 1993). The cysts are usually incidental findings on radiological investigation or at autopsy. Rarely, they may compress the aqueduct and cause hydrocephalus, or produce Parinaud's syndrome due to compression of the tectum of the midbrain (Fetell *et al.*, 1991).

Foci of mineralization (corresponding histologically to psammoma bodies) are radiologically detectable in a small percentage of children as early as the first 6 years of life (Winkler and Helmke, 1987). There is a steep rise in the incidence of pineal mineralization during the second decade of life after which the deposits may undergo remodeling (Schmid and Raykhtsaum, 1995), but there is no further significant change in their size or age-specific prevalence (Hasegawa *et al.*, 1987; Galliani *et al.*, 1989).

PITUITARY

The effects of aging on hypothalamo-pituitary function are discussed in **Chapter 119, The Pituitary Gland**. A mild degree of fibrosis, due to interstitial deposition of collagen, is common in the anterior lobe of the pituitary in the elderly,

particularly in men (Sano *et al.*, 1993). From early adulthood onwards, there is also a significant decline in the number and size of growth hormone-producing somatotroph cells in the lateral wings of the gland (Sun *et al.*, 1984; Sano *et al.*, 1993). Sano *et al.* (1993) did not find significant alterations in the relative numbers of other cell types in pituitaries of patients over 90 years of age. Zegarelli-Schmidt *et al.* (1985) observed thyrotroph hypertrophy and hyperplasia in some aged pituitaries but these changes bore no consistent relationship to the histological appearances of the thyroid gland in the same patients.

Small intracellular and interstitial accumulations of endocrine-type amyloid may be found in the normal pituitary from the third decade onwards (Tashima *et al.*, 1988). These become more numerous with increasing age and can be found in about two thirds of pituitaries in the elderly (Tashima *et al.*, 1988; Bohl *et al.*, 1991). Similar age-related intracellular and interstitial accumulations of amyloid occur in other endocrine glands, including the adrenals and parathyroid glands (Bohl *et al.*, 1991).

PERIPHERAL NERVE

Jacobs and Love (1985) found little change in the total number of myelinated and unmyelinated nerve fibers in the sural nerve from childhood through middle age. Over the same period, there is, however, a gradual decline in the densities of myelinated and unmyelinated nerve fibers in the sural nerve (and other peripheral nerves that have been studied) as the amount of endoneurial collagen and the separation between adjacent nerve fibers increase (Ochoa and Mair, 1969a,b; Tohgi *et al.*, 1977; Jacobs and Love, 1985). After 60 years, both the density and the absolute number of fibers tend to decrease, mild to moderate degeneration of myelinated and unmyelinated fibers becomes increasingly common and a small proportion of fibers shows changes of segmental demyelination and remyelination. The degeneration of myelinated fibers is accompanied by a variable amount of regenerative activity. These changes affect the relationship between the axon calibre and the myelin sheath thickness (*g* ratio), which is much more variable in old age than in younger age. Also affected is the normally linear relationship between internodal length and fiber diameter. The demyelination and remyelination causes marked variation in the internodal length along individual fibers, and the degeneration and regeneration produces relatively large fibers with long sequences of uniformly short internodes, 300–400 μm in length. Other findings in peripheral nerves of the elderly include a tendency to reduplication of endoneurial vascular basement membranes and some thickening of the basement membrane in the outer layers of the perineurial sheath (Jacobs and Love, 1985).

SYMPATHETIC GANGLIA

Lipofuscin can be identified within sympathetic neurons as early as at 4 months of age (Koistinaho *et al.*, 1986), and the amount increases steadily throughout life (Helen, 1983; Hervonen *et al.*, 1986; Koistinaho *et al.*, 1986). Hervonen and colleagues noted that the autofluorescent color of the lipofuscin under ultraviolet light changed from yellow to orange with increasing age, possibly due to the accumulation of neuromelanin in the noradrenergic neurons (Hervonen *et al.*, 1986; Koistinaho *et al.*, 1986). Another feature of aging in sympathetic ganglia is an increasing prominence of dystrophic preterminal axons (Schmidt *et al.*, 1990; Schroer *et al.*, 1992; Schmidt, 2002). These develop at an earlier age in patients with diabetes mellitus (Schroer *et al.*, 1992). The swollen argyrophilic axons tend to cluster around scattered nerve cells, which may be indented by the swellings. They are more numerous in the celiac and other prevertebral ganglia than in paravertebral ganglia such as the stellate ganglion. Schmidt *et al.* (1990) found that the dystrophic axons could be labelled with antibodies to tyrosine hydroxylase and neuropeptide tyrosine (NPY), but not other neuropeptides (vasoactive intestinal peptide (VIP), substance P, gastrin-releasing peptide/bombesin or met-enkephalin). Other age-related changes that have been noted in the sympathetic ganglia include a reduction in the number of neurons innervated by enkephalin-immunoreactive nerve fibers (Jarvi *et al.*, 1988) and, with the accumulation of lipofuscin, a decrease in the quantity of catecholamines in the neuronal perikarya (Hervonen *et al.*, 1978).

KEY POINTS

- Age is associated with progressive brain atrophy, much of which is due to loss of white matter.
- The extent of neuronal loss varies in different parts of the brain and spinal cord.
- Plaques, neurofibrillary tangles and Lewy bodies can occur in neurologically normal people but are much more numerous and extensive in Alzheimer's disease and Lewy body diseases.
- Other age-related changes include granulovacuolar degeneration and the formation of Hirano bodies in the hippocampus; dystrophy of axons in the posterior column and anterior horn of the spinal cord, in the substantia nigra and globus pallidus; accumulation of corpora amylacea; and development of cerebral amyloid angiopathy.
- Amyloid fibrils in the choroid plexus and ependymal cells are a constant finding in the elderly.

The Demography of Aging

Kenneth G. Manton
Duke University, Durham, NC, USA

INTRODUCTION

We examine several dimensions of past, current, and future demographic changes and the health dynamics of aging in the United States and other developed countries. Models of the demographic and health dynamics of elderly and oldest-old populations require updating as information about the characteristics of those populations accumulates from (a) demographic sources (e.g. population censuses and vital statistics), (b) specialized longitudinal surveys of elderly populations, (c) epidemiological and clinical studies of elderly subgroups, and (d) by integrating multiple data sources in comprehensive models of health, aging, and mortality (Manton *et al.*, 1994b). This later approach will increase in importance with time as the linkage of biomolecular mechanisms with population dynamics becomes increasingly important in assessing the macro/population influences of accumulated knowledge from epidemiological, clinical, and basic science studies. This is neither meta-analysis (statistical study of multiple clinical data sets) nor bioinformatics (analyses of laboratory studies to find common patterns). It is a new scientific discipline born of the mathematical integration of medicine, mathematics, and biodemography. When populations are successfully modeled at micro (biomolecular), meso (organ systems and individuals), and macro (population) levels the models can be applied to economic and policy studies – in both government and commercial service (to optimize the effects of medicine and medical research on population health). To understand how these models will evolve we start with a discussion of the application of basic demographic techniques.

Probably the most basic view of the demography of aging is that a trio of forces, each driven by multiple social and physiological processes, determines the current and future growth of the elderly and oldest-old populations in the United States and other developed countries. Two of these are the larger size of recent birth cohorts who will become the elderly in the near future, and decreases in mortality at earlier ages allowing larger proportions of birth cohorts to survive to ages 65+. The third factor, discussed separately, is mortality declines at late ages, and their age variable relation to, and interaction with, changes in health and functioning.

The first two forces are now well understood – though their magnitude is not appreciated. In the United States (as elsewhere), the oldest-old (85+) population in 2005 is composed of persons born in 1920 – or earlier. From the 1920 US birth cohort, 18.6% of males and 35.1% of females, or 796 100 persons, are expected to reach age 85. Since life expectancy (LE) at age 85 for this cohort is roughly 5.3 (males) to 6.6 (females) years, this implies a US population aged 85+ in 2005 of 4.9 million persons.

The largest US baby boom cohort (1961) was 4.3 million persons. If 1920 male and female survival rates were applied to the 1961 birth cohort, then 1 154 550 persons would survive to 85 – or 45% more persons than from the smaller 1920 birth cohort. US survival improved from 1920 to 1960. Of persons born in 1960, 34.4% of males and 49.9% of females are expected to reach 85. Applying these proportions to the 1961 birth cohort implies 1 812 450 persons would reach 85 – an increase of 57.0% over the number surviving to 85 from the 1961 birth cohort than if 1920 mortality rates had not changed. Increased birth cohort size and reduced early mortality increases the number of persons passing 85 by 127.7%.

If all cohorts were similar in size, these two forces would imply (assuming life expectancy at 85 increases to 7.5 years) 13.5 million persons aged 85+ – increases of 2.7 million persons due to larger cohort sizes and 5.9 million due to mortality declines. This increase would take 42+ years to realize, that is, the birth cohort of 1961 passes 85 in the year 2046. These simple calculations, using actuarial survival statistics and population counts, gives a sense of the relative contributions of birth cohort size and improved early mortality to increases in the size of future elderly populations. Uncertainty about exact changes in the size and composition of the elderly population is largely due to uncertainty about mortality declines at late ages. Some projections envision larger populations reaching ages 85+,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

for example, 40+ million persons might reach ages 85+ in 2050 if significant progress in improving known risk factors is assumed (Manton *et al.*, 1994b).

Thus, if US social, economic, and health conditions remain stable, the potential for large increases in the elderly and oldest-old population exists in the birth cohorts comprising the current US population and their early health and mortality experiences. Looking at the situation in reverse, the elderly and oldest-old populations currently being examined epidemiologically, clinically, and physiologically come from cohorts born long ago (e.g. in 1915, pre-WWI (World War I), and 1930, the beginning of the great depression), which were relatively small at birth, and which experienced what today would be extraordinary, and excessive, mortality risks and adverse early health experiences (e.g. exposures to many childhood diseases which are now prevented by vaccination, or for which there are effective medical treatments; for many European countries, there are also the effects of injuries suffered by combatant males in WWI and WWII).

This brings us to the third force, that is, mortality experienced at late ages (e.g. ages 85, 95, and 100+) and antecedent health conditions. Late age mortality interacts with antecedent health and disability conditions (e.g. by mortality selection) which have dramatically changed across current elderly, and near elderly, cohorts. An understanding of the demography of aging requires appreciating the health dynamics, current and historical, characterizing cohorts forming the elderly population.

MODELS OF CHRONIC DISEASE AND MORTALITY TRENDS

The idea that mortality, and other age-related health conditions, are mutable to late ages (i.e. age 85+) is relatively new (Lakatta, 1985). The idea that function can be regenerated, and the physiological clock run backwards, is even newer, although for open physical systems the possibility was identified by Prigogine and Stengers (1997). In the United States, mortality was thought to have reached irreducible levels by the late 1950s or early 1960s because male survival decreased in that period – though female survival continued to improve. Social Security actuaries assumed ultimate life expectancy limits would be reached in the United States in 2000 in Social Security Trust fund projections made in 1974. In 2001, the life expectancies of 74.6 and 80.0 years, for males and females respectively, were already 5.0 years and 2.9 years above this "ultimate" limit to life expectancy.

In Table 1, we present data (CIA, Central Intelligence Agency, Fact book http://www.cia.gov/cia/publications/factbook/) on total, male, and female life expectancy in 2004.

For the small country of Andorra, the total life expectancy of 83.5, and the female life expectancy of 86.7 years, causes one to think the ultimate limit to life expectancy of 85 years posited by Olshansky and Fries is too low. The female life expectancy of 84.5 years in Japan, and the total life expectancy of 81.0 years also suggests one be skeptical about "ultimate" life span limit estimates.

Other authors suggested US stagnant male mortality conditions 1954–1968 reflected increased chronic disease risks due to the nature of industrial societies. Antonovsky discussed why risks might be elevated for cardiovascular diseases. Omran posited a model of the stages of the epidemiological transition of which the third, and end, stage characterized economically developed societies as having a high prevalence of chronic degenerative and manmade diseases with static life expectancy. Much of this pessimism was due, however, to congenital disorders, like Down's syndrome, where life expectancy could increase past reproductive ages generating a "pandemic," or cascade, of chronic degenerative disease.

Many demographers generate model life tables to describe mortality and in estimating life expectancy "limits". Bourgeois-Pichat projected a maximum life expectancy of 73.8 years for males, and 80.3 years for females, in 1978. A 1982 study of the Japanese economy used life expectancy limits of 79.8 years for males (not yet achieved) and 80.7 years for females. Japanese life expectancy at birth, among the world's highest in 2004 (see Table 1), far exceeded limits assumed for females in 1982. In France, life expectancy in 2004 was 75.8 years for males and 83.3 years for females – exceeding Bourgeois-Pichat's 1978 estimate of a female life expectancy limit by 3.0 years.

Swedish data have been used to model late age mortality because of its high quality. Because vital statistic systems have now been computerized in many developed countries, for many years the Swedish data no longer have special status as the basis for "curve fitting" models to apply to other countries.

Life expectancy limits estimated only from total and cause specific mortality trends were problematic (Manton *et al.*, 1991). New models incorporating health data and biological mechanisms are necessary for forecasts (Manton, 2004a).

Table 1 Life expectancy for selected industrialized countries (2004)

Country		Japan	Andorra[a]	Germany	France	Sweden	Canada	United States
Population (Millions)		127	0.1	82	60	9	33	293
Life expectancy	Total	81	83.5	78.5	79.4	80.3	80	77.4
at birth	Male	77.7	80.6	75.6	75.8	78.1	76.6	74.6
(years)	Female	84.5	86.6	81.7	83.3	82.8	83.5	80.4

[a]Highest life expectancy in 2004 C.I.A. Fact book.

Analyses of mortality to late ages suggest why human life expectancy limits are difficult to estimate. First, human life spans are long (e.g. it will take 120 to 130 years for a recent, large birth cohort to die out at current mortality levels in Japan, France, and other developed countries (Manton and Stallard, 1996)), making it difficult to get reliable data on the full mortality experience of a birth cohort (let alone for multiple birth cohorts). Second, human populations are free living and cannot be studied in experimentally controlled environments. Hence, the proportion of human life expectancy potential realized in any population is a smaller, and less certain, proportion of their biological potential than can be observed in animal models in experimental conditions (Carey *et al.*, 1992). Third, for much of human history, fertility was a more dynamic factor controlling population growth, and shaping population structure, than mortality. Thus, after large increases in US life expectancy at birth from 1900 to 1950 (i.e. from 47.3 years in 1900 to 68.2 years in 1950, an increase of 20.9 years or 0.42 years of life per calendar year) the rate of increase in life expectancy at birth slowed (e.g. from 68.2 to 70.8 years for 1950 to 1970, or 0.13 years of age increase per calendar year). From 1970 to 2000, life expectancy increased from 70.8 to 77.0 (6.2 years), or 0.21 years per calendar year (a 50% acceleration over the 1950 to 1970 period), with recent increases accelerating owing to declines in cancer mortality.

For certain periods, US male life expectancy declined. From 1954 to 1968, male mortality rates increased 0.2% per year; they declined 0.8% per year for females. From 1970 to 2001, life expectancy at age 65 for males and females combined increased (i.e. from 15.2 years in 1970 to 18.1 years in 2001, or 0.1 years of age per calendar year) and represented a larger proportion (45%) of the gain in life expectancy at birth (6.4 years) than before 1970. Gains were, in part, achieved by reducing mortality in "uncharted" territory, that is, ages 85+. The first well-documented reports of centenarians occurred about 1800. The first reliably documented report of a survivor to 110 (a "super" centenarian) was in 1931. The first documented survivor to 120 (eventually dying at age 122 years) was recorded in 1995. It may be that a 130 year old is alive but not yet discovered.

For the last 30 years, the centenarian population in the United States and several other developed countries (Manton and Stallard, 1996) has grown 7% per year. As higher proportions of larger, more recent birth cohorts survive to late ages, reductions in mortality at those ages will contribute proportionately more to life expectancy gains. In response, we redesigned the 1994, 1999, and now 2004 NLTCS (National Long Term Care Survey) to have over samples (540, 600, and ∼1600 cases respectively) at ages 95+ to have adequate precision to study both health care use and the biological processes determining health and mortality at advanced ages.

What we observed about health changes in the 1982 to 1999 NLTCS was remarkable – and contrary to most models of human aging. In Figure 1(a) and (b), we show changes in (a) life expectancy and (b) active life expectancy (ALE) (i.e. period lived free of serious disabilities (Manton, 2004a)) in 1982 and 1999.

The change in life expectancy was 4.5 years. The change in ALE was 3.8 years. Thus, most (84%) of the gain in life expectancy was in healthy years of life. In Figure 2, we look at the acceleration of the improvement of functioning from age 65 to 100.

In Figure 2, we can examine rates of change in the difference between ALE and LE in 1982 and 1999. We see that differences between LE and ALE were similar in 1982 and 1999, never being much higher than 20% (left axis) – though 1999 differences shifted to the right about five years at age 85. Despite higher life expectancy at all ages 65+, the difference at age 85 is only slightly higher than (at age 80) in 1982. After age 85, the ratio of ALE and LE differences over age suggest a small difference, and stable rates of change from 1982 to 1999, up to age 105. This is why we can expect future declines in disability, and increases in ALE, that is, improvements are manifest to age 105.

Further complicating efforts to predict life expectancy are gender and cause specific differences in mortality. From 1950 to 1970, male life expectancy at 65 increased 0.3 years (i.e. from 12.8 to 13.1 years) with life expectancy declining 1954 to 1968. Female life expectancy increases were 2.0 years from 1950 to 1970 (i.e. from 15.0 to 17.0). From 1970 to 2001, life expectancy at 65 for both US males (13.1) and females (17.0) increased 3.3 and 2.4 years – to 16.4 and 19.4, respectively. There were larger changes in cause specific mortality. US age-standardized heart disease mortality declined 57.8%, and stroke mortality 68.0%, from 1950 to 2001. Age-standardized cancer mortality increased 11.4% up to 1990. From 1990 to 2001, they declined over 9%. This decline was due to both social (smoking cessation) and treatment innovation – despite the criticism of the "war on cancer" (Bailar and Gornik, 1997). Weisenthal (2004) suggests application of "drug efficiency testing" at the individual level could improve the efficacy of chemotherapy by 20 to 1.

An area recalcitrant to treatment until recently was neurodegenerative disorders, for example, Alzheimer's disease. Recent analyses of the 1982 to 1999 NLTCS show large declines in severe cognitive impairment. In 1994 and 1999, severe cognitive impairment was found to map to four ICD-9 (The Ninth Revision of the International Classification of Diseases) codes. Of these codes, those representing dementia due to circulatory disease (e.g. sequalae of stroke), or mixed processes, showed most of the declines, that is, Alzheimer's disease alone was stable (Manton *et al.*, 2004a; Manton and Gu, 2005a).

Epidemiological studies showed supplemental vitamins C and E and aspirin reduced dementia by circa 90% (Zandi *et al.*, 2004), ibuprofen by as much as 80% (in't Veld *et al.*, 2001), and statins by 73% (Wolozin *et al.*, 2000), which is "proof of concept" that not just circulatory dementia could be reduced with existing medications but also, in the future, Alzheimer's disease. This seems contradictory to many estimates of future Alzheimer's disease risk (Manton, 2004a; GAO, 1998; Evans, 1990).

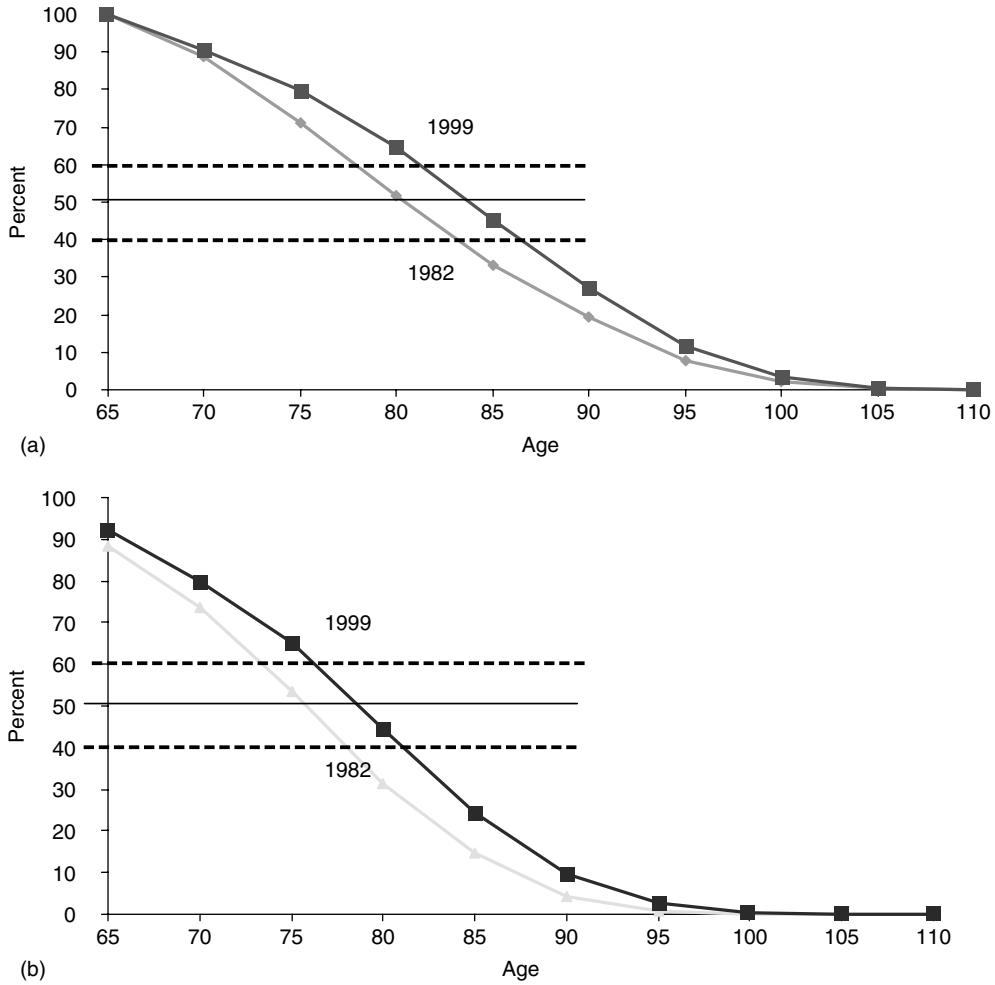

Figure 1 (a) 1982 and 1999 Life expectancy estimates; (b) 1982 and 1999 Active expectancy estimates

The nature of medical conditions evolved as more persons survived to late ages, for example, up to the 1940s and 1950s, much concern was directed to effects of rheumatic fever or syphilis on the heart, hypertension, and stroke (Kaplan and Keil, 1993). In the 1950s and 1960s, hypertensive heart disease declined while atherosclerotic heart disease increased. The mean age at which hip fractures occurred in Britain from 1944 to 1990 increased from 67 to 79 – a 12 year of age increase in 46 years. Concurrently, the nature of hip fractures shifted from intra- to extracapsular fractures. The nature of osteoporosis, the process underlying most US hip fractures, differs from ages 55 to 74, where it depends on postmenopausal change in estrogen levels, to ages 75+ where it is related to age-related defects in the vitamin D endocrine system.

Clearly, more basic physiological processes were at work, and over a longer period of time, than anticipated by efforts to estimate life expectancy limits based on total and cause specific mortality trends, and by efforts to relate changes to significant, but recent, changes in "standard" chronic disease risk factors. One study suggested US stroke mortality started to decline by 1925 (Lanska and Mi, 1993). Fogel (1994) showed US declines in chronic diseases may be even more long lived. He compared the prevalence of chronic diseases in Civil War veterans age 65 to 84 applying for pensions in 1910 (US birth cohorts of 1825 to 1844) with the prevalence of chronic diseases for WWII veterans over 65 assessed in the 1985–1988 National Health Interview Surveys (i.e. 1905 to 1924 cohorts). He found chronic disease prevalence at 65+ declined 6% per decade between 1910 and 1985–1988. The prevalence of heart diseases was 2.9 times higher in Civil War veterans aged 65+ in 1910 than in WWII veterans aged 65+ in 1985–1988. Declines in chronic diseases set the stage for subsequent declines in mortality up to several decades later.

Fogel (1994) attributed changes in chronic morbidity to economic and productive factors affecting early nutrition which increased stature and body mass index (BMI) over time. Many changes between Civil War and WWII veterans predate documented US increases in cholesterol and fat consumption – estimated to have peaked in 1959. One possible explanation of the effects of nutrition on health was the impact of protein, micronutrient, and caloric deficiency on fetal development. This was attributed to effects of

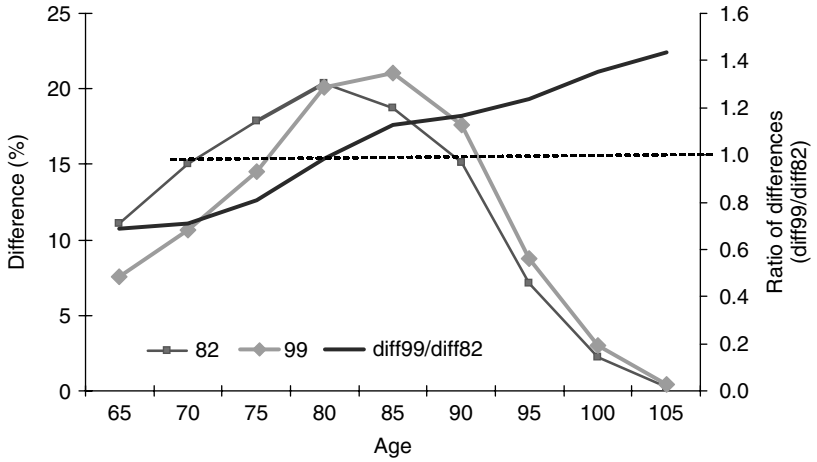

Figure 2 Difference between LE and ALE

maternal nutritional deficiencies on the fetal development of organs such that a physiological priority was assumed to exist which dictated which organs received adequate nutrition under conditions of protein and caloric deprivation. If the central nervous system received the highest priority for nutrients, organs like the liver (affecting cholesterol metabolism and thrombolic factors) and pancreas (affecting glucose metabolism) might be susceptible to developmental restrictions that became manifest in chronic disease risks at later ages. There is evidence for this in studies relating the ratio of placental to birth weight, and of weight at one year of age to chronic disease at later ages. Barker and Martyn found higher weight at one year inversely related to ischemic heart disease, systolic blood pressure, and impaired glucose tolerance in adults, and possibly to fibrinogen levels in men aged 59 to 70. The relation of systolic blood pressure to placental weight for women and men age 46 to 56 was direct.

Others suggest nutritional deficiencies affect persons most at ages where the most rapid physical growth occurs with the highest protein, caloric, and other nutrient needs. This is consistent with Fogel's (1994) use of the Waaler curve to plot changes in BMI and chronic disease risks. It is also consistent with the results of Tango and Kurashina, who found Japanese male cohorts born 15 years before WWII (i.e. birth cohorts of the early SHOWA period 1925–1939; aged 5 to 20 during WWII when there were nutritional shortages in Japan) had elevated mortality from diabetes mellitus, ischemic heart disease, peptic ulcer, cirrhosis, and suicide. These cohort differences in male cause specific mortality are likely due to poor nutrition during early, critical stages of adolescent male growth spurts. Deficiencies involved gross energy (caloric), proteins, and micronutrients, for example, in periods of rapid skeletal growth, vitamin D serum levels are highest; and vitamin C (affecting collagen formation) and B (affecting methionine metabolism and growth hormone release) needs are elevated (McCully, 1983). One large-scale population experience that could be definitive in testing the Barker hypothesis is the Leningrad siege in WWII where there were roughly ~250 000 survivors in 2004.

Two other models may help explain why chronic disease and mortality risks in specific birth cohorts may be related to nutritional and hygienic factors over long periods of time. One suggests that the effect of viral and bacterial infections on chronic disease has changed over time (as well as the natural history of the chronic diseases) due to changes in food processing and hygiene. Such arguments have been used to explain why some diseases have strong geographic patterns, for example, association of multiple sclerosis with temperate climates. For atherosclerosis, there is evidence to relate its initiation (i.e. injury to arterial endothelium starting inflammatory and wound building activity stimulated by dietary cofactors such as serum cholesterol and aggravating conditions such as hypertension) to viral and bacterial insults. This model derives support from evidence that atherosclerotic plaques have a monoclonal origin, suggesting a somatic mutation is involved in plaque initiation (Benditt and Benditt, 1973). Various infectious agents have been found in plaques; or in circulating immunological complexes in cases with circulatory disease versus controls. Among agents implicated are *Chlamydia Pneumoniae*, CMV (cytomegalovirus) (Mozar *et al.*, 1990), and other herpes viruses. One mechanism that could be involved in infectious agent damage to arterial endothelium involves platelet derived growth factor (PDGF). PDGF may play a central role in atherogenesis because it is both a mitogen and chemoattractant. There is a striking homology (87%) between the amino acid sequence of PDGF and a protein from an oncogene (v-sis) in the simian sarcoma virus. This homology suggests PDGF is important in the proliferation of cells transformed by a virus. Cells transformed by retrovirus, DNA viruses, and cells with somatic mutations appear to secrete PDGF molecules. Cells virally transformed appear to express a previously repressed cellular gene (c-sis) for PDGF. An immunological factor identified as raising the risk of myocardial infarctions, especially for males, is null allele C4B*Q0. There is evidence to suggest immune mechanisms are involved in hypertension, with some data pointing to predisposing genes in the

major histocompatability complex, either secondary to hypertension induced vascular damage (causing positive feedback in plaque growth) or as a primary abnormality. However involved, reductions in infectious disease exposures might reduce hypertension prevalence in recent cohorts.

Data from Hiroshima suggest ionizing radiation is another exogenous stressor involved in hypertension and cardiovascular disease. In Hiroshima, there was acute γ radiation. In Chernobyl, the most damaging radiation is β (electrons) due to biological incorporation of ^{90}Sr in bone and ^{137}Cs in soft tissue. The radiation flux of these isotopes is relatively high though they have a long half-life, that is, about 30 years. With this type of radiation, there appears to be an acceleration of basic age processes (Manton *et al.*, 2004a) consistent with the well-known free radical theory of aging. This syndrome involves cataracts, stroke, circulatory diseases, and neurodegeneration. Effects on neurodegeneration originally were not viewed as plausible because it was believed neurons seldom divided. There is now evidence neuronal regeneration occurs in several areas of the brain (e.g. in the hippocampus and the substanta nigra) for the brain is an area of high metabolic activity where baseline free radical production is high and where protein formation in synaptic gaps is sensitive to even very low doses of radiation (Manton *et al.*, 2004a).

The evidence suggests atherosclerotic circulatory diseases and their catastrophic manifestations are thrombotic, occlusive events leading to ischemia in critical organ systems, due to a multistage pathological process where initial damage to the arterial intima stimulates inflammatory and immunological responses, where LDL (low density lipoprotein) cholesterol becomes oxidized forming foam cells from monocytes/macrophages drawn to the site of the injury, which then are integrated in plaque. Involved in plaque elaboration are complex processes of autocrine and paracrine mechanisms of vascular response to injury (Dzau *et al.*, 1993). Other stages of the process involve intracellular absorption of calcium leading to calcification of plaques and inflammatory responses leading to plaque rupture. Immunological responses to infectious agents directly stimulating plaque ruptures (and subsequent thrombotic events) are also suggested by the antiphospholipid syndrome.

To explain how infectious disease involvement with atherosclerosis relates to long-term population health and mortality changes, Mozar *et al.* (1990) suggested changes in circulatory disease risk can be traced back at least to 1910, when 8% of US deaths were attributed to heart disease. This proportion rose to 30% by 1945, and to 54% by 1968. A similar trend occurred in the United Kingdom with diseases of the heart and blood vessels responsible for 11.4% of all deaths in 1910, rising to 36.3% in 1959. In the United States, the peak heart disease risk was reached in 1968. Mozar *et al.* (1990) suggest this was due to ingestion of atherogenic viruses during the prewar period (i.e. initial injuries led to processes with lengthy latency times; autopsy studies found fatty streaks and plaque development began at early ages, possibly as early as age 3 years in the aorta (Pathobiological Determinants of Atherosclerosis in Youth Research Group (PDAY), 1990), even in less developed countries where heart disease risks do not increase late in life), which interacted with increased fat consumption and other risk factors (e.g. the methionine-homocysteine model of atherogenesis) up to 1970.

The nutritional (hygienic) factor argued by Mozar *et al.* (1990) to be associated with declines in heart disease risk was commercial food processing – initiated before the turn of the century. The use of commercial food processing accelerated after WWII as economic conditions improved, large proportions of the US population moved from rural to urban areas, and efforts to control livestock infections such as vesicular xanthema (a viral disease of swine discovered in 1932) were started, for example, in California in 1945–1949. An outbreak of vesicular xanthema in 1952 mandated thermal preparation of food fed to swine. A hog cholera eradication program began in 1962. The Swine Health Protection Act passed in 1980.

The risk of viruses and other infectious agents in chronic circulatory disease is not limited to injuries to the arterial endothelium but may involve stimulation of autoimmunological factors. A well studied infectious disease important in chronic disease risk that was a major concern in past years (i.e. rheumatic heart disease) are group A streptococci infections, especially of virulent strains, for example, M types 3 and 18 associated with rheumatic fever and M1 with toxic shock due to production of a pyrogenic exotoxin A. Certain strains (e.g. M1) disappeared in the United States 30 to 40 years ago. They recently reappeared in selected geographic areas in the United States, suggesting a cyclical decline and reemergence of virulent strains (Kaplan, 1993). This cyclical pattern can be related to the HLA (human leukocyte antigen) typing of individuals to see how autoimmunological responses relate to rheumatic heart disease. The disappearance of the most virulent strains about 1950 to 1960 is consistent with declines in cardiovascular mortality due to atherosclerosis beginning in 1968 – suggesting a role as a disease cofactor.

Nutrition affects a host's immunological competency. Poor nutrition, especially in childhood, might lead to less effective immunological responses to viral and bacterial challenges. The physiological response to the acute phase of infection requires energy. Poor nutrition can reduce efficacy of the host's response to disease, allowing it to cause greater physiological damage requiring greater energy expenditures to fight the disease process and further reducing nutritional resources for normal development – setting the stage for future chronic disease.

A third factor that could become important is ionizing radiation, not necessarily from atomic bombs or nuclear terrorism, but environmental contamination of water and food sources due to the leaking of radionucleides from storage sites (e.g. the Hanford plant) or as might occur during decommissioning of nuclear power plants. This is the type of damage that occurred in the former Soviet Union, for example, from the Mayak plutonium production facility in Chelyabinsk, Russia.

As for cardiovascular disease, new genetic and molecular evaluation and assay techniques allow identification of viruses and other infectious agents causing several types of

cancer. Epstein-Barr virus is implicated in the etiology of human lymphoid and epithelial malignancies. *H. pylori*, a causative agent in peptic ulcers, is associated with gastric cancer, and possibly other malignancies (e.g. liver cancer). Both Rb and P53, growth regulating genes whose normal function is to arrest cell growth when mutations are detected, can be disturbed by viral infections allowing malignant growth. *H. pylori* is of interest in that its infection rate is related to water quality. Thus, long-term improvements in water quality may be responsible for US cohort specific declines in gastric cancer. Elevation of gastric cancer risks in the upper midwest of the United States may be due to the use of well water in rural areas (*H. pylori* grows well in still water in wells or cisterns). *H. pylori* remains highly prevalent in developing countries (e.g. West Africa) and has a high seroprevalence in elderly US cohorts.

Thus, long-term trends in both circulatory and neoplastic disease and mortality appear to partly depend on viral and bacterial infections as initiating events or cofactors and may depend in the future on radioecological events. Reductions in standard chronic disease risk factors can only be documented, in the United States population, from the early 1960s (e.g. smoking declines, reduction of unhealthy fat consumption). Reductions in hypertension were first documented in the National Health and Nutrition Examination Surveys in 1960–1962. As genetic and molecular biological assays become more sensitive, we may find many other chronic diseases are dependent on a variety of infectious and other environmental agents. Changes in the human environment (e.g. improvement in water quality reducing *H. pylori* infection) or in food processing (e.g. elimination of viral infections in livestock, or thermal processing of food) may be partly responsible for large cohort related declines in circulatory diseases in the United States.

Cancer risks are now decreasing in the United States. It has been proposed that common processes underlie both cancer and aging. Warner *et al.* (1995) related these processes to effects of caloric restriction (CR) on programmed cell death (PCD). They suggest CR upregulates expression of antioxidant genes and attenuates formation of reactive oxygen species – and possibly DNA and mitochondrial damage caused over age. The emphasis on effects of antioxidants on aging and cancer leads to a third model of changes in chronic disease risks and their contribution to late age health changes.

Another hypothesis is that long-term changes in micronutrients alter chronic disease risk. Antioxidant vitamins A, C, and E seem to affect cardiovascular disease by lowering the potential for LDL cholesterol to become oxidized, consumed by macrophages, and trapped in atherosclerotic plaques as foam cells. Vitamin A and E are redifferentiating agents that repair some genetic damage and antioxidants preventing certain chemical reactions from causing somatic mutations or other cell damage. They may improve immunological responses at late ages (Beregi *et al.*, 1991). Zandi *et al.* (2004) suggest that up to 93% of Alzheimer's disease may be prevented by supplementation with vitamins C and E and low dose aspirin.

Vitamin D, a vitamin/enzyme/hormone, has powerful effects on bone metabolism; especially in late onset (i.e. ages 75+) osteoporosis (type II) in females. This may interact with cardiovascular diseases by affecting cellular calcium metabolism, parathyroid hormone activity, and hypertension. It may interact with iron (Fe) and magnesium (Mg) metabolism (Moon *et al.*, 1992) and is a powerful cellular differentiating agent. As such it (or, its antagonists) might prevent strontium 90 uptake in radioecological disasters as Chernobyl.

Vitamin D supplementation in milk and other foodstuffs has been done for a long time in the United States and Canada. One strategy to examine its effects on chronic disease is to trace the epidemic of atherosclerosis and ischemic heart disease and the ratio of male to female deaths. In the United States, this ratio was near one until the mid-1920s. Then the male predominance in ischemic heart disease increased steadily until 1968. Moon *et al.* (1992) pointed out that curative effects of cod liver oil on rickets were documented in 1917. In 1923, the United States imported 0.5 million gallons of fish liver oil, and in 1930, 2.8 million gallons. UV irradiated milk was introduced in the United States in 1924. Manufacture of vitamin D_2 and D_3 increased from 35 lbs in 1948 to 14 000 lbs in 1972. By 1970, vitamin D_2 was added to many food products. There was a concurrent decline of Mg in the US diet. Mg mediates effects of vitamin D on cellular calcium absorption (Moon *et al.*, 1992). Vitamin D hypervitaminatosis infers with Mg absorption. Oversupplementation of D aggravated Mg deficiencies in the United States diet. Mg deficiency may have additional effects on circulatory disease because it appears to stimulate renin release through the elevation of prostaglandins; and suppress aldosterone production by mobilizing intracellular calcium.

In the late 1960s, the FDA began considering limiting vitamin D supplementation. Regulations restricting vitamin D supplementation were implemented in 1972 – coincident with the beginning of the decline in heart disease.

The sex ratio of femoral neck fractures was used to trace origins of the US osteoporosis epidemic. This ratio suggests (based on Rochester, Minnesota, data) that osteoporosis began its upsurge in the late 1920s – about the same time ischemic heart disease began increasing. Vitamin D intake, its increase from 1920 to 1970 and its subsequent decrease, could explain the interaction of atherosclerosis and osteoporosis for females, and their joint trajectories. Vitamin D increases Fe absorption, which may lead to increased free radical generation and oxidation of LDL cholesterol. This might explain the rapid increase of atherogenesis in females postmenopausally, that is, Fe stores in females increase and, with excess vitamin D, increase calcification of atherosclerotic plaques.

Another model for explaining long-term trends in circulatory diseases is the homocysteine theory (McCully, 1983). Ingestion of the sulfur based amino acid methionine (an essential amino acid for mammalian growth) produced, after demethylation, homocysteine. Elevated levels of homocysteine, due to genetic predisposition or dietary deficiency of vitamins B_6 and B_{12}, had toxic effects on arterial

endothelium. Lesions created by elevated homocysteine levels showed the characteristic fibrous nature of atherosclerotic plaques – but not with lipid deposition if cholesterol is not elevated. The theory suggests fibrous plaques are not produced unless vitamin B deficiency allows accumulation of homocysteine and a toxic metabolite, homocysteine thiolactone. The metabolism of homocysteine is affected by vitamin C. Though ascorbic acid is a potent reducing agent, after oxidative conversion to semidehydroascorbic acid, its physiological function is to oxidize the sulfur atom in homocysteine. Three stages for methionine utilization are (a) demethylation and dehydration of methionine to homocysteine thiolactone, (b) oxidation of homocysteine thiolactone to homocysteic acid by semidehydroascorbic acid, and (c) reaction of homocysteic acid with ATP (adenosine triphosphate) to form active coenzymes to synthesize sulfate esters of connective tissue proteoglycans.

Methionine deficiency inhibits growth and wound healing – like scurvy. In scurvy, the lack of dehydroascorbic acid inhibits formation of sulfated proteoglycans. Increased conversion of methionine to homocysteine thiolactone increases production of sulfated proteoglycans matrix, deposited in atherosclerotic plaques, which accelerates growth and stature in homocystinuria. Age changes in homocysteine hepatic metabolism may explain why children in rapid growth phases are less susceptible to atherogenic effects of homocysteine. Stimulation of growth is due to homocysteic acid, which has a similar effect to somatomedin (the serum polypeptide mediating the effect of pituitary growth hormone on cartilage) on sulfate binding in cultured cartilage fragments – suggesting a relation of homocysteic acid, somatomedin, and the action of growth hormone. After normal growth ceases, and epiphyses ossify, growth stimulation affects cells of blood vessels (especially smooth muscle cells) rather than chondrocytes and osteocytes in growing bone. The homocysteine model also suggests a basis for the age dependence of osteoarthritic diseases and effects of growth hormone and somatomedin on the aging of connective tissue. Some evidence suggests the agent mediating the growth of smooth muscle cells is carried by platelets and released during platelet aggregation and adherence to injured intima. Calcification of fibrous connective tissue is stimulated as is the disruption of intermolecular cross-linking in newly synthesized collagen fibrils, which may be due to the reaction of homocysteine with allysine to form tetrahydrothiazine adducts. This may interfere with intermolecular cross-linking in collagen and elastin.

The relation of this mechanism to increased heart disease in the twentieth century may be due to an increased dietary ratio of animal to plant protein (dietary intake of methionine is correlated with cholesterol intake). This may explain the relation of increased body size with atherosclerosis. Vitamin B_6 levels decrease through life to the eighth decade because serum glutamine oxaloacetic transaminase activity decreases. When the elderly are treated with pyridoxine, transaminase levels return to levels of younger persons (McCully, 1983; von Eckardstein *et al.*, 1994). Also, since pyridoxine is water soluble, as the lipid content of the diet increases, pyridoxine availability may decrease.

To explain US population trends in heart disease, quantities of synthetic pyridoxine hydrochloride were examined (McCully, 1983). US production increased from 1900 kg in 1944 to 30 000 kg in 1963. Imports increased from 9100 kg in 1963 to 17 700 kg in 1969, to 59 500 kg in 1972 (yielding a threshold consumption of 0.79 mg day^{-1}) to 275 000 kg in 1978 (3.42 mg day^{-1}). This increase is consistent with post-1968 declines in coronary heart disease. Since B_6 supplementation will prevent arterial damage, but not reverse it, the decline in circulatory disease should increase as younger cohorts who had adequate supplementation reach older ages. Supplementation is also necessary because thermal food processing (which may have decreased viral exposures in animal protein) degrades natural pyridoxine. This is controllable by consuming adequate synthetic vitamin B_6 and B_{12} (von Eckardstein *et al.*, 1994). The problem increases with age due to altered vitamin intake, absorption, or metabolism.

Dietary intake of at least two other trace minerals may affect long-term heart disease and stroke mortality trends by affecting blood pressure. One is reduced salt intake which lowers blood pressure and reduces abnormalities of calcium metabolism, incidence of renal stones and bone demineralization. Potassium, found in many fruits and vegetables, also decreases blood pressure. Increases in fruit consumption may be involved with early reductions in stroke.

New explanations of these processes derive from better understanding of cellular bioenergetics – especially the function of the mitochondria. This suggests that, in addition to the CR model, they are the effects of thyroid hormone on mitochondrial function (Manton, 2004b). It is known thyroid hormone administration increases oxygen consumption by mitochondria (Venditti *et al.*, 2003). The effect may be short- as well as long-term. Short-term influence (within minutes of the hormone treatment) results in enhanced expression of the mitochondrial genome. Thyroid hormone increases levels of mitochondrial transcription by elevating mRNA synthesis and improving their stability. Long-term influence (after 24 hours) involves the stimulation of mitochondriogenesis (Enriquez *et al.*, 1999; Wrutniak-Cabello *et al.*, 2001; Weitzel *et al.*, 2003). This may explain why honey bees, where a nutritional intervention (royal jelly) containing a protein with partial structural similarity to human thyroid hormone, may stimulate production of cytochrome C in mitochondria with life span epigenetically increased 30-fold or more despite elevated metabolic rate (Manton *et al.*, 2005). Intervention effects were shown in mice where mitochondrial functions of old mice was returned to that of young mice by administration of alpha lipoic acid (an antioxidant zwitterion) and L-acetylcarntine, an agent stimulating fatty acid metabolism (Hagen *et al.*, 2002; Liu *et al.*, 2002).

Historically, deficiencies leading to explicit disease syndromes were prevalent until the role of specific vitamins and minerals in those diseases were identified and supplemental sources sought. At levels less deficient than those causing specific deficiency syndromes (e.g. scurvy, pellagra, osteomalacia, rickets), vitamin deficiencies may have contributed to long-term population changes in chronic disease risks.

To make the ebb and surge of specific chronic diseases over time consistent with the models described above, there had to be changes, not only in mortality at late ages, but also in the nature of age-related chronic disease processes over the past 150 years as nutrition (both macro and micronutrients), food hygiene (e.g. *H. Pylori* infections; toxins due to food spoilage), and viral and bacterial exposures changed. Changes may also affect the expression of genetic diseases by altering gene–environment interactions or by changing the inflammatory response of the host to stress, for example, altering serum levels of IL-6 (Cohen *et al.*, 1997). The average health characteristics of the very elderly population may evolve in the future as different cohorts, with different early health experiences, enter this age group. As the profile of chronic diseases affecting elderly populations changes over their life span, one also is aware of long-term changes in age-related chronic disease – and in aging changes.

MORTALITY SELECTION AND TRAJECTORIES

Hygiene and nutritional changes caused differences in chronic disease risks across birth cohorts. These, and other, factors (e.g. smoking) may have altered age trajectories of cohort mortality. Specifically, many demographic models use a Gompertz function to describe age increases in mortality. However, at late ages the trajectory of human mortality deviates from the Gompertz overpredicting increases in mortality (Manton and Stallard, 1996).

One explanation of deviations from the Gompertz (beginning about age 85) is mortality selection. For example, the prevalence of the B gene of the fourth component of complement (C4B*Q0) is a risk factor, in men, for myocardial infarction. The prevalence of this gene dropped for males in the fifth and sixth decades of life due to adverse affects on longevity. Its prevalence declined at later ages in females. In Italian centenarians there was decreased thyroid autoantibodies compared to persons in their 80s (Marriotti *et al.*, 1992). The prevalence of the ApoE-4 genotype in Finnish centenarians was lower than at earlier ages. In lung cancer, genetic susceptibility involves the cytochrome P450 enzyme system. The proportion of genetically related lung cancer cases declines sharply between ages 50 and 70. In Swedish twins (Marenberg *et al.*, 1994), the relative risk of CHD (Congenial Heart Disease) mortality declined from 14 to 15 to 1 in midage to 1 to 1 above 85. Thus, many studies of genetically controlled diseases showed change in genotype prevalence due to mortality selection. In clinical examinations of long-lived groups, health at late ages (e.g. 80+) is often better than for persons, say, aged 70–79 (Campbell *et al.*, 1993).

Effects of mortality selection on the age trajectory of health parameters can be monitored in longitudinal studies where risk factors, or disabilities, are measured multiple times. In analyses of Framingham data (46 year follow-up), and of 18 years of follow-up in a nationally representative study of disabled elderly (1982 to 1999 NLTCS), the mortality selection of persons with adverse risk factor profiles, or poor functional status, was noted over age. At late ages (e.g. 95+) selection was so strong that prevalence of adverse risk factor profiles, or poor functioning, started to decrease because mortality rates for very elderly persons with impaired health were greater than the incidence of the adverse health state (Manton *et al.*, 1994a).

As a consequence of selection, whereas human mortality rates increase 8 to 10% per year in middle age, the rate of mortality increase at late ages is slower. In seven studies where mortality was observed to ages 100+, rates increased an average of 3.1% per year between 100 and 110 (Manton and Stallard, 1996). For US males, cohort mortality reached a high constant level at ages 100 to 110. US female cohort mortality increased 3.0% per year of age from 100 to 110. The average US cohort mortality rate at age 110 was 41%; the average for the seven studies was 45% (Manton and Stallard, 1996).

The 1982 to 1999 NLTCS data show this plateau. We examined an alternate model where a plateau is due, not only to a genetically heterogeneous population, but also to a balance of degenerative and regenerative physiological processes (Manton *et al.*, 2004b). This suggests engineering reliability models, such as the Weibull, are not sufficient in that they describe failure in a homogenous system – not a complex heterogeneous one. It is no longer sufficient to describe a plateau as a genetically determined trait but as a temporally (absolute clock-time – not simply age) changing equilibrium of decay and repair functions.

In analyses of the actuarial experience of 11 large insurance companies, there was no credible evidence of human mortality rates exceeding 50% at any age. Recently the level of the plateau was fixed at 40%. Ungraduated insurance data suggest that, above 95, mortality reaches 25% for both genders and then fluctuates randomly. In animal models, similar phenomena were observed. Carey *et al.* (1992) found, in large experimental populations, mortality reached a high constant level after a large proportion (90%) of the population died. This is manifest in the United States by a decline in per capita, per annum Medicare expenditures at late ages, that is, expenditures were several fold higher at ages 65–70 than for centenarians.

If human mortality rates increase very slowly at late ages, profound changes will be required in assessing elderly populations. One is that the number of extreme elderly persons will be larger than now anticipated. In developed countries with reliable data (Manton and Stallard, 1996), the centenarian population has grown 7% per year for 30 years. The number of US centenarians in 2000, 50 454, will increase to 150 000 by 2020 and to 313 000 by 2040 – without assuming large changes in life expectancy or dealing with the large post-WWII baby boom cohorts who become centenarians after 2047. In Social Security Trust fund projections, mortality rates are assumed to increase 5 to 6% per year of age above 100 – a rate of increase higher than in the data (Manton *et al.*, 2004b).

From 2035 to 2050, the US centenarian population is expected to grow to 0.6 million persons. The US population

aged 95+ in 2050 would be 3.8 million persons. The 85+ population would be 18.9 million persons – or 4.8% of the US population. The 65+ population would be 20.4% of the total US population. These are "middle" range projections. Alternate series, assuming greater life expectancy increases, project 2.6 million centenarians in 2050 with 26.4 million persons 85+ and 93.1 million 65+; or 0.63, 6.4, and 22.7% of the total US population (i.e. based on life expectancy at birth in 2050 of 83.8 versus 91.1 years for males and females respectively; the intermediate assumption was 79.7 and 85.6 years for males and females respectively in 2050). Second, for individuals at late ages one will have to use different estimates of life expectancy than are available from actuarial estimates (Manton, 2004a). This could change calculations for assessing cost effectiveness of specific medical interventions at late ages.

Third, the expectation about comorbid conditions, and the average health of individuals at specific ages, will have to be evaluated taking into account the birth cohorts from which the patient comes, and the likely prior health experiences of persons in that cohort who survive. It may be aging processes in such persons progress at slower rates than in the population.

FUTURE CHANGES IN THE DEMOGRAPHY AND HEALTH OF THE ELDERLY: POTENTIAL SOCIOMEDICAL RESPONSES

With extreme elderly populations of the size discussed, the levels and mixes of services to be provided will have to be adjusted. Changes projected for the United States are not the most extreme. In Japan, using 2004 life expectancies at birth of 76.7 years for males and 84.5 years for females, the 65+ population will be more than 28% of the population in 2024.

The implications of such changes are dramatic requiring coordinated changes in (a) societal views of aging, (b) monitoring health of persons at specific ages, (c) the organization of acute and LTC health services for elderly populations, and (d) how medical options are evaluated that are to be offered to persons at extreme ages.

First, the popular perception of aging, and elderly persons, will change so sociomedical implications of age are less distinct, that is, individuals have to be assessed more on functional age, and less on chronological age, when considering the economic and social roles they play and how they should be medically treated. For this to have an effect, two other processes must operate. The first, consistent with evidence on the plasticity of aging parameters, is that physiological function is being preserved (and possibly promoted) to late ages. Fiatarone *et al.* (1994) showed resistance training and supplemental nutrition could improve muscle strength of elderly, frail individuals, for example, the average strength gain in the quadriceps of frail persons aged 86 to 96 was 174%. Kasch *et al.* showed declines in cardiovascular function for active persons were half the rate found in other studies. The image of "normal" aging must also be changed in the mind of the elderly individual. By identifying elements of aging with treatable disease processes, senescence is transformed from a mysterious, global biological force into more manageable and specific disease mechanisms. With this image, individuals will be more likely to make lifestyle changes, and seek treatments, to modify health and function.

The potential can be illustrated using the 1982, 1984, 1989, 1994, and 1999 NLTCS to estimate changes in chronic disability prevalence by age (Figure 3).

In Figure 3 are estimates of changes in the US chronically disabled population representing (a) constant 1982 age and sex specific disability rates, and (b) extrapolating 1999 rates to 2004. The difference is a decline of 43% in the chronically disabled or institutionalized population by 2004 over what 1982 rates would have generated. At ages 65 to 74, the number of chronically disabled persons in 1999 is nearly constant despite a population increase of 30%. Growth of the disabled population is slowed at ages 75 to 84 and 85+. The difference in estimates is 2.6 million, that is, if rates had not changed from 1982 to 2004, there would be 9.9 million disabled persons in 2004 versus the 7.3 million using declines observed 1982 to 1999. Using the rate of decline in disability 1989 to 1999, the difference is 3.1 million (i.e. 9.9–6.8 million).

DISCUSSION

The evidence suggests we can expect future elderly cohorts to live longer, and to have better health and functioning. This raises the question as to how health service systems will deal with this rapidly growing group and their changing health characteristics. What has happened in the United States is that health and LTC (long-term care) services have been redirected toward the community, and housing options have been defined to bridge the gap between traditional nursing homes and standard housing. This is reflected in changes in the US health care system. Medicare coverage is now often supplemented by private health insurance. Hospitalization rates and lengths of stay are down. What increased dramatically are Home Health Agency (HHA) and skilled nursing facility use, which, by 1995, constituted 8% of all Medicare expenditures – roughly $14 billion. Concurrently, growth of Medicaid reimbursed nursing home use declined. Most recently, we have found, despite arguments of some economists that more resources will be required to keep individuals healthy at late ages, per capita inflation adjusted Medicare expenditures declined for the nondisabled population and increased for the disabled populations.

Efforts to prevent both morbidity and disability among the elderly should be extended. Medicare based demonstration programs show physical activity can be increased. Physical activity (actually the lack) is, itself, a primary risk factor for stroke – and possibly other chronic diseases.

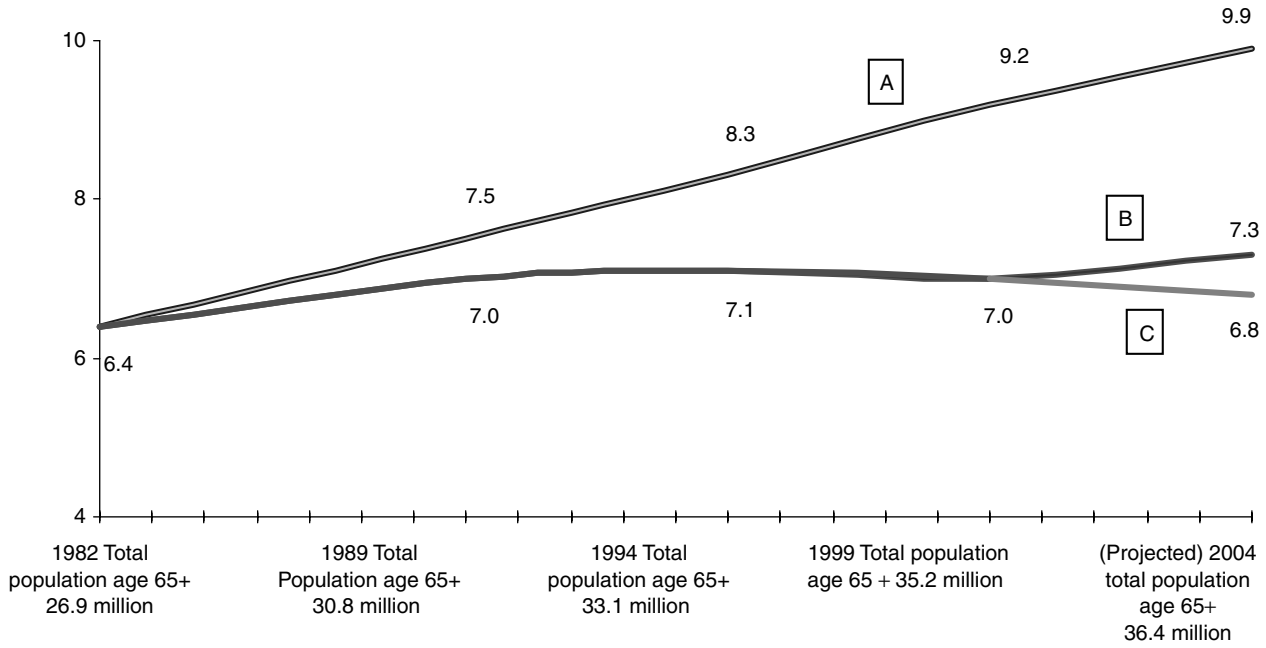

Figure 3 Number of chronically disabled Americans aged 65 and over (in millions)

Better evaluations of the efficacy of treatments at late ages are needed. Hosking *et al.* showed surgical interventions in patients aged 90 to 103 had become less hazardous – intra-operative mortality dropped from 30 to 8% over 30 years. Ko *et al.* show the increasing efficacy of coronary interventions in elderly (80+) patients. Elayda *et al.* showed uncomplicated aortic valve operations were successfully performed in patients aged 80+. Long-term (five years) survival rates in persons with simple aortic valve replacement were better than the survival in SSA (Social Security Area) cohort life tables. As pacemakers increase in sophistication, their use in elderly patients improves outcomes. Dual chamber, demand driven pacemakers may be particularly useful for the elderly because of increased reliance with age on atrial function for cardiac output. There are interventions with low mortality that increase the function of elderly persons. Hip and knee replacements are in this category, as well as plastic lens implants for cataracts.

Hence, the cost benefit ratios of medical procedures at late ages may be underestimated because the life expectancy of individuals at late ages, and the amount of functional capacity that can be regained, is underestimated (Manton and Gu, 2005b). A reason may be because trends in disability and mortality among populations with particular health characteristics may not be correctly represented in evaluations of patients for the medical and surgical procedures now available for elderly populations. Certain situations, such as long waiting periods for "elective procedures" in some European health care systems, may have more adverse effects at late ages than in younger populations and operate as a "self-fulfilling" prophecy about limitations to late age interventions. Such problems will emerge increasingly in the future as the number of very elderly persons increases and prior health histories evolve. One factor to which recent changes in disability may be related is education. Education is projected by Preston to improve with the proportion of persons aged 85 to 89 with less than eight years of schooling declining from 60+% in 1980 to 10 to 20% by 2015. A number of health behaviors are associated with education; as well as the risk of dementia.

The very elderly (95+) are a group for which we do not have extensive data from which to extrapolate effects of medical interventions. Studies focusing on the elderly, such as the isolated systolic hypertension intervention program, often find significant benefits in intervening in disease. Thus, evaluation of both future increases in health service needs for the elderly population, as well as evaluating potential gains for elderly individuals with specific health profiles, need to consider the implications of long-term demographic and health changes.

Social and Community Aspects of Aging

Rodney M. Coe, John E. Morley *and* Nina Tumosa

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

The interactions of social and community factors and aging are extraordinarily complex (Figure 1). It is important for the health-care professional to be aware of the impact of social and community factors on the health and well-being of the older person.

DEMOGRAPHY OF AGING

The Graying of Nations

The graying of nations (Butler, 1979) is a metaphor that has been used to describe the demographic changes that have taken place in all industrially developed countries during the past 100 years. It describes an increase both in the numbers of elderly people and in the proportion of the population that is elderly.

Absolute Aging

In both developed and developing nations, there has been a rapid growth in the numbers of elderly people. This has led to a need to shift resources from young to old and to redesign communities to deal with the problems of disability and aging. The rate at which a nation has aged, its gross domestic product and the political will of the nation to recognize the geriatric imperative are all factors that decide the quality of life for older persons.

The Causes of Absolute Aging

The increase in numbers of older people is primarily due to the increased expectation of life at younger ages that has resulted from improved sanitation, better nutrition, housing, and working conditions. More recently, vaccinations of children and older persons, treatment of infectious diseases, improved management of chronic conditions, enhanced neonatal survival and improved care for persons with disabilities have all further increased life span.

The number of elderly people in a society depends primarily on the number of births 70+ years previously and the subsequent mortality of that cohort over those 70 years.

Relative Aging

The relationship of the number of older to the number of younger people in a society is of importance. Three factors determine the rate of relative aging: fertility rates, mortality rates, and, at a national level, patterns of migration.

As a country develops economically, there is usually a decline in mortality, which increases the numbers of older people. However, it is not until fertility declines, usually about 20 years later, that the relative age of the population begins to increase. This has happened in all the developed countries, except those whose age structure has been significantly affected by immigration.

Rising life expectancy and declining birth rate have noticeable effects on the age structure of a population. The old age dependency ratio, that is, the number of people aged over 65 per 100 persons of working age (15–64 years old), will increase by 2050 to over 2.5 times in the developed countries from just under 8.7 to over 22.6. In the developed countries, it will double to 4.4. The old age dependency ratio is most useful both for those primarily concerned with the management and planning of staff-intensive caring services and for economists and actuaries trying to forecast the financial consequences of pension policies (Figure 2). The demographic trend in many less-developed countries has a less dramatic effect on the economic systems than in many industrial countries, primarily due to the fact that less-developed countries usually have no or only rudimentary

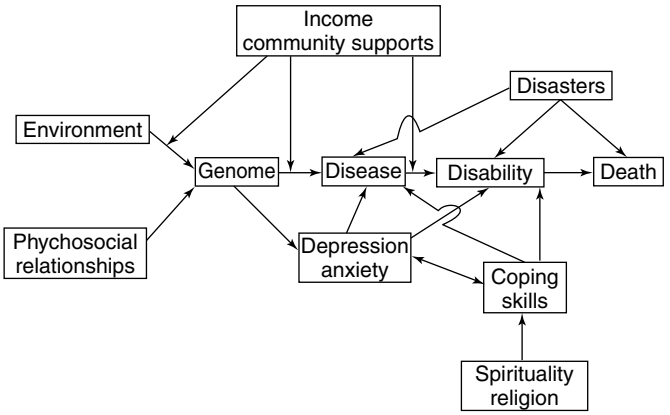

Figure 1 An illustration of the complex interrelationship between community/social aspects of aging, the genome and the progression of disease and disability toward death in the older person

pension systems. However, the societal implication of the demographic development in these countries remains precarious as a declining number of young people are available to take care of an increasing number of older people (UN website, 2004).

Retirement Migration

The distribution of old people, and thus their proportion in the population, varies very much from one part of a country to another. Although the main reasons for this range are variations in mortality and fertility rates, the migration of retirees also affects distribution.

In the United States, the general trend has been a migration from colder to milder climate, especially to Florida, South Carolina, Arizona, Nevada, and California. Longino (1990) described migration patterns of older people in terms of three moves. The first generally occurs at retirement, and involves moving for improved amenities (such as weather) and to maintain friendship contacts. The second move is precipitated by moderate functional disabilities, complicated by widowhood, and is often toward the community in which an adult child resides. The third move is due primarily to severe disabilities, and is local and toward an institution such as a congregate living or custodial facility (see discussion on Housing Problems).

In England, there has also been a southern migration, particularly to the southern coastal areas. Karn (1977) showed that people moved soon after retirement for a variety of reasons (Table 1). With the development of the European Union, many persons from the United Kingdom now migrate upon retirement to Southern Europe. The effect on aging of these diverse language, cultural, and health-care systems represents fascinating study for the future. Migration over the lifetime from a poor to a more advantaged community could improve the mortality of the migrants (Brimblecombe *et al.*, 2000).

While migration for functional elderly to better climates is on the whole positive, the development of disability often leads to frustration. With aging and the onset of cognitive and other problems, older persons often require

an advocate to help them make health-care decisions and to deal with financial problems. The loss of the ability to drive safely dictates that choosing a place to migrate to, must take into account the availability of transportation and the juxtaposition of essential shopping and entertainment facilities. In the United States, a new profession of case manager has developed. Case managers are used extensively by concerned adult children to provide care for their older parents who live at a distance.

Effects of Immigration

Two forms of immigration can affect the older person: (1) migration as an adult and (2) migration beyond pensionable age. Adult immigrants may have different rates of certain diseases in older age than the population they immigrated to, for example, immigrants from Yugoslavia and Hungary had a higher stroke incidence than Swedes living in Malmo, Sweden (Khan *et al.*, 2004). Alternatively, immigration can lead to altered disease patterns. Japanese immigrants to Brazil have different cancer mortality rates than do Japanese in Japan (Iwasaki *et al.*, 2004). Immigrants may or may not adapt to diet and health practices of their host country. For example, older Koreans in the United States often continue to utilize traditional Korean medicine (Hanbang) (Kim *et al.*, 2002). Surprisingly, immigrants to the United States have a lower overall mortality than their American born counterparts (Singh and Siahpush, 2001). Quality of life may also change. Polish-American ethnic elderly had a significantly better subjective quality of life than Polish-immigrant elderly, who in turn had a better subjective quality of life than Poles in Poland (Berdes and Zych, 2000). Studies of Chinese immigrants to Canada and New Zealand have suggested a high rate of depression in older Chinese immigrants compared to the general population.

Immigration has assorted effects on aging. These may either be beneficial or deleterious. Awareness of health attitudes and health problems specific to older immigrant populations are an essential part of the therapeutic armanterium of health-care professionals.

The Male-to-female Ratio

The sex ratio of men to 100 women in the older age-groups is an aspect of population aging meriting special mention. The expectation of life at birth (Table 2) is about 5 years greater for females in most developed countries than it is for males. In Britain, the difference between the life expectancy at the age of 60 is about 3.5 years. In the United States, the sex ratio declines by 67% from ages 65–69 to 100+ (Figure 3).

There are biological and social reasons for the differences in life expectancy and also for the fact that there are more older women than old men. Biologically, the high mortality of male fetuses and infants and the inhibitory effect of estrogens on the development of atherosclerosis both play a part. However, social influences appear to be more important. In the early twentieth century, there were more men than women among the elderly of several developed countries, so the reversal of the sex ratio is a relatively recent phenomenon. The change would seem to have been due to the differing lifestyles of men and women. The prevalence of cigarette smoking, high alcohol consumption, and exposure to hazards of the workplace have penalized men in comparison to women. In some rapidly developing nations, such as India and Bangladesh, the ratio of older males to females is close to 1.

A higher death rate of men than women during wars has also affected the ratio, while higher rates of mortality from homicide and road traffic accidents continue to have an effect during peacetime. This is particularly evident in modern Russia where there is an 11-year difference between males and females related to societal problems, following the fall of the Soviet Empire. Finally, decreased death rates during pregnancy and decreased number of pregnancies has dramatically decreased female mortality (Table 3).

As the lifestyles of men and women become more alike, the gap will probably narrow; changes in female morbidity and mortality associated with increased consumption of

alcohol and cigarettes are trends already apparent in younger cohorts.

The Changing Family

The structure of the modern family in the postindustrialization period has been influenced by increased age at marriage, increased divorce rate (50% in the United States), high geographic mobility, an increasing proportion of women in the labor force and fewer children. In the United States, these trends have been exacerbated in the "baby boomer" generation (those born between 1945 and 1965).

These trends would seem to make it more difficult for people to look after their elderly relatives when they become dependent. In many cases, this has created the "Sandwich Generation", where the middle-aged person needs to provide care for both dependent children and parents. Nevertheless, there is no evidence that the modern family in Britain or the United States cares less for its elders than did the family in the past. In fact, in the United States about 80% of older persons have living children, two-thirds of whom live within 30 minutes of the elderly parent. Furthermore, about 75% of those over 65 have some contact (personal or by telephone) each day. Support from adult children (transportation, financial and emotional) make it possible for 95% of people over 65 to live in the community and, of those, 54% live with spouse alone, 15% with other relatives, and 31% live alone (Administration on Aging, 2004). The vast majority (82%) live independently. Of those who need assistance for functional disabilities, 30% of the needs are met by family members, with the balance being met by a combination of family and formal community agency services.

Only 4.5% of older persons in the United States live in nursing homes, belying myths that families do not provide at least as much support as they did in the past.

GROWING OLDER – THE SOCIAL PROCESS

Although the distinction is arbitrary, it is useful to try to separate the effects of the physical processes affecting people as they grow older from the effects of the social consequences of attaining an advanced chronological age. There are three of these physical processes – aging, disease, and disability – and these overlap with each other and with the social process which is often called *growing old* (Figure 4).

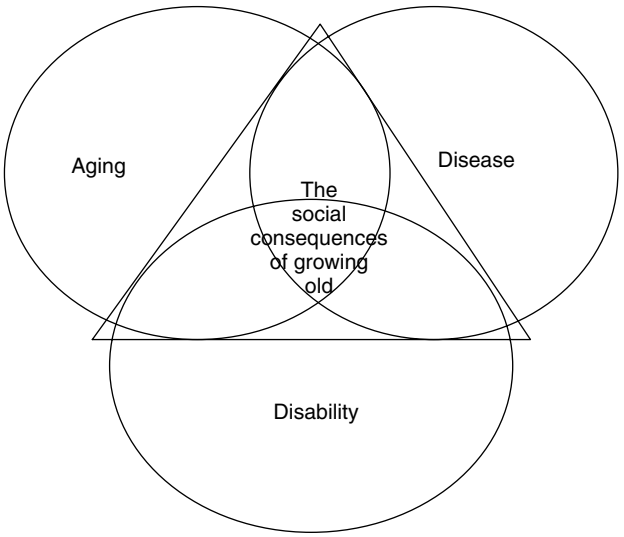

Figure 4 Aging, disease, disability and the social consequences of growing old

In this chapter, we will consider the social problems that occur as a result of growing old.

A Life Course Perspective on Age

It is useful to view older people as a product of life course events. These are depicted in Figure 5, in which life activities are arrayed against chronological age, representing what is culturally the "normal" course of events. Thus, infancy, childhood and adolescence occur in the first two decades of life and involve preparation for a job while living at home as a dependent. Adulthood and middle age bring with them increasing involvement in work, marriage and creating a family in an independent setting. Persons in old age, however, will have experienced departure of grown children, retirement, perhaps death of a spouse, family and friends and increasing dependency, especially from functional health limitations.

From a social psychological perspective, the transition from youth to adulthood may be seen as increasing attachment to one's social groups through meaningful and productive roles. Likewise, the transition from adulthood to old age may be seen as detachment from one's social groups as these meaningful and productive roles are given up. This may help account for the reports that the very old are, or at least perceive themselves to be, isolated, a "burden to society" and to have feelings of unworthiness. In fact, clinical depression is a common problem for older people, which could be exacerbated by these perceptions.

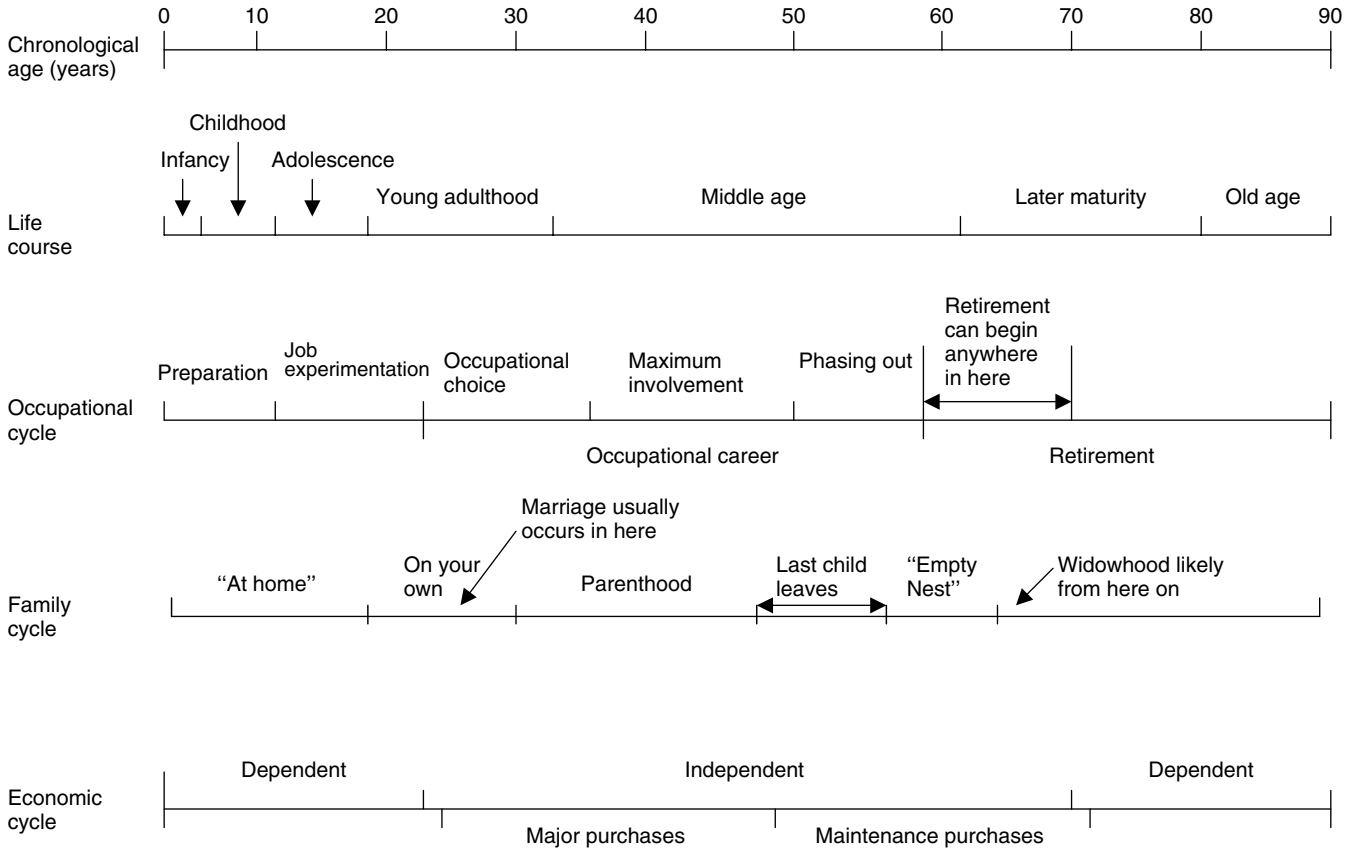

Figure 5 Relationships among age, life cycle, occupational cycle, and family cycle (These relationships fluctuate widely for specific individuals and for various social categories such as ethnic groups or social classes) (Reproduced from (Atchley RC, 1977). Copyright The Thomson Corporation)

Social Problems

When people talk about the social problems of elderly people, they are usually referring to certain practical problems that occur more frequently among older people, principally poverty, housing problems, difficulties with transportation, and isolation.

The reasons why older people suffer from certain types of social problems more frequently than younger people are listed in the following.

Poverty

Many of the problems of older people are simply due to the inability to purchase needed services to maintain an acceptable quality of life.

Immobility

The high prevalence of disabling disease combined with the difficulties older people have with public transport, compounded by poverty that restricts their use of cars and taxis, makes them less mobile than younger people. Immobility is the cause of many social problems.

Attitudes of Older People

Because of their upbringing, older people are, in general, less assertive than younger people. Because many were brought up in a culture in which the individual had fewer rights than he/she has today, many are less inclined to appeal against official decision, to seek the help of elected representatives, or to try to overcome bureaucratic inertia than younger people. In the United States, this is changing rapidly, with older persons becoming much more assertive. This began with the "gray panther" movement, and is expected to become even more prominent as the "baby boomers" generation reach old age.

POVERTY

The word poverty is so commonly used that it may seem unnecessary to define, but the word has two aspects which need to be distinguished – poverty threshold and relative poverty – and this distinction is particularly important at a time when there are rapid fluctuations in prices and wages.

Poverty threshold is defined by comparing a household's income with the level of prices of the basic commodities

necessary for life – the subsistence level, sometimes called the "*poverty line*" or "*bread line*". Those whose incomes are below the minimum level necessary for subsistence are deemed to be living in poverty.

The definition of relative poverty is made by comparing a household's income with the average level of incomes in their society. Although individuals' incomes may be sufficient to provide themselves and their dependents with the necessities of life, they may find their relative poverty upsetting because it symbolizes their low status. J. K. Galbraith, a famous American economist, has described the condition of relative poverty eloquently: "People are poverty stricken when their income, even if it is adequate for survival, falls markedly below that of the community. Then they cannot have what the larger community regards as the minimum necessary for decency and they cannot wholly escape, therefore, the judgment of the larger community that they are indecent. They are degraded, for in the literal sense they live outside the grades or categories which the community regards as acceptable".

In the United States, the median household income in persons over 65 years of age has increased from $16 882 to $23 152 (in 2002 dollars). Since the mid-1960s, poverty rates for persons 65 years and older have declined from nearly 30% to 10%. Older persons now have similar poverty rates to those seen in working persons. Over the same period, there has been an increase in poverty rates for those under 18 years of age (Figure 6). Between 1984 and 2001, the median net worth of households headed by a person age 65 years or more has increased by 82%. However, older white households have nearly 5 times the net worth of older black households.

Figure 6 Poverty rates by age: United States, 1966–2002. Note: Data shown are the percent of persons with family income below the poverty level. See Data Table for data points graphed and additional notes (*Source*: US Census Bureau, Current Population Survey)

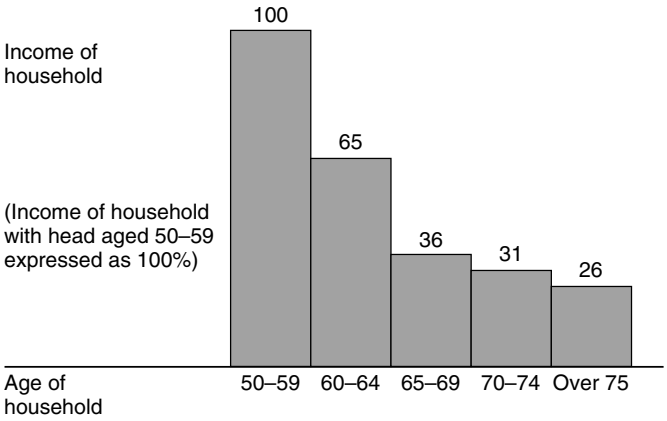

Figure 7 Income of household for various age-groups. From Age Concern (1977)

Social security provided 90% of income for one-third of Americans over 65 years of age. Other sources of income reported were assets (55%), private pensions (29%), government pensions (14%), and earnings (22%).

What is hidden by a simple comparison of "pensioner households" with "young households" is that there is a very wide range of wealth within the group of pensioner households. In general, older people are poorer (Figure 7).

The wide disparity is not due to a drop in income as people grow older, but to the fact that the proportion of people in each age-group who have an occupational pension decreases the older the age-group considered. This, in turn, is due to the fact that occupational pensions are a relatively recent innovation and it is therefore only younger retired people, those retiring more recently, who have qualified for them. The difference between the income of different age-groups of retired people is accentuated because men die younger than women, on average, so that the older groups consist of relatively more women, many of whom are eligible for neither national insurance nor occupational pensions and depend on a supplementary pension which is set at the lowest social security rate. Poverty is most common, therefore, among elderly women, particularly among those who never married.

HOUSING PROBLEMS

Environmental Problems

For some older people, the cause of their housing problem is not their dwelling but its environment. Many of those who lived in the city centers when they were first married have seen the neighborhood change. Some feel that the area has "gone down", that those who now live there do not have the same standards as they do, and that they are now aliens in a hostile environment in which they once felt at home.

The problems of elderly people in city centers and areas of urban deprivation are serious and difficult to remedy because often the best remedy is a move to another area in which the person may feel equally alien, although the majority of those who move do settle well and happily.

Structural Problems

Often, it is the dwelling itself that is the principal cause of the older person's concern. Common problems and their solutions can most easily be presented in a table (Table 4).

The services listed here are not universally available, and even where such services exist, older people often have difficulty mobilizing them. Every health professional can help by being aware of the range of services available, suggesting ways in which the dwelling can be improved and helping the person to contact the appropriate services.

Difficulties Caused by Disability

Sometimes the dwelling itself is suitable until the onset of disability, and the type of problem that most commonly causes a housing problem is the onset of a disabling disease that affects the older person's ability to climb the stairs, either stairs inside the house leading to the bathroom and toilet or the stairs leading to an apartment. Sometimes the circulation space within the house is too small to allow easy movement from room to room for a person using a wheelchair or walking aid.

The optimum solution to this type of difficulty is adaptation to the dwelling, and the domiciliary occupational therapist is the professional with the skill to do this. Solutions include the installation of ramps and indoor elevators. Adaptation of the kitchen and bathroom and addition of handrails can increase the safety of the house.

Table 4 Solutions to housing problems

Problem	Solution
Lack of toilet, bath, or hot water	The provision of grants and loans to help those who do not have the necessary capital
Difficulties with decorating, minor repairs such as broken windows and major repairs such as rewiring	Help from voluntary services with decorating and minor repairs Provisions of grants and loans for major repairs
The cost of rent and rates or property taxes	The provision of financial help with heating costs
Problems caused by disability	Adaptation of the dwelling, for example, ramps, rails, chair elevation
Difficulty with heating	Installation of more effective and efficient heating Improved insulation

Making a Move

The doctor's opinion about housing decisions is often as highly respected as his or her opinion about health decisions, particularly on that most difficult decision – "should I move or stay put"? Obviously, each case is unique but it is possible to list guidelines for decision making. Tables 5 and 6 give good and bad reasons for moving. One of us (JEM) uses the analogy of bungee jumping. When living alone is no longer as safe as bungee jumping, then it is time to move to a protective environment.

In general, every attempt should be made to solve the housing problem from which the old person feels he or she has to move away to remove the need for a move. That is not to say that there is never a need to move. Children often want their parents to move before it is necessary and older adults put off the move as long as possible. The development of "smart homes", lifeline alarms, and so on, are further delaying the time to when a decision has to be made to move. The decision of whether an older adult should move into a relative's home or to an institutional environment represents one of the hardest decisions associated with aging for both the older person and the caregiver.

Sheltered or congregate housing in the United Kingdom and senior apartment buildings or assisted living facilities in the United States are the types of housing that most people think of when new housing for elderly people is mentioned, although many move to independent flats or bungalows. Congregate housing offers security and reassurance and a well-designed and heated environment to elderly people and thus meets the needs of many frail elderly people, particularly those who are:

- nervous of living alone;
- anxious that they are not able to call anyone if they should fall ill;
- at risk of hypothermia or hyperthermia;

Table 5 Bad reasons for moving

- Because of structural problems; the possibility of solving the structural problems should always be explored first
- Because of financial problems; the provision of the full range of financial benefits may solve the problem
- Because of disability; the advice of an occupational therapist should be sought
- To move away from an area in which the old person feels "no one cares"; more people may be assisting than he or she is prepared to recognize

Table 6 Good reasons for leaving

- To move nearer a son, daughter, or relative who is willing and able to offer care
- To move away from a dwelling that is impossible to repair, improve, or adapt
- To move away from an environment that is causing severe depression or anxiety
- To move to sheltered housing if living alone is no longer safe

- isolated, although it should be said that some people feel just as isolated in sheltered housing as in an independent dwelling.

Sheltered housing is not always suitable for the person who has antisocial tendencies or for the very confused person because the caregiver cannot cope with a large number of dependent people or with very dependent people. The fact that the caregiver lives on site has many benefits, but it also has its drawbacks because he or she may be called incessantly by a confused person. It may be that the provision of more staff, that is, the creation of "very sheltered housing", will overcome some of the problems in sheltered housing, but it is always important to remember that the majority of disabled elderly people live and will continue to live in independent dwellings.

RETIREMENT

The concept of retirement was developed by the German chancellor Otto von Bismarck in the nineteenth century. His generals had asked that at some time they might be allowed to stop leading troops into battle. Bismarck asked his actuaries to calculate the age at which a general was unlikely to still be alive. When they told him it was 65 years, he magnanimously told his generals that they would be allowed to retire at 65 years of age with a state pension. He then introduced a national pension scheme to undermine the growing power of the Socialist Democratic Party.

Before World War II, retirement in Britain was a rarity with only the rich and those who were incapable of keeping a job retiring. In 1901, 60% of men over 65 years of age were in paid work. This number had declined to 48% in 1931 and to 13% by 1980. Following the passage of the Old Age Pensions Act of 1908, the first old age pensions were paid in England to just under half a million people (mainly women) in 1909. Following World War II, there was an increase in occupational pensions and deliberate attempts by employers and the government to force retirement. Technological developments were, in part, responsible for the erosions of the light work jobs often held by older persons. To some extent, the "Structured retirement" of the 1950s and 1960s was partly responsible for the marginalization of older people and their definition as a distinct, dependent social work. Toward the end of the twentieth century, retirement has become more acceptable, with many persons retiring in their early 50s.

In the United States, retirement became a reality for most old persons with the introduction of Social Security. The concept of retirement to "the golf course" has become a glamorized component of American Life. While Social Security is the bedrock of American retirement, for many it is their pension from their employer and personal investment that has allowed earlier retirement. In the present, insecurity about the ability of the government to fund social security and the government health plans for the old (Medicare) and the poor (Medicaid) is creating numerous, often scatterbrained, schemes on how to alter the retirement system. Some older Americans have, in retirement, been at the forefront of the modern globalization movement by retiring to Mexico or Costa Rico, where they can better leverage the buying power of the dollar.

THE "GOLDEN AGE" MYTH

Not only are modern societies those in which work is seen to be important, they are also societies in which wealth is an important determinant of status. The low income of elderly people, therefore, not only symbolizes the low esteem in which they are held but also perpetuates it. There is a myth about old age in times past that states that there was at one time a "Golden Age" for elderly people, an age in which it was good to be old and in which elderly people were loved and respected. The myth has become elaborated with time and some people believe that the Golden Age was destroyed by the industrial revolution because the traditional skills of elderly men and women, which they passed on to the younger generations by the fireside and in the inglenook, were rendered redundant by the speed of change at that time (Fischer, 1977).

Attractive though this myth is, there is no substance for it in fact. There never was a Golden Age for elderly people (Laslett, 1968). Rich and powerful elderly people were certainly able to hold onto their position of power and respect.

Poor elderly people usually finished up in the workhouse, and it is important to remember that in many societies the proportion of elderly people living in this situation was higher in times past than it is today, and that the quality of care in modern institutions far surpasses that seen even a quarter of a century ago. If ever there was a "Golden Age" for older persons, it is today.

AGISM

"Agism", like "racism" and "sexism" is a prejudice. People who hold agist views believe that all people over the age of 65 are of declining intelligence, unable to change or learn, rigid, conservative, and dull. They assume that any physical or mental change is due to the aging process and is, therefore, untreatable. They also have a certain set of expectations about the way older people should behave, for example, that it is not normal for older people to drink to excess, show an interest in sex, or even to argue forcibly with people with whose views they disagree. Many people, both old and young, hold agist views and assume that all physical and mental changes are due to "old age", that is, the aging process.

It is only in the last few decades that health professionals have begun to appreciate the difference between the effects

of the aging process and the effects of disease; it is not surprising that many people assume that all the changes they see in old age are due to "old age". It is extremely important to recognize that older persons, like young persons, show large variability in most characteristics.

The two main effects of agist beliefs among older persons are:

1. Failure to seek help for treatable medical problems – "What else can you expect at my age"?
2. Failure to comply with medical advice – "It was kind of the doctor to give me tablets but there's no point in taking them, it's just old age that's the problem".

Societal agist beliefs lead to undervaluing the contributions of older persons and providing inadequate societal resources for them. Political activism is needed to combat agism. Persons at all levels of the community and health professions often pay lip service to the aging demographic imperative, but fail to provide the financial benefits needed to overcome agist policies. Much of the media has recognized "agism" as politically incorrect and has tended to overcompensate by making older persons highly functional and cute. Some realistic movies about persons with Alzheimer's disease have attempted to be more balanced.

THE EFFECT OF SOCIAL FACTORS ON THE AGING PROCESS

George Valiant (2003) in his pioneering studies on aging in Harvard graduates and inner city persons living in Boston provided a framework for the effect of social relationships on aging successfully (Figure 8). He found that not smoking, exercise, not drinking alcohol to excess, obesity, and a stable marriage were the factors that predicted successful aging. Modern studies support the concept that social connection and perceived social support have an effect on health but mainly in persons facing crises, stressors and/or adversity (Johnson and Krueger, 2005). When *drosophila* flies are placed in a stressful environment they have increased mortality (Parsons, 2002). In humans, social isolation or perceived lack of social support leads to more diseases and a higher mortality rate.

Allostatic load is an index of wear and tear on the physiological systems of the body. Allostatic load has been shown in a longitudinal study to be related to heart disease, physical function, cognitive function, and death (Karlamangla *et al.*, 2002). The degree of allostatic load could be significantly modulated in men with strong emotional supports. This was not true in women. Other studies have demonstrated the importance of perceived control and economic variables in modulating the health effects of the social environment. This has led to the development of the concept of socioeconomic resiliency. An example of these interrelationships was shown by Suda *et al.* (2001) when they found that having the person delivering meals-on-wheels sit with the older persons while they ate decreased both their nutritional risk and their dysphoria.

Thus, the effect of social relationships on an older person developing and coping with disability depends not only on the strength of the relationship but also on the ability for the person to accept the relationship (e.g. are they depressed? Or did they have a lifelong inability to bond with others?) and their innate coping skills, as well as their economic status and the inherent severity of the disease process (Figure 9).

Over half of men and women over 65 years of age do not engage in leisure-time physical activities (Figure 10). This is despite the fact that endurance and resistance exercise can modulate disease processes and slow down the development of frailty, disability, and death. Exercise enhances frontal lobe cognitive function and may slow down the development of cerebral atrophy. Thus, there is a need for increasing the awareness of the benefits of physical activity with aging. It is important that simple ways to improve physical fitness,

Figure 8 Valiant, G – effect of social relationships on aging successfully

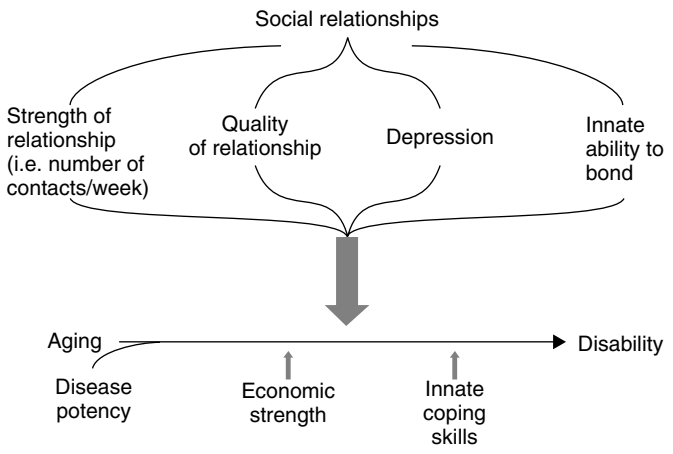

Figure 9 Factors modulating the ability of social relationships to modulate the aging process

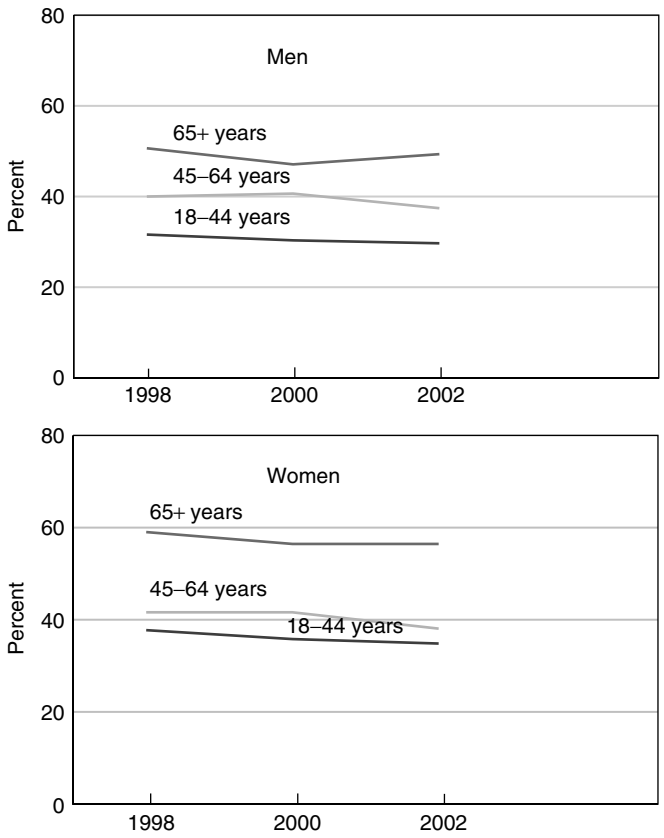

Figure 10 Adults not engaging in leisure-time physical activity by age and sex: United States, 1998–2002. Note: See Data Table for data points graphed, standard errors, and additional notes defining leisure-time physical activity (*Source*: Centers for Disease Control and Prevention, National Center for Health Statistics, National Health Interview Survey)

for example, climbing stairs rather than taking the elevator, can be as effective as organized activities. The importance of balance exercises, such as Tai Chi, to reduce falls needs also to be stressed.

LIFESTYLE, NUTRITION, AND HEALTHY AGING: LESSONS FROM THE SENECA STUDY

The Survey in Europe on Nutrition and The Elderly: A Concerned Action (SENECA) examined lifestyle and nutrition in 19 towns throughout Europe, from Denmark to Portugal. All participants were born between 1913 and 1918. There was a large variation in lifestyle factors (de Groot *et al.*, 2004). In Padua, Italy, 78% of older persons drink alcohol on most days compared to Culemborg in the Netherlands where less than 20% drank regularly. Smoking varied from 7% in Vila Franea de Xira in Portugal to 41% in Roskilde, Denmark. The percent of people who still played sports varied from 4% in Portugal to 32% in Yverdon, Switzerland. Physical activity and smoking habits both predicted death and dependency. However, the relationship varied greatly from town to town, with the highest mortality rate in males being in the Netherlands, while the lowest death rate was in Bentanzor, Spain, a city in which the percentage playing sports was only half of that in Culemborg, but alcohol intake was nearly double. Cross-sectional studies such as the SENECA represent an important tool to understand how social factors modulate disability and mortality.

Another tool to examine the effects of social factors on aging is longitudinal studies in populations that are undergoing rapid change in their lifestyle. One such population is the Okinawans in Japan. This area, famous for its centenarians, has undergone rapid change from a caloric restricted, sweet potato-based diet to a rice and meat diet with greater calories and, at the same time, has decreased their energy expenditure. Early reports suggest that these lifestyle changes may be deleterious as males in Okinawa now have a life span that has sunk from 1st to 26th among the prefectures in Japan.

RELIGION AND SPIRITUALITY

There is an emerging literature recognizing the role of religion and spirituality in the preservation of psychological and physical health of older persons. Thus, for example, Koenig *et al.* (1995) reported that in medical inpatients religiosity correlated with a lower likelihood of feeling downhearted and blue, boredom, loss of interest, restlessness, feeling hopeless or feeling as if other people were better off. Brown and Gary (1994) found that fewer depressive symptoms were associated with religious involvement in a group of urban African-American males. In Israel, religious orthodoxy was found to be protective against death from coronary heart disease, independent of lifestyle correlates (Goldbourt *et al.*, 1993). Lack of comfort from religion and failure to participate in church events was associated with an increase in death following heart surgery (Oxman *et al.*, 1995). In patients with lung cancer, prayer was, in part, responsible for psychological well-being (Meraviglia, 2004). Positive religious coping methods were found to be associated with health improvements. On the other hand, persons who were not at peace with religious issues, or saw God as punishing, had worse outcomes. Spirituality in Britain was shown to be a significant predictor of psychological well-being in frail older persons. Spirituality, but not religiosity, was associated with self-appraised good health (Daaleman *et al.*, 2004). Spirituality is associated with a greater ability to deal with grief. In non-Judeo-Christian cultures, the role of spirituality is less clear; a study in Japan showed mixed effects; spirituality was positive in Thais (Pincharoen and Congdon, 2003; Kawa *et al.*, 2003). Of interest, religious television or radio was associated with worse physical functioning and greater medical comorbidity (Koenig *et al.*, 2004).

Overall, the role of religion and spirituality can be summarized as predominantly improving psychological health with a lesser effect on physical health. There is a small literature suggesting that not all forms of religion are positive. The

most parsimonious model for describing the role of religion and spirituality on health is to assume that it increases coping skills and enhances access to support groups. Health-care professionals need to be aware of the religious and spiritual affiliations of their patients and, in appropriate cases, be prepared to incorporate them into a holistic model of health care. Prayer is a commonly used coping strategy for many older persons dealing with disability or life-threatening illnesses. Involvement of a person's religious leader as part of the team approach to health care is important. In some countries, this may stretch to the need to involve the local shaman in the health-care team.

ANTIAGING MEDICINE

Since the beginning of time, persons have sought the mythical fountain of youth (Fisher and Morley, 2002). This has led over the centuries to numerous unscrupulous people selling their version of "snake oil" to vulnerable older persons. Within recent times, pseudoscientific claims associated with the growth hormone and dehydroepiandrosterone as agents that will "reverse the aging process" regularly appear in newspapers, magazines, and books. Many of these claims are based on flawed studies originally published in mainstream medical journals. Others are based on hypotheses developed by scientists and published in mainstream literature and then translated as fact by the lay press. A recent example of this is the theories of Aubrey de Grey, which are futuristic and not yet ready for "prime time" (de Grey *et al.*, 2002). In a 2003 book, Ronald Klatz and Robert Goldman claimed that "the future of antiaging medicine promises the elimination of the disability, deformity, pain, disease, suffering and sorrow of old age. In a few decades, the traditional enfeebled, ailing elderly person will be but a grotesque memory of a barbaric past". Hyperbole such as this is reminiscent of the popular book, *The Art of Living Long* written by the Italian, Luigi Comaro, in 1550.

The desire for longevity has led to eloquent claims by Linus Pauling that megavitamins will protect the cells from free radical damage. The concept that excess vitamins will rejuvenate remains alive today, despite studies suggesting that instead of prolonging life, they may shorten it.

Within the next decade, we will be faced with the possibility that stem cells can reverse aging of muscle and cure Alzheimer's disease. This research is accruing at increasing speed in Israel and South Korea, while under embargo in the United States. Such social factors will limit the rigor of scientific exploration into the role of stem cells and may eventually limit their use only to the very rich.

From this brief recounting, it is clear that social factors have played, and will continue to play, a major role in the development of antiaging medicine. Further, its availability to the general public depends on the decision of regulatory agencies such as the Food and Drug Administration in the United States.

THE ENVIRONMENT AND THE GENOME

There is an increasing literature that the environment can modulate gene expression. Two examples of the environment interaction have been found with the APOE4 gene: (1) Head injury accelerates Alzheimer's disease in persons who have the APOE4 allele (Mayeux *et al.*, 1995); (2) APOE4 is a risk factor for ischemic heart disease predominantly in smokers (Humphries *et al.*, 2001). The interaction of a major life event with a genetic predisposition increases the likelihood of major depression. Physical exercise produces different responses depending on the person's angiotensin converting enzyme insertion deletion genotype.

Similarly, the development of the fledgling science of pharmacogenomics has shown that the efficacy and side effects of drugs are associated with specific alleles. For example, persons with the apolipoprotein E allele have different responses to the antidepressant, paroxetine, dependent on the allele (Shanahan and Hofer, 2005). Side effects from paroxetine are related to the number of C alleles of HTR2α.

These simple examples represent only the start of the exploration of gene/environment interactions. As shown by centenarians and other long-lived persons, it is both the genome and the environment that eventually determines the successful aging potential of a person. The new social science of aging in the twenty-first century will require the inclusion of the person's genetic background to allow full interpretation of environmental effects.

ELDER ABUSE

Approximately 5% of older persons suffer elder abuse. In most cases, this is not due to physical violence or theft (though these instances are unfortunately not rare), but are more often due to neglect. Thus, poor nutrition or worsening of pressure ulcers is commonly associated with poor care. Even health professionals have practiced elder abuse, ranging from the notorious English physician serial killer, Dr. Shipman, to the use of physical restraints. Overall, persons who abuse older persons are more likely to have been abused when they were young and to have a mental illness. The solutions to elder abuse are complex ranging from criminal prosecution and separation of the elder from the abuser to psychosocial therapies including such options as daycare, respite for the caregiver and increased home care.

THE INTERNET

At present, older persons are much less likely to use the Internet than are middle-aged adults or children. However, this is changing rapidly. Many nursing homes offer Internet facilities for older persons to communicate with the children and grandchildren as well as to access the news. Older

persons are also using the Internet to obtain health-care information. With the movement of the "baby boomers" in the United States into the young-old over the next decade, these uses are expected to increase exponentially. There will also be increased communication between physicians and their patients via the Internet. We can also expect to see an increase in telemedicine as a more technologically adept group of persons join the aging cohort.

CULTURAL COMPETENCY

Shifts in populations have led to the requirement that health professionals acquire cultural competency and that social policy adapts to create more health professionals from ethnic minorities. A dramatic example of the effect of migration has been seen in the United Kingdom. In the 1950s, Bethnal Green was a predominantly white, working-class neighborhood, whereas in the 1990s it had changed to Tower Hamlets, the home of large numbers of Bangladeshi immigrants. Woodford has transformed to the home for many affluent Asians and Wolverhampton now has a substantial population of persons of Caribbean origin. Changes such as these require training programs for health professionals in the beliefs of different cultures and how they impact the interactions between older persons and their health-care providers.

DISASTERS

The events of 9/11 focused the attention of the world on the devastating effects of disasters. In all disasters, older persons are disproportionately affected. Studies in North Africa have shown that older persons are more likely to be left behind when genocide occurs and younger persons flee, creating separation between the generations. Older persons are also more likely to die during migrations from enemy troop areas and during periods of famine. In developed countries, heat waves are the most common disaster causing death. Over 400 older persons a year die from heat-associated death in the United States. Heat waves are often associated with power outages, which lead to air-conditioning being unavailable. This has been characterized as a "disaster within a disaster". The appropriate measures for preventing heat-related deaths are outlined in Table 7.

During disasters, such as hurricanes and earthquakes, one-third of older persons have a worsening of their medical conditions. The disruption of services following these disasters can lead to isolation of the older person, loss of home services and loss of access to prescription medicines. The appropriate contents of a disaster kit for older persons are listed in Table 8. Following disasters, there is an increase in myocardial infarctions. For example, the Hanshen-Awagi earthquake in Japan was associated with a threefold increase in myocardial infarctions.

Table 7 Preventing heat-related deaths

- When available, use home air-conditioning
- If no home air-conditioning is available, try to go to an air-conditioned mall
- Check frequently on persons at high risk
- Wear lightweight, light-colored clothing
- Reduce strenuous activities
- Drink plenty of fluids
- Avoid alcohol and caffeine
- Take cool showers or baths frequently
- Municipalities should develop a comprehensive heat emergency response plan including early warnings, appropriate health messages, and transportation to emergency shelters

Table 8 Items to be included in a senior disaster preparedness kit

Identification bracelet
Extra pair of glasses/hearing aids
List of medications
List of diseases
Set of emergency prescriptions
3 days to 1 week medication supply
Flashlight
Extra batteries
Pet evacuation plan
Family pictures
Emergency numbers (including a contact for at least one family member who lives in another geographical area).
A copy of FEMA's "Are You Ready?" emergency preparedness handbook

Table 9 Symptoms of nerve agent

- Excessive tearing and salivation
- Miosis
- Ptosis
- Nausea
- Vomiting
- Bronchospasm
- Bradycardia
- Muscle fasciculations
- Paralysis
- Restlessness
- Delirium

Deaths from fires are common in older persons. Persons living in mobile homes or old homes with faulty electrical work are at particular risk. Smoking and excessive alcohol use are human behaviors that are often associated with fires. Smoke detectors are a community action that can save lives.

Terrorism affects many countries. While a bombing incident is easily recognized, there is a need for surveillance techniques to detect outbreaks of disease as was shown in the slow recognition of the salmonella outbreak by the terrorist cult in Oregon in 1980 and the anthrax outbreak in the United States in 2001. The anthrax outbreak demonstrated that older persons had a greater susceptibility to biological agents and a poorer outcome than young persons. Terrorist attacks may include (1) biological agents, for example, smallpox, ricen, anthrax, plague, salmonella, ebola; (2) chemical agents, for example, vesicants (blistering agents) such as lewisite or mustard gas or cholinesterase inhibitors from the G group (GB-Sann, GD-Soman) or the V-group (VX); (3) nuclear

weapons or attacks on nuclear power plants or nuclear waste transport systems. The symptoms produced by cholinesterase inhibitors are listed in Table 9.

It is the responsibility of all to see that older persons are properly prepared for disasters, cared for during disasters, and returned to their homes after disasters.

KEY POINTS

- Genome/environmental interactions play an important role in the development of disease and disability with aging.
- Disasters have a disproportional effect on older persons.
- Religion and spirituality have positive effects on aging.

Sexuality and Aging

John E. Morley

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Sexuality remains an important component of quality of life throughout the life span. The spectrum of sexuality and aging is outlined in Table 1. The full expression of sexuality is dependent on biological, psychological, and social factors. Testosterone is a driver of sexuality in both sexes, but its effect is modulated by psychological and social factors. The effects of aging on sexuality can create major anxiety, but with adequate education, sexuality can remain enjoyable throughout life. There is much misinformation about sexuality. While open discussion of sexuality has become much more common in the last 40 years, many older persons come from a generation where sexuality remains a taboo subject. This chapter will explore both the biology of sexuality and aging, as well as the emergence of the special needs of a substantial cohort of older gays and their unique needs. The role of disease in sexuality of older persons will be addressed. Finally, the problems faced by older persons who have had lifelong paraphilias will be considered.

SEXUALITY AND THE OLDER WOMAN

The major sexual problems reported by older women include lack of orgasm, lack of sexual interest, a decline in lubrication, failure to find an appropriate partner, dyspareunia, problems with safe sex, sexual aversion, and extramarital affairs (Nusbaum *et al.*, 2004). The number of older females who have intercourse decline from 30 to 78% at 60 to 70 years to 8–43% at 80 years. Most older persons who are still sexually active have intercourse on an average of once a week. Approximately 45% of older women masturbate. Of those still having intercourse, 73% enjoy intercourse and the rest tolerate it. Only 21% of women over the age of 75 years still have a partner. Most studies have shown that the majority of physicians do not include sexual concerns and questions as part of their general history taking. Figure 1 provides the spectrum of sexuality and the older female.

A number of diseases have a major impact on sexuality in women. The disease that most alters a woman's self-image is breast cancer. Up to 40% of women with breast cancer have a reduction in their sexual activity (Kaiser, 2003). The effect of breast cancer on sexuality is highly dependent on the relationship the woman has with her partner. Urinary incontinence can modify sexual interactions in up to a third of women. Severe incontinence may lead to the need for separate beds. Uterine prolapse is more likely than incontinence to alter sexual relationships.

Urogenital atrophy, due to estrogen deficiency, leads to vaginal dryness, vaginal bleeding, urge incontinence, urinary frequency and dysuria, irritation and pruritus of the labia and mons, dyspareunia, and urinary tract infections. All of these changes can lead to sexual dysfunction. A number of lubricants are now available to allow women to overcome vaginal dryness. Estrogen creams, tablets, and rings may also be useful in the management of severe vaginal dryness. However, it must be remembered that vaginal estrogen is absorbed and may have all the effects of oral or parenteral estrogen.

Menopause occurs in women with an average age of 52 years. Epidemiological studies have suggested that the older a woman is at menopause, the longer she will survive following menopause. Smoking is a major cause of an early menopause.

The major symptom of menopause is hot flashes. These occur in 85% of women at the time of menopause. While in most women hot flashes last less than 5 years, a few women continue to have hot flashes into their 80s. Environmental factors such as spicy foods and hot weather, and psychological factors, for example, stress, can be precipitants of hot flashes.

Menopause is not necessarily associated with a decline in libido. Some women find the cessation of menses liberating. Use of estrogen is declining following the results of the Women's Health Initiative and the HERS study. These studies showed that both estrogen alone and estrogen plus progesterone were associated with an increase in myocardial

infarction, stroke, pulmonary embolism, and breast cancer (Grady *et al.*, 2002; Rossouw *et al.*, 2002). This was balanced by a decrease in hip fracture and colon cancer. Unfortunately, estrogen also appears to accelerate the onset of cognitive impairment in older women (Espeland *et al.*, 2004).

Testosterone levels decline rapidly between the ages of 20 to 40 years in women (Morley and Perry, 2003). There is then a slight increase in testosterone levels in women between the ages of 60 to 80 years. Testosterone, tibilone (an estrogen-progestagen-testosterone), and dehydroepiandrosterone (DHEA) all improve libido in older women. Besides increasing libido, testosterone has also been reported to improve general well-being, decrease mastalgia, decrease headaches, and increase bone mineral density and muscle mass (Table 2). The testosterone products available for women are listed in Table 3.

better ascribed to another psychiatric condition, for example, depression, or to the effects of a substance, for example, medication or a general medical condition. The approach to the management of sexual dysfunction in older women is given in Table 4.

It is important to recognize that for many older women intimacy and "cuddling" are more important than intercourse. The sensitive clinician needs to recognize the specific needs of the individual and then work with her to obtain her goals. Some women will choose to use complementary therapies such as black cohosh or dong quai soy. It is important to recognize that there is no long-term data on their efficacy or safety. At present, the use of estrogen in women over 60 years of age should be avoided whenever possible. There is a clear need for increased research on sexuality in older women.

ERECTILE DYSFUNCTION

Erectile dysfunction is defined as the inability to attain or maintain a penile erection sufficient for sexual performance on at least two-thirds of occasions (Morales, 2003). Physiologically, older males have an increased time for development of erection and less full erections with a decreased pre-ejaculatory secretion. During orgasm, there is a decline in expulsive force and urethral contractions. Following ejaculation, there is a rapid tumescence with rapid testicular descent. The refractory period is markedly prolonged.

A number of older males have an active sex life (Bortz *et al.*, 1999). However, studies in Germany and South America have found that 53% of men 70 to 80 years have some degree of erectile dysfunction (Rosen *et al.*, 2004). The Massachusetts Male Aging Study showed that at 40 years of age, severe erectile dysfunction was present in 5.1% and moderate erectile dysfunction in 17% (Derby *et al.*, 2000). By the age of 70, 15% had severe dysfunction and 34% moderate dysfunction. In the Olmsted County Study, 30% of men over 70 years of age had no erections, and only 10% had intercourse more than once a week (Masumori *et al.*, 1999). The major risk factors for developing erectile dysfunction are heart disease, diabetes mellitus, and hypertension.

Erections occur when the smooth muscle of the corpora cavernosa relaxes, allowing pooling of blood. Figure 2 demonstrates the different neurotransmitters involved in producing penile erection.

Approximately half the males with erectile dysfunction are found to have vascular disease as a cause. Other causes include medications, psychogenic causes, neuropathy, diabetes mellitus, thyroid disease, and hyperprolactinemia. Thiazide diuretics is the number one medication-associated cause of erectile dysfunction worldwide. Tobacco use is associated with increased erectile function. In dogs, nicotine decreased cavernous nerve stimulation and increased erections. In humans, smoking two cigarettes decreases the quality of papaverine-induced erections.

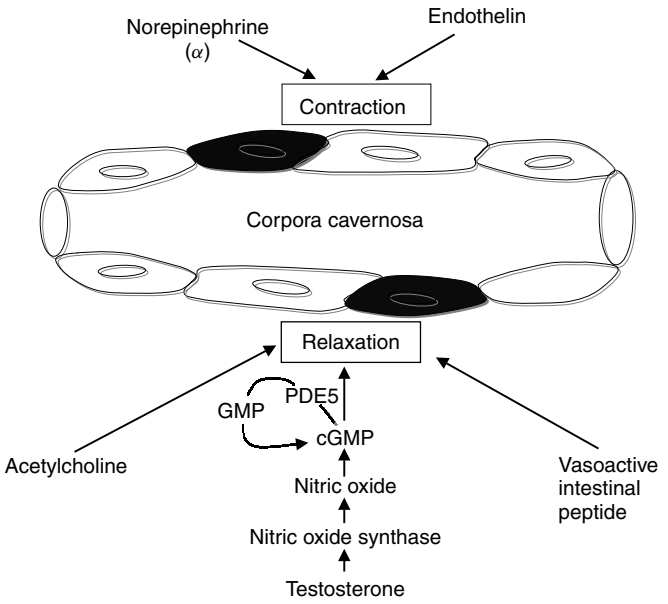

Figure 2 Neurotransmitters involved in producing a penile erection

While low testosterone levels decrease the production of nitric oxide synthase, most studies have failed to show that hypogonadism is a major cause of erectile dysfunction (Slag *et al.*, 1983). Nevertheless, persons with low testosterone have poor quality erections. Testosterone treatment improves the quality of erections produced by phosphodiesterase-5 inhibitors.

Table 5 lists the causes of erectile dysfunction and Table 6 lists the available management strategies for erectile dysfunction.

Table 5 Causes of erectile dysfunction

Vascular	– Atherosclerosis – Vascular leak
Medications	
Neurological	– Peripheral neuropathy – Spinal cord disease – Temporal lobe epilepsy
Urologic	
Endocrine	– Diabetes mellitus – Hypothyroidism – Hyperthyroidism – Hyperprolactinemia
Peyronies Disease	
Recreational Drugs	– Tobacco – Alcohol – Opiates

T 1/2	4	4–6	17.5

Table 8 Side effects of phosphodiesterase-5 inhibitors

- Headache
- Flushing
- Dyspepsia
- Rhinitis
- Visual disturbance
- Hypotension
- Death (avoid nitrates)

The most common treatment for erectile dysfunction is a phosphodiesterase-5 inhibitor. This works by blocking the breakdown of cyclic GMP that has been generated by nitric oxide. There are 3 phosphodiesterase inhibitors in general use viz sildenafil, vardenafil, and tadalafil. The pharmacokinetics of these drugs is given in Table 7. The major side effects of phosphodiesterase-5 inhibitors are headache, flushing, dyspepsia, rhinitis, visual disturbances, hypotension, and death (Table 8). Persons on nitrates and α-adrenergic blockers should avoid phosphodiesterase-5 inhibitors. With aging, all phosphodiesterase-5 inhibitors have increased plasma concentration or area under the curve.

Vacuum tumescence devices are useful for older persons who wish to have intercourse rarely, for example, once a month. Intracavernosal injections with vasoactive agents can produce a response rate as high as 74% in older males.

A number of complementary medicines claim to improve erections, such as canthandrin or ginsenorides. These do not work and can produce hematuria.

Overall, modern medicine will allow the majority of older males to obtain an erection (Table 6). It is important to include the partner in decisions concerning which approach is best. It is important not to assume that an older male's partner is his spouse.

ANDROPAUSE

It is now recognized that testosterone levels decline at the rate of 1% per year (Matsumoto, 2002). This decline leads to 3–5% of persons 40 to 50 years of age and 30 to 50% of persons over 70 years of age having biochemical hypogonadism. Other estimates suggest that 20% of persons 40 to 70 years of age are hypogonadal. When testosterone levels fall below the normal level for men 20 to 40 years of age and this is accompanied by symptoms, such as a decline in libido or fatigue, the person is recognized as having andropause or androgen deficiency in aging males (ADAM). Other terms that have been used historically, for example, climacteric or male menopause, are no longer considered acceptable. Two symptom-screening tests have been developed to screen for males with andropause. These are the aging male symptom (AMS) and the ADAM questionnaires (Morley *et al.*, 2000) (Tables 9 and 10). Both have excellent ability to detect males with biochemical hypogonadism but also are answered positively by a large number of males who are not hypogonadal, for example, older persons with depression.

The cause of the fall in testosterone with aging is multifactorial (Table 11). While levels of luteinizing hormone are slightly higher in hypogonadal older males, it is rarely out of the normal range. Thus, these males are considered to have secondary (hypothalamic-pituitary) hypogonadism. The major cause for this seems to be irregular (chaotic) secretion of gonadotrophin-releasing hormone from the hypothalamus. There is also an increase in negative feedback of testosterone at the pituitary level. A decline in testosterone response to human chorionic gonadotrophin is present in older men. There is a decrease in Leydig cell number.

With aging, there is an increase in sex hormone binding globulin (SHBG). This leads to less testosterone being available to the tissues. Thus, the tissue available testosterone can either be measured directly using a free testosterone value by dialysis or a bioavailable testosterone (ammonium sulfate precipitation technique). Alternatively, tissue available testosterone can be calculated using an SHBG, total testosterone, and albumin by utilizing the program available at www.issam.ch. Most experts feel that some measure of tissue available testosterone is preferable to measuring a total

Table 9 ADAM questionnaire

Yes	No	1. Do you have a decrease in libido (sex drive)?
Yes	No	2. Do you have a lack of energy?
Yes	No	3. Do you have a decrease in strength and/or endurance?
Yes	No	4. Have you lost height?
Yes	No	5. Have you noticed a decreased enjoyment of life?
Yes	No	6. Are you sad and/or grumpy?
Yes	No	7. Are your erections less strong?
Yes	No	8. Have you noticed a recent deterioration in your ability to play sports?
Yes	No	9. Are you falling asleep after dinner?
Yes	No	10. Has there been a recent deterioration in your work performance?

A positive answer represents yes to 1 or 7 or any 3 other questions. (Circle one)

Table 10 AMS questionnaire Which of the following symptoms apply to you at this time? Please mark the appropriate box for each symptom. For symptoms that do not apply, please mark "none."

Symptoms:	None	Mild	Moderate	Severe	Extremely Severe
Score =	1	2	3	4	5
1. **Decline in your feeling of general well-being** (general state of health, subjective feeling)	☐	☐	☐	☐	☐
2. **Joint pain and muscular ache** (lower back pain, joint pain, pain in a limb, general backache)	☐	☐	☐	☐	☐
3. **Excessive sweating** (unexpected/sudden episodes of sweating, hot flushes independent of strain)	☐	☐	☐	☐	☐
4. **Sleep problems** (difficulty in falling asleep, difficulty in sleeping through, waking up early and feeling tired, poor sleep, sleeplessness)...	☐	☐	☐	☐	☐
5. **Increased need for sleep, often feeling tired...**	☐	☐	☐	☐	☐
6. **Irritability** (feeling aggressive, easily upset about little things, moody)...	☐	☐	☐	☐	☐
7. **Nervousness** (inner tension, restlessness, feeling fidgety)...	☐	☐	☐	☐	☐
8. **Anxiety** (feeling panicky)...	☐	☐	☐	☐	☐
9. **Physical exhaustion/lacking vitality** (general decrease in performance, reduced activity, lacking interest in leisure activities, feeling of getting less done, of achieving less, of having to force oneself to undertake activities)...	☐	☐	☐	☐	☐
10. **Decrease in muscular strength** (feeling of weakness)...	☐	☐	☐	☐	☐
11. **Depressive mood** (feeling down, sad, on the verge of tears, lack of drive, mood swings, feeling nothing is of any use)...	☐	☐	☐	☐	☐
12. **Feeling that you have passed your peak**...	☐	☐	☐	☐	☐
13. **Feeling burnt out, having hit rock-bottom**...	☐	☐	☐	☐	☐
14. **Decrease in beard growth**...	☐	☐	☐	☐	☐
15. **Decrease in ability/frequency to perform sexually**...	☐	☐	☐	☐	☐
16. **Decrease in the number of morning erections**	☐	☐	☐	☐	☐
17. **Decrease in sexual desire/libido** (lacking pleasure in sex, lacking desire for sexual intercourse)...	☐	☐	☐	☐	☐
Have you got any other major symptoms? If Yes, please describe:	Yes	☐	No	☐	

Table 11 Age-related changes in testosterone regulation

- Loss of circadian rhythm
- Asynchronous production of GnRH
- Increased inhibitory effect of T at pituitary
- Reduced GnRH release of LH
- Decreased T response to HCG
- Altered receptor and postreceptor effects

testosterone in making the diagnosis of andropause (Morley and Perry, 2003).

It is essential to recognize that the response to testosterone depends on the ability of testosterone once it is in the cell to translocate to the nucleus and bind to the receptor, and the receptor responsiveness. The binding capacity of the receptor depends on the number of CAG repeats in the receptor. The lower the number of CAG repeats, the better the binding capacity of the receptor. The effect of aging on the intracellular trafficking of testosterone, the ability of testosterone to bind to the receptor, and receptor responsiveness is just starting to be explored.

The symptomatic concept of andropause has been recognized since the time of the Chinese Text of Internal Medicine. The major symptom of andropause is a decline in libido. A decline in libido may also be due to depression, illness, or death of a spouse. Testosterone replacement restores libido in 70–80% of persons. Testosterone is also essential for the production of nitric oxide synthase. Production of nitric oxide is essential for firmness of the erection. Thus, low testosterone levels can lead to soft erections or failure of phosphodiesterase-5 inhibitors to produce an erection. Low testosterone levels are associated with a low ejaculatory volume.

The effects of testosterone in older males are listed in Table 12. Testosterone increases muscle mass and strength. Testosterone stimulates the stem cells to produce satellite cells (these are responsible for repair of skeletal muscle)

Table 12 Effects of testosterone in older males

- Improved libido
- Improved erectile function
- Increased hematocrit
- Increased muscle mass
- Increased muscle strength
- Increased IGF-1
- Decreased fat mass
- Decreased leptin
- Increased bone mineral density
- Decreased LDL and HDL cholesterol
- Increased brachial artery flow
- Decreased ST depression and angina
- Enhanced spatial cognition

Table 13 Testosterone therapies and the older male

- Injections
- Patches
- Gel
- Oral
- Inhalation
- Pellets
- Buccal/sublingual

and also increase protein synthesis in skeletal muscle and inhibit the ubiquitin-proteasome system, which is responsible for muscle breakdown. Testosterone inhibits adipocyte precursor cells, resulting in a loss of fat mass. Testosterone may improve function, but at present, there is limited data in this regard. Testosterone increases bone mineral density in the lumbar spine and the hip. Testosterone improves visuospatial cognition. Testosterone increases the hematocrit. Testosterone may have beneficial effects on the cardiovascular system. Testosterone's negative effects include gynecomastia, water retention, and possibly sleep apnea. The effects of testosterone on the prostate are uncertain. Testosterone cannot be given to persons with active prostate cancer.

The history of testosterone replacement stretches from the end of the nineteenth century when Brown-Sequard injected himself with an animal extract of testosterone. During the early twentieth century "monkey gland," goat testicle, and even human testicular transplants were done on the rich in an attempt to rejuvenate them. The available and experimental forms of modern testosterone replacement are listed in Table 13. At present, most men with andropause choose to use the testosterone gel forms of treatment. After the gel, the next most popular form of treatment is testosterone injections. Selective androgen receptor molecules (SARMs) have been developed to avoid the sexual stimulant properties of testosterone and enhance the anabolic features of testosterone replacement. These can be steroids, for example, nandrolone or oxandrolone, or a series of nonsteroid moleculares that can be ingested orally.

Libido represents an important component of sexuality in older men. The treatment of depression, and where appropriate testosterone replacement, can markedly enhance libido in older men.

SEXUALITY AND DISEASE

Disease can greatly alter the sexuality of an individual. Pain and disability can interfere with sexual intercourse. Fatigue reduces libido. Negative self-image is commonly associated with diseases. Depression, with or without other systemic diseases, can lead to a decline in libido or erectile function. Many systemic diseases reduce testosterone, leading to a decrease in libido (Morley and Tariq, 2003).

Diabetes mellitus causes early onset of erectile dysfunction and a decreased libido. Males with diabetes mellitus have low testosterone. Women with diabetes mellitus have clitoral damage. Women with diabetes have a decline in libido and vaginal lubrication, but minimal change in the ability to attain orgasm. Amputations and dysphoria can further alter sexuality in persons with diabetes.

Hip arthritis causes both stiffness and pain, which interfere with sexual intercourse. Judicious use of pain medication prior to intercourse, alterations in positions for intercourse, and positioning of pillows can all enhance the sexual experience for persons with arthritis.

Persons with left cerebrovascular hemisphere strokes have a marked decrease in libido. Coital frequency is markedly decreased in two-thirds of persons following a stroke. Persons with a stroke can often have hemineglect and their partners need to be aware of this problem. Men and women with Parkinson's disease have a high prevalence of sexual dysfunction. Very low testosterone levels have been reported in men with Parkinson's disease.

Death during sexual intercourse in persons with cardiovascular disease are extremely rare, with an estimated rate of 0.2 per 100 000 being reported in males (Jackson, 2000). Cardiovascular disease and hypertension are major risk factors for erectile dysfunction. Persons with two or three vessel disease have softer erections and more erectile dysfunctions than those with one vessel disease. In females, heart disease is associated with decreased libido, vaginal dryness, dyspareunia, orgasmic difficulty, and decreased genital sensation. Saint Louis University has developed a series of instructions for patients for resuming coitus following myocardial infarction (Table 14).

THE OLDER HOMOSEXUAL

There are approximately 3 million older gays in the United States. It is estimated that approximately 4% of older women are lesbian and/or bisexual. Older gays tend to have a higher use of alcohol and tobacco. The Women's Health Initiative found a slightly greater rate of obesity and dysphoria in older lesbians (Valanis *et al.*, 2000). Breast cancer was more common in lesbians.

Over 10% of AIDS cases occur in persons over the age of 65 years. Half of these cases are due to contaminated blood products. Condom use is extremely rare in gays over 50 years of age. HIV testing is rare in older gays.

Table 14 Instructions for patients and their spouses after myocardial infarction

- Sexual activity may be resumed as soon as you can bring your heart rate to 120 beats per minute without occasioning chest pain or shortness of breath, the equivalent of climbing two flights of stairs rapidly.
- If chest pain develops during intercourse, take a nitroglycerine. If the pain does not subside within 15 minutes, consider that an emergency.
- If chest pain regularly develops during sexual intercourse, take a nitroglycerine 10 minutes before attempting sex.
- No sexual position is the best or is prohibited. Some patients may find one position preferable for their needs.
- Altered desire after a heart attack is usually due to psychological factors, such as fear of another attack. Please discuss these problems with your physician.
- Altered ability to obtain an erection after a heart attack may be due to medications or to vascular disease of the penis. These are both treatable. Please discuss this with your physician.
- If the female has decreased vaginal lubrication or pain during intercourse, ask your physician to prescribe a lubricant or, in some cases, you may need estrogen replacement.
- There is no time of day during which we know that sex is safer or more dangerous. Please be advised that sexual activity in a novel situation, for example, with a partner other than your spouse, appears to be associated with increased problems.
- Discuss your sexual needs and concerns frankly with your spouse.
- Any questions or concerns you have should be brought to the attention of your physician or nurse. It is best that both you and your spouse read these instructions. Feel free to have your spouse discuss his or her problems with the health professional team.

Homophobia leads to many older gays not identifying themselves to health-care providers. Many physicians assume that their older patients are heterosexual. Unmarried homosexual partners are often poor as they grow old as they are ineligible, in the United States, for social benefits such as Social Security. A major issue occurs when the partner becomes sick, as the homosexual partner often has no rights to make health-care decisions for their ill partner. It is important that older gays have a durable power of attorney for health, designating their partner as the decision maker.

PARAPHILIAS

Paraphilias are unusual sexual behaviors. The advent of the Internet has greatly increased awareness of persons indulging in these behaviors. The most common paraphilias are erotic talk on the telephone or the Internet. Substantial numbers of persons practice exhibitionism, voyeurism, sadomasochism, sexual bondage, anal eroticism, and fetishes. Many of these practices are still indulged in by older persons. Some become exaggerated as the older person develops dementia and loses the normal social sensibilities. The physician needs to be aware that many of these are variants of normal sexuality and be able to help the older person.

Pedophilia is sexual abuse of a child by an adult. In one series of 261 cases, the child abuser was the grandfather in 16 cases (Jenny *et al.*, 1994). Pedophilia needs to be reported to the appropriate authorities.

SEXUALITY IN THE NURSING HOME

Sexuality does not necessarily cease on entry into a nursing home. However, within the nursing home there are multiple barriers to sexuality (Hajjar and Kamel, 2004). These include lack of privacy, lack of a partner, staff and resident attitude, and knowledge concerning sexuality and family attitudes. Special ethical problems arise when two demented patients form a romantic liaison. Most ethicists feel that older persons should retain their right to continue appropriate sexual behavior in the nursing home. It has been suggested that older persons may wish to develop an advanced directive for sexual behavior.

From the facility point of view, it is essential that staff are educated and taught to be accepting of sexual behavior. Residents of nursing homes are entitled to privacy and, where wanted, conjugal visits. Unfortunately, sexual abuse of residents, including rape, is also a problem in nursing homes. Maintenance of a healthy sexual environment in the nursing home is often extremely difficult. Society needs to come to terms with the sexual needs of older persons in nursing homes.

CONCLUSION

Awareness of the sexual needs of older persons is an important quality-of-life issue. Health-care providers need to be open to discussing sexual needs of older persons and providing treatment where appropriate. Education of society and increased awareness of sexuality in elders is a key component of sexual health in the future.

KEY POINTS

- Sexuality remains important to quality of life throughout the life span.
- There are biological, psychological, and social components of sexuality.
- Depression is a major cause of disruption of sexual enjoyment.
- Alternative sexual lifestyles are not unusual in older persons.

Physical Fitness and Exercise

Maria A. Fiatarone Singh

University of Sydney, New South Wales, Australia, Hebrew Rehabilitation Center for Aged, Roslindale, MA, USA, and Tufts University, Boston, MA, USA.

INTRODUCTION

The interaction of physical activity, exercise, and physical fitness with health and aging is complex and multifaceted. Although many questions remain about mechanisms of effect and dose–response curves (Bouchard, 2001), a synthesis of the literature indicates many potentially positive effects of participation in physical activity on the aging process (Mazzeo *et al.*, 1998. Most recent position stands and policy recommendations include physical activity prescriptions for health promotion and disease prevention (American College of Sports Medicine *et al.*, 1998) as well as chronic disease treatment in older adults. However, there is still skepticism among some clinicians and investigators as to the actual potency of exercise for disease and/or disability prevention and treatment, particularly in already frail or near frail adults (Keysor and Jette, 2001). Exercise has not become fully integrated into usual geriatric medicine practice, and is still virtually absent from the core training of most geriatric medicine physicians and health-care professionals. Therefore, this chapter will attempt to provide a rationale for the use of exercise and physical activity for health promotion and disease prevention in older adults. Exercise will be discussed in terms of the specific modalities and doses that have been studied in randomized controlled trials for their role in the physiological changes of aging, disease prevention, and treatment of older persons with chronic disease and disability. Recommendations will be offered to address gaps in knowledge as well as clinical implementation needs in this field.

WHAT IS EXERCISE?

Any discussion of these issues must begin with definitions of the terminology. Physical activity has been traditionally defined as any bodily movement produced by contraction of skeletal muscle that significantly increases energy expenditure, although the intensity and duration can vary substantially. It should be noted that some forms of physical activity which may have particular relevance to an aging population (e.g. balance training) may not conform to this standard definition. This activity may be performed in leisure or occupational hours, and surveys for the older adult should capture both paid and unpaid (volunteer) work. Exercise is a subcategory of leisure time physical activity in which planned, structured, repetitive bodily movements are performed, with or without the explicit intent of improving one or more components of physical fitness.

Recently, efforts have been focused on merging these formerly distinct entities in order to promote "lifestyle integration" of exercise as a means to enhance long-term adherence. For example, taking the stairs instead of the elevator, standing on one leg while doing the dishes, or slowly standing and sitting without use of the arms represent ways of incorporating aerobic, balance, and strengthening exercises, respectively, into everyday activities. Current investigations are exploring whether such prescriptive techniques are superior to standard approaches for the promotion of behavioral change in older adults.

Physical fitness, by contrast, is defined as a set of attributes that contribute to the ability to perform physical work (e.g. cardiorespiratory endurance, muscle power, balance, flexibility, and body composition) or influence health status. "Metabolic fitness" has been advanced more recently as a term that encompasses a range of biologically important traits (increased insulin sensitivity, lipoprotein lipase activity, endothelial cell reactivity, heart rate variability, etc.) which may contribute to health status, but do not directly affect exercise capacity. Both genetic predisposition and lifestyle factors contribute to physical and metabolic fitness and the extent to which they are modifiable with exercise training.

Dose–response relationships between changes in fitness and better health outcomes have been defined for some, but certainly not for all diseases and syndromes (Bouchard,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

2001). Some modalities or doses of exercise that are promoted for older adults (mild calisthenics, slow-paced walking) have little or no discernable effects on physical fitness, but may possibly yield benefits in some domains. This area of investigation is critical for defining *threshold and optimal* levels of activity that are necessary for health promotion and disease management. It should be recognized that what is suitable for prevention may be entirely inadequate for treatment, as is the case with pharmacological management of chronic diseases as well. For example, aspirin may reduce the risk of ischemic heart disease, but a host of potent agents may be required once coronary occlusive disease is present and symptomatic.

DOES EXERCISE INCREASE LIFE EXPECTANCY?

The effects of exercise on total mortality are unlikely to ever be substantiated via randomized controlled clinical trials, given the impossibility of random assignment to various physical activity regimens over many decades. However, there is clear evidence of an inverse, linear dose–response relationship between the volume of physical activity reported in epidemiological studies (with sample sizes ranging from less than 500 to over 2.5 million individuals) and all-cause mortality rates. These relationships are demonstrable for both men and women, and for older as well as younger adults. Volumes of energy expenditure during exercise of at least 1000 kcal/week reduce mortality by about 30%, whereas reductions of 50% or more are seen with volumes closer to 2000 kcal/week, when more precise measures or estimates of physical activity participation incorporating fitness assessments are utilized instead of surveys. These changes in all-cause and cardiovascular mortality translate to an increase in life expectancy of approximately 2 years for those exercising at such volumes. Despite the consistency of the data from well-designed observational studies, many questions still remain regarding the minimum threshold for efficacy, the effect of exercise intensity, duration and frequency (apart from contributions to overall volume), the effect of nonaerobic modalities of exercise, and the mechanism of benefit. From a public health perspective, if small, effective doses of moderate-intensity activity are found to be as beneficial as longer bouts of vigorous activity, adoption of mortality-reducing physical activity recommendations by sedentary middle-aged and older adults may be more successful. Of particular relevance to the geriatric exercise prescription are studies which have demonstrated that a change from a sedentary to more active lifestyle in midlife or beyond is associated with a reduction in mortality. In the sections that follow, the focus is on changes in physical fitness and body composition, quality of life and disease burden, rather than on changes in longevity itself. It is in these domains that the centrality of physical activity patterns to optimal aging is perhaps most relevant to the concerns of the health-care professional and the older individual.

PRESERVING EXERCISE CAPACITY WITH AGE VIA AN ACTIVE LIFESTYLE

There is a great similarity between the physiologic changes attributable to disuse and those which have been typically observed in aging populations, leading to the speculation that the way in which we age may be modulated with attention to activity levels (Bortz, 1989). The most important physiological changes associated with aging or disuse that impact upon exercise capacity are presented in Tables 1–4. In most physiologic systems, the normal aging processes do not result in significant impairment or dysfunction in the absence of pathology and under resting conditions. However, in response to a stress, or significant disuse, the age-related reduction in physiologic reserves ("homeostenosis") may result in difficulty completing a task requiring near-maximal effort.

Although changes in maximal work capacity (aerobic fitness, or maximal oxygen consumption) will be immediately noticeable and disastrous for an elite athlete, they may accrue insidiously in nonathletic populations because most sedentary individuals rarely call upon themselves to exert maximal effort in daily life. Women are particularly susceptible here, because their initial reserve of muscle mass is so much lower than that of men, due to gender differences in anabolic hormonal milieu as well as lifestyle/occupational factors. They will therefore cross this threshold where losses of

Table 1 Changes in exercise capacity due to aging or disuse potentially modifiable by physical activity

Component of exercise capacity	Effect of aging or disuse
Maximal aerobic capacity	Decrease
Tissue elasticity	Decrease
Muscle strength, power, endurance, mass	Decrease
Oxidative and glycolytic enzyme capacity, mitochondrial volume density	Decrease
Gait speed, step length, cadence, gait stability	Decrease

Table 2 Changes in cardiorespiratory function due to aging or disuse potentially modifiable by physical activity

Cardiorespiratory function	Effect of aging or disuse
Heart rate and blood pressure response to submaximal exercise	Increase
Maximal heart rate[a]	Decrease
Resting heart rate	No change
Maximal cardiac output, stroke volume	Decrease
Endothelial cell reactivity	Decrease
Heart rate variability	Decrease
Maximal skeletal muscle blood flow	Decrease
Capillary density	Decrease
Arterial distensibility	Decrease
Vascular insulin sensitivity	Decrease
Plasma volume, hematocrit	No change, decrease
Postural hypotension in response to stressors	Increase
Total lung capacity, vital capacity[a]	Decrease
Maximal pulmonary flow rates[a]	Decrease

[a]No evidence yet that exercise can prevent or reverse these changes of aging.

Table 3 Changes in metabolism and body composition due to aging or disuse potentially modifiable by physical activity

Metabolic/body composition change	Effect of aging or disuse
Resting metabolic rate	Decrease
Total energy expenditure	Decrease
Thermic effect of meals	Decrease, no change
Total body water	Decrease
Total body potassium, nitrogen, calcium	Decrease
Protein synthesis rate, amino acid uptake into skeletal muscle, nitrogen retention, protein turnover	Decrease
Gastrointestinal transit time	Increase
Appetite, energy intake	Decrease, no change
Glycogen storage capacity, glycogen synthase, GLUT-4 transporter protein content, translocation to membrane	Decrease
Lipoprotein lipase activity	Decrease
Total cholesterol, LDL cholesterol	Increase
HDL cholesterol	Decrease or no change
Hormonal and sympathetic nervous system response to stress	Increase
Growth hormone, IGF-1[a]	Decrease
Heat and cold tolerance, temperature regulatory ability	Decrease

LDL, low density lipoprotein; HDL, high density lipoprotein.
[a]Most training studies show no change in growth hormone or circulating IGF-1 although tissue levels of IGF-1 may increase.

Table 4 Changes in central and peripheral nervous system due to aging or disuse potentially modifiable by physical activity

REM and slow wave sleep duration	Decrease
Cognitive processing speed, accuracy	Decrease or No change
Attention span	Decrease or No change
Memory	No change, Decrease
Executive function	Decrease or No change
Motor coordination, force control	Decrease
Neural reaction time, neural recruitment	Decrease
Autonomic nervous system function	Decrease

REM, rapid eye movement.

musculoskeletal capacity impact on functional status, at least 10 years before men do on average. (Guralnik *et al.*, 1993).

Another important consequence of age-related changes in physiologic capacity is the increased perception of effort associated with submaximal work (a lowering of the anaerobic threshold, or the approximate level at which significant dyspnea occurs). This changing physical capacity has the unfortunate negative side effect of increasing the tendency to avoid stressful activity. Such behavioral change compounds the sedentariness caused by changing job requirements or retirement, societal roles and expectations, and other psychosocial influences. Thus, a vicious cycle is set up: "usual" aging leading to decreasing exercise capacity, resulting in an elevated perception of effort, subsequently causing avoidance of activity, and finally feeding back to exacerbation of the age-related declines themselves secondary to the superimposition of disuse on biological aging.

Many studies suggest that chronic adaptation to physical activity can markedly attenuate decrements in exercise capacity that would otherwise occur with aging (see Tables 1–4), with the notable exception of maximal heart rate (due to declining sensitivity to β-adrenergic stimulation in the aging heart (Scarpace *et al.*, 1992)). Although peak exercise workload achievable is therefore always lower in aged individuals, the cardiovascular and musculoskeletal adaptations to chronic aerobic exercise enable the trained individual to sustain higher submaximal workloads with less of a cardiorespiratory response (heart rate, blood pressure, and dyspnea), as well as less overall and musculoskeletal fatigue.

Musculoskeletal function (strength, power, muscle endurance) in aging is dictated largely by the size of the muscle mass which is contracting, and to a lesser extent by changes in surrounding connective tissue in the joint (cartilage, tendons, and ligaments) and neural recruitment, conduction velocities, glycolytic and oxidative enzyme capacities, and fatigue patterns. Sedentary individuals lose large amounts of muscle mass over the course of adult life (20–40%), and this process, termed *sarcopenia*, plays a major role in the similarly large losses in muscle strength observed in both cross-sectional and longitudinal studies (Asmussen and Heeboll-Nielsen, 1961; Hughes *et al.*, 2002). However, unlike many other changes which impact on exercise capacity, muscle mass cannot usually be maintained into old age even with regular aerobic activities in either general populations or master athletes. Only overloading of muscle with weight-lifting exercise (resistance training) has been shown to largely avert losses of muscle mass (and also strength) in older individuals. For example, Klitgaard *et al.* (1990) found that elderly men who swam or ran had similar measures of muscle size, strength, and metabolism as their sedentary peers, whereas the muscle of older men who had been weight lifting for 12–17 years was almost indistinguishable, and even superior in some aspects, to healthy men 40–50 years younger than them.

Clearly, habitual exercise has the potential to lessen the impact of biological aging on two of the major elements of exercise capacity: aerobic fitness and muscle strength. Similarly, there is evidence that balance training and flexibility training (American College of Sports Medicine *et al.*, 1998) induce adaptations in associated declines in these areas.

OPTIMIZATION OF BODY COMPOSITION WITH AGING

"Usual aging" is associated with significant losses of bone and muscle (lean mass), and increases in adipose tissue, along with central and visceral shifts in the regional distribution of adipose tissue stores. The extent to which these changes occur in an individual depends upon a combination of genetic, lifestyle, and disease related factors that are all interrelated. All of these body composition changes may negatively impact upon metabolic, cardiovascular, and musculoskeletal function (Hughes *et al.*, 2001), even in the absence of overt disease, and therefore it is important to anticipate them and optimize lifestyle choices and other treatments

which can counteract the negative effects of aging and/or disease on body composition. As detailed in the sections that follow and outlined in Table 5, one of the most potent pathways from physical activity to health status involves the modulation of these age-related shifts in body composition by habitual exercise patterns.

Role of Exercise and Physical Activity in Bone Health and Fracture Risk

Age-related Changes in Bone

Bone mass begins to decrease well before the menopause in women (as early as the 20s in the femur of sedentary women), and accelerates in the perimenopausal years, with continued declines into late old age. Similar patterns are seen in men, without the acceleration related to loss of ovarian function seen in women. As with losses of muscle tissue (sarcopenia), many genetic, lifestyle, nutritional, and disease and medication-related factors enter into the prediction of bone density at a given age.

Physical Activity and Bone Health

A wealth of animal and human data provide evidence for a relationship between physical activity and bone health at all ages. Mechanical loading of the skeleton generally leads to favorable site-specific changes in bone density, morphology, or strength, whereas unloading (in the form of bed rest, immobilization, casting, spinal cord injury, or space travel) produces rapid and sometimes dramatic resorption of bone, increased biochemical markers of bone turnover, changes in morphology such as increased osteoclast surfaces, and increased susceptibility to fracture.

Comparative studies of athletic and nonathletic populations usually demonstrate significantly higher bone density in the active cohorts, ranging from 5 to 30% higher, depending upon the type, intensity, and duration of exercise training undertaken, and the characteristics of the athletes studied. Exceptions occur with nonweight-bearing activities such as swimming, or amenorrheic or competitive distance runners, who appear similar to controls. Similarly, on a smaller scale, differences are often observed between habitually active and sedentary nonathletic individuals.

Experimental evidence in animal models as well as some human data suggests that changes in bone strength not directly correlated with density may contribute to the overall benefits of mechanical loading for skeletal integrity and resistance to fracture (e.g. increased bone volume or altered trabecular morphology), so that evaluating bone density changes alone likely underestimates the skeletal effects of loading.

Consistent with bone density findings noted above, hip fracture incidence has been observed to be as much as 30–50% lower in older adults with a history of higher levels of physical activity in daily life, compared to age-matched, less active individuals. For example, in the prospective epidemiology of osteoporosis study (EPIDOS) study of 6901 white women over the age of 75 followed for 3.6 years, investigators found that a low level of physical activity increased the risk for proximal humerus fracture by more than twofold. The relative risk of fracture in sedentary women (RR = 2.2) was greater than that attributable to low bone density (RR = 1.4), maternal history of hip fracture (RR = 1.8), or impaired balance (RR = 1.8). The interaction

Table 5 Exercise recommendations targeting optimal body composition for older adults

Exercise recommendations	Decreased adipose tissue mass and visceral deposition	Increased muscle mass and strength	Increased bone mass, density, and reduced fracture risk
Modality	Aerobic or resistance training	Resistance training	• Resistance training or aerobic training[a] • High impact activities (jumping using weighted vest during exercise) if tolerated by joints • Balance training
Frequency	Aerobic: 3–7 days/week Resistance: 3 days/week	3 days/week	• Resistance or aerobic training: 3 days/week • Balance training: up to 7 days/week
Volume	Aerobic: 30–60 minutes/session Resistance: 2–3 sets of 8–10 repetitions of 6–8 muscle groups	2–3 sets of 8–10 repetitions of 6–8 muscle groups	• 30–60 minutes of aerobic training • 2–3 sets of 8–10 repetitions of 6–8 muscle groups • 50 jumps per session for high impact[b] • 2–3 repetitions of 5–10 different static and dynamic balance postures
Intensity	Aerobic; 60–75% of maximal exercise capacity (VO2 max or maximal heart rate) or 13–14 on the Borg Scale of perceived exertion Resistance: 60–80% of maximal strength (one repetition maximum)	60–80% of maximal strength (one repetition maximum)	• 60–80% of maximal capacity (one repetition maximum) as load • 5–10% of body weight in vest during jumps; jumps or steps of progressive height • Practice most difficult balance posture not yet mastered

[a]Aerobic exercise should be weight-bearing modalities of exercise with high ground-reaction forces (e.g. walking, jogging, running, stepping, rather than swimming or cycling).
[b]Thus far proven only in premenopausal women.

of these risk factors is indicated by the fracture rate, which rose from about 5 per 1000 woman-years in individuals with either bone fragility or high fall risk to 12 per 1000 woman-years for women with both types of risk factors. Such data suggest the great potential utility of multifactorial prevention programs for osteoporotic fracture that can address *both* bone density and fall risk (sedentary behavior, sarcopenia, muscle weakness, poor balance, polypharmacy, etc.) simultaneously.

Exercise Intervention Trials in Postmenopausal Women and Older Men

Metanalyses of the randomized controlled trials of exercise and bone density in postmenopausal women are outlined in Table 6. Significant changes in the femur, lumbar spine, and radius have been seen following aerobic training, resistance training, and combined programs of aerobic and resistive exercise. Unlike results obtained in younger women, isolated high impact training (jumping, skipping, heel drops) has not yet been found to be effective in studies of postmenopausal women. High dropout rates (30–50%) are problematic in these trials, raising the issue of generalizability and sustainability of the outcomes observed. This is particularly relevant to fracture prevention efficacy of exercise, as several studies have shown complete or partial reversal of gains in bone mineral density (BMD) after the cessation of training.

For older men and women, a combination of decreased anabolic hormones (estrogen, testosterone, growth hormone), increased catabolic milieu (higher leptin and cortisol associated with visceral adipose tissue), the emergence of musculoskeletal and other diseases, retirement, and reduced recreational activities have a major negative impact on bone as well as muscle tissue. The majority of studies demonstrating the efficacy of aerobic or resistive exercise on bone density have been conducted in women between 50 and 70 years of age, and it is not yet known if efficacy would be similar in older women with multiple comorbidities, who have usually been excluded from such trials. Both types of exercise have approximately equivalent effects on bone health in postmenopausal women of about 1–1.5% per year between exercisers and nonexercisers in meta-analyses of well-designed trials (Kelley, 1998a,b; Wolff *et al.*, 1999; Wallace and Cumming, 2000; Kelley *et al.*, 2001).

Optimal Exercise Modality and Intensity for Bone Health

The predominant exercise training factor that influences bony adaptation is the intensity and novelty of the load, rather than the number of repetitions, sets, or days per week, or even total duration of the program. This observation is also true for animal models of mechanical loading, in which bone is most sensitive to short periods of loading characterized by unusual strain distribution, high strain magnitudes, and rapid rate of loading.

The relative efficacy of aerobic versus resistive exercise regimens for postmenopausal women may be perhaps best assessed via studies that have directly compared various intensities of these two exercise modalities in randomized subjects. Kohrt *et al.* (1997) found that both aerobic activities with high ground-reaction forces (walking, jogging, stair climbing) and exercises with high joint-reaction forces (weight lifting, rowing) significantly increased BMD of the whole body, lumbar spine, and Ward's triangle, whereas only the ground-reaction group increased BMD at the femoral neck (Kohrt *et al.*, 1997). The weight-lifting group preserved femoral neck BMD relative to controls, as has been seen in other resistance training studies (Kerr *et al.*, 2001). However, lean mass and muscle strength increased only in the weight-lifting group, leaving overall benefits of these two types of exercise for ultimate fall and fracture prevention still unresolved. Kerr randomized 126 postmenopausal women to 2 years of high-intensity weight-lifting exercise, moderate-intensity aerobic training (circuit training and stationary cycling), or sedentary control condition. Total hip and intertrochanteric BMD was improved only by strength training, and was significantly different from aerobic training or control groups (+3.2% at 2 years). As most comparative studies other than Kohrt's (Kohrt *et al.*, 1997) and Kerr's (Kerr *et al.*, 2001) have not sought to optimize both modalities, it is still not possible to definitively choose one best modality for all bone sites. In general, the older the individual, the more favorable the resistance training appears, due to its broader benefits on muscle, bone, balance, and fall risk, relative to aerobic training. If aerobic training is chosen, however, activities that are weight bearing and higher impact have a greater efficacy than nonweight-bearing or low-impact aerobic activities.

It is important to consider not only the optimal modality of exercise, but also the relative intensity, as the skeletal adaptation is critically linked to the *intensity* of the loading (whether due to increased amount of weight lifted during resistance training, or higher ground-reaction forces during aerobic/jumping activities). Interesting results have been reported recently by Cussler *et al.* (2003), in a randomized trial of 140 postmenopausal women participating in a multimodal exercise program (high-intensity resistance training, and a weight-bearing circuit of moderate-impact activities including walking/jogging, skipping, hopping, stair climbing/stepping with weighted vests). Bone density improvements at the femoral trochanter were significantly and linearly related to total weight lifted during the 12 months, as well as total weight lifted in leg press, squats, and military press exercises, but not to volume or quality of the nonresistance training components of the program. High-intensity resistance training is also more beneficial than low-intensity training for muscle strength gains and muscle hypertrophy, as well as associated gait disorders, functional impairments, and disability, making it ideal as a multiple risk factor intervention strategy for injurious falls in osteopenic women.

Exercise in the Treatment of Osteoporotic Fracture

In older men and women who have already sustained an osteoporotic fracture, exercise is still extremely important to assist in recovery of function as well as prevent recurrent

Table 6 Metanalyses of physical activity and bone density

Reference	Population	Studies included	Total number of trials, subjects	Type of exercise	Study treatment effect[a]	Significance level
Berard *et al.* (1997)	Healthy women >50 years of age without osteoporosis	Prospective controlled intervention trials	18 trials 1966–1996	Walking, running, physical conditioning, aerobics		Lumbar spine <0.05 Forearm = ns Femoral neck = ns
Kelley (1998a)	Postmenopausal women	Prospective controlled intervention trials	10 trials 1975–1994; 330 subjects	Aerobic activity	Lumbar spine +2.83%	Lumbar spine <0.05
Kelley (1998a)	Postmenopausal women	Prospective controlled intervention trials	6 studies, 1978–1995	Aerobic exercise	Hip +2.42%	Hip <0.05
Kelley (1998b)	Postmenopausal women	Randomized controlled trials	11 studies 1975–1995; 719 subjects	Aerobic or strength training	Any exercise +0.27% Aerobic +1.62% Strength +0.65%	All sites <0.05
Wolff *et al.* (1999)	Pre and postmenopausal women	Prospective controlled intervention trials	25 studies, 1966–1996	Aerobic, high impact, or strength training at least 16 weeks duration	Premenopausal Aerobic + strength Lumbar spine +0.90% Femoral neck +0.90% Postmenopausal Aerobic Lumbar spine +0.96% Femoral neck +0.90% *Strength training* Lumbar spine +0.44% Femoral neck 0.86% Aerobic + strength Lumbar spine 0.79% Femoral neck 0.89%	All sites and modalities significant (<0.05) except for strength training in postmenopausal women

Kelley *et al.* (2001)	Pre- and Postmenopausal women	Prospective controlled trials	29 studies 1966–1998, 1123 women	Resistance training	Femur +0.38% Lumbar spine +1.26% Radius +2.17%	Femur nonsignificant Lumbar spine <0.05 Radius <0.05

[a] Study treatment effect is the difference between the percentage changes per year in bone mass (bone density or bone mineral content) in the training group minus the control group. A positive figure indicates a protective effect of exercise. Results are annualized for studies less than 12 months duration, assuming a linear rate of change in bone mass.

injurious falls (AGS/BGS, 2001; Hauer *et al.*, 2001). Progressive resistance training has been shown to be superior to standard physical therapy during the recovery from hip fracture in elderly patients. In addition, resistance training has been shown to be a potent treatment for depression in the elderly, and may thus be able to substitute for antidepressant medications, which are known to increase the risk of falls and hip fracture. A combination of resistance training and balance training may offer the best approach to rehabilitation in this setting, as it optimally targets several of the remediable physiological risk factors for falls, fractures, and disability in this cohort. Additional studies are needed to define the effects of training in this clinical setting on bone density and strength itself, as well as the optimal timing and duration of such interventions in the postfracture recovery period.

Role of Exercise and Physical Activity in Adipose Tissue Accretion and Distribution

The rising epidemic of obesity is now recognized internationally in both younger and older cohorts, and is projected, if it continues, to lead to major changes in related diseases such as diabetes, as well as life expectancy itself. Prevention of excess adiposity is both protective, and in some cases therapeutic, for many common chronic diseases, offering significant risk reduction in the case of osteoarthritis, cardiovascular disease, gall bladder disease, type 2 diabetes, breast, colon, and endometrial cancer, hypertension, stroke, and vascular impotence, for example. Although generalized obesity is associated with excess mortality, cardiovascular disease, osteoarthritis, mobility impairment, and disability, it is predominantly excess visceral fat that is associated with the derangements of dyslipidemia, elevated fibrinogen, hyperinsulinemia, glucose intolerance or diabetes, vascular insulin resistance, hypertension, and cardiovascular disease (Despres *et al.*, 2001) known as *metabolic syndrome* or *insulin resistance syndrome*. Reductions in visceral fat have been shown to improve glucose tolerance and insulin sensitivity in nondiabetic (Ross *et al.*, 2000), and type 2 diabetics subjects and changes in trunk fat correlate with improved glycemic control in type 2 diabetics (Castaneda *et al.*, 2002). Thus, the potential for exercise to impact favorably on the accretion and distribution of adipose tissue, as reviewed below, has enormous significance in that it may reduce the burden of disease expressed in the aging population.

Cross-sectional Studies of Physical Activity and Fat Mass

Numerous cross-sectional analyses have confirmed an inverse relationship between physical activity and abdominal fat. Master athletes compared to age and BMI-matched controls have lower waist circumference, and physically active women have lower waist-to-hip ratios than inactive women. Tremblay and colleagues determined that the higher the intensity of activity independent of energy expenditure, the lower the abdominal fat estimates for men and women. In a study of monozygotic and dizygotic female twins, physical activity was the strongest predictor of central obesity after controlling for genetic and environmental factors, and this persisted for those with a genetic predisposition to obesity.

Experimental Studies of the Influence of Physical Activity on Abdominal Fat

In the last few years, there has been accumulating evidence from well-designed studies supporting the benefit of physical activity in reducing total abdominal fat. There is no evidence that age limits abdominal fat loss secondary to exercise. In fact, most studies have included middle to older age populations who have higher accumulation of abdominal and visceral fat than younger adults. They are more likely to demonstrate a greater magnitude of change than subjects who have lower abdominal fat mass at baseline (Smith and Zachwieja, 1999). Furthermore, the potential for physical activity to attenuate the gain in visceral fat is evident in the obese as early as childhood.

Decreases in both total adipose tissue accumulation and its abdominal (visceral) deposition are achievable by both aerobic and resistive training, with significant changes in total body fat usually only in conjunction with an energy-restricted diet (Ballor and Keesey, 1991) or very large volumes of exercise (7 hours per week). Preferential visceral fat mobilization is often seen in response to exercise and dietary intervention, which means that small amounts of total body weight or fat mass (5%) may be associated with substantial changes in visceral fat (25% or more), with important metabolic implications for the prevention or treatment of the insulin resistance syndrome (Despres *et al.*, 2001).

Exercise and diet in combination are the most effective nonsurgical treatment for obesity, and this approach is uniformly advocated by international consensus panels (Grundy *et al.*, 1999). The advantages of adding exercise to diet alone include greater weight loss, preservation of fat-free mass, and resting metabolic rate, improved fitness levels, correction of metabolic abnormalities associated with visceral obesity, and better long-term adherence to dietary modifications producing sustained weight maintenance. Therefore, robust exercise plus diet appear to represent an optimal evidence-based treatment for obesity.

Relationship between Exercise Intensity and Changes in Body Fat

In general, weight loss parallels energy expenditure via exercise, whether achieved by greater volumes, intensities, or durations of the exercise prescription. There is no evidence yet from well-designed studies that low-intensity exercise is effective for reducing abdominal fat. Most robustly designed studies have used moderate- to high-intensity aerobic interventions. An overall higher-intensity stimulus can be delivered via intermittent intensities with resistance or interval

training, a prescription which may be effective and more easily tolerated by "at-risk" populations than sustained, intense exercise.

Relationship between Exercise Modality and Changes in Body Fat

There is no evidence that aerobic training is better than resistance training for reducing abdominal fat. Both resistance and aerobic exercise, at doses resulting in a sustained negative energy balance for several months, will generally result in significant reductions in fat mass when sensitive measurement techniques (generally not anthropometrics) are used. Resistance exercise may be more suitable as a fat reduction strategy for older obese individuals who have cardiovascular disease, arthritis, osteoporosis, or mobility disorders, who may not tolerate moderate- to high-intensity aerobic training, or who may need the added benefits of resistance training for maintenance of muscle and bone mass. Importantly, energy restriction results in significant losses of muscle and bone, and the addition of resistance training to hypocaloric dieting has been shown to prevent such adverse body composition changes (Ballor *et al.*, 1996), while aerobic exercise alone does not. Combined aerobic and resistance training has demonstrated a superior effect to aerobic training alone on trunk fat for older men. More well-designed studies are needed, particularly in overweight older adults, to explore the relative benefits of these modes of exercise for optimizing body composition.

Role of Exercise in Muscle Mass Preservation with Age

An increase in muscle mass, in contrast to changes in fat and bone, is only achievable to a significant degree with progressive resistance training or generalized weight gain from extra energy and protein consumption (McCartney *et al.*, 1995), and has a potential role in prevention of diabetes (Tuomilehto *et al.*, 2001), functional dependency (Chumlea *et al.*, 1997), and falls and fractures (Lauritzen *et al.*, 1993), as well as being important in the treatment of chronic diseases and disabilities which are accompanied by disuse, catabolism, and sarcopenia. For some diseases, like type 2 diabetes mellitus, there are potential advantages to both minimizing fat tissue as well as maximizing muscle tissue, since these compartments have opposite and likely independent effects on insulin resistance in the elderly (Despres, 1998). Muscle wasting or atrophy from any cause will exacerbate problems related to the extent and rate of the peripheral disposal of glucose into skeletal muscle, which is essential for maintenance of euglycemia in response to normal metabolism, meals, or other stressors. There is evidence from a variety of epidemiological and experimental studies that muscle weakness, decreased muscle mass, decreased activation of glycogen synthase, and alterations in numbers of Type IIb skeletal muscle fibers are related to, and may precede, insulin resistance, glucose intolerance, and type 2 diabetes expression. Thus, the typical alterations in body composition with aging (decreased muscle mass and increased visceral adiposity) are potentially independently related to the development of impaired glucose homeostasis in older adults.

Exercise to Maintain or Increase Muscle Mass

Appropriate progressive resistance training programs of 3–6 months' duration can be shown to increase muscle strength by an average of 40–150%, depending on the subject characteristics and intensity of the program, and to increase total body lean mass by 1–3 kg, or muscle fiber area by 10–30% (Fiatarone *et al.*, 1994; Pyka *et al.*, 1994). Thus, even if some of the neural control of muscle and absolute number of motor units remaining is not affected by exercise, the adaptation to muscle loading, even in very old age (Fiatarone Singh *et al.*, 1999) causes neural, metabolic, and structural changes in muscle which can compensate for the strength losses, and in some cases the atrophy, of aging. Generally, strength gains after exercise far exceed, and are not directly correlated with, changes in muscle size, due to the importance of neural adaptation in this process.

Predictors of Muscle Hypertrophy After Exercise

There is some controversy as to whether or not there are significant gender differences in the functional or hypertrophic response to resistance training in the elderly. Some studies have found women to have smaller gains in muscle strength and power (Jozsi *et al.*, 1999) or hypertrophic response (Ivey *et al.*, 2001) to training, while others have found no differences or even greater gains in women (Haikkinen *et al.*, 1998). It is likely that differences in training regimens (particularly related to intensity) and measurement techniques used to assess muscle mass, cross-sectional area, or volume may explain some of these discrepant results. Malnutrition, impaired protein synthesis rates, inflammatory cytokines, and depression are other factors that have been identified as detrimental to robust anabolic adaptations to resistance training in some studies.

High-velocity Resistance Training

A relatively recent area of investigation is that of power training (high-velocity resistance training), which has been proposed as a better way to target the selective fast-twitch fiber atrophy characteristic of aging muscle, as well as the earlier and more precipitous decline in muscle power and its associated disability, relative to muscle strength in older men and particularly women. Power training has been shown to be effective in both healthy (de Vos *et al.*, 2005) and frail elders (Fielding *et al.*, 2002), and results in muscle hypertrophy, strength and power gains, improvements in balance, and functional performance. Optimal training regimens for maximization of muscle power are still being defined.

PROMOTION OF PSYCHOLOGICAL WELL-BEING

Psychological well-being is vital to optimal aging, and is dependent on a host of factors, including genetic traits, social support systems, personality types, and the presence of positive and negative psychological constructs such as happiness, optimism, morale, depression, anxiety, self-esteem, self-efficacy, and vigor. Physical activity participation has been shown to be associated with more positive psychological attributes and a lower prevalence and incidence of depressive symptoms in cross-sectional and prospective epidemiological studies (McAuley and Rudolph, 1995) and experimental trials (Singh *et al.*, 2001, 2005). It is notable that effects are most significant in those with comorbid illness, such as cardiovascular or pulmonary disease (North *et al.*, 1990) or major depression (Blumenthal *et al.*, 1999; Singh *et al.*, 2001), attesting to the clinical relevance of this exercise adaptation.

The experimental evidence for exercise as an isolated intervention for the treatment of clinical depression in both younger and older cohorts is robust and consistent. Both aerobic and resistance training exercise produce clinically meaningful improvements in depression in such patients, with response rates ranging from 25 to 88%. In the studies that have addressed the issue of exercise modality, resistance training was found to be equivalent to aerobic training in young adults with depression (Doyne *et al.*, 1987), and yoga as effective as aerobic exercise. Blumenthal directly compared high-intensity aerobic exercise to antidepressant medications in older adults with major depression, and found the two approaches equipotent, with no added benefit of combined exercise and medication (Blumenthal *et al.*, 1999). Singh has compared high and low-intensity progressive resistance training to GP referral and care in older adults with major depression, and found that a clinical response (50% reduction in Hamilton Rating Scale for depression) was achieved in 61% of high-intensity training, 29% of low-intensity training, and 21% of the GP care group (Singh *et al.*, 2005). Similarly, low-intensity aerobic training in older adults with depression has been shown to be similar in efficacy to social contact, reducing depression scores by only 30% (McNeil *et al.*, 1991). Thus, the literature on exercise and depression suggests that it is effective in young and old, it is approximately as effective as antidepressants in clinical cohorts, that both aerobic and resistance modalities appear equally beneficial, and that optimal responses are seen with higher intensities of training.

EXERCISE AND COGNITIVE FUNCTION

There is a growing body of observational data and experimental evidence that physical activity can exert significant influences on a wide range of cognitive functions (Kramer *et al.*, 2004). The earliest lines of evidence were provided by cross-sectional studies of athletes or physically active individuals versus sedentary controls, with active or fit individuals demonstrating superior performance in tests of reaction time, motor control, or visual-spatial tasks. Changes in executive-control processes as well as changes in brain structures and functions most closely related to these processes are disproportionately affected by aging and exercise in some studies (Cotman and Berchtold, 2002; Kramer *et al.*, 2004). This has led to speculation that age-related cognitive dysfunction might be partially mediated by suboptimal and diminishing participation in physical activity across the lifespan. Virtually all of these studies have focused on cardiorespiratory fitness (maximal oxygen consumption) or aerobic exercise as the putative protective factor. However, approximately 50% of the variance in maximal oxygen consumption in children and adults is thought to be mediated by genetic factors rather than physical activity patterns (Fiatarone Singh, 2002), raising the possibility that shared predisposition to low fitness, vascular risk factors, and cognitive decline may explain these associations, rather than adaptation to an active lifestyle. In addition, changes in maximal oxygen consumption with aging are explained as much by losses of muscle mass (sarcopenia) as they are by losses of cardiovascular reserve (Fleg and Lakatta, 1988), suggesting that nonaerobic activities could be just as important as aerobic activities for the prevention of cognitive decline.

More recently, well-designed prospective cohort studies that have controlled for many known risk factors for cognitive dysfunction have in large part supported cross-sectional associations between physical activity patterns and risk of dementia (Laurin *et al.*, 2001). For example, in the Honolulu-Asia Aging Study (Abbott *et al.*, 2004), 2257 physically capable, cognitively intact men aged 71–93 were followed for 7 years for incident dementia. Walking significantly reduced the risk of dementia in a dose-dependent fashion, with a 1.8-fold increased risk for those who walked less than 0.25 m/day compared to >2 m/day, controlling for other possible risk factors.

Acute exposure to even one bout of aerobic exercise may result in improved cognitive test performance, as well as reduced depressive symptoms and anxiety. It is not known how long such acute bout effects persist, whether weight-lifting exercise has similar acute effects on cognition, or what proportion, if any, of the chronic exercise effects are explained by cumulative acute bout effects. Animal data demonstrate that voluntary wheel running (not stressful forced swimming) is a powerful means to enhance neural plasticity and function (Rhodes *et al.*, 2003), improving learning and memory, as well as increasing the availability of brain-derived neurotrophic factor (BDNF), formation of new neurons, and synaptic transmission in the hippocampus. Exercise also protects against the neurotoxicity of aging, stress, cortisol, or estrogen withdrawal in these animal models, and potentiates the beneficial effect of estrogen and antidepressants on hippocampal volume and metabolism.

The evidence from human trials is mixed, but three (Etnier *et al.*, 1997; Colcombe and Kramer, 2003; Heyn *et al.*, 2004) recent meta-analyses have concluded that exercise improves cognitive function, with an average effect size of approximately 0.4–0.6. The systematic review by Colcombe and

Kramer (2003) suggests that exercise effects are strongest when aerobic and weight-lifting exercises are combined, and when the dose of exercise is adequate (at least 30 minutes per session, greater than 6 months in duration).

Potential mechanisms by which exercise could improve cognitive function include changes in fitness, increased cerebral blood flow, reduction in depression, increase in presence or activity of neurotrophic factors (BDNF, insulin-like growth factor-1, IGF-1), downregulation of neurotoxic factors (C-reactive protein, cortisol, interleukin-6 (IL-6), and other inflammatory cytokines, and prevention or better control of chronic disease (e.g. stroke, diabetes, cardiovascular disease). Considering the nonrobust nature of most of the interventions reported in Heyn's meta-analysis of cognitively impaired elders (Heyn *et al.*, 2004), it does not appear that increases in aerobic capacity are required for cognitive benefits to accrue, as was previously thought. Cognitive benefits seen after nonaerobic exercise also cast doubt on a central role for aerobic capacity. The other mechanisms noted above appear more likely at this time. Exercise does increase cerebral blood flow acutely, as do cognitive tasks, and increased frontal cortex capillary density has been observed in animal models after exercise training, suggesting a possible common pathway for improved brain oxygenation and, thereby, function. Many of the most promising mechanisms in animal models have yet to be confirmed in human studies. Further exploration of the potential mechanisms of benefit in this crucial domain of health and function is needed, including studies linking changes in cerebral blood flow, depressive symptoms, physical fitness or burden of chronic disease, and disability to cognitive changes associated with exercise participation.

DISEASE PREVENTION THROUGH EXERCISE

Both healthy and chronically ill older adults are candidates for preventive strategies that will lessen the burden of comorbidity, disability, and premature death caused by incident disease. Physical activity patterns may be influenced by aging and genotype, and physical activity in turn may influence physiological capacity, psychological health, dietary intake, other adverse behaviors, or risk factors for chronic disease. All of these are potential pathways by which exercise could ultimately influence the prevalence of chronic disease in a population. Other than genetic factors and environmental insults (pollution, asbestos, heavy metals, infectious agents, etc.), most of the major contributors to the development or severity of chronic diseases are in some way related to habitual levels of physical activity. Examples would include cardiovascular disease (Blair *et al.*, 1995), stroke (Hu *et al.*, 2000), type 2 diabetes (Tuomilehto *et al.*, 2001), obesity, hypertension (Pereira *et al.*, 1999), osteoarthritis (Ettinger *et al.*, 1997), depression (Blumenthal *et al.*, 1999), and osteoporosis. A notable exception to these patterns is the diseases of the central nervous system (CNS) (e.g. Parkinson's disease, other degenerative neurological diseases) that have not been substantively linked etiologically with exercise or physical activity.

While appropriate levels of physical activity may optimize such risk factor profiles, on the other hand, the presence of risk factors may lead to reduced physical activity and thus heightened risk of disease. For example, inactivity may lead to sarcopenia, followed by muscle weakness and further restriction in activity levels, subsequently contributing to the development of osteopenia and gait abnormalities, and finally hip fracture.

Although observational studies can never completely separate the effects of physical activity from genotype or other unmeasured characteristics of individuals who self-select an active lifestyle, the best studies attempt to control for demographic differences, other known risk factors for the incident disease, and eliminate early or occult disease at baseline if possible prior to analysis. So, for example, exercise reduces the risk of cardiovascular disease by approximately 50%, even after controlling for such risk factors as smoking, obesity, hypertension, and dyslipidemia.

Longitudinal cohort studies have generally confirmed the cross-sectional data linking exercise to reduced disease risk. Of particular interest are studies such as those by Blair *et al.* (1995), in which middle-aged sedentary adults with low fitness levels have become fit at follow-up, and have markedly reduced cardiovascular mortality compared to those remaining unfit or inactive. These findings suggest that preventive exercise prescriptions instituted in middle age or beyond may be as important as those initiated at younger ages.

Randomized clinical trial data is now available for prevention of some disease states (cardiovascular disease, diabetes mellitus, and falls) but not yet available for others (stroke, osteoporotic fracture, depression). Diabetes is clearly preventable in high-risk obese adults with impaired glucose tolerance randomized to exercise and diet, as shown in the Finnish Diabetes Study (Tuomilehto *et al.*, 2001) and the Diabetes Prevention Program (DPP) (Diabetes Prevention Program Research Group, 1999). Similar to Finnish subjects, DPP participants randomly assigned to the intensive lifestyle intervention of diet and exercise reduced their risk of incident type 2 diabetes by 58% by 3 years. Of particular interest is the finding that those over the age of 60 responded best, with a 71% reduction in incident diabetes in this time frame.

The major diseases and syndromes for which exercise may be beneficial as a preventive strategy are listed in Table 7, along with the postulated mechanisms of exercise benefit, and the specific modality of exercise most relevant for these outcomes.

EVIDENCE FOR THE ROLE OF EXERCISE IN THE TREATMENT OF DISEASE

Mechanisms of Benefit

There are many ways to conceptualize the integration of exercise into the treatment of established disease. For example,

Table 7 Potential mechanisms by which exercise can prevent disease

Disease or syndrome	Postulated mechanisms of exercise effect	Recommended exercise modality
Arthritis	• Decreased body weight • Maintenance of cartilage integrity • Maintenance of muscle and tendon strength	Aerobic exercise[a] Resistance exercise[a]
Cancer (breast, colon, prostate)	• Decreased body fat • Decreased estrogen levels • Altered dietary intake • Decrease in gastrointestinal transit time • Increased prostaglandin F_2	Aerobic exercise
Chronic renal failure	• Reduced risk of hypertension • Reduced risk of type 2 diabetes mellitus	Aerobic exercise Resistance exercise[a]
Congestive heart failure	• Decreased risk of ischemic heart disease • Decreased risk of hypertension • Decreased risk of type 2 diabetes mellitus	Aerobic exercise[a] Resistance exercise[a]
Coronary artery disease	• Decreased blood pressure • Decreased cholesterol, LDL • Increased HDL cholesterol • Decreased fibrinogen • Decreased total body fat, visceral fat • Decreased insulin resistance, hyperinsulinemia • Decreased cortisol levels, inflammatory cytokines • Increased adherence to smoking cessation, dietary behaviors • Decreased depression, anxiety • Improved endothelial cell function	Aerobic exercise Resistance exercise
Dementia	• Improved cerebral blood flow • Increased neurotrophic factors in CNS • Hippocampal neurogenesis	Aerobic exercise
Depression	• Increased self-efficacy, mastery • Internalized locus of control • Decreased anxiety • Improved sleep • Increased self-esteem • Increased social engagement; decreased isolation • Decreased need for drugs associated with depression (beta-blockers, alpha-blockers, sedative hypnotics) • Decreased body fat, improved body image	Aerobic exercise Resistance exercise[a]
Osteoporotic fracture	• Increased bone density • Increased tensile strength • Increased muscle mass • Improved gait stability and balance • Improved nutritional intake (energy, protein, calcium, vitamin D) • Reduced fear of falling, improved self-efficacy • Increased overall activity levels, mobility • Decreased need for drugs associated with postural hypotension, falls, hip fractures (antidepressants, antihypertensives, sedative-hypnotics)	Resistance exercise[a] Aerobic exercise[a] Balance exercise[a]
Stroke	• Decreased obesity • Decreased blood pressure • Decreased cholesterol	Aerobic exercise Resistance exercise[a]
Type 2 diabetes mellitus	• Improved insulin sensitivity • Increased GLUT-4 protein and translocation to membrane sites • Reduced visceral fat mass • Decreased cortisol response to stress • Improved dyslipidemia • Decreased blood pressure • Increased muscle mass	Aerobic exercise Resistance exercise (combined with diet and aerobic exercise)

[a]Indicates that the modality of exercise has been shown to affect the postulated mechanistic factors, but not yet shown to prevent the distal disease outcome.

traditional medical interventions do not typically address disuse syndromes accompanying chronic disease, which may be responsible for much of their associated disability. Exercise is particularly good at targeting syndromes of disuse, and may thus significantly impact on disability without altering the underlying disease itself in any primary way. Examples would include Parkinson's disease (Reuter *et al.*, 1999), chronic obstructive pulmonary disease (Cambach *et al.*, 1999), and chronic renal failure. Exercise may also lower the risk for recurrences of a disease, such as secondary events in patients with cardiovascular disease (U.S. Department of Health and Human Services, 1996) or prevention of recurrent injurious falls in an individual after a hip fracture. Some pathophysiological aberrations that are central to a disease are specifically addressed by exercise, which may therefore serve as an adjunct to standard care. For example,

losses of visceral fat achieved through resistive or aerobic training improve insulin resistance and complement dietary and pharmacological management of type 2 diabetes in the older adult with central obesity (Weinstock *et al.*, 1998). Exercises designed to stimulate skeletal muscle hypertrophy in congestive heart failure provide benefit that counteracts the catabolic effects of circulating cytokines in this disease (Anker *et al.*, 1998), and is not achievable with cardiac medications alone. Functional improvements in individuals with arthritis (American Geriatrics Society Panel on Exercise and Osteoarthritis, 2001; McCarthy and Oldham, 1999) who are given quadriceps exercises improve joint stability and may thus add to the benefits of anti-inflammatory and analgesic medications. It is not possible in this chapter to review every disease in which exercise has beneficial effects, and therefore we will use type 2 diabetes as one example of the diseases outlined in Table 8.

Exercise in the Treatment of Type 2 Diabetes

The prevalence of type 2 diabetes appears to be rising precipitously, linked to the rise in obesity throughout the world (Shaw *et al.*, 2000). The vast majority of these individuals have scope for lifestyle modification, in particular, suboptimal levels of physical activity. Cardiovascular disease accounts for one-half of the mortality in older type 2 diabetics (Tan *et al.*, 2004), emphasizing the complex clinical syndrome represented by this cohort.

The value of tight regulation of glucose in type 2 diabetics has been convincingly demonstrated in the UK Prospective Diabetes Study, among others (American Diabetes Association, 2005). This is particularly important in the elderly, who may have glucose intolerance and then diabetes for many decades, and are therefore at extremely high risk of end organ damage due to glycosylation of body proteins. Although glycemic control has been proven to be highly effective in controlling diabetes, the deleterious effects of central obesity and lack of exercise can undo the benefits of proper medical management, and therefore may hasten the emergence of disease complications in susceptible individuals with insulin resistance. Weight loss diets are clearly central to the management plan of obese type 2 diabetics, and may be aided by the use of metformin as an appetite suppressant or acarbose as a means to decrease the extent of carbohydrate absorption. However, the difficulty of long-term weight management via

Table 8 Exercise and disease treatment

Disease state	Exercise of choice	Considerations
Arthritis	Aerobic	Low impact
	Resistance training	Sufficient volume to achieve healthy weight if obese
Chronic insomnia	Aerobic	Exercise 4–6 hours before desired bedtime to maximize effects
	Resistance training	
Chronic obstructive pulmonary disease	Aerobic	Resistance training may be more tolerable in severe disease; combined effects complementary if feasible
	Resistance training	Time exercise sessions to coincide with bronchodilator medication peak
		Use oxygen during exercise as needed
Chronic renal failure	Aerobic	Exercise reduces cardiovascular and metabolic risk factors, improves depression
	Resistance training	Resistance training offsets myopathy of chronic renal failure
Congestive heart failure	Aerobic	Resistance training may be more tolerable if dyspnea severely limits aerobic activity
	Resistance training	Cardiac cachexia targeted by resistance training
Coronary artery disease	Aerobic	Complementary effects on exercise capacity and metabolic profile from combined exercise modalities
	Resistance training	Resistance training may be more tolerable if ischemic threshold is very low due to lower heart rate response to training
Depression	Aerobic	Moderate- to high-intensity exercise more efficacious than low-intensity exercise in major depression
	Resistance training	Minor depression may respond to wider variety of exercise modalities and intensities
Hypertension	Aerobic	Small-moderate reductions in systolic and diastolic pressures seen
	Resistance training	Larger changes if weight loss occurs
Obesity	Aerobic	Sufficient energy expenditure to induce deficit
	Resistance training	Resistance training maintains lean tissue (muscle and bone) better than aerobic training during weight loss
Osteoporosis	Aerobic	Aerobic exercise should be weight bearing
	Resistance training	High impact, high velocity activity (e.g. jumping) potent if tolerable; avoid if osteoarthritis present
	Balance training	Resistance training effects are local to muscles contracted
		Balance training should be added to prevent falls
Peripheral vascular disease	Aerobic	Vascular effect is systemic, upper limb ergometry may be substituted for leg exercise if necessary
		Resistance training has positive but less robust effect on claudication
		Need to exercise to the limits of pain tolerance each session to extend time to claudication
Venous stasis disease	Aerobic	Local muscle contractions stimulate return of fluid via lymphatic system
	Resistance training	Utilize lower body training, elevate legs when possible

dietary restriction is well known in the clinical setting, due to a variety of factors that impede such behavioral change in older adults. In addition, weight cycling due to repetitive attempts at sustained weight loss leads to losses of lean tissue (muscle and bone) and decreases in metabolic rate, thus worsening the energy balance equation in the end, and making dietary management more and more difficult. Therefore, the standard care of obese type 2 diabetics leaves the majority of them suboptimally managed in relation to their primary metabolic derangement: *insensitivity to the action of insulin.*

All consensus panels recommend aerobic exercise as part of the management plan in type 2 diabetes. Moderate- or high-intensity aerobic exercise of 3–4 hours per week results in improved insulin sensitivity and glucose homeostasis, assists in attainment or maintenance of lower body weight, reduces visceral fat depots, modestly improves blood pressure and lipids, and lowers the risk of cardiovascular morbidity and mortality.

However, the clinical management of the obese elderly patient with this disease is often complicated by increasing insulin resistance and resultant polypharmacy, as well as multiple other comorbid health conditions that impede compliance with both diet and aerobic exercise and reduce quality of life. For example, it would not be unusual for an older diabetic to present with obesity, osteoarthritis, ischemic heart disease, hypertension, gout, hyperlipidemia, peripheral vascular disease, sleep apnea, peripheral neuropathy, a gait and balance disorder, functional impairment, renal disease, postural hypotension, bladder dysfunction, retinal disease, and depression. Such *disease clustering* makes the application of standard dietary and exercise recommendations as well as intense pharmacological management a challenge to practitioner and patient alike. It is not surprising that aerobic exercise recommendations, endorsed by all international consensus panels, are often difficult or impossible to implement in such patients. In particular, obesity, osteoarthritis, amputations, visual impairment, foot problems, fall risk, orthostatic hypotension, peripheral vascular disease, and a low threshold for ischemia may make aerobic exercise at the volumes and/or intensities shown to produce metabolic benefits in clinical trials unrealistic in practice.

An alternative approach to aerobic exercise recommendations for diabetics is the use of progressive resistance training. Insulin resistance is worsened by loss of muscle mass, decreased glucose transport into skeletal muscle and subsequent glycogen storage, catabolic/inflammatory mediators, inactivity, visceral fat, and related inflammatory cytokines such as IL-6 and C-reactive protein. The specific indications for resistance training in older diabetics include its ability to combat age and diabetes-related sarcopenia, to prevent loss of muscle and bone mass and reduced resting metabolic rate which otherwise accompanies hypocaloric dieting, to increase glucose uptake and storage in skeletal muscle, to reduce visceral fat depots, to reduce C-reactive protein, as well as its beneficial effects on resting blood pressure, functional status, mobility, sleep, and depressive symptoms. The effects on muscle mass are unique to high-intensity resistance training, and clearly distinguish it from aerobic exercise. For this reason, some experts are currently recommending its addition to recommendations for aerobic exercise and dietary modification (Sigal *et al.*, 2004). A review of the randomized controlled trial evidence upon which such recommendations are made is presented in Table 9. Although there is strong preliminary evidence that weight lifting exercise improves metabolic control and cardiovascular risk factors in type 2 diabetes, there have been only two published, randomized controlled trials of resistance training as an *isolated* intervention to augment usual care in type 2 diabetes (Castaneda *et al.*, 2002; Baldi and Snowling, 2003) to date.

Exercise to Counteract Iatrogenic Disease

Finally, exercise may counteract undesirable side effects of standard medical care, a use of exercise that is just emerging in the literature. Such use of exercise would include resistance training for patients receiving corticosteroid treatment to counteract the associated proximal myopathy and osteopenia (Storer, 2001), neutralizing the adverse effects of energy-restricted diets in obesity (Ballor *et al.*, 1996) or protein-restricted diets in chronic renal failure (Castaneda *et al.*, 2001), for example.

Osteopenia associated with corticosteroid usage appears to be completely eliminated by concurrent progressive

Table 9 Randomized controlled trials including resistance training in type 2 diabetes

Author	N (age)	Duration of training (months)	Resistance training intensity	Other additional intervention	Significant improvement in insulin sensitivity or glucose homeostasis
Dunstan *et al.* (2002, 2005)	36 (60–80 years)	12 (6 months supervised)	High	Moderate weight loss program	Yes, for supervised phase but not home-based, free-weight phase
Balducci *et al.* (2004)	120 (60.9 years)	12	Moderate	Aerobic at 40–80% HR	Yes
Baldi and Snowling, 2003	18 (46.5 years)	2.5	Moderate	None	Yes
Cuff *et al.* (2003)	28 (60.0 years)	4	Low	Aerobic at 60–75% HR	Yes
Loimaala *et al.* (2003)	50 (53.3 years)	11	High	Aerobic at 65–75% HR	Yes
Attema *et al.* (2002)	85 (age not reported)	6	High	Aerobic at 75% HR	Yes
Castaneda *et al.* (2002)	62 (66 years)	4	High	None	Yes
Dunstan *et al.* (1998)	27 (51 years)	2	Moderate	Low-intensity cycling between each set	Yes

resistance training, which should be recommended for all such patients (Braith *et al.*, 1996). Although bisphosphonates have also been shown to be very effective for corticosteroid osteopenia, they do not address the coexisting steroid myopathy, as does resistance training, and are therefore an insufficient antidote for corticosteroid side effects. An excellent target group for such health promotion efforts would be older men with steroid-dependent chronic lung disease (Storer, 2001), in whom pulmonary cachexia, malnutrition, tobacco use, and steroid myopathy and osteoporosis combine to produce profound wasting, osteoporotic fracture, and impaired exercise tolerance. Aerobic training will improve functional status in this clinical cohort, but is insufficient to address the musculoskeletal wasting.

EXERCISE AND THE PREVENTION AND TREATMENT OF DISABILITY

There are many ways in which physical activity may influence the development and expression of disability in old age. These theoretical relationships are now borne out in many epidemiological investigations, and provide the rationale for both the experimental studies and exercise recommendations that are found in many recent reviews of this topic (Andrews, 2001). For example, 1097 participants from the Established Populations for Epidemiological Studies of the Elderly (EPESE) study sites who were not disabled at baseline were analyzed for factors related to disability-free survival until death in old age (Leveille *et al.*, 1999). Physically active adults were more likely to survive to age 80 or beyond, and had approximately one-half the risk of dying with disability compared to their sedentary peers.

The most obvious conclusion from a review of the literature in this area is that there is a great deal of overlap between the identifiable risk factors for disability and the consequences or correlates of habitual inactivity. At the most basic level, shared demographic characteristics between those at risk of disability and those more likely to exhibit sedentary behavior include advanced age, female gender, non-Caucasian ethnicity, and lower educational level and income. Psychosocial features common to both cohorts include social isolation, low self-esteem, low self-efficacy, depressive symptoms, and anxiety. Lifestyle choices more prevalent in disabled and/or inactive adults include smoking and excess alcohol consumption. Body composition changes associated with both functional decline and inactivity include sarcopenia, obesity, visceral obesity, and osteopenia. Exercise capacity is typically reduced in both conditions in all domains, including aerobic capacity, muscle strength, endurance and power, flexibility, and balance. Gait instability and slowness, as well as impaired lower extremity function and mobility characterize both disabled and inactive populations. Since most studies have not assessed the full complement of factors known to be associated with disability, and many have made observations at a single point in time, it is not possible to say with certainty how all of these complex relationships fit together, which relationships are causal, and which risk factors are independent of each other.

In addition to the associations above, chronic diseases associated with inactivity, such as obesity, osteoarthritis, cardiovascular disease, stroke, osteoporosis, type 2 diabetes, hypertension, and depression are all risk factors for disability as well. In some cases, data linking inactivity to disability-related diseases is available from cross-sectional or prospective cohort studies as well as experimental trials (e.g. diabetes (Miller *et al.*, 1999), cardiovascular disease (Posner *et al.*, 1990)), and in other cases from epidemiological data alone (colon and breast cancer (Thune *et al.*, 1997)). Disability is complex and not fully explained by deficits in physical capacity such as strength and balance, and other pathways may be operative, including sensory function, glycemic control, psychological constructs, and other aspects of health status.

Recent prospective and experimental studies have strengthened the hypothesized causal relationship between sedentariness, functional limitations, and disability in older adults. Miller has reported results from 5151 participants in the Longitudinal Study of Aging (Miller *et al.*, 2000), and shown that physical activity results in a slower progression of functional limitations, and thereby slower progression to ADL/IADL disability were observed at 6 months of follow-up after the intervention ended. In the largest reported randomized controlled trial of exercise and disability to date (Fiatarone Singh *et al.*, 2004), 704 residents of nine different nursing homes were randomized into resistive exercise, nursing rehabilitation, or control conditions. After 17 months, residents in both intervention homes had significantly less decline in ADL functioning than those in control homes.

A review of studies targeting disability in disease-specific populations such as depression, cardiovascular disease, stroke, chronic lung disease, and arthritis is beyond the scope of this review, but there is evidence that exercise is beneficial in all of these conditions as a primary or ancillary treatment. The largest body of data exists for older adults with osteoarthritis, which is the commonest condition related to disability in the elderly (McCarthy and Oldham, 1999). Five of the 11 randomized controlled trials reported up to 1999 demonstrated improvements in disability scores relative to controls in trials from 4 weeks to 18 months in duration. Weight-bearing functional exercises, walking, and resistance training were used in various combinations in these studies, and there is no clear indication of the superiority of one modality over another in the reduction of pain and disability from osteoarthritis. It is likely that the disability reductions in arthritis are due to the impact of exercise on a variety of factors, including muscle strength, gait and balance, body weight, pain, comorbid disease expression, self-efficacy, and depressive symptoms, among others.

Table 10 Exercise recommendations for optimal aging and prevention and treatment of disease in older adults

Modality	Resistance training	Cardiovascular endurance training	Flexibility training	Balance training
Dose				
Frequency	2–3 days/week	3–7 days/week	1–7 days/week	1–7 days/week
Volume	1–3 sets of 8–12 repetitions, 8–10 major muscle groups	20–60 minutes per session	Major muscle groups 1 sustained stretch (20 seconds) of each	1–2 sets of 4–10 different exercises emphasizing dynamic postures[a]
Intensity	15–17 on Borg Scale (70–80% 1RM), 10 seconds/repetition, 1 minute rest between sets	12–13 on Borg Scale (40–60% heart rate reserve or maximal exercise capacity)	Progressive neuromuscular facilitation (PNF) technique[c]	Progressive difficulty as tolerated[b]

[a]Examples of balance enhancing activities include T'ai Chi movements, standing yoga or ballet movements, tandem walking, standing on one leg, stepping over objects, climbing up and down steps slowly, turning, standing on heels and toes, walking on compliant surface such as foam mattresses, maintaining balance on moving vehicle such as bus or train, and so on. [b]Intensity is increased by decreasing the base of support (e.g. progressing from standing on two feet while holding onto the back of a chair to standing on one foot with no hand support); by decreasing other sensory input (e.g. closing eyes or standing on a foam pillow); or by perturbing the center of mass (e.g. holding a heavy object out to one side while maintaining balance, standing on one leg while lifting other leg out behind body, or leaning forward as far as possible without falling or moving feet). [c]Proprioceptive neuromuscular facilitation involves stretching as far as possible, then relaxing the involved muscles, then attempting to stretch further, and finally holding the maximal stretch position for at least 20 seconds.

SUMMARY AND DIRECTIONS FOR FUTURE RESEARCH

There is sufficient data from both epidemiological studies and experimental trials to warrant the training of all physicians, including geriatricians in the basics of exercise prescription for health-related and quality of life benefits, as outlined in Table 10. Screening for sedentariness should take place at all major encounters with health-care professionals, given its role as a potent risk factor for all-cause and cardiovascular mortality, obesity, hypertension, insulin resistance, cardiovascular disease, diabetes, stroke, colon cancer, depression, osteoporosis, recurrent falls and disability, among other conditions. Exercise recommendations should be integrated into the mainstream of other health-care recommendations, rather than being marginalized as at present. Exercise advice should be specific in terms of modality, frequency, duration, and intensity, accompanied by practical implementation solutions and behavioral support systems for monitoring progress and providing feedback. Ultimately, the penetration of these recommendations into the most inactive cohorts in the community, who have the most to gain from increases in levels of physical activity and fitness (Blair and Garcia, 1996), will depend on a combination of evidence-based guidelines coupled with health professional training and behavioral programs (King *et al.*, 1991; Dunn *et al.*, 1999) tailored to age-specific barriers and motivational factors.

KEY POINTS

- The reduction in exercise capacity typical of the older adult is largely explained by reduced muscle mass and function, decreased maximal heart rate and cardiac output, and impairment of central and peripheral nervous system processing, recruitment, and conduction velocity.
- Aging and a sedentary lifestyle or disuse syndromes have very similar effects on a multitude of physiological changes attributed to chronological age which reduce exercise capacity.
- Habitual physical activity increases average life expectancy by approximately 2 years, but the mechanism of this effect is likely multifactorial and not precisely defined.
- Prevention of many of the typical changes attributed to biological aging is possible with chronic participation in physical activity, particularly alterations in body composition: decreased muscle mass, decreased bone mass and strength, increased adipose tissue mass and its central deposition.
- Prevention and/or treatment of many of the most common chronic diseases which afflict older adults, including obesity, cardiovascular disease, type 2 diabetes, hypertension, osteoarthritis, osteoporosis, stroke, peripheral vascular disease, and depression are possible with targeted, robust doses and modalities of exercise.

Transportation, Driving, and Older Adults

Desmond O'Neill[1] ***and*** **David Carr**[2]

[1] Adelaide & Meath Hospital incorporating the National Children's Hospital, Dublin, Ireland, and [2] Division of Geriatrics and Nutritional Science, Park Provence, St Louis, MO, USA

INTRODUCTION

The importance of transportation to health and social inclusion has been underrecognized in both the medical and the gerontological literature. Transportation is a crucial factor in maintaining older adult independence and the automobile is the most important source of transportation for older people. Not only is social connectedness a major priority for older people but problems with transportation have been recognized as barriers for access to health care for older people (Okoro *et al.*, 2005). Concerns over access to adequate transportation among older people have been voiced by a number of international agencies, including the Organization for Economic Cooperation and Development (2001 OECD) and the Conference of the European Ministers for Transport (CEMT, 2001). This has been augmented by major national reviews which have also emphasized the need to adapt transportation systems to the needs of older people (Committee for the Safe Mobility of Older People, 2004).

However, the major emphasis of much of the medical literature on transportation and aging is disproportionately skewed toward risk and crashes. This is particularly unfortunate, as older adults are the safest group of drivers (Fain, 2003), and even the often-quoted increased crash risk per mile is an artifact due to limited exposure or fewer miles driven per year. A number of studies have shown that the apparent increased crash risk disappears when one controls for mileage (low mileage is intrinsically risky) (Hakamies-Blomqvist *et al.*, 2002). However, a major issue for older adults is an increase in crash fragility. Whether as car occupants (Braver and Trempel, 2004) or as pedestrians, older people are more likely to suffer serious injury or death than younger people given the same crash severity. In traffic terms, older adult fragility exposes weaknesses in the design of the traffic environment. This clearly needs a societal response, in particular attention to in-car safety measures, which recognize the altered physiology and increased frailty of older people. A good analogy can be made with the danger posed by air bags for children who are front seat passengers: the response was not to stop children riding in cars, but rather to adapt an injury control measure (putting the children in the back seat, making occupants use seat belts).

For pedestrians, several responses are possible. Possibly the most important of these is to ensure that we do not unnecessarily turn older people into involuntary pedestrians through inappropriate driver screening programs: there is evidence that this phenomenon underlies the negative impact of medically screening older drivers in Finland and Australia (Hakamies-Blomqvist *et al.*, 1996; Langford *et al.*, 2004a; Langford *et al.*, 2004b). Other approaches include radically modifying traffic speed, the time needed for pedestrians to cross busy intersections, better organization where vulnerable road users (pedestrians and cyclists) share the road with vehicular traffic, and educating other road users to exercise caution in environments shared with older pedestrians.

Illness and Transportation

The most important impact of age-related illness on transportation is likely to be a reduction of personal mobility. This has been demonstrated for people with dementia (Taylor and Tripodes, 2001), but happens with other illnesses as well. Older people report that health is the commonest reason for driver cessation (Persson, 1993; Rabbitt *et al.*, 1996; Hakamies-Blomqvist and Wahlstrom, 1998; O'Neill *et al.*, 2000), and it should be of some concern that they rarely discuss this radical decision with a health-care provider (Johnson, 1995). Physicians dealing with older people need to be aware of these limitations and to be able to support their patients to maintain their independence.

The issue of crash risk has been overstated but sadly forms a negative public backdrop to our professional practice: a recent study of British and Irish media showed an overwhelmingly negative portrayal of older drivers, despite

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

their excellent safety record (Martin *et al.*, 2005). Physicians must not allow a negative but inaccurate popular perception interfere with their task of assessing, treating, and advising older people in relation to their independence. This extends to the interpretation of studies on crashes: for example, certain illnesses are more common in older people who have crashes (McGwin *et al.*, 2000). However, since older people have less crashes in the first instance, the likelihood of effective public health interventions to further reduce this low rate are unrealistic and may cause further problems recognized with screening of older drivers.

Clearly for individual patients the maintaining of autonomy must be balanced with public safety to an extent consistent with that applied to the rest of the population. Age-related visual and cognitive diseases, in particular macular degeneration, dementia, stroke, and Parkinson's disease (Wood *et al.*, 2005), are likely to be the conditions most often associated with mobility and safety problems. Our main ethical prerogative is to preserve a sense of dealing with the issue in a hierarchical fashion common to good practice for all health-care conditions. This emphasizes in turn the World Health Organization's approach of health gain, health maintenance, compensation, and finally palliation (World Health Organization, 2001).

The Older Drivers Project, an initiative between the American Medical Association and the US National Highway Traffic Safety Administration has reaffirmed this principle, stating that a primary objective of its approach involves helping older drivers stay on the road safely to preserve their mobility and independence (Wang and Carr, 2004). The Older Drivers Project recommends that this can be accomplished through three methods: (1) optimizing the driver, (2) optimizing the driving environment, and (3) optimizing the vehicle. In this approach, driving cessation is recommended only after the safety of the driver cannot be secured through any other means. An algorithm to assess older drivers as recommended by the AMA (American Medical Association) is described in Figure 1 (American Medical Association, 2003).

Clinicians may be reluctant to address the driving issue in the office practice setting. There is a clear need for education in the assessment of mobility and driving: the good news is that such education appears to be effective (Byszewski *et al.*, 2003). Evaluating driving skills should not be viewed differently from the evaluation of risk for falls or other risk for injuries in older adults. Clinicians should consider the recommendation for driving retirement in older adults in a similar way to the decision that a previously ambulatory patient is now wheelchair bound for life: efforts should be made to preserve mobility when possible. Definitive guidelines on how clinicians can intervene effectively to ensure adequate mobility, driving safety, or effect driving cessation in impaired older adults still are needed, but current evidence and available resources indicate a general approach to this issue. There is an increasing body of evidence on the subject and some helpful guides.

Of particular importance has been the recognition that a relatively wide number of interventions can improve driving ease and safety (Table 1). It is also quite remarkable that most reviews on medications and driving emphasize possible negative effects on driving, rather than reflecting that anti-inflammatory, anti-Parkinsonian, and antidepressant medications might actually improve driving ability and comfort! The possibility that cholinesterase inhibitors might improve or maintain driving skills in dementia has not yet been tested, but remains an interesting area for future research.

WHAT WE NEED TO KNOW TO ASSESS OUR OLDER PATIENTS?

Physicians assessing older people for transport/driving capability need to know:

1. How do the older adults meet their transportation needs?
2. What intrinsic factors contribute to driving ability and how can we measure them?
3. What common illnesses in late life can affect the driving task?
4. What, if any, interventions should office-based clinicians pursue?
5. What is the physician's responsibility with regard to driver licensing and insurance authorities?

Taking a Driving/Transportation History

Although it may seem obvious that transportation should figure in a comprehensive assessment, this is not necessarily the case. An extreme example of this is the failure by the referring physician to advise on driving restriction for a significant number of people *referred* to a syncope clinic (MacMahon *et al.*, 1996). It is also likely that many patients do not obtain formal advice or assessment about driving after stroke (Fisk *et al.*, 1997). As there is potential to improve driving and transportation options, there is also a need to discuss restrictions or planned withdrawal from driving for many patients.

What Factors are Important in Driving Assessment?

The most major advance in this area has been the understanding that a purely cognitive model of driving ability does not adequately reflect the complexity and hierarchical nature of the driving task. Psychometric approaches have generally been disappointing for a number of reasons (Ranney, 1994), and efforts to find a best cognitive battery resemble the alchemist's search for transforming base metal to gold rather than a carefully thought out scientific endeavor.

The most common model for driver assessment would involve a combination of physician, occupational therapist, neuropsychologist, specialist driving assessor and social worker. Not all levels will be required by all patients: a patient with severe dementia clearly cannot drive, and

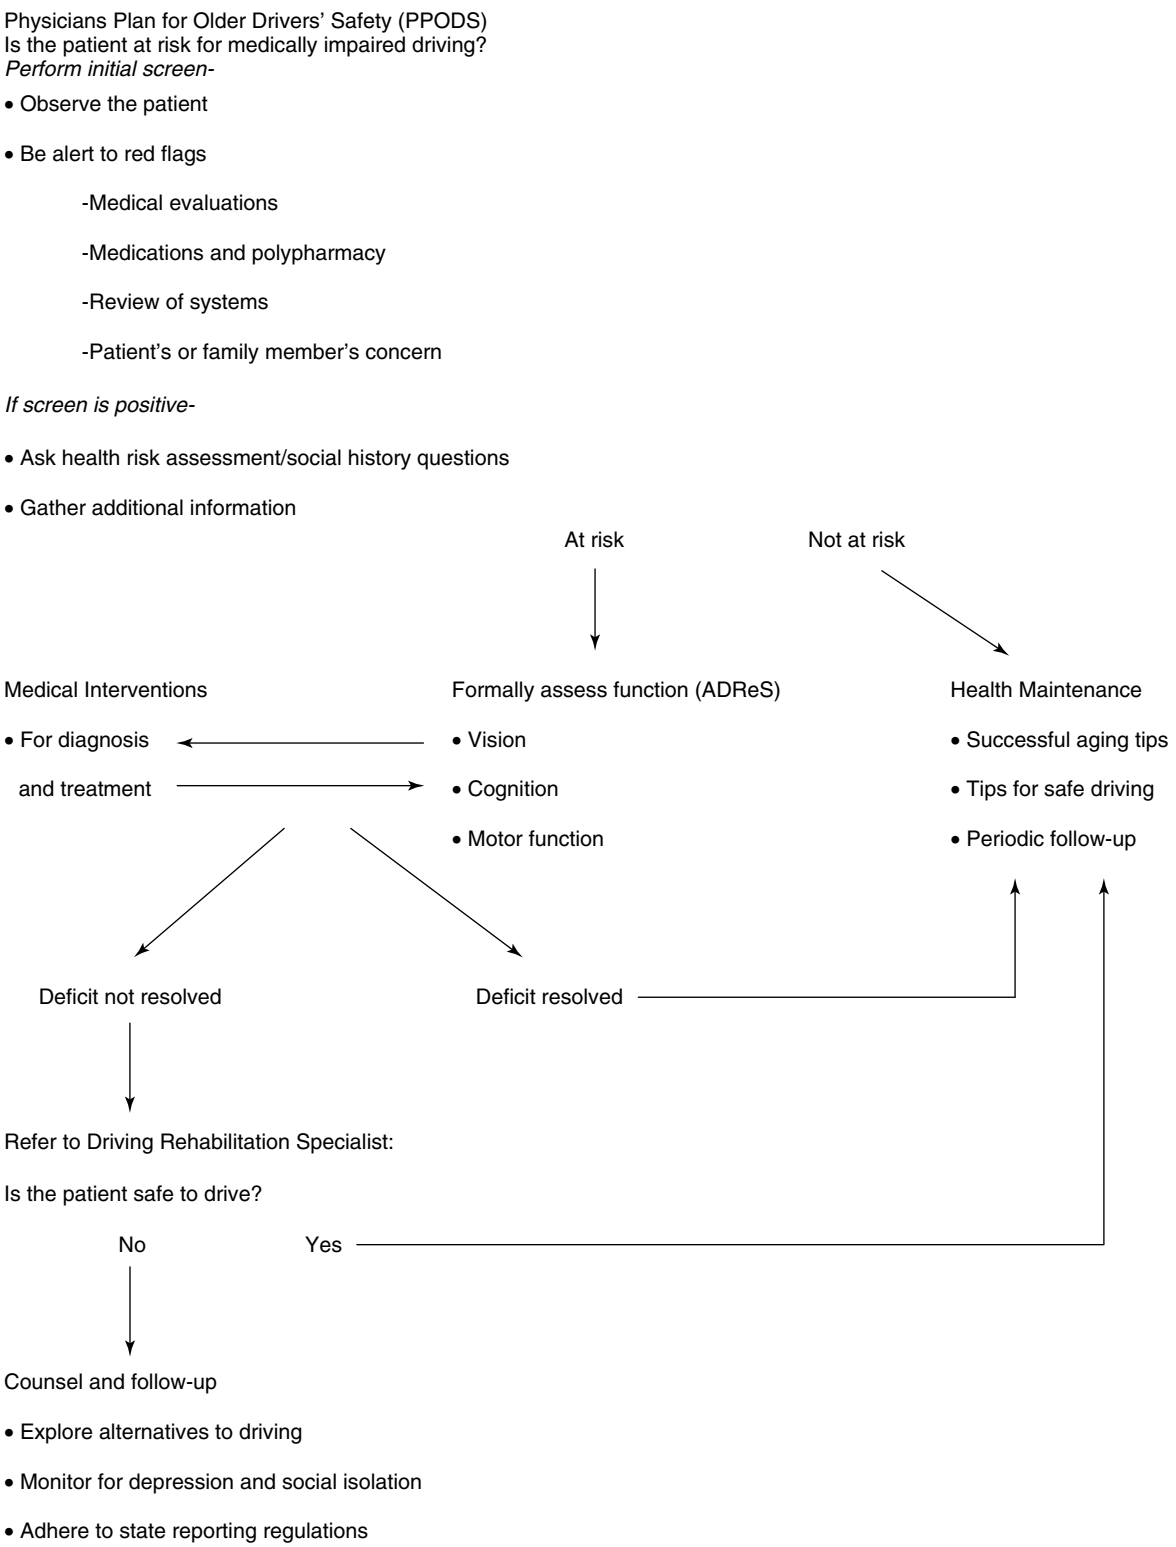

Figure 1 PPODS Chart

referral to the social worker to plan alternative transportation is appropriate. Equally, a mild cognitive defect may only require a review by the physician and occupational therapist. The overall interdisciplinary assessment should attempt to provide solutions to both maintaining activities and exploring transport needs. However, even in a skilled rehabilitation setting, the predictive value of team assessments may be low for diseases such as stroke (Akinwuntan

If driving too hazardous, consider alternative mobility strategies

et al., 2002) and the on-road test is the current best assessment available.

The on-road test may be helpful, as it may demonstrate impairments to a patient or caregiver who is ambiguous about the patient stopping driving. At a therapeutic level, members of the team may be able to assist the patients in coming to terms with the losses associated with stopping driving. The occupational therapist may be able to maximize activities and function and help focus on preserved areas of achievement, while the social worker can advise on alternative methods of transport. This approach should save time and valuable resources for occupational therapy, neuropsychology, and on-road driver assessors.

In addition to the usual workup, the medical assessment should include a driving history from patient and ideally (with the patient's permission) from a carer as well. The physician needs to judiciously weigh the collateral history, taking into account whether or not the carer is also dependent on the patient operating a motor vehicle. Physicians should also inquire about new unsafe driving behaviors. These behaviors can be apparent in mild dementia and would raise concerns about continuing driving privileges. It is important to recognize that these behaviors represent a *change* from baseline. They include becoming lost in familiar areas, driving too fast, reacting too slowly, consistently making poor judgments, failure to notice street signs, having more accidents, receiving indecent gestures from other drivers, miscalculating speed and distances, new dents on the car, knocking off rear view mirrors, showing poor judgment when making turns, or impaired ability to recognize or understand road or traffic signs.

The interested clinician can check static visual acuity (Snellen chart), hearing (whisper test or handheld audiometry), attention and reaction time (Trails A or B), visual spatial skills (clock drawing task), judgment, insight, joint range of motion, and muscle strength (Underwood, 1992; Reuben, 1993; Marottoli *et al.*, 1994; Foley and Mitchell, 1997). Many of these tests were recently endorsed by the AMA for assessing and counseling older adult drivers and are available on their website along with evidence based medicine references. These tests are probably more important for gaining an overall perspective on the patient's abilities and disabilities, rather than relying overly on the performance of any one component (American Medical Association, 2003).

The next stage of testing includes evaluations from occupational therapists and/or neuropsychologists. None of the studies have been sufficiently large to have a reasonable predictive value or to determine cutoff points on neuropsychological test batteries. This situation is paralleled in Memory Clinics where there is a wide variation in test batteries used: it is likely that the important elements of successful assessment are choice of key domains, familiarity with a test battery, and the development of an understanding and close liaison between the physician and the occupational therapist and/or neuropsychologist.

A wide range of tests have been correlated with driving behavior but few have been sufficiently robust to calculate cutoff points for risky driving. All of these tests can be criticized for taking an overcognitive view of the driving task (De Raedt and Ponjaert-Kristoffersen, 2000). A comprehensive review of tests is available from the US National Highway Transportation Safety Administration (Staplin *et al.*, 1999), and a rather futile attempt has been made at a "meta-analysis" of neuropsychological tests (Reger *et al.*, 2004). The other interesting aspect is that there may be a disparity between scores on a test battery and the clinical assessment of the neuropsychologist. In a small paper by Fox *et al.*, the neuropsychology test scores and the neuropsychology prediction were not found to be significantly associated, suggesting that the clinicians made their decisions on items not formally measured in the neuropsychology test battery (Fox *et al.*, 1997). In conjunction with the clinical assessment and collateral history, these tests will guide the physician as to which patients require on-road testing, as well as those who are likely to be dangerous to test!

At the moment simulators of sufficient sophistication are not widely available but may represent opportunities for both driver rehabilitation (analogous to training airplane pilots) and assessment. The main benefit of large sophisticated simulators such as the Iowa simulator has been to try to develop and understand neuropsychological and behavioral test batteries in a safe and reliable method and to correlate them with unsafe driving behavior and crashes. The classic paper by Rizzo in 1997 revealed that 29% of AD patients experienced crashes in the simulator versus zero of 18 control participants (Rizzo *et al.*, 1997). The drivers with AD were also more than twice as likely to experience "close calls". There was also evidence that some drivers with mild Alzheimer's disease did not crash and showed fair control of their vehicles compatible with the idea that some patients with mild dementia should be allowed to continue to drive.

On-road driver testing is the gold standard and should be offered to all patients who are not clearly dangerous when driving. The assessor will require a full clinical report, and may choose to use one of the recently developed scoring systems for on-road testing of patients with dementia. At

least three different road tests have been devised specifically for dementia although the numbers put through these in published series are still relatively small with 27 patients in the Sepulveda Road Test (Fitten *et al.*, 1995), 65 in the Washington University Road Test (Hunt *et al.*, 1997) and 100 in the Alberta Road Test (Dobbs *et al.*, 1998). The tests should ideally involve some degree of cognitive loading, which will tend to bring out the degree and extent to which the older driver can manage complex situations safely (Uc *et al.*, 2004).

The quantification, operationalization, and validation of these road tests need to be done repeatedly in environments other than that of the originators of the test. Current reliability of standardized tests seems promising (Akinwuntan *et al.*, 2003). An additional spin-off may well be that just as the simulators may provide information on which behavioral or neuropsychological tests might be helpful in deciding which drivers are safe to drive, so too may road test schedules help in the development of neuropsychological tests. Psychological batteries have been developed from both the Sepulveda and Alberta Road Tests.

There are certain limitations with road tests. Expenses for driving evaluations may vary from $200–$500 and health insurance or government health providers may not cover the cost. In addition, they often occur in an unfamiliar environment and in an unfamiliar car. However, professional organizations representing geriatricians need to undertake advocacy to ensure that on-road testing is available, of a high standard, and affordable to our patients.

What Risks are Associated with Common Diseases of Later Life?

While early papers on dementia and driving emphasized the potential risks from those with dementia, subsequent research has not unequivocally shown that drivers with dementia pose a public health hazard. The precise contribution of the dementias to overall crash hazard is uncertain. Although Johansson suggested a major role for dementia as a cause of crashes among older drivers on neuropathological grounds (Johansson *et al.*, 1997a), subsequent interviews with families did not reveal significant problems with memory or activities of daily living (Lundberg *et al.*, 1999). The Stockholm group also showed that older drivers who had a high level of traffic violations had a high prevalence of cognitive deficits (Lundberg *et al.*, 1998). Retrospective studies of dementia and driving from specialist dementia clinics tend to show a high risk (Friedland *et al.*, 1988; Lucas-Blaustein *et al.*, 1988; O'Neill, 1993), whereas those which are prospective and which look at the early stages of dementia show a less pronounced pattern of risk. In the first 2 years of dementia the risk approximates that of the general population (Drachman and Swearer, 1993; Carr *et al.*, 2000). The most carefully controlled study yet of crashes and dementia showed no increase in crash rates for drivers with dementia (Trobe *et al.*, 1996). Likely causes for this counterintuitive finding include a lower annual mileage, using state records for crash data, and restriction of driving by the patient, family, and physicians.

Extrapolating from special populations may skew predictions of risk. For example, epilepsy, for which there are relatively clear-cut guidelines in most countries, would seem to pose a clear threat to driving ability as viewed from a clinic setting. Recent population-based studies seem to suggest that the increased risk is relatively low (Hansotia and Broste, 1991; Drazkowski *et al.*, 2003 #1819). In a population renewing their licenses in North Carolina, the lowest decile had a relative crash risk of 1.5 in the 3 years previous to the cognitive testing (Stutts *et al.*, 1998), A somewhat reassuring finding from this cohort is that those with the poorest scores for visual and cognitive function also drove less and avoided high-risk situations (Stutts, 1998). A reasonable conclusion from these studies is that dementia among drivers is not yet a public health problem. Although increasing numbers of older drivers may change this situation, it is also possible that "Smeed's law" will operate, whereby increasing numbers of drivers among a defined population are associated with a drop in fatality rates per car (Smeed, 1968).

Older drivers report less driving at night or during adverse weather conditions, and avoid rush hour or congested thoroughfares. Most importantly, cognitively impaired older adults who renewed their licenses appear to even further restrict their exposure, many to less than 3000 miles per year (Stutts, 1998). Demented drivers may further limit their exposure when compared to age-matched controls (Dubinsky *et al.*, 1992). The data on exposure will require some confirmation, since there certainly are questions raised regarding the accuracy of reporting mileage in any cognitively impaired group. However, decreased exposure may explain why many crash studies have not observed major differences in crash rates from controls when comparing rates on the number of crashes per year and not factoring in total mileage.

Polypharmacy is common in older adults and medication may be additive to crash risk in older adults with cognitive impairment. This is a complex area and it can be difficult to tell whether it is the illness or the medication, which is causing the problem. There are many medication classes that have been studied and noted to impair driving skills when assessed by simulators or road tests. These decrements may not translate into increased safety risk. These include, but are not limited to, narcotics, benzodiazepines, antihistamines, antidepressants, antipsychotics, hypnotics, alcohol, and muscle relaxants. Very few studies have focused on the older adult driver. However, long acting benzodiazepines have been associated with increased crash rates (Hemmelgarn *et al.*, 1997). Another report suggests that there may be a significant number of older adults driving while intoxicated or under the influence of other medications (Higgins *et al.*, 1996; Johansson *et al.*, 1997b). Clinicians should review medications closely with each individual and attempt to discontinue medications that have the potential to adversely affect cognition when appropriate. Screening for alcohol abuse or misuse is also reasonable.

What Interventions Can We Make?

Depending on the illnesses present, there is potentially a wide range of interventions that we can undertake (Table 2). Adaptation of the car, following advice from the occupational therapist, physiotherapist, or specialist driving assessor can improve driving comfort and safety. Follow-up review should be organized for those with progressive illnesses such as dementia and Parkinsonism. A review period of 6–12 months would seem to be reasonable with dementia (Duchek *et al.*, 2003) but patients and carers should be asked to seek earlier review if they perceive a significant decline in the status of the dementia or in driving abilities. Although some studies have concluded with recommendations that all older adults with dementia should refrain from driving (Lucas-Blaustein *et al.*, 1988), the majority of clinicians would likely base this decision on dementia severity (Dubinsky *et al.*, 2000) or a demonstration of impaired driving competence (Drachmann, 1988). The American Academy of Neurology guidelines (Dubinsky *et al.*, 2000), proposing that no one with a Clinical Dementia Rating Scale (CDR) of 1 should drive, have been superceded by research which judged 41% of those with a CDR 1 as safe (19% were considered to be marginal, and 41% to be unsafe) (Duchek *et al.*, 2003). This reinforces the need for a full assessment and appropriate follow-up.

Table 2 Sample diseases for which appropriate assessment and remediation may be of benefit

Neuropsychiatric	
Stroke	Driving-specific rehabilitation (van Zomeren *et al.*, 1987)
Parkinson's disease	Maximizing motor function, treatment of depression, assessment of cognitive function (Anonymous, 1990)
Delirium	Treatment and resolution
Depression	Treatment: if antidepressant, choose one with least potential of cognitive/motor effects (Rubinsztein and Lawton, 1995)
Mild Dementia	Assess, treat depression, reduce/eliminate psychoactive drugs, advice not to drive alone (O'Neill, 1996a)
Cardiovascular	
Syncope	Advice pending investigation: treat cause (O'Neill, 1996b)
Respiratory	
Sleep apnoea	Treatment of underlying disease (Haraldsson *et al.*, 1992)
Vision	
Cataract	Surgery, appropriate corrective lens and advice about glare (Monestam and Wachtmeister, 1997)
Metabolic	
Diabetes	Direct therapy to avoid hypoglycemia (Frier, 1992)
Musculoskeletal	
All arthritides	Driving-specific rehabilitation program (Jones *et al.*, 1991)
Iatrogenic	
Polypharmacy	Rationalize medications (Ray *et al.*, 1993)
Psychoactive medication	Rationalize, minimize (Ray *et al.*, 1992)

For the progressive neurological conditions, the physician needs to help the patient and their family prepare for eventual withdrawal from driving. Early and appropriate diagnosis disclosure is likely to be important here (Bahro *et al.*, 1995). A helpful description of this process is the modified Ulysses contract (Howe, 2000), named after the hero who made his crew tie him to the mast on the condition that they did not heed his entreaties to be released when seduced by the song of the sirens. It forms the basis of a useful patient and carer brochure from the Hartford Foundation which is also available online (Hartford Foundation, 2000).

The very act of highlighting the potential of compromised driving ability may have a therapeutic benefit, promoting an increased vigilance on the part of the patient and carers that their social contract for driving privileges is not the same as that of the general public. Support is given to this concept by the success of restricted licensing for people with medical illnesses in the state of Utah (Vernon *et al.*, 2002). While the effect might arise from the restrictions (avoidance of motorways, nighttime driving) it is also possible that the very act of labeling these drivers may heighten self-awareness.

A clear recommendation should be made to the patient and recorded in the medical record: this should include advice to inform their insurance company of relevant illnesses, as well as any statutory requirement to inform their driver licensing authority.

When driving is no longer possible, alternative options should be discussed with the patient. For the fortunate minority who have access to a paratransit system (tailored, affordable personal transportation systems (Freund, 2000)), the graduation may be more easy. For the rest, although public transportation systems (Roper and Mulley, 1996) may have reduced fares for senior citizens, the very disabilities that prevented driving also render such services suboptimal (O'Neill, 1997). Owing to restricted sites and cognitive limitations of our older drivers, these services are typically underutilized. State or local sponsored services may provide door-to-door transport for older adults in large vans, many of which are lift-equipped. Local communities, societies, retirement centers, or local church groups may use funds or volunteers to provide services to physician offices, grocery stores, and meetings. In our experience, transportation is often provided by family members once the older adult can no longer perform the task (O'Neill *et al.*, 2000).

What is the Physician's Responsibility with Regard to Driver Licensing and Insurance Authorities?

In general, the welfarist role of the physician extends to reminding the patient that most insurance companies require disclosure by the driver of "illnesses relevant to driving" when they arise. Two issues arise: the medical advisers of the insurance companies may not make calculations of insurance rates (or continued insurance) on the basis of reason and evidence but rather on ageist grounds and prejudice against disability. We may be unwittingly exposing the patient to this prejudice. The answer to this lies in continued advocacy

efforts by advocacy and professional groups at a societal level as well as support by the physician in individual cases if the assessment supports preserved driving skills. A second issue is whether it is sufficient to recommend disclosure to someone who will not remember this advice. However, the physician's role is primarily to ensure safe mobility. In general, it is reasonable to assume that removal of insurance coverage is a secondary matter in such cases. It is reasonable to share the disclosure information with the carers.

The actual process of breaking confidentiality in the event of evidence of hazard to other members of the public is almost universally supported by most codes of medical practice – but to whom this should be reported poses some ethical challenges. The traditional route of reporting to driver licensing authorities (DMV (US), DVLA (UK)) may have relatively little benefit – removal of a driving license is likely to have little impact on many drivers whose insight into deteriorating driving skills is poor. It is important that this disclosure has some likelihood of impact and results in the least traumatic removal of the compromised older driver from the road. In such instances, the family may be able to intervene in terms of disabling the car and providing alternative modes of transport. In our own experience, we rarely have to invoke official intervention, but find that a personal communication with a senior police officer in the patient's locality may result in a sensitive visit to the patient and cessation of driving.

Mandatory reporting represents a different ethical challenge. It is unlikely that it is of significant benefit and unless significant benefit can be shown in future studies, the profession should resist the introduction of such schemes. For individual practitioners in jurisdictions where such regulations exist, a twin-track approach is probably necessary – professional advocacy with lawmakers and a considered approach as to whether disclosure is in the patient's best interests on a case-by-case basis. If the physician is confident that the state or province has a mechanism for fair assessment and an enlightened approach to maintaining mobility, compliance is not difficult. If the assessment is cursory and aimed at unduly restricting mobility, physicians may be faced with a problem recognized with other laws, which may put patient's welfare at risk and where professional obligations may require noncompliance with an unfair law.

CONCLUSION

Transportation and driving assessment have become an integral part of the assessment of older people. Geriatricians, appropriately supported by their interdisciplinary team and specialist on-road assessment, can help support safe mobility and social inclusion in later life. There is a need for more research to further clarify the most appropriate and economical assessments and interventions which further this end (OECD, 2001).

KEY POINTS

- Driving is an important component of the health and well-being of older people.
- The most important priority for geriatricians is to preserve the same proportionality of mobility to safety for older people as society accords to other age-groups.
- Many age-related conditions affect comfort, ability, and safety of the driving task but these effects can be ameliorated by appropriate interventions.
- The most important factors in assessing fitness to drive are likely to be measures of function and driving behavior: cognitive testing is less clearly helpful.
- Eventual driving cessation with progressive neurodegenerative diseases will be aided by early diagnosis disclosure and discussion of eventual driving cessation, as well as the provision of suitable alternative transportation options.

Smoking in the Elderly

Norman J. Vetter

University of Wales College of Medicine, Cardiff, UK

PREVALENCE OF SMOKING IN THE OVER-60s

The prevalence of smoking in Great Britain has declined overall since the early 1970s. In 1994, the proportion of smoking men was 28%. In 2002, it was back down to 27%, having reached a peak of 30% in 1996. The prevalence of smoking rises initially, then falls with age to reach 10% in men and 7% in women aged 75 and over. Figure 1 shows the difference in prevalence of cigarette smoking between the different ages in 2002 (National Statistics, 2003).

Figure 1 shows that the prevalence of smoking is greatest in young middle-aged people and that in the youngest age groups, women smoke more than men. This reflects a cohort effect; women smoked very little in the post-World War II period, but gradually increased the habit with time. In different socioeconomic groups, the prevalence of smoking in the professional groups has fallen much more rapidly than for people who are in semiskilled or unskilled employment.

When one examines the proportion of people who had ever smoked and those who have never smoked, figures show that a high proportion of people aged over 75 are exsmokers. It has been suggested that many people give up smoking as they reach retirement age, both because of the effects upon their finances and on their health. The highest proportion of people who have never smoked (54%) are females aged 75 and over. This figure has been constant for at least 10 years. This reflects the relatively stable attitudes of society in the 1940s to smoking among women when they were young.

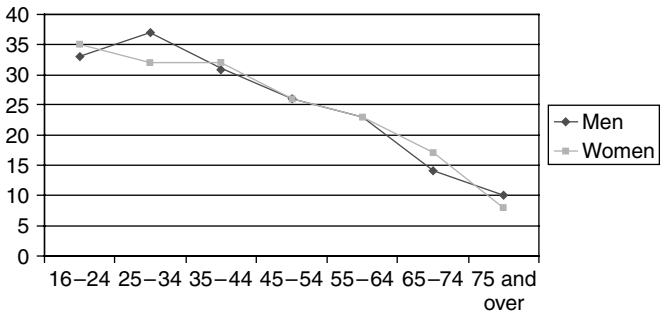

Figure 1 Prevalence of cigarette smoking by age in 2002

DISEASES ASSOCIATED WITH SMOKING IN ELDERLY PEOPLE

Heart Disease

Clear-cut evidence linking cigarette smoking to the development of ischemic heart disease has existed for many years. In the Multiple Risk Factor Intervention Trial (Neaton *et al.*, 1993) in the early 1990s, the risk of death increased steadily with cigarette consumption, reaching a plateau in those who smoked more than 35 cigarettes per day. The increased risk associated with cigarette smoking declined over the 12 years of follow-up. In addition, continued smoking after thrombolytic therapy was associated with a fourfold increase of reinfarction at 12 months (Rivers *et al.*, 1990).

More recently, a systematic review has shown that quitting smoking is associated with a substantial reduction in risk of all-cause mortality among patients with CHD (Critchley and Capewell, 2003). This risk reduction appears to be consistent, regardless of age, sex, index cardiac event, country, and year of study commencement (*see* **Chapter 46, Ischemic Heart Disease in Elderly Persons**).

The cardiovascular risk in older people who smoke is less well defined, possibly because they tend to smoke less than younger people. This contrasts with hypertension as a risk factor, where the risk increases steadily with age. The risk of cardiovascular disease in old people may be affected by a survivorship effect. In middle-aged people, smoking is such an important risk factor and heart disease is so common that the resulting high early mortality may appreciably reduce the numbers at risk in older people. In the Framingham study, men and women aged 65 to 94 who smoked were not at a significantly higher risk of coronary disease compared to

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

nonsmokers. Diabetes was found to be increasing greatly in prevalence and operating more powerfully in women, countering their coronary disease resistance compared to men. It may be that insulin resistance promoted by abdominal obesity that has become so common in elderly people is to blame (Kannel, 2002). The older men in the Framingham study who smoked over 40 cigarettes a day had an increased risk. Other studies, admittedly some years ago, including the American Cancer Society Study and Canadian Veterans Study, found no excess risk in older smokers (Bush, 1991).

Stroke

Cigarette smoking is firmly established as a risk factor for stroke in older people (*see* **Chapter 71, Acute Stroke**), being associated with more than 50% of the deaths from cerebrovascular disease (Wilson, 1994). A meta-analysis of 32 separate studies provided strong evidence of an excess risk of stroke among cigarette smokers (Shinton and Beevers, 1989). A dose–response relationship was found between the number of cigarettes smoked and the risk of stroke. In the Framingham study, after a follow-up of 26 years, cigarette smoking was found to be a significant independent risk factor for stroke and specifically for brain infarction (Wolf, 1998). After cessation of smoking, risk of stroke decreased significantly within 2 years and reached the level of nonsmokers after 5 years. This rapid reduction in risk after cessation suggests that smoking plays a role in precipitating a stroke, possibly by increasing the fibrinogen level and promoting platelet aggregation.

Twenty-eight to sixty-eight per cent of the lacunar stroke patients in different studies were found to be cigarette smokers (Lodder *et al.*, 1990). Smoking therefore seems to be a nonspecific high-risk factor for lacunar infarction.

Effects on Bone

A meta-analysis of 29 published studies showed the importance of the relationship between smoking, bone mineral density, and risk of hip fracture (Law and Hackshaw, 1997). These studies reported the difference in bone density in 2156 smokers and 9705 nonsmokers according to age and that of 19 cohort and case-control studies recording 3889 hip fractures that reported the risk in smokers relative to nonsmokers.

The study showed that in premenopausal women bone density was similar in smokers and nonsmokers but in postmenopausal women bone loss was greater in current smokers than nonsmokers, diminishing by about an additional 2% for every 10-year increase in age, with a difference of 6% at age 80. In current smokers relative to non-smokers, the risk of hip fracture was similar at age 50 but greater thereafter by an estimated 17% at age 60, 41% at 70, 71% at 80, and 108% at 90. These estimates of relative risk by age, derived from a regression analysis of the studies of smoking and hip fracture, were close to estimates using the difference in bone density and the association between bone density and risk of hip fracture.

The estimated cumulative risk of hip fracture in women in England was 19% in smokers and 12% in nonsmokers up to age 85 and 37% and 22% up to age 90. Among all women, one hip fracture in eight is attributable to smoking. Limited data in men suggest a similar proportionate effect of smoking as in women. The association was not explained by smokers being thinner, younger at menopause, and exercising less or by the effect of smoking on estrogen secretion, but smoking may have a direct action on bone (*see* **Chapter 110, Epidemiology of Osteoporosis** and **Chapter 15, Alcohol Use and Abuse**).

Effects on the Mouth

Smoking has many negative effects on the mouth (Reibel, 2003). These include staining of teeth and dental restorations (*see* **Chapter 22, Oral Health**); reduction of the ability to smell and taste (*see* **Chapter 107, Smell and Taste**); the development of oral diseases such as smoker's palate, smoker's melanosis, and coated tongue; and possibly oral candidosis and dental caries, periodontal disease, implant failure, oral precancer, and cancer (*see* **Chapter 23, Oral Disease**). From a qualitative point of view, the latter is obviously the most serious tobacco-related effect in the mouth. Quantitatively, however, importance has been attached to periodontitis, which affects a large proportion of the population, and during recent years, more attention has been given to implant survival rates. All of these factors are increasingly important with age and therefore vital for elderly people.

Dementia

The EURODEM research group did a reanalysis of seven case-control studies, which included about 1700 patients in the early 1990s. This study suggested that the odds ratio associating a family history with a high prevalence of dementia tended to be *lower* for those with a positive smoking history (Van Duijn *et al.*, 1994).

However, researchers did further work to investigate the risk of Alzheimer's disease (AD) and smoking. They undertook a fuller meta-analysis of case-control and cohort studies (Almeida *et al.*, 2002). The authors systematically searched 21 case-control studies reporting data on 5323 subjects. As part of this study, they adjusted for confounding variables (such as age, sex, schooling, and alcohol use), and found that case-control and cohort studies produced conflicting results on the direction of the association between smoking and Alzheimer's disease.

They believed that survival bias, high mortality in smokers at earlier ages, and other methodological problems associated with case-control studies might explain the difference. There is still some debate about the possibility that smoking may actually mitigate against the onset of dementia on the basis of observations that nicotine improved performance on cognitively demanding tasks in normal

healthy adult human subjects (Wesnes and Warburton, 1984) and that nicotinic receptor binding sites were reduced in brains of patients with AD. This suggested that nicotine may be an effective therapeutic agent, or protective in AD, but the overall consensus presently is that smoking is associated with a higher prevalence of Alzheimer's disease.

Postmyocardial Infarction

A large systematic review (Critchley and Capewell, 2003) by Critchley looked at 20 studies. They showed a 36% reduction in crude relative risk of mortality for patients with coronary heart disease (CHD) who quit smoking compared to those who continued smoking. Results from individual studies did not vary greatly despite many differences in patient characteristics, such as age, sex, type of CHD, and the years in which the studies took place. The authors mention that few studies included large numbers of elderly persons, women, ethnic minorities, or patients from developing countries. Overall, they state that patients with CHD who stop smoking have a substantially reduced risk of all-cause mortality. This risk reduction appears to be consistent regardless of age, sex, index cardiac event, and country (*see* **Chapter 46, Ischemic Heart Disease in Elderly Persons**).

Blindness

Smoking is associated with several eye diseases, including nuclear cataract and thyroid eye disease, but the commonest cause of smoking-related blindness is age-related macular degeneration (Kelly *et al.*, 2004). Treatment is of only partial benefit so that identifying modifiable risk factors to inform efforts for prevention is a priority (*see* **Chapter 103, Disorders of the Eye**).

The authors cited above estimate that 53 900 UK residents older than 69 years may have visual impairment because of age-related macular degeneration attributable to smoking; of these, 17 800 are blind.

Observational studies show that smoking cessation reduces the development of macular degeneration, as former smokers have only a slightly increased risk of age-related macular degeneration compared to never smokers (Smith *et al.*, 2001). This reversibility is important for patients with macular degeneration in one eye, as a way of preventing involvement of the second eye.

POSITIVE EFFECTS

Parkinson's Disease

One of the consistent and perplexing pharmacoepidemiologic aspects of Parkinson disease is its negative association with cigarette smoking, especially in people with no family history of Parkinson's disease (Allam *et al.*, 2003) (*see* **Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly**). This has led some investigators to conclude that some aspect of cigarette smoking may exert a neuroprotective influence concerning the development of Parkinson disease. Consequently, the effect of nicotine upon the tremor of Parkinson disease and upon neurotoxin lesion in animal nigrostriatal dopaminergic neurons has been studied, although without definitive conclusions. Some studies have questioned the notion of a protective effect because of the observation that the age at diagnosis of Parkinson disease in smokers is less and there is no observed dose–response relationship. However, twin studies have maintained the suggestion that smoking may be protective (Bharucha *et al.*, 1986).

VARIABLE EFFECTS

Asthma

Some work in Finland has shown odd associations between asthma and smoking. A survey in rural Finland used a standardized questionnaire to identify people with asthmatic symptoms (Isoaho *et al.*, 1994). The study showed that current asthma was rare in men aged 75 and above and absent in those who smoked. In contrast, current asthma was commoner in women smokers. It is possible that this finding was due to a high mortality at younger ages in male smokers. Alternatively, men who have smoked for many years may get other symptoms that mask their asthma. Having said this, the prevalence of asthma was said to be similar to that found elsewhere (*see* **Chapter 61, Respiratory Disease in the Elderly**).

STOPPING SMOKING

An important factor in helping elderly people fulfil their desire to stop smoking is the important effect that this can have on younger generations. In particular, grandchildren, who often have a close relationship with their grandparents, will be strongly affected by their attempts to discontinue smoking. Family attitudes are one of the strongest influences on children taking up and stopping smoking.

Time for Effects to Occur

It stands to reason that some time is likely to elapse before an exsmoker achieves the status of a nonsmoker. For cardiovascular disease, it has been said that the effects are very rapid. For other causes of death, especially lung cancer and bronchitis, the benefit of stopping smoking takes up to 5 years to appear. There are suggestions that exsmokers move

reasonably quickly toward the state of nonsmokers for bone density, pulmonary function, and muscle strength (Mellstrom and Svanborg, 1987).

METHODS OF HELPING PEOPLE TO STOP SMOKING

Following personal advice and encouragement to stop smoking given by physicians during a single routine consultation, approximately 2% of all smokers stopped smoking and did not relapse up to 1 year. This effect is modest but cost-effective: the cost of saving a life is about £900, an extremely cheap intervention by most measures.

Advice and encouragement are much more effective for smokers at special risk. In particular, 8% of pregnant women give up, and patients with ischemic heart disease are likely to respond in larger proportions, though the former is not relevant in the elderly population. Behavior modification techniques such as relaxation techniques, rewards, and punishment have an effect that is statistically significant compared to no intervention, but no greater than simple advice by a physician. Nicotine replacement therapy is effective in approximately 13% of smokers who seek help to stop. The effect is greater in those who are nicotine dependent.

Both sudden cessation and gradual reduction in smoking are similar in their efficacy on average. Physicians should take time to advise all their patients who smoke to quit. In general, smokers who are intent on stopping should be given additional support and encouraged to use nicotine replacement therapy, as long as this is not contraindicated.

Attempts to Stop Without External Help

Many smokers give up smoking on their own, but materials giving advice and information may help them and increase the number who quit successfully (Lancaster and Stead, 2002). This Cochrane systematic review was set up to determine the effectiveness of different forms of self-help materials, compared to no treatment and to other strategies; the effectiveness of adjuncts to self-help, such as computer-generated feedback, telephone hotlines, and pharmacotherapy; and the effectiveness of approaches tailored to the individual compared to nontailored materials.

The study included randomized trials of smoking cessation with follow-up of at least 6 months, where at least one arm tested a self-help intervention. Self-help was defined as structured programming for smokers trying to quit without intensive contact with a therapist.

The authors identified 51 trials. Thirty-two compared self-help materials with no intervention or tested materials used in addition to advice. In 11 trials in which self-help was compared with no intervention, the pooled effect just reached statistical significance. They failed to find evidence of benefit from adding self-help materials to face-to-face advice or to nicotine replacement therapy. There was evidence from 14 trials that personalized materials were more effective than standard manuals or no materials.

The reviewers concluded that self-help could increase quit rates compared to no intervention, but the effect was likely to be small. They found no evidence that self-help was better than advice from a health care professional or nicotine replacement therapy. There is evidence that materials that are tailored for individual smokers are more effective.

METHODS OF HELPING ELDERLY PEOPLE TO STOP SMOKING

In the past, publications on helping elderly people stop smoking tended to underplay its importance. This appears to have changed in the last few years as topics such as the importance of smoke pollution for children and nonsmokers have gained ground. In addition, the importance of smoking to diseases that are normally associated with elderly people, such as fractured head of femur, have made it clear that it is never too late to stop. Good evidence has also pressed home the importance of smoking cessation at any age, in relation to the big killers: CHD (Critchley and Capewell, 2003), COPD (chronic obstructive pulmonary disease) (Garcia-Aymerich *et al.*, 2000), and type II diabetes (O'Connor *et al.*, 1998).

There is still evidence, however, that primary care physicians, in particular, are still less likely to give advice to older people (Ellerbeck *et al.*, 2001). This is disappointing, especially when methods of assisting people stop smoking are becoming more effective.

The National Institute for Clinical Effectiveness (NICE) has guidelines for the use of smoking cessation therapies, notably the use of nicotine replacement therapy and the drug bupropion, said to reduce the craving for tobacco (NICE, 2002). NICE does not give any specific advice for elderly people using these therapies, but states: "People with conditions such as heart disease, overactive thyroid, diabetes, severe kidney or liver disease, and stomach ulcers are advised to use nicotine replacement therapy only after they have carefully considered the risks and benefits of the treatment and after discussion with a healthcare professional." In addition, "bupropion must not be prescribed for smokers who have a current seizure disorder (e.g. epilepsy) or any history of seizure. Smokers who are at risk of seizures must not be prescribed bupropion unless the benefits of smoking cessation are likely to outweigh the risks of taking the drug. There are other factors that may increase the risk of seizures in people taking bupropion, including taking other drugs that are known to increase the risk of seizures, alcohol abuse, or head injury. People with diabetes who are using glucose-lowering drugs or insulin and people who are using drugs to treat anorexia may also have a higher risk of seizures with bupropion". NICE does not recommend using both methods together.

The prevention of smoking in retired people is not fully researched. There appear to be only a small number of

randomized controlled trials on the effects of trying to reduce smoking in the community on a group of elderly people, and most of these were available some years ago. One, which looked at helping people stop smoking as part of a general health promotion approach gave generally negative results (Burton *et al.*, 1995).

Others were more effective. For instance, a US study tested the effectiveness of an office-based smoking cessation program tailored to midlife and older smokers, using a randomized controlled trial to compare usual care with physician-delivered brief quit-smoking advice and counseling for midlife and older smokers (ages 50–74) (Morgan *et al.*, 1996). Thirty-nine practices that managed to include five or more patients in the study were included in the study. Self-reported quit rates at 6-month follow-up were 15% for the Immediate Intervention group versus 8% of subjects in the Delayed Intervention group ($P < 0.005$). They concluded that smoking abstinence was significantly increased by training physicians and key office and clinical staff to intervene with older smokers. They state that brief interventions tailored to this age cohort can be successfully and efficaciously integrated into routine care.

Some years ago, we carried out a trial of assisting elderly people aged 60 and above to stop smoking in primary care (Vetter and Ford, 1990). Each member of the intervention group was invited by letter to come to see their general practitioner, who informed them of the importance of stopping smoking and of the availability of a nurse to help them stop. The subject was given the opportunity to discuss problems associated with stopping smoking with the practice nurse.

In contrast to the above studies, smoking abstinence was tested objectively by the use of a carbon monoxide monitor. There was a reduction in the proportion smoking in both groups, but the intervention group's reduction at 14% was greater than that of the control group (9%). Four per cent of the intervention group and 2% of the controls claimed to have stopped but had a positive reading on the carbon monoxide monitor. The difference between the groups in the numbers of validated nonsmokers was statistically significant. Figure 2 shows changes in breathlessness in the two groups. There was a statistically significant difference for an improvement in breathlessness in the intervention group compared to controls.

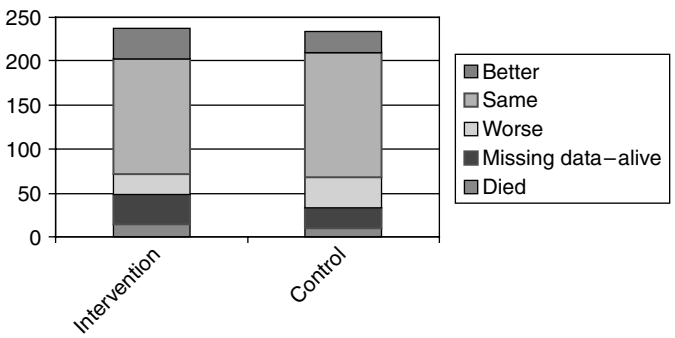

Figure 2 Changes in breathlessness after 6 months

KEY POINTS

- Smoking in elderly people shows a well-documented deleterious effect on health as in younger people.
- There are some minor differences in emphasis in old age.
- Some of these differences are likely to be due to a survival effect, given the high impact that tobacco use has on mortality.
- The most under-researched area is that of helping elderly people give up smoking.
- The small amount of research that is available suggests that such approaches have great potential.

Alcohol Use and Abuse

Mary C. Dufour

CSR Incorporated, Arlington, VA, USA

INTRODUCTION

Young adults are more likely than older adults to be drinkers, to drink heavily, and to report more alcohol-related problems (Grant *et al.*, 2004). Why, then, should physicians be concerned about alcohol consumption and problems in their older patients? No health-care provider in any health-care delivery system can responsibly and intelligently carry out the practice of geriatric medicine without a solid working knowledge of the patterns of alcohol use, abuse, dependence, and consequences among older patients. First, while the current magnitude of the problem may not be overwhelming, with the burgeoning of the elderly population, the burden can be expected to increase. Second, alcohol use and abuse are, in fact, significant health issues for older patients. Third, alcoholism is an eminently treatable disease with remission rates superior to many cancers. Intervention and treatment yield improved quality of life. Finally, all the recent media play regarding the cardioprotective effects of moderate drinking has undoubtedly attracted the attention of older individuals for whom heart disease is the number one killer. They may well ask the physician to articulate the risks and benefits of alcohol consumption for them. It behooves the physician to be able to respond intelligently.

In the twenty-first century, dramatic shifts will continue to occur in the age distribution of the world's population. In the more developed regions of the world, the population aged 60 and older currently constitutes 20% of their total population; by 2050, it will account for 32% (Population Division of the Department of Economic and Social Affairs of the United Nations Secretariat, 2005). In the United Kingdom, those aged 60 and older comprised 21% of the population in 2005; they will account for 29% of the population by 2050 (United Nations Population Division, 2005). Globally, the number of persons aged 60 and older is expected to nearly triple by 2050. In 2005, 86 million persons in the world were aged 80 or older. By 2050, this fastest growing segment of the population is projected to reach 377 million, increasing more than fourfold. The elderly population in developed countries has already surpassed the number of children and by 2050, there will be two elderly persons for every child (Population Division of the Department of Economic and Social Affairs of the United Nations Secretariat, 2005). This fastest growing group uses medications and other health services to a far greater extent and more often than any other segment of society. Elderly individuals fall prey to multiple chronic conditions; as a result, physicians see more individuals in the older population and see them more frequently, providing a welcome opportunity to discuss alcohol consumption and detect problems.

EPIDEMIOLOGY

Estimates of the magnitude of later life alcohol consumption and problems vary widely. In the field of studies on alcohol consumption, extreme variability of the definitions of terms such as "a drink", "abstainer", "moderate" drinker, "heavy" drinker, "harmful" drinking, "hazardous" drinking, "alcoholism", "alcohol abuse", and "problem drinker" is problematic both for those who conduct and those who read such studies. The term "Elderly" may also be variously defined, which further contributes to the wide range of prevalence estimates (Adams and Cox, 1995). In the United States, about half of those aged 65 and older report consuming alcohol (Moore *et al.*, 2002). In the United Kingdom, two-thirds of the men and nearly half of the women aged 65 and older reported consuming alcohol in the previous week (Rickards *et al.*, 2004). For most alcohol measures, prevalence estimates are progressively lower with increasing age; however, this does not hold for daily drinking. Older individuals consume less alcohol per occasion, but drink on more occasions (Adams and Cox, 1995). In the United Kingdom, 28% of men and 15% of women aged 65 and older reported drinking five or more times in the week prior to their interview and 21% of the men and 11% of the women reported drinking every day compared to 4% of the men and 2% of the women aged 16 to 24 (Rickards *et al.*, 2004).

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Best estimates of serious alcohol problems are those that measure alcohol abuse or dependence by utilizing rigid diagnostic criteria such as the International Classification of Diseases of the World Health Organization, or the Diagnostic and Statistical Manual of Mental Disorders (DSM) of the American Psychiatric Association. For example, among the US general population aged 65 and older, in 2001–2002, the 1-year prevalence estimates for alcohol abuse were 2.36% for men and 0.38% for women by DSM-IV criteria (Grant *et al.*, 2004). The 1-year prevalence estimates for alcohol dependence were 0.39% for men and 0.13 for women (Grant *et al.*, 2004). Although the DSM criteria have been invaluable in standardizing definitions of alcohol abuse and dependence, they yield extremely conservative estimates of the number of elderly who may get into trouble with alcohol use. Because of physical and psychosocial age-related changes, and other coexisting medical conditions and concomitant medication usage, older individuals may have problems caused by their drinking even though they do not meet diagnostic criteria for abuse and dependence. The alcohol use disorders identification test (AUDIT), a screening measure developed by the World Health Organization, identifies not only those who abuse and/or are dependent on alcohol but also those who may be hazardous drinkers because of the amount they consume (Coulthard *et al.*, 2002). In a survey of adults aged 16 to 74 in Great Britain in 2000, the prevalence of alcohol problems in the year prior to their interview was assessed using the AUDIT. Individuals who scored 8 or more on the AUDIT were classified as hazardous drinkers. Among men, 24% of those aged 65–69 and 14% of those aged 70–74 were classified as hazardous drinkers. Among women, 6% of those aged 65–69 and 5% of those aged 70–74 were so classified. Not unexpectedly, in this survey, the rates of the past 6-month's prevalence of alcohol dependence were much lower. Among the women aged 65–69, 0.7% met criteria for alcohol dependence, and among those 70–74, no cases were identified. Among the men, 2.9% of those aged 65–69 and 2.0% of those aged 70–74 were classified as alcohol dependent (Coulthard *et al.*, 2002).

At every age, men are more likely to be drinkers and to have drinking problems. The alcoholism rate is appreciably higher for elderly men than women, but because women live longer and seek medical care more often, the disparity in the patient population is not so great (Blow, 1998). Nevertheless, women alcoholics are more likely to go undiagnosed due to bias and social isolation. These rates vary widely depending on the definition of problem drinking and the population from which the sample is drawn. Among clinical populations, however, estimates of alcohol abuse or dependence are substantially higher because problem drinkers of all ages are more likely to present themselves in health-care settings. Rates of concurrent alcoholism range from 15 to 58% among older patients seeking treatment in hospitals, primary care clinics, and nursing homes for medical or psychiatric problems (Barry *et al.*, 2001).

Most older patients are not recognized as problem drinkers by health-care personnel. Since health-seeking encounters provide an excellent opportunity for the identification of and intervention for problem drinking, it is critical that physicians and other health-care providers take advantage of these opportunities. The presence of consequences, even if drinking levels are low, should drive the need for intervention. In the United States in 1999–2000, individuals aged 65–74 made an average of six ambulatory care visits per year while those aged 75 and older averaged eight visits (Burt and Schappert, 2004). In 2002, in the United Kingdom, the average number of National Health Service General Practitioner consultations was seven for those aged 65–74 and eight for those aged 75 and older (Rickards *et al.*, 2004).

Since heavy drinking is known to cause increased morbidity and mortality, it is not surprising that the prevalence of problem drinking is significantly higher in health-care settings. Alcohol abuse is a prevalent (14%) and important problem among the elderly in the emergency department setting and is not well detected by physicians there (Adams and Cox, 1995). Alcohol abuse was found to be less common among elderly trauma patients (falls and other injuries) than among their younger counterparts but very common (22%) among older patients with gastrointestinal problems (Adams *et al.*, 1992). The prevalence of alcohol-related problems among older hospital inpatients is even higher – 8–21%, with some estimates as high as 60% in certain select subgroups (Seymour and Wattis, 1992). Clearly, alcohol-related hospitalizations are common among older individuals. A landmark study of US national hospital claims data revealed that among patients aged 65 and older, alcohol-related hospitalizations occurred as frequently as those for myocardial infarction (Adams *et al.*, 1993). Psychiatric settings also show a high frequency of alcohol-related problems among older adults, ranging from 10% among the psychiatric outpatients to 23% of the elderly psychiatric inpatients (Adams and Cox, 1995). Among nursing home residents aged 65 and older, 2.8–49% have alcohol-related problems (Joseph *et al.*, 1995). Alcoholic dementia accounts for 10–20% of all admissions to US state mental hospitals (Smith, 1995). One study of elderly patients admitted to a US veterans nursing home reported that a quarter of these patients had active alcohol problems and nearly half were returned to independent living, suggesting that nursing homes serve as an important transition between hospital and home for older patients with alcohol problems, offering an ideal opportunity for identification and intervention (Joseph *et al.*, 1995). A quarter of elderly, cognitively impaired residents of long-term care facilities suffer from alcohol-related dementia (Carlen *et al.*, 1994).

SENSIBLE DRINKING GUIDELINES

In the early 1990s, advice about sensible drinking in the United Kingdom centered on the amount of alcohol consumed weekly, and advised that men consume 21 or fewer units per week and women consume no more than 14 units. Appreciating the potential harm that could be realized from consuming all 21 drinks on one occasion, the focus changed in 1995 to daily guidelines, which recommend a maximum

intake of 2–3 units per day for women and 3–4 for men, with two alcohol-free days after heavy drinking. Continued alcohol consumption at the upper levels is not advised (Prime Minister's Strategy Unit, 2004).

The standard definition of a unit of alcohol is that which contains 8 g of ethanol or 10 ml by volume. One unit is contained in half a pint of beer, a small glass of wine, and a single measure of spirits. Results from a national survey of drinking behavior and knowledge in the United Kingdom in 2004 revealed that the majority of respondents reported having heard of measuring alcohol consumption in units. Far fewer knew how to define a unit. Knowledge of the concept of units decreased with increase in age. Those aged 65 and older were least likely to report having heard of measuring alcohol in units. Likewise, 60% had heard of daily benchmarks but far fewer knew what they were (Lader and Goddard, 2004).

In a survey conducted in 2002, 16% of the men and 5% of the women aged 65 and older reported exceeding the daily number of units (more than four units for men and more than three units for women) on at least 1 day during the preceding week. In addition, 5% of the men in this age-group reported drinking more than eight units on at least one day and 1% of the women reported drinking more than six units on at least one day. In terms of weekly consumption, 15% of the men drank more than 21 units in the week and 3% drank more than 50 units. Among women, 7% reported totaling more than 14 units and 1% reported drinking more than 35 units over the course of the week (Rickards *et al.*, 2004).

AGE DIFFERENCES IN ALCOHOL EFFECTS

Increasing evidence suggests that the pharmacokinetic and pharmacodynamic effects of ethanol differ in older individuals compared with younger ones. Elderly people appear to be more sensitive to a given dose of alcohol. Between the ages of 25 and 60, the proportion of total body weight represented by fat doubles in men and increases by 50% in women, resulting in a corresponding decrease in total body water (Dufour *et al.*, 1992). Since alcohol is distributed in total body water, with a smaller volume of distribution, an alcohol dose identical to that given to a similar-sized younger individual of the same gender will produce a higher blood alcohol concentration in the older individual (Dufour *et al.*, 1992).

Research also suggests that mechanisms which are more complicated than simply differential volumes of distribution may contribute to differential sensitivity (Beresford and Lucey, 1995). Differential metabolism and intoxication were assessed in nonalcoholic younger and older individuals in three different metabolic settings using small doses of alcohol ($0.3\,g\,kg^{-1}$). This amount of alcohol resulted in considerable subjective feelings of intoxication in older subjects of either gender and the effects lasted longer (Beresford and Lucey, 1995). In addition, the elderly participants not only began with less perceptual motor capacity but also experienced a greater degree of impairment after ethanol intake and took longer to return to baseline functioning on some measures. While fasting markedly increased alcohol absorption for all study participants, the increased absorption in elderly women compared with younger women was particularly striking (Beresford and Lucey, 1995).

Although evidence is conflicting, some researchers suggest that, among young adults, gender differences appear to exist in ethanol metabolism by alcohol dehydrogenase (ADH) in the stomach, the so-called *first pass metabolism*, with the gastric ADH activity significantly higher in young adult men than in women. In elderly subjects, the gastric ADH activities were low in both sexes (Parlesak *et al.*, 2002). In addition, *Helicobacter pylori* infection is associated with decreased antral ADH activity. Eradication of the *H. pylori* normalizes ADH activity within 2 months (Kechagias *et al.*, 2001).

It was once thought that chronic heavy drinking accelerated the aging processes in the brain. The preponderance of scientific evidence now suggests that alcoholism does not cause premature aging. Rather, the effects of alcoholism are disproportionately expressed in older alcoholics (Oscar-Berman and Marinkovic, 2003). In other words, the aging brain is more vulnerable to the toxic effects of alcohol than is the younger brain, both acutely and with regard to reversibility of atrophic changes in the brain related to abstinence. Memory and executive skills appear to be resistant to recovery, or at least slower to recover with abstinence in older alcoholics (Munro *et al.*, 2000).

Not surprisingly, older subjects have been found to perform significantly worse in driving simulation than do younger subjects at the same alcohol dose (Beresford and Lucey, 1995), and have a dramatically higher risk of meeting the criteria for dependence at a given level of alcohol consumption than do younger individuals (Dawson and Archer, 1993).

MEDICAL CONSEQUENCES

Alcohol affects every organ in the body, manifesting itself in a wide array of pathology. For the elderly individual who already has reduced reserves because of normal aging and disease, the medical consequences of alcohol abuse are of paramount importance. They are important in their own right and provide clues to the diagnosis of alcoholism, and heavy alcohol consumption and alcoholism can cause symptoms that are also commonly seen in other conditions that beset the elderly.

In addition to alcohol dependence, alcoholic brain damage includes brain atrophy, dementia, and Wernicke–Korsakoff syndrome (Gambert and Katsoyannis, 1995). Peripheral neuropathy is frequently seen in clinical practice, where it is often first diagnosed as diabetic peripheral neuropathy (Smith, 1995). Alcohol disturbs normal sleep patterns and increases the risk of sleep apnea (Prinz *et al.*, 1990).

Alcoholic liver disease, primarily alcoholic hepatitis and cirrhosis, is a leading cause of death among alcoholics (Dufour *et al.*, 1993). Cirrhosis, secondary to hepatitis C

viral (HCV) infection is now the leading cause of adult liver transplants in the United States (OPTN, 2004). For people with HCV infection, alcohol consumption accelerates progression to cirrhosis and hepatocellular carcinoma (Lieber, 2001). For a variety of reasons, continued alcohol consumption is considered a major contraindication to treatment with current antiviral agents (Lieber, 2001). HCV infection is currently most prevalent among those aged 35–55 (CDC, 2004) but it does occur in older individuals also. In addition, as those currently infected age, HCV infection will become a greater problem in older individuals.

Heavy alcohol consumption is one of the leading causes of acute pancreatitis (Dufour and Adamson, 2003). Approximately three-quarters of the patients with chronic pancreatitis have a history of heavy alcohol consumption, and, while alcoholic liver disease and pancreatitis are much more likely to be encountered in younger patients, they do occur in the elderly (Dufour and Adamson, 2003). Alcohol use can cause esophagitis and gastritis, and exacerbate existing peptic ulcers (Smith, 1995). Alcohol-related testicular atrophy may contribute significantly to sexual problems in male alcoholics (Gambert and Katsoyannis, 1995). In women, it may cause premature menopause (Gambert and Katsoyannis, 1995).

Excessive alcohol consumption interferes with nutrition in many ways, including decreased budget for food, consumption of only empty calories available in alcohol, decreased appetite, decreased absorption of vitamins, amino acids and fats by a variety of mechanisms, and increased metabolic demand (Smith, 1995). Excess alcohol consumption is associated with iron deficiency anemia (gastrointestinal bleeding), macrocytic anemia, and coagulation defects. Alcohol-induced impairment of the immune system plays a role in increased vulnerability to tuberculosis and pneumonia (Gambert and Katsoyannis, 1995).

Hypertension is extremely prevalent among older people, affecting close to half of those aged 65 and older. Since hypertension is a major risk factor for stroke, myocardial infarction, and other vascular events, control of blood pressure is important (Adams, 2002). Alcohol consumption of above three drinks a day for men (1.5 oz ethanol or 36 g) and two for women is a major risk factor for hypertension (Zakhari and Wassef, 1996). Alcohol-related hypertension readily improves when alcohol consumption is decreased (Adams, 2002).

Cardiac manifestations include rhythm disturbances and alcoholic cardiomyopathy (Zakhari and Wassef, 1996). Extremely high levels of consumption are associated with an increased risk of coronary heart disease and ischemic stroke (Zakhari and Wassef, 1996). On the other hand, over 100 observational studies and more than 80 short-term metabolic studies have documented a strong association between moderate alcohol consumption and reduced risk of occurrence and death from myocardial infarction and ischemic stroke in both middle-aged and older men and women (Hines and Rimm, 2001). Experimental studies have found beneficial effects of alcohol on lipids, coagulation factors, and other cardiovascular markers. Genetic factors appear to modify the effects of alcohol on the risk for coronary heart disease, resulting in population variability in the amount of benefit (Hines and Rimm, 2001). Even low levels of alcohol consumption increase the risk of hemorrhagic stroke, especially in women (Scherr *et al.*, 1992).

Much remains to be learned about the relationship between alcohol consumption and diabetes mellitus. Light to moderate alcohol consumption appears to decrease the risk of developing type 2 diabetes in both men and women, with frequent (5 or more days a week) consumption conferring the most benefit (Conigrave *et al.*, 2001; Wannamethee *et al.*, 2003). Once diabetes has developed, alcohol consumption makes the control of blood sugar levels more difficult. Patients should be warned that hypoglycemia may occur several hours after alcohol consumption, and if likely to drink excessively, should be advised on how to modify their insulin doses and eating habits accordingly. The current recommendation of 2–3 units of alcohol per day should not be exceeded by diabetic patients (Gallagher *et al.*, 2001).

Alcohol abuse is associated with an increased risk of cancer of the liver, esophagus, nasopharynx, and larynx (Smith, 1995; Gambert and Katsoyannis, 1995). Some studies suggest that alcohol may play a role in cancer of the stomach, large bowel, and female breast (Smith, 1995; Gambert and Katsoyannis, 1995). Alcoholics with a variety of cancers have a poorer survival rate and an increased risk of developing a second primary than do nonalcoholics with the same cancer (Gambert and Katsoyannis, 1995). Chronic alcoholic myopathy causes muscle wasting and weakness. Even in the absence of muscle wasting, muscle strength is diminished (Smith, 1995). Aging is associated with a decrease in bone density in both men and women; however, the impact of alcohol on bone varies with dose and gender (Gambert and Katsoyannis, 1995). Male alcoholics are at greatly increased risk for osteoporosis. In addition, drinking leads to poor mobility and increased falls, leading to an increase in fractures. In the elderly, fractures tend to heal more slowly and to be associated with more complications. However, research also suggests that moderate drinking in both older men and postmenopausal women actually increases bone mineral density and improves bone mass relative to that of nondrinkers (Turner and Sibonga, 2001). Likewise, studies indicate that among healthy, mobile, independent, community-dwelling older individuals, alcohol may not play as big a role in falls (Nelson *et al.*, 1992; Sheahan *et al.*, 1995) as in more impaired individuals (Carlson, 1993).

ALCOHOL–MEDICATION INTERACTIONS

An older patient need not be alcohol dependent to get into trouble with alcohol use. A prime example is alcohol–medication interactions. In the United States, those aged 65 and older use 30% of the prescription drugs sold and 40% of over-the-counter medications (FDA, 1997). One study of community-dwelling elderly showed that 75% of those interviewed took at least one prescription drug and 52% reported taking three or more (Adams, 1995). In another

community study, all of the elderly drinkers reported utilizing at least one prescription or over-the-counter medication associated with an alcohol–drug interaction, reinforcing the concept that the profile of the older person at risk for an alcohol–drug interaction is that of the older person who drinks (Forster *et al.*, 1993). Alcohol interacts with over 100 prescription and over-the-counter medications (Dufour *et al.*, 1992), including over half of the 100 most frequently prescribed medications (Weathermon and Crabb, 1999). Acutely ingested, alcohol impairs the clearance of some drugs by the liver. In contrast, chronic alcohol consumption induces the synthesis of enzymes, leading to enhanced metabolism and increased clearance of some drugs, including anticonvulsants, anticoagulants, and oral hypoglycemic agents.

Psychotropic drugs such as antipsychotics and antidepressants are frequently prescribed for older patients: benzodiazepines or other sedative hypnotics are the most commonly prescribed classes of these drugs. Antipsychotic drugs inhibit the metabolism of alcohol and may markedly enhance its effects on the central nervous system (CNS) in the elderly. Antidepressants exaggerate the response to alcohol and impair motor skills (Weathermon and Crabb, 1999). Depression of the CNS may range from drowsiness to coma. The alcohol interaction with benzodiazepine drugs, especially diazepam and chlordiazepoxide, is much greater in the elderly than in other age-groups. Commonly observed side effects include hypotension, sedation, confusion, and CNS depression that may progress to respiratory depression (Weathermon and Crabb, 1999). These effects are especially hazardous in a population with decreased agility and a greater danger of serious complications from falls and accidents. Since older individuals are more sensitive to the effects of psychotropics, it is wise to reduce the dosages of benzodiazepines, analgesics, and sedative hypnotics in the elderly and to discourage the concomitant usage of alcohol. As a general rule, elderly patients should be instructed to refrain from using alcohol while taking CNS depressants, including benzodiazepines, barbiturates, muscle relaxants, and antihistamines – both in prescription form as well as over-the-counter cold preparations or sleeping aids (Weathermon and Crabb, 1999).

Alcohol is a vasodilator that enhances the absorption of nitroglycerin. Use of alcohol when vasodilation by nitrates is needed may result in severe hypotension. β-Blockers may mask the signs of delirium tremens. Use of alcohol with digoxin produces increased effects of alcohol and may result in seizures. Alcohol in combination with heparin can cause increased bleeding. Alcohol with tolbutamide or chlorpropamide can cause an Antabuse-like reaction (Weathermon and Crabb, 1999).

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the most prescribed drugs worldwide when grouped by generic categories (Adams, 1995). Aspirin is the active ingredient in countless over-the-counter preparations. Aspirin and other NSAIDs with alcohol increase the possibility of gastritis and gastrointestinal hemorrhage (Adams, 1995). Acetaminophen in therapeutic doses can result in severe hepatotoxicity in heavy drinkers (Adams, 1995).

Herbal medications currently are widely used and many people assume that because these products are "natural", they are also safe to use. Unfortunately, this assumption is not always correct. Chamomile, echinacea, and valerian are commonly used as sleep aids, and like prescription and OTC products that produce sedation, these products may produce enhanced sedative effects in the CNS when combined with alcohol. In addition, liver toxicities caused by various natural products have now been identified and their combination with alcohol may enhance potential adverse effects. To date, limited scientific documentation of such interactions exists due to lack of scientific studies on the subject (Weathermon and Crabb, 1999).

BARRIERS TO DIAGNOSIS AND TREATMENT

Attitudes toward alcoholism and aging on the part of the patient, physician, family, and society still often represent formidable obstacles to identification, diagnosis, and treatment. "Enabling" is an activity that is meant to "help" the alcoholic, but this also shields them from taking responsibility or being held accountable for the consequences of their drinking. In a recent study of elderly alcoholics presenting to an emergency department, one-third were found to have active "enablers" who blocked intervention for the alcohol problem. One-fifth of these enablers were physicians (Tabisz *et al.*, 1993).

Busy physicians may not consciously erect barriers, but rather, may be reluctant to assume clinical responsibility for a patient who is both elderly and alcoholic. A recent study among house officers in a US hospital found that they accurately diagnosed alcoholism in only 37% of elderly alcoholic patients compared with 60% of their younger patients (Egbert, 1993). Similar results were found among house officers in three Australian hospitals (Whelan, 1995).

Health-care providers may be unaware of age differentials in the signs and symptoms of alcohol-related problems, or, if able to make the diagnosis, may hesitate to do so because they are unsure about how to address the problem in the elderly, or may be unfamiliar with treatment resources for the elderly in their community, or with specialists in geriatric medicine or addiction medicine, with whom they might have to consult (Gurnack *et al.*, 2002).

Alcohol problems in the elderly are easy to miss. In a population in which there is already an overabundance of conditions requiring immediate medical attention, health-care providers may simply neglect to factor alcohol into the diagnostic equation. History taking can be a challenge with confused patients. Older patients may have difficulties remembering past average alcohol consumption. Denial, a hallmark of the disease at any age, may be reinforced in many older individuals who believe that alcoholism is a moral weakness or a character flaw rather than a disease. Elderly women are especially prone to delay seeking treatment until problems are more severe (Dunne, 1994). Social isolation

makes it easy to hide alcohol consumption – nearly a third of community-dwelling elderly live alone (Egbert, 1993).

A trap for the physician and family to avoid is unwillingness to discuss the patient's drinking problems with the individual, because he or she "has only a few years left". This is a myth. Older recovering alcoholics report that they began to live fuller, more satisfying lives after they stopped drinking and thus avoided the tragedy of wasting their remaining precious years. By recognizing and appreciating the broad patterns of problem drinking in the elderly population, physicians will be better able to recognize and understand the individual cases that they encounter.

DIAGNOSIS

Alcohol dependence is a serious medical and psychiatric disorder characterized by narrowing of the drinking repertoire, priority of drinking over other activities, increased tolerance to alcohol, repeated withdrawal symptoms relieved by further drinking, subjective awareness of a compulsion to drink, and reinstatement of drinking after abstinence (Seymour and Wattis, 1992). Problem drinking is drinking that causes harm, but the patient does not meet enough criteria to qualify for a diagnosis of abuse or dependence. Dependence and other drinking problems can occur in older patients, especially women, with substantially less alcohol than in younger individuals. Even older patients who do meet diagnostic criteria for abuse or dependence may differ in their presentation of key symptoms. For example, tolerance is characterized by requiring greater amounts of alcohol to achieve the same effect. Because of the reduction in body water, the elderly alcoholic may honestly report consuming a relatively smaller amount of alcohol to achieve the same effect as previously achieved, although there is the same induction of liver enzymes that cause tolerance in younger individuals.

Likewise, a person who is retired, widowed, and no longer driving, will obviously not report work-related problems, marital problems, or legal problems, such as arrests for drinking and driving – classic indicators of alcohol problems in the younger person.

Elderly alcoholics fall into two groups: those whose alcoholism began early in life (early-onset alcoholism) and those whose alcohol problems began later in life (late-onset alcoholism). Once again, definitions vary, with age cutoffs for "late onset" ranging from age 25 to 60 with most studies selecting age 40, 45, or 50 (Liberto and Oslin, 1995). Some investigators prefer the term "recent onset". An 85 year old who began drinking abusively at age 55 would hardly be considered a recent-onset alcoholic, but would qualify as one of "late onset". The importance of this distinction lies in the amount of damage linked to the amount of alcohol over time, the implication being that the "recent-onset" problem drinker may have a better prognosis and that intervention may be more effective when the drinking pattern is still being formed and before the illness has robbed the drinker of necessary physical and social resources (Liberto and Oslin, 1995). One-half to two-thirds of the elderly alcoholics are early-onset alcoholics (Liberto and Oslin, 1995). Usually they are more identifiable because of previous treatment contacts or earlier dysfunctional behavior that brought them to the attention of others.

The etiology of late-onset alcoholism appears to be more related to specific situational factors, such as retirement, death of a spouse or loss of friends, rather than family history or genetic influences (Brennan and Moos, 1995). However, many individuals in this group may have had undetected/undiagnosed alcoholism or a pattern of heavy drinking for years, with recent life events causing the disease to become manifest. Problem drinking tends to occur later in elderly women.

Patients suspected of having an alcohol-related problem should have a complete physical examination with special emphasis on peripheral manifestations of alcohol excess and chronic liver disease (parotid enlargement, Dupuytren's contracture, spider nevi, gynecomastia, jaundice, etc. *see* **Chapter 33, Liver and Gall Bladder**), including a thorough neurological assessment to rule out nystagmus, cerebellar ataxia, and peripheral neuropathy. When indicated, selected laboratory tests should be done to support the preliminary diagnosis – liver function tests and blood alcohol concentration may be informative. A mental status examination is necessary to assess the reliability of self-reported consumption as well as alcohol-related brain damage.

A careful history of current and past alcohol, tobacco, and other drug use, including prescription and over-the-counter medications, is mandatory. Frequency of drinking, beverage type, quantity per occasion, spirits added to tea or coffee, and corroborative history from caregivers or family are critical. Attention to definitions is at the heart of communication between the doctor and patient. It is critical to know whether a beer now and then means a 12 oz can of beer or a 32 oz bottle of beer and whether a "glass of wine" is a full 16 oz tumbler rather than a 5 oz wine glass. Many older individuals may not consider taking a tot of whiskey or rum in coffee or tea to be "drinking" and may neglect to mention such consumption. Hence this should be explicitly inquired about (Naik and Jones, 1994). Patients who have alcohol problems are also more likely to use anxiolytics, hypnotics, and other psychoactive substances. Inquiries about diet and nutrition are also pertinent.

Several self-administered screening instruments are available to assist in the diagnosis. Screening questions that work in busy general primary care samples of older adults include questions on quantity and frequency of alcohol consumption, binge drinking, and the CAGE questions (Mayfield *et al.*, 1974). A brief four-item questionnaire, the CAGE, originally developed for screening for alcoholism in younger patients, has been found to have excellent sensitivity and specificity among older patients as well (Fleming, 2002). Since it takes less than a minute to administer, the CAGE can be woven into a standard brief clinical history (see Table 1) and, for this reason, is probably the most commonly used screening instrument. If at least two questions are answered

Table 1 CAGE questions (Mayfield *et al.*, 1974)

1. Have you ever felt you should **C**ut down on your drinking?
2. Have people **A**nnoyed you by criticizing your drinking?
3. Have you ever felt bad or **G**uilty about your drinking?
4. Have you ever taken a drink first thing in the morning (**E**ye opener) to steady your nerves or get rid of a hangover?

affirmatively, the probability of alcoholism is high; however, in the elderly, even one affirmative response is strongly suggestive (Blow, 1998).

The AUDIT developed by the World Health Organization, identifies not only those who abuse or are dependent on alcohol but also those who may be hazardous drinkers because of the amount they consume (Blow, 1998; Allen and Wilson, 2003). The Michigan Alcoholism Screening Test (MAST) is a 25-item instrument that provides a quantifiable screen of alcohol abuse, has excellent reliability and validity, and is a widely used instrument for screening for alcoholism in younger individuals; however, some of the items may not be relevant for older drinkers (Blow, 1998). A version of this instrument developed especially for use with geriatric patients (MAST-G) has several elder-specific items such as "After drinking, have you ever noticed an increase in your heart rate or beating in your chest?" and "Does alcohol make you so sleepy that you often fall asleep in your chair?" (Blow, 1998). This instrument is highly valid and reliable among older problem drinkers and can be given as a paper-and-pencil self-administered assessment or by interview and takes about 10 minutes to complete (Barry *et al.*, 2001). A short version of the MAST-G, the SMAST-G, has been developed for use in busy clinical settings where the length of the instrument and its administration time are major barriers to its use (Barry *et al.*, 2001).

While all very useful, none of these measures identify people who may be at risk of, or experiencing, adverse consequences as a result of their drinking in combination with their comorbidities (e.g. hypertension, depression, etc.) and concurrent medication use, and yet do not qualify as "problem drinkers" on the above-mentioned screening instruments. Such risks are particularly relevant to older individuals. The alcohol-related problems survey (ARPS) has been developed to fill this gap – to identify older persons whose use of alcohol alone or in combination with their comorbidities, medications, symptoms, and functional status may be causing them harm or putting them at risk for harm. The ARPS is a 10-minute paper-and-pencil questionnaire that contains 60 items and is completed by the patient alone or with family assistance. On the basis of their responses, patients are designated as harmful, hazardous, or nonhazardous drinkers. Respondents completing the shorter 32-item version, the shARPS, are dichotomized as either harmful/hazardous or nonhazardous drinkers (Fink *et al.*, 2002).

Clues to an alcohol-related problem unearthed in the medical history include falls, bruises, emergency department visits, hyperuricemia, gastrointestinal problems, hypertension, insomnia, malnutrition, unstable diabetes and depression, as are self-neglect, urinary incontinence, diarrhea, decrease in functional status or apparent dementia (Barry *et al.*, 2001).

Laboratory investigations showing a raised mean corpuscular volume (MCV) or unexplained liver function test abnormalities, including elevated gamma glutamyltransferase, should alert the physician to the possibility of alcohol abuse. Hyperuricemia, hypertriglyceridemia, and hypoglycemia may also be caused or exacerbated by alcohol abuse (Seymour and Wattis, 1992).

Differentiating alcoholism from other psychiatric disorders is challenging but necessary because of the frequent occurrence of other psychopathology, especially depression, among elderly problem drinkers, particularly those who are hospitalized. The primary care provider, with consultation when necessary, should be prepared to make a comprehensive psychiatric evaluation of the patient to determine whether one or more diagnoses are in order and to determine which is the primary condition

INITIAL TREATMENT APPROACHES

With older problem drinkers, it is generally recommended that the least intensive treatment options be explored first. These initial approaches, which can function either as a pretreatment strategy or treatment itself, are brief intervention, intervention, and motivational counseling. Brief intervention is recommended as the first step, supplemented or followed by intervention and motivational interviewing (Blow, 1998). Brief interventions are time-limited, patient-centered counseling strategies that focus on changing their behavior and increasing compliance. Brief intervention is not unique to the treatment of alcohol problems. These counseling strategies are widely used by health-care providers for changing behavior, and have been found to be effective in reducing overall drinking, episodes of binge drinking, and frequency of excessive drinking in older adults. The clinical elements of brief intervention for the prevention and treatment of alcohol problems vary across trials and clinical programs, but they all contain a number of common elements: assessment; direct feedback; contracting, negotiating, and goal setting; behavior modification techniques; self-help directed bibliotherapy; follow-up and reinforcement. The number and duration of brief intervention sessions have varied widely. The classic brief intervention performed by a physician or nurse typically lasts 5–10 minutes and is repeated 1–3 times over a 6–8 week period (Barry and Blow, 1999). Numerous trials on primary care patients, including older individuals, have demonstrated that brief intervention is effective in reducing alcohol consumption in hazardous drinkers (Adams *et al.*, 1996; Gordon *et al.*, 2003).

If the older problem drinker does not respond to brief intervention, two other approaches – intervention and motivational interviewing – should be considered (Blow, 1998). In an intervention, several significant people in a problem drinking patient's life confront the patient with their firsthand experiences of his or her drinking. The formalized

intervention process includes a progressive interaction by the counselor with the family or friends for at least 2 days before meeting with the patient. For older patients, no more than two relatives or friends should be involved along with the health-care professional. Having too many people present may be emotionally overwhelming or confusing for the older person. Also, inclusion of grandchildren is discouraged, because many older adults may resent their problems being aired in the presence of much younger relatives (Blow, 1998).

Motivational counseling acknowledges differences in the readiness to address problem drinking and offers an approach for "meeting people where they are", which has proven effective with older adults. An understanding and supportive counselor listens respectfully and accepts the older patient's perspective on the situation as a starting point, helps him or her identify the negative consequences of drinking, helps the patient shift perceptions about the impact of drinking, empowers the patient to generate insights about and solutions for the problem, and expresses belief in and support for the patient's capacity to change. Motivational counseling enlists patients in their own recovery by avoiding labels and confrontations, accepting ambivalence as normal, inviting clients to consider alternative strategies for solving problems, and placing the responsibility for change on the patient (Blow, 1998).

SHORT-TERM STABILIZATION AND MANAGEMENT

The medical consequences of prolonged or heavy alcohol use can be severe and may require immediate attention. Conditions such as internal bleeding, fractures, other trauma resulting from falls, ischemic incidents, and mental confusion are not unusual and may, in fact, be the presenting complaint. If the patient is intoxicated when initially seen, the first step is detoxification. An intoxicated patient cannot engage in meaningful discussion of rehabilitation. Intoxicated elderly patients who threaten suicide should be taken seriously and given a prompt psychiatric examination and probably hospital admission as the suicide rate in these individuals is alarmingly high (AMA, 1995).

Although outpatient detoxification is often effective and safe for younger alcoholics who have mild to moderate withdrawal symptoms and no accompanying serious diseases, detoxifying elderly alcoholics is best carried out in a hospital setting where doses of benzodiazepines and/or other medications can be carefully monitored and emergency medical care is readily available (Seymour and Wattis, 1992). Sedatives should be used just vigorously enough to relieve withdrawal symptoms and not so vigorously as to result in somnolence, otherwise pulmonary complications may ensue. Dangers associated with alcohol-withdrawal syndrome are predominantly those of seizures and delirium tremens. For elderly alcoholics with a history of previous episodes of withdrawal, the risk is especially high (Seymour and Wattis, 1992). Delirium tremens, characterized by disorientation and confusion, visual or tactile hallucinations, and autonomic hyperactivity, must be considered a medical emergency; the death rate is 10–15% in untreated cases (AMA, 1995). With many older patients taking diuretics, careful attention to hydration and electrolyte balance is important (Seymour and Wattis, 1992). Vitamin supplements, especially thiamine, initially given parenterally may need to be continued orally, particularly if the patient has peripheral neuropathy (Seymour and Wattis, 1992). Acute withdrawal often persists longer in older alcoholics. In addition, confusion may be more severe and prolonged after discontinuation of drinking (Oscar-Berman and Marinkovic, 2003). Careful attention must be given to the patient's cognitive state during this period. Patients who have been medically detoxified should not be screened for cognitive dysfunction until several weeks after detoxification is completed because a patient not fully recovered from detoxification may exhibit some reversible cognitive impairment (Blow, 1998). However, counseling, didactic sessions, and mutual help groups, which otherwise would be appropriate are not useful to the patient whose mental faculties are too impaired to participate meaningfully.

LONG-TERM MANAGEMENT

After emergency situations have been addressed and detoxification completed, the next step is to work with the patient and family to develop a long-term treatment plan. This rehabilitation phase begins with the physician presenting the patients with the facts about their drinking problem in a concerned, nonjudgemental manner. Whereas the negative aspects of uncontrolled drinking are generally obvious to others, the alcoholic usually perceives benefits from drinking. Frank, compassionate discussion often helps the individual to recognize the negative consequences of their drinking and makes them consider the need for treatment. Although this discussion may be painful for the patient and may occasionally result in the patient leaving the physician's practice, people in recovery from alcoholism often date the beginning of their remission from such a discussion.

In general, the ultimate goal of treatment is abstinence. The patient can be referred to an addiction program, an addiction specialist or Alcoholics Anonymous (AA) or other mutual help groups. Addiction programs usually provide group therapy and/or individual counseling, relapse prevention training and support from an AA group. Patients who perceive that many AA members are too young should be informed that one-third of all AA members in North America are over the age of 50 and that compatible groups are likely to be found. There are more than 3000 AA groups in the United Kingdom today. Information about AA in the United Kingdom for the health-care professional can be found on the Internet at http://www.alcoholics-anonymous.org.uk/prof/. Older individuals respond well to group therapies, especially when increased socialization is also encouraged. Currently, older patients are "mainstreamed" with patients of all ages and do just as well in treatment (Blow, 1998). While age-specific treatment is intuitively appealing, research to date does not

support the view that older alcoholics require age-specific treatment. Whether they would have better outcomes in such settings is under investigation. Some studies have indicated more favorable outcomes for elder-specific groups than mixed age-groups. Treatment programs that emphasize social relationships and positive aspects of a patient's life have demonstrated better outcomes for those aged 60 and older, than programs using traditional confrontation and focusing on past failures (Blow, 1998).

The prognosis for patients with late-onset alcoholism is usually better than for those with early onset (Brennan and Moos, 1995). Late-onset patients seem to comply more readily with treatment plans and remain in treatment longer (Brennan and Moos, 1995). Among the early-onset patients, those having more drinking problems, financial stressors, and those who sought professional help were more likely to quit drinking (Brennan and Moos, 1995). Among the late-onset individuals, social influences and physical health stressors were more important in predicting remission and abstinence (Brennan and Moos, 1995). Studies have shown that older alcoholic individuals demonstrate greater adherence with alcohol treatment visits and medication than younger ones, with a greater reduction in the rates of relapse (Oslin *et al.*, 2002). Prior to making a referral, the physician should become familiar with programs available in the community, or elsewhere if necessary, and determine their accessibility both in terms of distance and time. The longer the waiting period, the less likely the patient will show up for admission.

PHARMACOTHERAPIES FOR ALCOHOLISM

Advances in the neurobiology of addiction and methodologies of improved clinical trials have accelerated the evaluation of medications for alcoholism. Because of the complex nature of alcohol use disorders, no single treatment strategy has thus far proven fully effective. While the psychosocial treatments for alcohol abuse and dependence can be effective in reducing alcohol use and increasing health and well being, they are not always completely successful for all patients and can be costly (Litten *et al.*, 2005). In addition, medications are being increasingly used in the treatment of other addictive disorders such as buproprion for smoking cessation.

No discussion about the pharmacotherapy of alcoholism would be complete without acknowledging the historical and practical utility of aversive therapies. Disulfiram (Antabuse®) is an example of a medication that can increase the unpleasant actions of alcohol (nausea, vomiting, flushing) by inhibiting acetaldehyde dehydrogenase, an enzyme involved in alcohol metabolism, leading to the accumulation of acetaldehyde after alcohol is consumed. While the efficacy of this drug is variable, disulfiram is widely used throughout the world in both tablet and implant form. Data suggests that the drug is most effective in older, highly motivated individuals, and in those who are supervised during daily ingestion. Some clinicians advise against the use of disulfiram to help enforce abstinence in the elderly because of the increased potential for adverse cardiovascular effects. Because of the risk of hepatotoxicity, physicians review the signs and symptoms of hepatotoxicity and liver function tests at the onset of treatment and at regular intervals thereafter (Anton and Swift, 2003).

Acamprosate (Campral®) has been licensed for the treatment of alcohol dependence in France for over 10 years and in the United Kingdom since 1996. The drug is currently approved and available in 29 countries including the United States, where it was approved in 2004. Over 20 clinical trials have been conducted, and overall it was found that acamprosate is effective in increasing the rates of abstinence and treatment retention. Acamprosate may also decrease the frequency of drinking as well as reduce alcohol consumption if a relapse has occurred. Neither type nor intensity of any concomitant psychosocial intervention has been found to improve outcome over the use of acamprosate alone. A current favored explanation for acamprosate's effect in alcohol-dependent patients is that it reduces the tendency to relapse in situations that have been linked to the negative sensations associated with the absence of alcohol, the so-called *negative craving*. The use of acamprosate varies within and among countries of Europe. In a survey in Scotland, all the National Health Service units specializing in treating alcohol problems prescribed it. It is generally recommended that in order to achieve the greatest chance of an effect, acamprosate should be started as soon as the patient is near successful detoxification. If the patient manages to abstain, the drug should be continued for 1 year. Given that acamprosate also appears to have a small effect in reducing the drinking following a lapse, the drug should not be stopped if the patient lapses – if the lapses are less severe and less frequent than prior to treatment, the drug may be helping. Diarrhea is the most common side effect. Since acamprosate is not metabolized by the liver, it is not contraindicated in liver disease (Soyka and Chick, 2003).

Naltrexone (ReVia®) was first approved for alcoholism treatment in the United States in 1994. The medication is an opioid antagonist, which has reportedly been shown to decrease the positive reinforcing effects associated with alcohol consumption and the sensation of wanting to drink (craving). Results for naltrexone studies have been less consistent than those reported for acamprosate, and several European studies have been negative or partly negative. Several studies have indicated that cognitive behavioral therapy with teaching of coping skills leads to the best outcomes when naltrexone is used (Litten *et al.*, 2005). Studies have shown that naltrexone is well tolerated and efficacious in preventing relapse in older patients who drink following entry into alcoholism treatment (Oslin *et al.*, 1997). Side effects of naltrexone are generally moderate at the 50 mg dose used in most studies and include nausea, vomiting, diarrhea, headache, and fatigue. A recent report of interaction between NSAIDs and high-dose naltrexone (>100 mg) leading to hepatotoxicity is a cause for concern and patients should be cautioned. In general, clinicians should start naltrexone at $25\,\text{mg}\,\text{day}^{-1}$ for a few days and move the dose to 50 mg as tolerated (Anton and Swift, 2003).

Alcoholism is a chronic, relapsing condition like arthritis or diabetes. Elderly patients, like alcoholics of every age, may well have "slips" and return to drinking. The resultant guilt and shame may prevent their return to the physician. Missed appointments should therefore be routinely followed up by a nonjudgemental invitation to return for treatment. One study examining the outcomes at 1 and 5 years after treatment for alcohol use disorders showed that elderly patients had better outcomes than did young and middle-aged patients receiving the same levels of services (Lemke and Moos, 2003).

CONCLUSION

The cornerstone of prevention is the inclusion of an alcohol history in *every* history and physical examination. Primary prevention of alcohol-related problems and alcoholism among the elderly consists mainly of alerting patients to possible alcohol–medication interactions and other risk factors that can lead to late-onset alcoholism. Physicians are more likely to be involved in secondary prevention where the role is recognizing early warning signs in their patients and intervening at the onset of harmful drinking behavior.

Even in the absence of signs and symptoms of alcohol-related problems, physicians must provide education on the adverse effects of alcohol with age and must define and advise moderation.

All other things being equal, there is no evidence to suggest that older individuals are any more or any less able to cope with the stresses of life. Old age *per se* is not a contraindication to moderate alcohol consumption. In older individuals who have no medical conditions for which alcohol is contraindicated, particularly prior history of alcohol dependence, and who take no drugs (prescription or over- the- counter) that adversely interact with alcohol, the physician may feel comfortable affirming the acceptability of sensible drinking.

The operative word here is "sensible". What is sensible? In fact, what is a drink? Once again, definitional differences create confusion. In the United States and Canada, one "standard drink" is about 0.5 oz or 12 g of ethanol, 12 oz of beer, 5 oz of wine, or 1.5 oz of distilled spirits. In Australia and New Zealand, a drink is 10 g of alcohol. In the United Kingdom, the measure of consumption is the "unit of alcohol" (8 g of ethanol) – half a pint (284 ml) of beer, a glass (125 ml) of wine, a glass (50 ml) of sherry, or a single measure (24 ml) of spirits. The Royal College of Physicians, Psychiatrists, and General Practitioners have expressed concern that British drinkers, being unaware of the actual size of a "unit", may think they are following drinking guidelines but are actually consuming more than recommended. For example, cans of beer frequently exceed half a pint by as much as 40% but may be mistaken for a unit. Elderly drinkers need to know the serving size of a drink. Given the aforementioned changes in body water and lean body mass, a reasonable definition of sensible drinking for both elderly men and women is one drink or 1.5 units a day.

Patients should be counseled to avoid alcohol consumption immediately prior to going to bed in order to avoid sleep disturbances, cautioned against potential drug–alcohol interactions, and told to avoid alcohol consumption prior to activities such as driving. The decision to recommend a particular level of alcohol consumption in any given patient must, however, be carefully tailored not only to the individual's specific medical needs but also to their social and environmental circumstances as well.

Finally, at each stage in life sobriety has special rewards, and old age is no exception.

KEY POINTS

- Alcohol consumption is relatively common among older individuals; therefore, all patients should be screened for alcohol consumption and related problems.
- While most older drinkers have heard of a "unit of alcohol" and "sensible drinking guidelines", far fewer are able to define these terms. Therefore, health-care providers should view patient visits as opportunities for providing alcohol education.
- Polypharmacy is highly prevalent among older patients. Alcohol reacts negatively with over 100 prescription and over-the-counter medications. Therefore, alcohol–medication interactions are a very real possibility among older drinkers.
- Alcohol dependence is a highly treatable condition. Older individuals do as well or better in treatment than younger individuals.
- Current pharmacotherapies for alcoholism are effective for some patients but not for others. The fields of neurochemistry and medications development are very active and rapidly evolving. New, more effective medications will soon be on the horizon.

On the Evolution of All-cause and Cause-specific Mortality in the Age Class 75–84 years: a Worldwide Overview

Hugo E. Kesteloot

Katholieke Universiteit Leuven, Leuven, Belgium

INTRODUCTION

The mean age of most industrialized populations is increasing. This is essentially due to two independent facts: a decrease in birth rate and an increase in life expectancy. Actually, the segment of the population above the age of 75 years is the fastest growing. The decrease in birth rate is an exceptionally important problem, but is of social origin and beyond the scope of this study. In view of the important consequence of the increase in life expectancy, we will address the evolution of mortality specifically in the age class 75–84 years of the population worldwide.

METHODS

Data were provided by World Health Organization (WHO). Mortality data for all-cause (AC), total cardiovascular (TCV), total cancer (TCA) and residual (RES) (noncardiovascular, noncancer) mortality were obtained for 5 years classes within the age range 35–84 years. All data, including these from the 75–84 years age ranges, were age-standardized according to the old European population standard, which is equal for men and women. The data from the initial year 1970 or the earliest available year, till the last available year, about the year 2000, were analyzed. Only populations with acceptable population and mortality statistics and with a low mortality due to infectious diseases were included. The period is covered by ICD-9 and ICD-10 of the international classification of diseases (WHO, 1977). This is of lesser importance since only broad disease categories are used. The data were submitted to linear regression analysis with time and the intercept, slope, t-value and the yearly decline as a percentage of the initial value (intercept) are provided. The t-value of the equation depends to a great extent on the linearity of the occurring changes. During the period considered, some countries show both increase and decrease in mortality. Only the evolution compared to the starting value can thus be appreciated. For a limited number of countries (Japan, United States, and the mean of France, Italy, and Spain), Gompertz equations (Gompertz, 1825) and second-degree polynomial equations between mortality and age (Kesteloot and Huang, 2003) will be provided. This will allow us to situate the evolution in the 75–84 years age class within the frame of the changes over a wider age range. This study is an extension and upgrading of previous work in this field (Sans *et al.*, 1997; Kesteloot *et al.*, 2002).

RESULTS

In Table 1 the crude all-cause, total cardiovascular, total cancer, and residual mortality rates are provided for 45 countries in the age class 75–84 years for men, and in Table 2 for women. The countries are listed according to the lowest all-cause mortality. All-cause mortality is the most reliable index of mortality in developed countries since it does not need standardization. Of the 10 highest AC mortality rates for men, 8 are provided by Eastern European countries. For women, the ratio is 10 out of the 12 highest. The greatest degree of variation exists for total cardiovascular mortality rates. Countries with the highest all-cause and cardiovascular mortality rates have the lowest total cancer rates. Albania has a lower mortality than Canada for men, and a similar mortality to Denmark for women. Albania is the poorest country of Europe and Denmark the richest of the European

AC, All Causes; TCV, Total Cardiovascular; TCA, Total Cancer; RES, Residual; Myear: mean of 3 latest available years.
[a]for AC: mean year = 1999.

Union. Countries from the Mediterranean region (France, Italy, Spain, Greece) have low AC and TCV mortality rates for both sexes.

The changes in mortality rates in the age range 75–84 years are given in Tables 3–10. In Table 3, the results of the changes in mortality rates for all causes during the last 20–30 years for men are presented. The countries are ranked according to the magnitude of the percental decline. With the exception of increases in Ukraine (NS) and Belarus ($p < 0.001$) mortality is decreasing everywhere. Note the limited decline in Denmark and Iceland. Belgium is doing better than the Netherlands. The worst results are once again obtained in Eastern Europe with the exception of the Czech Republic. In the best performing countries, mortality has almost been halved over a period of 30 years.

In Table 4, the same results are presented for women. Although the starting mortality is lower, the percental decline is even more impressive than for men. Denmark and Iceland are performing poorly, and Belgium is again performing better than the Netherlands. Of all Eastern European countries, over the last 16 years, Czechoslovakia is performing best for both sexes. In Tables 5 and 6, the changes in total cardiovascular mortality are given for men and women. The most impressive changes occur for

both sexes in Japan and Australia. Belgium is performing better than the Netherlands and Estonia better than the other Baltic States. Greece is performing badly, especially when compared with France, Italy, and Spain, the other Mediterranean countries.

With total cancer mortality, the picture changes dramatically. In a great majority of countries, mortality increases (Tables 7 and 8). Japan, notwithstanding a dramatic decrease in stomach cancer mortality, is no longer the leader of the decline. The significant decreases in Hong Kong and Singapore in this older age class, especially in women, remain unexplained. In Tables 9 and 10 the changes in remainder mortality (noncardiovascular, noncancer) are given. This is an important category consisting essentially of chronic diseases (respiratory insufficiency, liver cirrhosis, and others) and acute causes of mortality (suicide, homicide, accidents, and others). Included also are unspecified causes of mortality. This rubric is often neglected but the death rates are more important than those for total cancer mortality. The changes are also impressive both for the decreases and increases. These changes are difficult to interpret. The United States, the Russian Federation, Denmark, and Canada have some of the highest increases. The question arises as to how many of these changes could be due to misclassification of TCV or TCA in this higher age class.

n determines the number of years preceding the latest available year (LAY); *a*: intercept; *b*: slope; *t* : *t*-value; *d*: percental decrease per year.

In Table 11, the summary mortality data are given for both sexes and in Table 12, the Pearson correlation matrix of the data. The most salient points are the following: All mortality rates are lower in women but the male/female ratio is lower than at younger ages. The ratio of the highest/lowest mortality rates is higher for women and highest for residual and total cardiovascular mortality. For both sexes, residual mortality is a major part of all-cause mortality, more important than total cancer mortality. The correlation matrix (Table 12) shows that for all mortality rates the correlations between male and female mortality are very high (all $p < 0.0001$). In both sexes, total cancer mortality correlates negatively with total cardiovascular mortality ($p < 0.001$). Residual mortality does not correlate significantly with total cancer mortality, but negatively, of borderline significance, with total cardiovascular mortality.

Mortality and Age

Age is the most important determinant of mortality. The relationship between mortality and age can best be expressed by Gompertz equations, ln mortality versus age or by second-degree polynomial equations, ln mortality versus age and age^2. The differences between Gompertz and polynomial

n determines the number of years preceding the latest available year (LAY); *a*: intercept; *b*: slope; *t* : *t*-value; *d*: percental decrease per year.

equations are minor concerning all-cause and total cardiovascular mortality, but the polynomial equations always give the most significant results. This is not the case for total cancer and remainder mortality. For those diseases the relationship between ln mortality and age are clearly not linear, and polynomial equations are vastly superior. The quadratic term of age in the equation is highly significantly negative for total cancer mortality and highly significantly positive for remainder mortality. The data are illustrated for both sexes separately in Figures 1–6 for Japan, the United States, and a combination of France, Spain, and Italy. Countries with an oriental-type diet, a Western-type diet and a Mediterranean diet are thus compared. The mirror image between total cancer and remainder mortality is notable.

DISCUSSION

The great differences in mortality rates existing between countries in the age class 45–74 years are also present in the age class 75–84 years. It is imperative to be able to identify the causes of these differences. Of all possible explanations – the level of medical care, genetics, smoking, pollution, stress, socioeconomic factors, obesity, food additives, and others – nutrition has been identified as the most plausible explanation

n determines the number of years preceding the latest available year (LAY); *a*: intercept; *b*: slope; *t* : *t*-value; *d*: percental decrease per year.

(Kesteloot, 1992, 1996). A look at the ranking of mortality in the 40 countries considered makes it clear that the level of medical expenditure cannot explain the ranking, for example, the ranking of the United States and Denmark. This is even more evident at younger ages (Kesteloot, 2001). The important changes in mortality rates cannot be attributed to genetic factors since the genetic constitution of a population does not change to any significant extent over a period of 40 years. Hong Kong has high levels of pollution and stress, but has a low mortality. Singapore, with the lowest levels of pollution in the world (The World Bank, 1998), has a high mortality. Obesity is increasing worldwide, but mortality is decreasing. Owing to the globalization of the world food market, the same additives are used worldwide. Socioeconomic factors cannot explain the differences, for

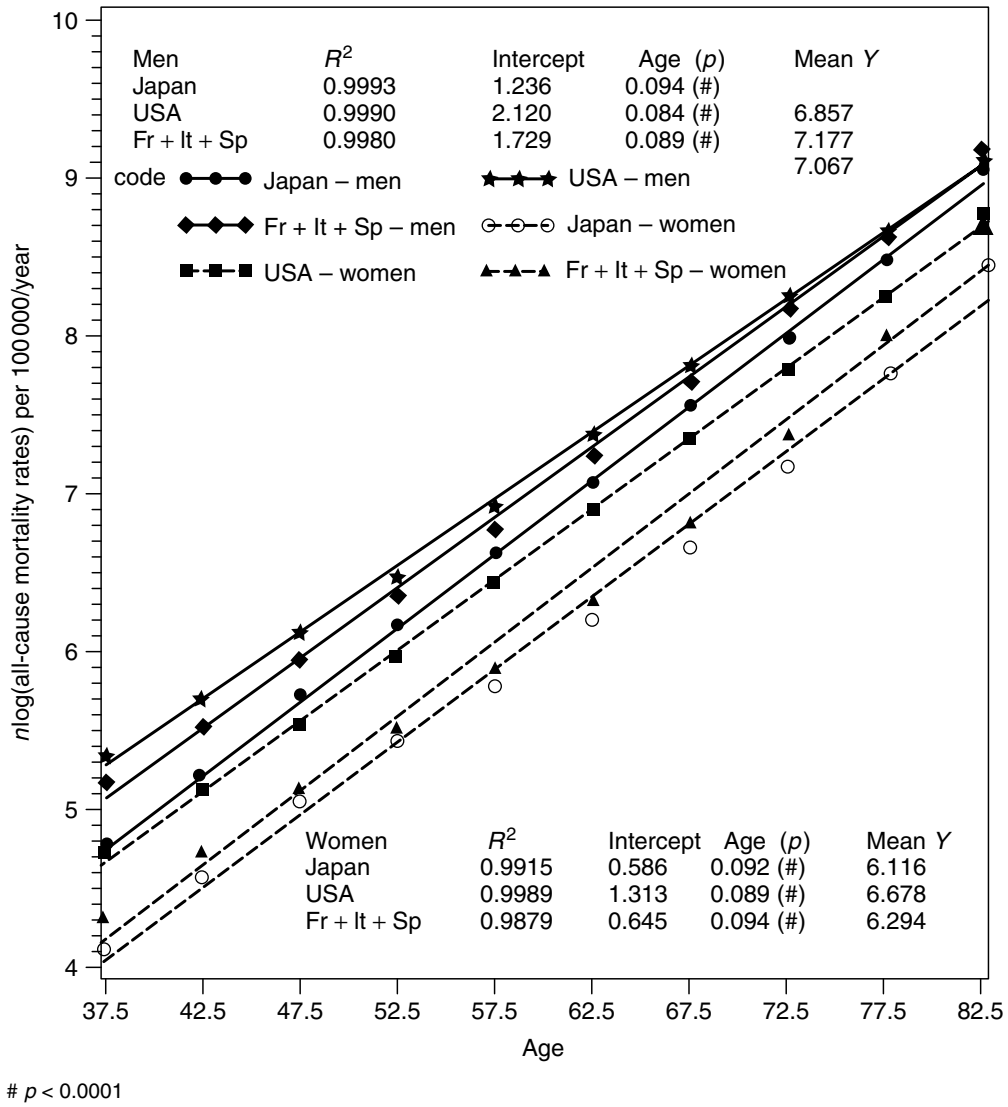

Figure 1 *n*log(ALL–CAUSE mortality rates) versus age for Japan, UnitedStates, and mean of (France, Italy, Spain), mean of 3 latest available years

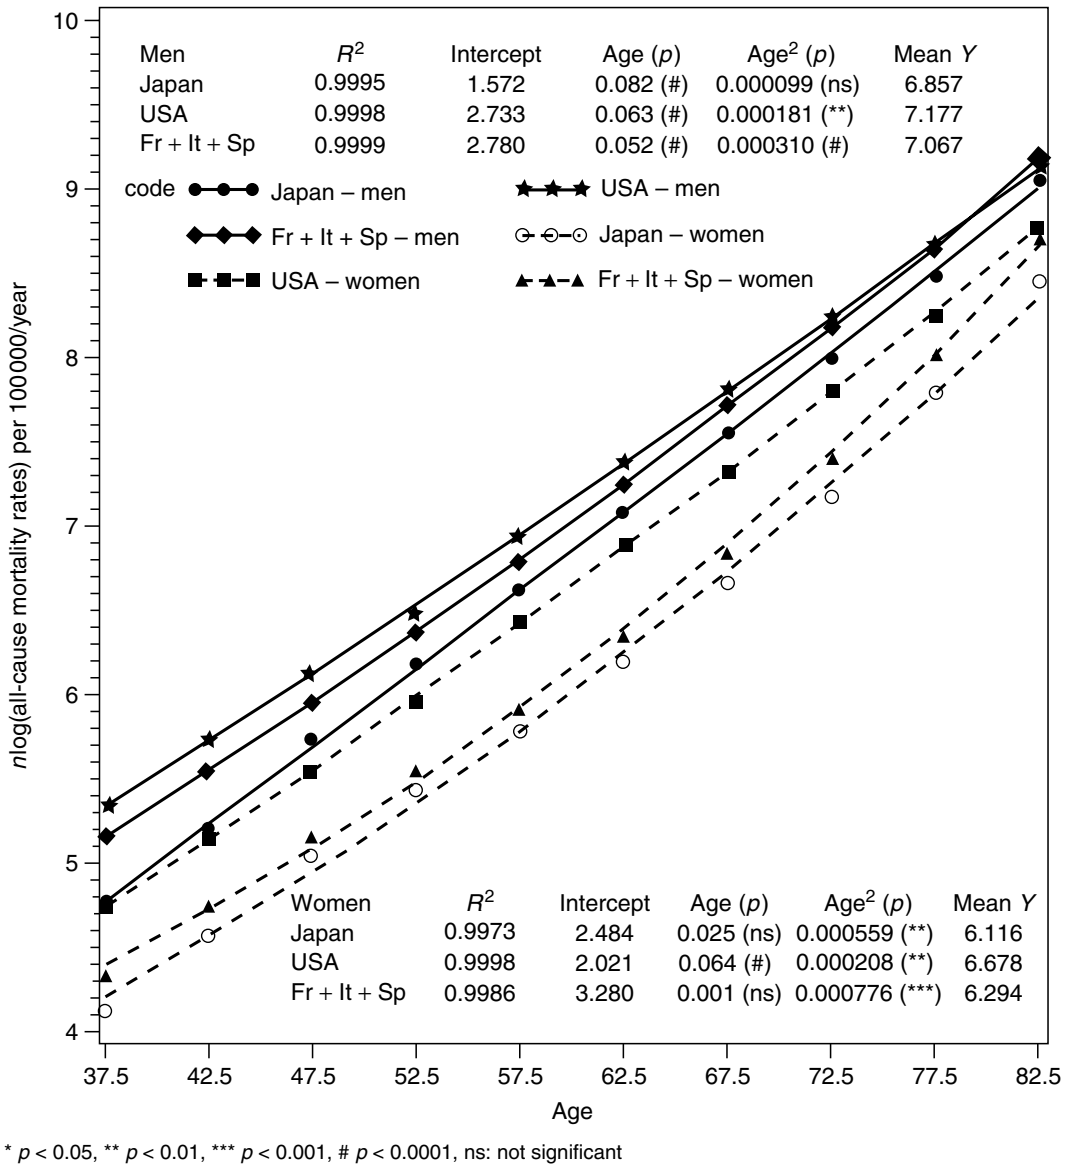

Figure 2 $n$log(ALL–CAUSE mortality rates) versus age, age^2 for Japan, United States and mean of (France, Italy, Spain), mean of 3 latest available years

example, the relative position of Albania and Denmark. Albania is the poorest country of Europe, and Denmark the richest of the European Union. Denmark has the highest mortality of the countries of the European Union in the year 2000 ($N = 15$). Much of the differences can be explained by smoking, especially for women; for example, the high smoking levels of Danish and Scottish women. Japanese men, however, have the highest smoking prevalence and level of cigarette smoking in the world, but a low mortality. Smoking is especially deleterious in combination with a high intake of saturated fat (Xie *et al.*, 1991). The ongoing changes in nutrition are impressive: a decrease in salt intake, especially in oriental populations; a decrease in the intake of saturated and trans-fatty acids, especially in Western populations; an increase of the intake of mono-, polyunsaturated, and omega-3 fatty acids; an increase in the consumption of fresh fruit and vegetables, and others. These changes should result in a better health at the population level.

The highly significant correlations between male and female mortality rates demonstrate that essentially the same causes of mortality are operative in men and women, but at lower levels in women (Kesteloot, 1987). The lower correlation for TCA mortality can be explained by differences in smoking habits between the sexes. A negative correlation ($p < 0.01$) exists between total cardiovascular and total cancer mortality. Several factors influence cardiovascular disease and cancer in the same direction, for example, salt, smoking, and saturated fat. As factors which could act in different directions, omega-6 polyunsaturated fat should be considered, protecting against heart disease, but possibly promoting some cancers, for example, colon

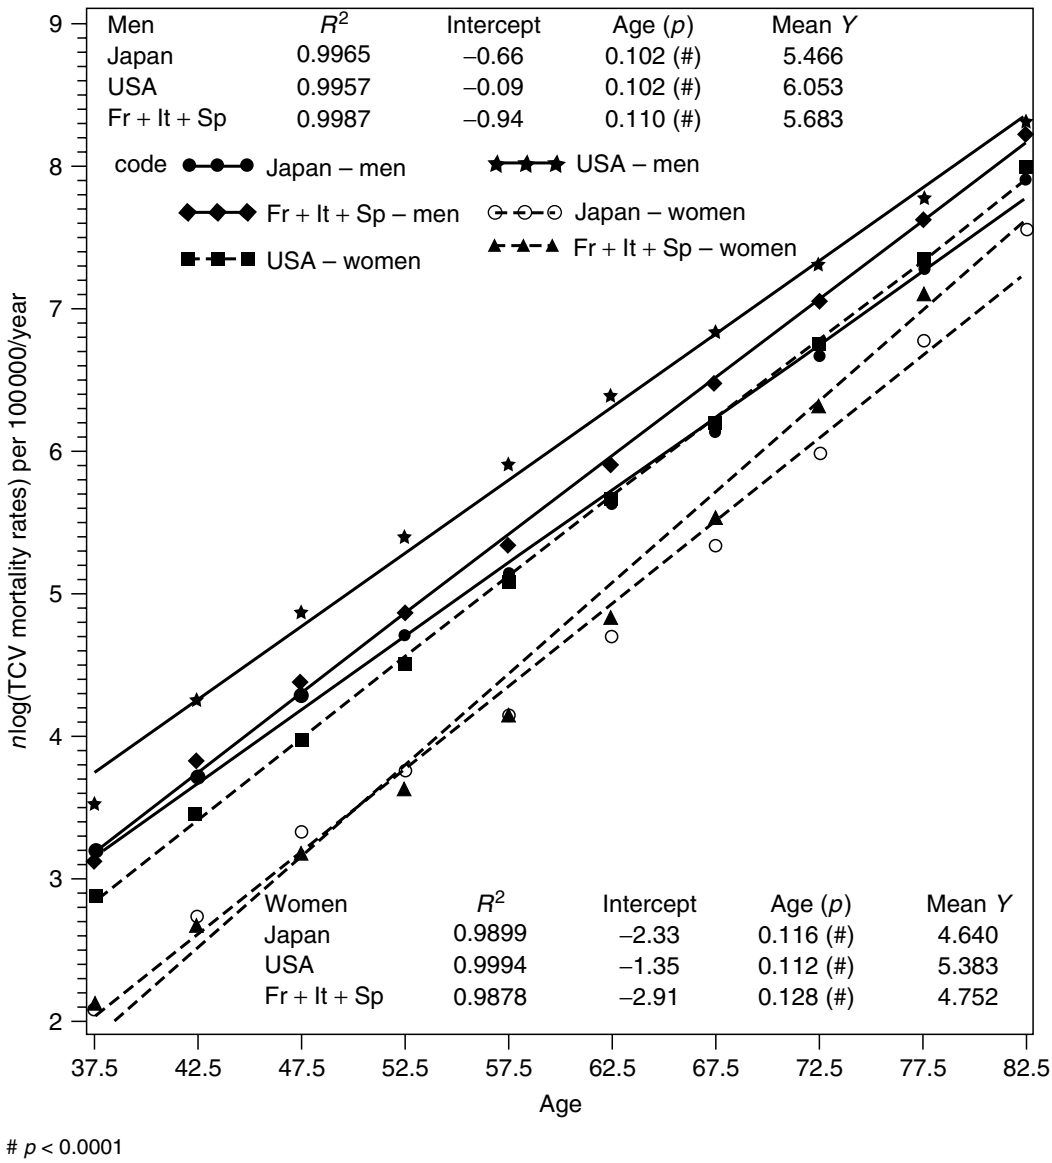

Figure 3 *n*log(TCV mortality rates) versus age for Japan, United States and mean of (France, Italy, Spain), mean of 3 latest available years

and breast cancer. An additional explanation could be that of an increase in cardiovascular mortality at the population level and because of life-style changes occurring earlier than an increase in cancer mortality, thus not allowing changes in cancer incidence to manifest themselves. This negative relationship should be further explored.

As can be seen from the equations relating ln mortality to age (Figure 1–6), the mortality rate in the age class 75–84 years is closely related to the mortality rates in the preceding age classes. The factors influencing mortality influence the total population between the ages of 35 and 84 years. Preventive measures should thus be directed toward the whole population. The extremely high R^2 of the correlation persists even when important mortality changes occur over a short period of time, for example, in the Russian Federation between 1985 and 1998 (data not shown).

The quadratic term of the polynomial equation is mostly positive, but negative in men from the United States for total cardiovascular mortality. The strongest quadratic term values are found in women, especially from France, Italy, and Spain. A more rapid increase in mortality occurs in women after the menopause. A negative quadratic term can be explained when the mortality level is high. Under such conditions, only the strongest individuals survive until the age of 75 years, and have a lower mortality rate later on. The relationship between ln mortality rate and age, age^2 is totally different for total cancer and remainder mortality. For total cancer, the quadratic term is always negative in both sexes, and highly significant in men (Kesteloot *et al.*, 1994). The possible explanations for this finding have been published before; briefly, the negative curvature could be due to a selective survival of cancer resistant

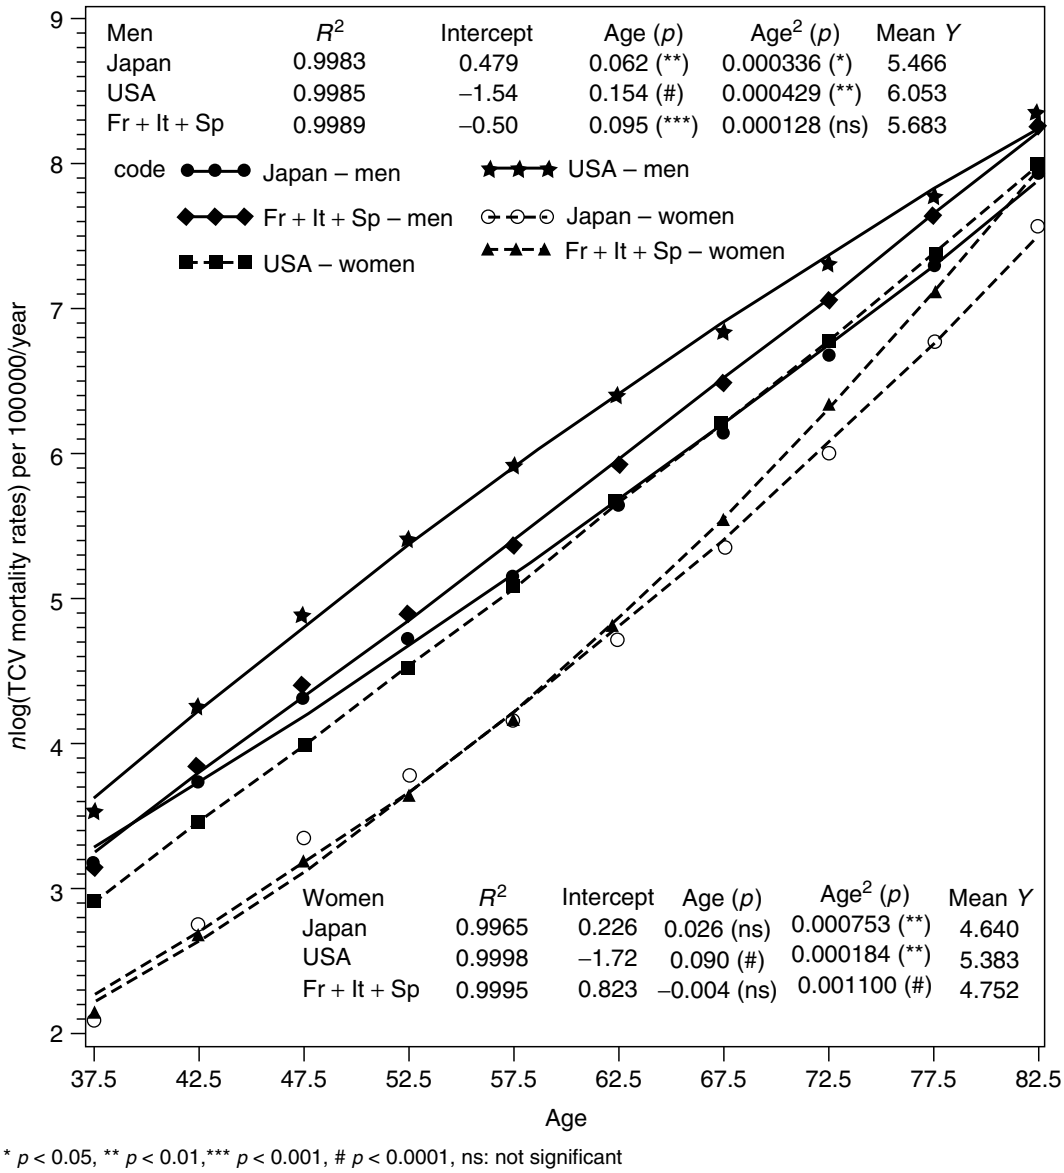

Figure 4 *n*log(TCV mortality rates) versus age, age^2 for Japan, United States, and mean of (France, Italy, Spain), mean of 3 latest available years

patients; to a slower growth of cancer at higher ages or to underdiagnosis of cancer at higher ages. The possibility of underdiagnosis and misclassification cannot be neglected since the evolution of remainder mortality is nearly a mirror image of that of cancer. As can be seen from the figures for all mortality causes considered, Japan has the lowest mean mortality rate (mean Y), followed by the Mediterranean countries and finally by the United States. One exception exists for total cancer in men where the United States is second.

In the United States for the year 2001, yearly mortality rates are available between the ages 1 and 100, separately for men and women and for Blacks and Whites (Arias, 2004). Within the age range 25–94 years and 35–94 years, all r^2, R^2 for Gompertz and second-degree polynomial equations were >0.99 and 8 out of 16r^2, $R^2 > 0.999$. The polynomial equations are always superior to the Gompertz equations and in the age range 35–94 years, slightly superior to the age range 25–94 years. A greater part of the mortality in the age range 25–34 years is not age related (accidents, suicide, and others) and this lowers the overall correlation coefficients. These findings largely extend the age range within which these equations are valid.

In summary, important changes in mortality are occurring in the age class 75–84 years. These changes are closely related to changes in mortality at younger ages. All-cause and cardiovascular mortality rates tend to accelerate at ages above 75 years, while the contrary occurs for total cancer mortality. The differences in mortality at older ages can best be explained by differences in nutrition. Much can be learned by comparing the mortality rates of different countries and the dynamics of the ongoing changes.

Elder Abuse

Jed Rowe

Moseley Hall Hospital, Birmingham, UK

Based in part on the chapter 'Elder Abuse' by Gerald C. J. Bennett and Mark S. Lachs, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

'. . .there I met an old man who wouldn't say his prayers
so I took him by the left leg and threw him down the stairs'

Goosey Goosey Gander (nursery rhyme)

INTRODUCTION

Elder abuse is the long-lost grandparent of child abuse. With a legislative background of child protection at least in the industrial sphere and as a theme in the Victorian Novel, it seems surprising that child abuse within the home did not register in the medical literature until 1946 or into general medical consciousness until Kempe's book "the Battered Child Syndrome" in 1962. Less enshrined in popular culture, elder abuse was first described in similarly emotive terms as "Granny battering" by Baker and Burston in the mid 1970s (Baker and Burston, 1975; Burston, 1977).

Perhaps the cultural milieu with its intrinsic agism helped suppress this violence phenomenon. Even today, agism is not proscribed in the United Kingdom by an equal opportunities law. Section 47 allows people who, through age or infirmity, aren't able to devote to themselves or aren't receiving appropriate care to be forcibly removed to an institution. There is a fine for obstructing the process. It is to my knowledge the only instance where you can be arrested when you aren't criminal, mentally ill or infectious. Mobility allowance can only be claimed *de novo* by those below the age of 65 while those presenting to doctors with falls or immobility have diagnoses recorded for coding purposes as "senility". Within medicine, a wealth of literature attests to the disenfranchisement of older people from the best treatment. Who when looking at job applicants has not excluded some on the grounds that they were too old?

In the United Kingdom, the initial reports of violence toward older people were met with apathy and denial. Claims were repeatedly made by a social worker, Mervyn Eastman (1984) without effect, and even as late as 1991 the Secretary of State for Health was denying, on national television, that the problem existed. Only when faced with a press campaign, evidence from the Social Services Inspectorate, research from America, and powerful advocacy did elder abuse become recognized in 1993 as a bona fide social problem and manifestation of domestic violence. Thereafter, movement from this position has occurred and in 2000, the British Government published "No Secrets" – a report providing "Guidance on developing and implementing multiagency policies and procedures to protect vulnerable adults from abuse". Although not statute this at least provides a basis for critical appraisal of those areas that have not introduced appropriate practice.

By contrast in the United States, the challenge was immediately accepted and the subject rapidly gained academic respectability. In 1978, the House of Representatives Select Committee on Aging conducted an inquiry, which concluded that States should enact laws to address the problem. Some legislatures responded by giving elder abuse a notifiable disease status. The development of agencies with a specific remit and powers to investigate and intervene was driven by political acceptance and will. Adult protective services are now established in all states although their criteria for intervention and powers vary widely. They do share a mechanism for reporting and investigating elder abuse, which is linked to a social service provision to support the victim and prevent further harm. A broader remit covering vulnerable adults is usual although the definitions of abuse, criteria for engagement and character of interventions (e.g. civil or criminal) vary according to individual jurisdictions.

In the United States, self-neglect is included in this taxonomy, whereas in Europe this is seen as a separate issue although it is still the particular responsibility of local authorities.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

DEFINITIONS

Elder abuse is not a universally accepted term and some have used the terms "inadequate care" and "elder mistreatment" in recognition that a forensic approach may not be the most useful.

Similarly, a simple global definition, which is nontautological and utilitarian, is hard to come by. Individual organizations have tended to define elder abuse by their own criteria for intervention. Such an approach naturally causes problems not least for the scientific community wishing to standardize the terminology and thus generalize the significance of survey findings.

A reasonable stab at the problem was made by Action on Elder Abuse in 1994.

"Elder abuse is a single or repeated act, or lack of appropriate action occurring within any relationship where there is an expectation on trust, which causes harm or distress to an older person"

(Action on Elder Abuse, 1995)

DIMENSIONS OF ABUSE

More useful to practitioners perhaps are descriptions of the dimensions of elder abuse, where a systematic listing of the spectrum of phenomena allows an individual case to be recognized and categorized. These include:

- *Physical abuse*: inflicting physical harm or injury, physical coercion, sexual molestation, and physical restraint;
- *Psychological abuse*: inflicting mental anguish;
- *Material abuse*: illegal or improper exploitation and/or use of funds or resources;
- *Active neglect*: refusal or failure to undertake a care-giving obligation (including a conscious and intentional attempt to inflict physical or emotional stress on the elder);
- *Passive neglect*: refusal or failure to fulfill a care-taking obligation (excluding a conscious and intentional attempt to inflict physical or emotional distress on the elder).

PREVALENCE

Research into elder abuse was originally descriptive and based on the experience of interested workers and cataloguing referrals to responsible agencies. This naturally led to a distorted view of the subject. Random sample population surveys are better but are restricted by the capacity and willingness of those interviewed to disclose relevant information. As dementias may be particular stressors of dysfunctional relationships, these limitations may be significant. Even so prevalence studies do show some consistency. Rates are shown in Table 1.

These studies have been much more significant in elucidating the range and contexts of elder abuse. The seminal population-based random sample study from Boston (Pillemer and Finkelhor, 1988) had implications far beyond pure numbers. In a city where mandatory reporting, elder abuse teams, and structured interventions were already established, only 1 in 14 of the cases discovered were known to the responsible agency. This emphasized the fact that personal and institutional expertise is derived only from those that the individual or agency knows about. Thus physicians, for example, are more likely to see cases of serious physical abuse. Furthermore, themes from these studies have been expanded and used to integrate elder abuse more securely in the spectrum of domestic violence. So if the chief risk factor for being abused is the presence of a potential perpetrator, then it is not surprising that abuse by spouses turns out to be the most common form – a contrast with earlier reports suggesting that offspring were the most likely culprits. Presumably, dysfunctional marital relationships, where the currency of communication is aggression and violence, may not significantly change with aging. Encroaching disability leading to greater dependency, carer stress allied with the resultant inability of a person to leave the home, call the police or domestic violence unit leads to the special timbre that characterizes elder abuse. This makes it convenient for consideration as a discreet form of domestic violence.

It is not clear whether sex is an independent variable for victim or perpetrator. The Boston study found that men were more likely to be abused than women (although they suffered less psychological and physical harm), which may be a reflection of the number of relatively fitter women with power over older frailer partners.

Table 1 Comparison of rates and abuse by country

	Rates (%)				
Types of abuse	United States	United Kingdom	Canada	Australia	Finland
All types	3.2	–	–	–	6.7
Physical	2.0	2.0	0.5	2.1	
Verbal	1.1	5.0	1.4	2.5

RISK FACTORS

Risk factors have been derived from in-depth exploration of those presenting to responsible agencies and thus may reinforce a tendency to miss those cases that do not present in the first place. The following are well recognized:

Functional impairment and chronic illness: may limit capacity to leave the situation, seek help, or defend oneself.

Home circumstances: the presence of an abuser being a prerequisite for abuse; those living alone may enjoy a degree

of protection. However, where there are few social contacts abuse is less likely to be identified or reported.

Cognitive impairment: dementia appears to be a risk factor for abuse presumably because of increased carer stress and disturbed behavior triggering antipathetic responses.

Stress: financial hardship and stressful life events may limit a family's caring capacity.

Abuser characteristics: the likelihood of abuse seems to be defined by characteristics of the abuser rather than those of the abused. Abusers are more likely to have personality disorders or a history of drug abuse or violent behavior. Financial dependence on the victim or for housing is often seen.

History of violence: domestic violence does not necessarily disappear with years. A history of violent conflict within a marital relationship predicts future abuse.

RECOGNITION

Recognition depends primarily on awareness and some knowledge of the subject – a prerequisite that cannot be taken for granted even amongst highly trained professionals (McCreadie *et al.*, 2000). However, this may be aided by the use of protocols that have been developed in the United States. These suggest that some consensus already exists, as there are many common components in these protocols (Mount Sinai Victim Services Agency Elder Abuse Project, 1988).

Certain features in the presentation should act as alerting calls to the clinician (Lachs and Pillemer, 1995). These include:

- Delays between injury or illness and seeking medical attention – examples include lacerations, healing by secondary intention, X-rays revealing healed but misaligned fractures, and decompensated chronic disease presenting in extremis where the carer has been monitoring the patient.
- Differing histories from patient and abuser – examples include different mechanisms of possible injury and a different chronology of injuries.
- Implausible or vague explanations provided by either party – for example, fractures that are not quite explained by the mechanisms of injury.
- Frequent Accident and Emergency Department attendance for chronic disease exacerbations despite a care plan and available resources – for example, chronic obstructive airway disease or chronic heart failure due to lack of medicines or their administration.
- The functionally impaired patient who arrives without the main carer – an example is a patient with advanced dementia who presents at the Accident and Emergency Department on his own.
- Laboratory findings inconsistent with the history provided – for example, subtherapeutic drug levels (e.g. Digoxin) despite carer-reported concordance. Toxicology may reveal that psychotropic agents have not been administered or that unprescribed ones have.

Characterization of psychological or perhaps material abuse in isolation from physical assault will not be revealed by a pattern of injuries and so requires a careful approach to the history and collateral history.

THE INITIAL ASSESSMENT

Although protocols undoubtedly help bring down barriers to recognition, like cognitive function testing, suspicion must be aroused to initiate their use although thereafter there should be an educational reinforcing effect on the clinician. Unfortunately, with little standardization and validation of these instruments, progress is limited and the differing needs of a simple alerting device and a more comprehensive elucidating protocol is as yet unrealized (Fulmer *et al.*, 2004).

The assessment may cover the following aspects:

1. Although adult protective services training has sometimes included courses on adversarial interviewing this probably is not appropriate for those working in the caring services. The victim should probably be interviewed alone, although a case can be made for the presence of someone to record the meeting so that the flow of information is not repeatedly halted by the necessity to write down names, times, places, and so on. As in geriatric medicine, history taking also subserves as the physical examination of intellectual function. Cognitive impairment (or the lack of it) and some assessment of its severity should be recorded. There needs to be direct enquiries about physical violence, restraints or neglect, and elucidating details about the precise nature, frequency, and nature of these events. This is easiest after sympathetic scene setting with exploration of the history of relationships, coping with previous life stresses, new problems intervening, and so on. Recording a day in the life of the subject starting at midnight and continuing for 24 hours will document the patient's functional capabilities and provide details of the care that is provided. Expanding this template over a week or so will usually give a good idea of the patterns of care taking place. When rapport is established, the use of escalating nonjudgmental questions is more likely to finesse a truthful response. It is easiest to write down in advance the questions that need to be answered and a form of words with which to introduce them.
   Questions like *What stresses did this situation place on you/your carer? How did you/your carer cope with this? Did you/your carer ever lose control? What happened then?* are better than unintroduced bald questions like *Did he/she hit you?*
   Writing down the full names, addresses, and contact details of all those entering the home will be essential at some stage.

2. *History from the alleged abuser*: the alleged abuser should also be interviewed alone and a similar approach is appropriate. Once again confrontation and accusation should be avoided in the information-gathering stage. Check the carer's understanding of the patient's physical or mental health (care needs, prognosis) and ask for the carer's explanations for the injuries or physical findings.
3. Other sources should also be interviewed if possible. Recent psychosocial factors (bereavement, illness, unemployment, and financial hardship) should also be enquired about. It must be remembered that the care workers visiting the home are the most likely to know what is happening, but because of their lowly status they are often the last to be asked.
4. *Behavioral observation*: Interactions between the subject and their carers and other contacts should be observed. Abuse can take place within relationships where actions of the victim are themselves abusive and hence trigger similar responses. The patient can be checked for any withdrawal or infantilism by the carer. Generational inversion where offspring take a parent-like approach to their own parents and insist on giving the history and making decisions for them is so common that specific safeguards may need to be taken.
5. *General appearance*: The patient's state of hygiene and nutrition, general cleanliness, and appropriateness of clothing must be observed.
6. *Skin/mucous membranes*: It should be noted that dehydration cannot reliably be diagnosed by skin turgor and that blood chemistry is a much better indicator. The patient must be examined for multiple skin lesions in various stages of evolution. Note bruises and pressure sores and record how such lesions have been treated. A body chart is useful and medical photography is even better provided informed consent can be obtained. Some elderly people bruise easily (senile purpura and the transparent skin syndrome/photoaging) even from normal caring activities. Pressure sores are one of the "geriatric giants" and hence in addition to implying neglect can indicate underlying disease.
7. *Head and neck*: Traumatic alopecia (distinguishable from the male pattern alopecia on a basis of distribution), scalp hematomas (raised, blood-filled bruises), lacerations, and abrasions must also be checked for.
8. *Trunk*: The patient should be examined for bruising, welts, and weals: the shape may suggest the implement used (e.g. a belt). Particular attention must be given to lesions in protected areas of the upper thighs, arms, and so on.
9. *Genitourinary*: The patient must be examined for rectal bleeding, vaginal bleeding, infestations, evidence of trauma, and pressure sores. Most clinicians have neither the expertise to collect samples in recent suspected rape nor the forensic support to process them (e.g. how many clinicians have combed pubic hair to find those shed by an attacker). The help of a forensic medicine specialist is essential here.
10. *Extremities*: wrist or ankle lesions suggest the use of restraints or immersion burns (glove/stocking distribution).
11. *Musculoskeletal*: The patient should be examined for occult fractures or pain and the gait must be observed.
12. *Neurological/psychiatric*: this needs formal examination to ascertain the site of any lesion. Anxiety and depressive symptoms need to be assessed. Where symptoms are indicative, formal testing using depression-rating scales should be carried out or the patient must be referred to a psychiatrist.
13. *Mental state*: formal testing should be carried out using the Folstein Mini-Mental State Examination. Cognitive impairment suggests that either delirium (acute confusional state) or dementia (chronic confusional state) is present. This then needs further assessment to rule out the treatable causes. Psychiatric symptoms may include delusions and hallucinations. Mental testing gives little indication of decision making capacity and this may need discrete assessment.
14. *Imaging*: Clinical indications will indicate this requirement.
15. *Laboratory investigations*: again the tests ordered will be indicated from the history and examination and may include drug levels, albumin, blood urea and electrolytes, hemoglobin, and occasionally toxicology. For those with extensive bruising, coagulation studies and platelets are useful. Unfortunately, diagnosis of scurvy is difficult not least because subjects have usually been fed prior to the institution of the studies.
16. *Social and financial resources*: The social networks (formal and informal) available to assist the patient must be documented and all available financial resources must be recorded. Those most vulnerable to financial abuse tend to be those living on modest incomes where a continuous small drain on the resources has a large effect. Overpayment for services is hard to judge and written records will probably not be available.

In England and Wales, those who have lost financial capacity as a result of dementia will almost certainly have inappropriate transactions taking place with regard to collecting pensions, managing bank accounts, and so on (Rowe *et al.*, 1993). In most cases, this is benign and a product of confused and confusing jurisprudence. This information may be crucial if interventions, which include alternative living arrangements and/or the provision of home services are considered later.

ONGOING INVESTIGATION AND INTERVENTION

Ongoing investigation and interventions should follow local agreements and policies. Most areas will have a lead agency defined and a management algorithm. The initial phase is information gathering.

For serious crime where assault or other major felony is indicated, involvement of the police is mandatory. Health

workers do not have the skills, resources, or probably the temperament to investigate significant crime. In the United Kingdom, local constabularies have domestic violence units who are a useful first port of call. In most areas, these officers do not investigate crimes. This has the advantage of allowing advice to be taken on how to use the law before embarking down that route. Further investigation in the United Kingdom requires arrest of the suspected perpetrator and a taped interview perhaps in the presence of a solicitor under the exigencies of the Police and Criminal Evidence Act; underlining the importance of previous screening by the domestic violence unit. A concomitant disadvantage is apparent when the officers who have been consulted and who are familiar with the case have to hand it on for investigation to a different team.

Wide experience of injuries from assaults including sexual ones is not usually the forte of geriatricians; so the skills of forensic medicine specialists should be actively sought.

There are other services with investigatory powers and their involvement may be required. For example, in the United Kingdom those who have lost financial capacity should have an appointee collecting and supervising their pension and benefits. The Benefits Agency has a duty to investigate the worthiness of the appointee and the appropriateness of their use of these resources.

Inevitably, collecting this information takes time. Pressure on beds notwithstanding, there are often requests for discharge both from the victims and the suspected abusers. Some households are dependent on the benefits and welfare payments received by the victim and so this pressure may be intense.

Most policies and guidelines are useful in identifying agencies and procedures to initiate investigation but thereafter the path tends to become less clear and the issues more fraught.

If the victim is significantly and cognitively impaired, it may be difficult not to compound abuse if they cannot give consent to photography or investigation. Even proceeding with the use of a duty of care mandate causes problems if he/she is not a competent witness. Where criminal charges may be brought, the testimony of the victim is an important factor and without this prosecution is difficult. Experience with domestic violence in younger people where a complaint has not been made has been addressed by emphasizing that public interest prosecutions, which do not have this prerequisite can be used. In practice, without a good witness this approach is nearly always ineffective.

In cases where serious physical assault is suspected, clinicians may find themselves in the invidious position of being informed that prosecution can only take place if an expert witness is willing to testify that the observed injuries could only have been precipitated by unlawful violence. As there are really no pathognomonic signs of assault on older people and even the most suspicious lesions may have benign explanations, this is a dangerous area. Expert prejudice has been held responsible for serious miscarriages of justice in child protection and has probably led to a backlash where clinicians are reluctant to go on record and voice their suspicions.

Where the victim has capacity it is unusual for them to be willing to testify against relatives or carers on whom they may be dependent. Indeed, pushing this issue raises the possibility of alienating the victim and further reducing the chances of effecting any significant change in their circumstances.

These problems notwithstanding, practical experience suggests that recourse to the criminal justice system should not be shunned. It clearly takes time for practitioners not least the police to develop expertise in these areas. In some cases, the process of arrest, caution, or a tape-recorded interview with the offer of a solicitor's presence may be the catalyst for changes in circumstances and behavior – the mere fact that the process has occurred deterring further abuse even when other factors are apparently immutable.

Many of these aspects will be discussed at meetings specially convened to decide which actions need to be taken. Such meetings need to be inclusive especially as the most useful witnesses are unlikely to be managers and senior professionals. Development of trust, communication, and working relationships between relevant agencies is important and only goes forward if those involved are willing and available.

All multidisciplinary meetings may suffer from decision making at the lowest common denominator. Obliging someone not present to make an intervention, which is of doubtful value, will not advance the cause. When abuse is characterized by sins of omission rather than commission or the abusers actions are a result of ignorance or frustration rather than malice, a less forensic approach may be appropriate.

Although triggering behavior from the victim is recognized as a precipitant, it is worth remembering that risk of abuse is better determined by the characteristics of the abuser than the dependency of the abused. Where there is a dysfunctional relationship, which has developed over years or decades, there can be little expectation that offering more domiciliary services will necessarily alter patterns of abuse. Indeed some interventions are probably ineffective. A study of older people on a respite care program in a community hospital showed that 40% were being abused (Homer and Gilleard, 1991). Such respite care did not significantly reduce anxiety, depressive symptoms, or carer strain (Homer and Gilleard, 1994).

If investigation often leads into a fog where doubt increases with time, practitioners are often left with no justifiable interventions. In contrast, failures of care as suggested by poor nutrition, repeated injury perhaps as a consequence of falls, inadequate care, and an inability to materially affect the situation with domiciliary services frequently leads to institutionalization. In fact, referral to the adult protective services is an independent risk factor for nursing home placement (Lachs *et al.*, 2002). This not only occurs in those who are neglecting themselves but also where mistreatment is suspected. It is perhaps a reflection of the difficulties presented by these cases and the level of development of responses that those victims of mistreatment should be removed from their homes to an institution. The irony presented by this approach where the victim is institutionalized rather than the

abuser in contrast to other jurisdictions must cause concern to practitioners.

This is just one of the varied outcomes where intervention may actually make things worse for the abused.

ISSUES AROUND COMPETENCE

While all would support an approach that offers empowerment and increases the choices available to victims a few caveats apply here. Assessing competence, for example, should be a rapier not a blunderbuss. Legally, competence is assumed and must be disproved. Naturally, this implies there is no such thing as global competence, and the ability to make decisions needs to be tested in the specific area in which there is doubt. So global assessments of mental function that merely measure the capacity to perform that test are not particularly useful. Thus, where financial capacity is in doubt questions about the abstract and symbolic fiduciary processes (such as what is a mortgage? what happens if in arrears?) as well as the subject's resources, claims on them, and the relative merits of these claims are essential. Although the precise constituents of a capacity have only been legally defined for testamentary capacity, there is good helpful literature available (British Medical Association/The Law Society, 2004).

Those with broad knowledge in this area are aware that this is as much a mask of ignorance. A subject living at home suffering repeated falls and unaware of these failings and his/her surroundings may be felt to be better off in residential care. Indeed, a common practice of dubious ethics is to use such lack of capacity to endorse such a move. What little science there is suggests that residential care is an independent risk factor for hip fracture so that the subject is more likely to suffer an injurious fall therein (although less likely to lie on the floor undiscovered) (Norton *et al.*, 1999). The ethical principle of the least restrictive intervention comes into force and is now a statute law in Scotland. It seems worrying that no controversy, legal cases, or campaigns have sprung up over this issue, which may be proscribing what is common practice.

If negative outcomes have been reported, is there positive evidence of benefit beyond the anecdotal or case series? Presumably due to serious methodological problems in a difficult area, there have been no well-conducted intervention trials for the prevention of elder abuse. The one study attempting to detect a difference between a group where an intervention had taken place and controls showed a greater reporting of subsequent abuse in the intervention group (Davis and Medina-Ariza, 2001). It was not clear whether this was a function of raised awareness in the group.

INSTITUTIONAL ABUSE

Tragic cases, subsequent media interest, public shock, and official inquiries that have surfaced in child protection are noticeable by their absence in the elder abuse field. By contrast, exposes of derisory care in institutions have reached the public agenda. Abuse naturally sits at the lower end of the spectrum of institutional care. This is care which may be done down for a price but which may not be up to a quality standard. Those charged with delivering care are likely to be relatively untrained, working unsociable hours in difficult conditions for close to the minimum wage. Even in hospitals the inverse care law applies with the most disabled people being afforded the least nursing by those with the least training. There are of course perverse incentives that may lead to institutional abuse. Perplexed people with dementia constantly wandering or calling out on a quest inexplicable even to themselves may be perceived as harrying. How much easier it is if they sprawl quietly sedated in a chair where the price of their consequent immobility is relative peace and an occasional need for help with going to the toilet or to bed. Sedative use has been consistently noted to be excessive in UK nursing homes and yet there is little or no evidence for its effectiveness, and much can be withdrawn with only beneficial consequences. This is one of the features of inadequate medical care for residents (Fahey *et al.*, 2003).

Physical restraint sits between the unethical and the illegal. Once again the evidence for effectiveness is absent but the adverse effects are well documented. Perversely, the counterintuitive nature of the science may result in public pressure to protect people while the expected interventions are harmful. Bed rails exemplify this as instruments that do not reduce falls from the bed but can result in serious injury and death (Parker and Miles, 1998).

The risk factors for abuse in institutions have been explored (Pillemer and Bachman-Prehn, 1991). These include exogenous factors from the cultural milieu to the legal framework, funding, and political aspects of the care system. The design and fabric of the buildings and their suitability for the task along with the organizational structure is influential. As might be expected, the staff providing the care is the most important factor. With younger people having more negative attitudes to aging, an immature, uneducated workforce laboring for little monetary reward and accorded low status is worrying. With such circumstances leading to demoralization and burnout, the ground becomes fertile for abusive practices to spring up. The characteristics of those residents are also a factor. It is more difficult to care for very dependent, demanding subjects who can offer little reward for caring acts.

Naturally then quality can be deduced from the absence of risk factors and the converse of this scenario (Gibbs and Sinclair, 1992). A well-designed unit with staffing appropriate in numbers and quality to the dependency of the residents is to be desired. Of course, the key element is the culture imbued from a clear and effective leadership that is eager to maintain high standards. Those high standards pertain to the treatment of staff. In abusive institutions, it is often a feature that the staff is being abused by their managers (e.g. in some residential homes care staff are also expected to cook, clean, and launder residents' clothing, etc.).

There is of course potential to improve institutional care through both formal and informal monitoring. The regular inspection of units by the responsible authorities or the funding agencies is usual.

AGENCIES RESPONSIBLE IN THE UNITED KINGDOM (*see* Chapter 161, Health and Care for Older People in the United Kingdom)

The Commission for Social Care Inspection (CSCI) has a remit to "*carry out local inspections of all social care organizations – public, private, and voluntary – against national standards and publish reports; register services that meet national minimum standards; carry out inspections of local social service authorities; publish an annual report to Parliament on national progress on social care and an analysis of where resources have been spent; validate all published performance assessment statistics on social care; publish the star ratings for social services authorities*" www.dh.gov.uk/PolicyAndGuidance/HealthAndSocialCareTopics/SocialCare/NationalCareStandardsCommission#, 2005.

The Healthcare Commission (the Commission for Healthcare Audit and Inspection) carries a responsibility for health services "*The Inspectorate will: encourage improvement in the quality and effectiveness of care, and in the economy and efficiency of its provision; inspect the management, provision, and quality of health care services and tracking where, and how well, public resources are being used; carry out investigations into serious service failures; report serious concerns about the quality of public services to the Secretary of State; publish annual performance ratings for all National Health Service (NHS) organizations and produce annual reports to parliament on the state of healthcare; collaborate with other relevant organizations including the CSCI; carry out an independent review function for NHS complaints*".

Within hospitals the diversity of patient needs, specialties, morbidities, resources, staffing numbers and training, and so on virtually ensures that some patients will be inappropriately housed in inadequate facilities where there is neither the interest nor the knowledge to provide the best care. So the infantilized patient sedated in a bed with rails, wearing a diaper-type continence pad unable to reach fluids kept in a feeder cup may still be seen. A "nature trail" approach whereby markers of poor care are identified can be easily constructed as a training device. The patient walking down a ward exposed by an open-back gown, catheter bags on frames as clear stigmata of incontinence, locked doors, and so forth indicates an acceptance of poor quality care tantamount to abuse.

Doctors are powerful and frail people in the hospitals are vulnerable. It is easy to provide inadequate explanations of diagnostic or management plans, take consent that is barely "informed", or suggest solutions in a coercive manner. The traditional ward round where conversations can carry on at the end of the bed without the patient's involvement or where confidential matters can be easily overheard are still common practice. All geriatricians will be familiar with relatives who wish to know the patient's diagnosis before they do and then request that the victim is kept in ignorance. All geriatricians also know that collusion may prevent a complaint and its tedious ramifications.

It is beholding on all clinicians to be introspective about their practice with the idealism and humanity that brought them to medicine in the first place and to strip out the cultural education and conditioning that breeds tolerance of these wrongs.

Acknowledgment

The chapter on elder abuse in the previous edition was written by Gerry Bennett and Michael Lachs of whose erudition I have borrowed freely. Gerry was pre-eminent amongst the UK claims makers and undoubtedly the most important person in promoting our understanding of the subject. That he did this with courtesy, quiet enthusiasm, and masterful persuasion is all the more remarkable. This was just one of the many achievements of his tragically short life.

KEY POINTS

- Elder abuse is common and is found in all societies which have been studied.
- Those presenting to responsible agencies are not representative of the spectrum of abuse.
- Abuse is better defined by the characteristics of the abuser than the dependency of the victim.
- Provision of more domiciliary services and support is unlikely to improve a dysfunctional abusive relationship.
- The effectiveness of intervention strategies has not been systematically studied although there is clear evidence that some may increase institutionalization of victims.

Smart Homes

Roger D. Orpwood
University of Bath, Bath, UK

INTRODUCTION

The adjective "smart" seems to be added to so many items of technology these days, primarily, it would seem, to try and persuade the public that such items are in a rather special category, and hopefully aid sales. Smart homes also sound somewhat pretentious but there is no doubt that this developing technology can provide many benefits to support elderly people and there is a growing body of experience which demonstrates its potential. This chapter looks at the ways in which smart homes can provide support based on the experiences of a number of groups. It considers the issues that have to be addressed if it is to be successful, as well as the community infrastructure needed to support the technology, and it concludes with a look at the future of this work.

WHAT IS A SMART HOME?

So what constitutes a smart home? The term smart homes has been confused by some to describe technology that relies on sensors in the home that can send messages to call centers. Such technology is really telecare and will be referred to as such in this chapter. The primary property that endows a house with the smart home label is its ability to support the user in an autonomous fashion. In other words, it can monitor the user's activities and the way they interact with appliances in the home, but it is also able to supply a response itself to support the user. So if a smart home detects a running bath being nearly full it will respond by turning off the taps rather than calling for someone to come and intervene.

What needs to be incorporated in a house to enable it to qualify for this lofty label? A smart home requires three facilities to be installed in order to operate (see Figure 1). First of all it requires sensors that can monitor the occupant's behavior and activities as described above, for example, by sensing water level in the bath. Secondly, it requires a series of support devices so that it can autonomously provide the backup needed to support the user, for example, means for automatically turning off the bath water. And thirdly, the particular feature that distinguishes a smart home, it requires a means whereby all the sensors and the support devices can talk to each other. This facility is achieved through the use of a communication bus, which is conventionally a form of wiring that enables messages to be sent. The communication bus is linked to a computer or other logic controller that can see all the information being provided by the sensors and make judgments about the user's behavior. If it decides some action is needed then it can initiate the activities of the relevant support device.

So there is nothing particularly complicated about smart technology. It has been around for a long time in installations in larger public buildings such as airports, hotels, and so on. In such buildings, the technology primarily enables environmental control to be provided autonomously so that the building is able to ensure appropriate temperatures and ventilation, and so on, are maintained automatically. The communication bus, a key feature of such installations, has been the subject of some standardization so that different manufacturers' components can talk to each other. Many of the components developed for these purposes, such as lighting controls, can be directly applied to usage in domestic homes (Figure 2).

One variable in this equation, which has a major impact on the suitability of smart home installations, is that the communication bus can exist in several forms. Traditionally it has been a separate form of wiring installed in the building that just carries the information, or telegrams as they are known, between the sensors and the support devices. However, it can be in the form of a radio link between all these devices, or carried as a signal superimposed on top of the mains power. As will be discussed later, these alternative forms have much potential for retrofit into people's own homes.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

APPLICABILITY TO ELDERLY PEOPLE

Given the ready availability of smart home components, a number of groups have explored the possibility of using them in a domestic setting to provide support that augments the help received from carers. A lot of work has been carried out to see if people with physical disabilities can be supported. The Joseph Rowntree Foundation (JRF) has provided a number of installations in York that aim to do just this, with a fair amount of success. The Edinvar Housing Association in Edinburgh has also completed some pioneering work to explore the potential of this technology. JRF has published a number of guides about the technology (Gann *et al.*, 1999; Pragnell *et al.*, 2000). The installations have primarily used commercial smart home components developed for public buildings and configured them in a form that enables their use in a domestic environment. A variation on this theme is the work developed at Brunel University through the Millenium Homes project (Lines and Hone, 2002). The main feature of the Brunel approach is the use of several items of purpose-designed technology to enable the home to give voice prompts to the user to check if they need outside support. This development is currently being further developed commercially, and several installations are in use. Some pioneering work in Norway has also explored the potential of this technology to support people with dementia (Bjoerneby, 1997).

The majority of these installations, unlike the Brunel work, have used the ready availability of smart home components to provide the technology that is used. For lighting and ventilation, these components are very appropriate. However, there are a number of situations where such technology is not so appropriate and where support devices need to be better tailored to the needs of the end user. A typical example is the use of commercially available technology to provide tap control. Several installations have used taps that are controlled through an infrared sensor. These are standard components that would be very useful for someone with poor hand function. All the user has to do is wave their hands in front of the sensor, usually mounted just underneath the tap, and the tap will turn on. Water will continue to be provided whilst the hands are in position. However, this operation is somewhat unnatural and for someone with a cognitive problem such taps would be totally confusing. These kinds of installations take a somewhat technology-led approach to their design. In other words, the installations start from looking at what technology is available and then configuring it in a form that seems to be close to providing the support needed. The work carried out on the Gloucester smart house project at Bath University explores these issues from a somewhat different perspective (Orpwood, 2001). This project is being run by the Bath Institute of Medical Engineering, and is aimed specifically at supporting people with dementia and uses a design technique that is very user-led. In other words, user needs are explored initially to provide a definition for the kind of problems that have to be supported by the technology. Having made these definitions, the design work then moves on to create purpose-designed devices that provide the care needed.

ENSURING USER FRIENDLINESS

There is a common perception that elderly people are inevitably going to be technophobic. Of course there is a spectrum of reaction to technology on the part of elderly people in the same way as there is for any other age group, and some elderly people are very excited and very proficient in using equipment such as computers. However, there is no doubt that interaction with sophisticated technology can cause a lot of anxiety, which may deter many people from using it. Consequently, when it comes to providing supportive technology for the majority of users it is preferable that the cognitive load on the user is kept as low as possible.

The technology should really provide support with as little intervention as possible from the user.

The problems of designing user-friendly installations are exacerbated when it comes to providing support for people with dementia. For such a user group, having to learn new skills or make sense of a new piece of technology is out of the question. The technology really does have to be invisible and just intervene and provide support when the house deems it to be necessary. Designing for such users is a useful discipline when it comes to ensuring user friendliness on the part of the smart house technology. For people with dementia, installations have to be provided where the technology is totally in the background, and where the home appears to be just the same as any other home, where the user does not have to learn any new skills, and does not have to interact with the new technology. But such installations are going to be very user-friendly for more cognitively able users as well, and will be suitable for those who are less able to cope with new technology. Design approaches that embody this approach have been published (Orpwood *et al.*, 2003; Orpwood *et al.*, 2004a).

The individual nature of so many problems that need to be dealt with has a big impact on the installation of smart home systems. As with all assistive technology, any means of tailoring it to the needs of the individual is going to make it more effective. Smart home technology is inherently flexible in that the way a system responds depends on the control software and this in turn can be quite easily configured for the individual. Ideally, installations need to be set up for an individual client by a nontechnical professional such as an occupational therapist (OT), and this in turn means that such configuring interfaces also need to be user-friendly.

SOME EXAMPLES OF USAGE

It is difficult to imagine how new technology can be supportive of someone but require little or no learning. A few examples would be useful. A situation that causes a lot of concern is the problem of an elderly person getting out of bed at night and finding the toilet. For someone who is a little unsteady on their feet, rising from lying down to standing is particularly dangerous. The problem is exacerbated by the fact that they are probably in a dark environment. How can smart home technology assist in this situation? First of all the house can know whether it is dark or not through ambient light sensors. It can also detect whether someone is in bed and about to get up by means of bed-occupancy sensors. These are usually either placed underneath the bed legs and detect a weight change (see Figure 3), or they lie across the mattress to sense the same changes. Sometimes pressure sensitive mats are used on the floor next to the bed, although experience has shown that some users will make a point of not treading on the mat once they have learnt that it is there. Given this information the house can ensure that when someone gets out of bed in the dark the bedroom lights are turned on, or a bedside lamp. To reduce the possibility of alarming the user the light can be activated through faders so that lights do not just suddenly come on. They fade up to quite a low level in a gentle manner (Figure 4). In this way, the user is provided with lighting to help them orientate more easily and move around without tripping or bumping into things. The process can also be reversed. If the user gets back into bed but forgets to turn off the light, the house can again detect that this has happened and can turn the lights off automatically.

This simple use of smart home technology can be taken further. The movements of an occupant about a room can be easily and reliably detected using passive infrared sensors (PIRs). These are the kind of sensors that are used in most home security systems and burglar alarms. If the user has got out of bed and begins to go out of the bedroom, the house lighting can be used to provide further support. It is

Figure 3 A bed-occupancy sensor that fits under a bed leg

Figure 4 An automatic bedside lamp in use

quite easy to arrange for lights to come on automatically as the user moves around the house, again ensuring they have illumination and help reduce falls. The work carried out for the Gloucester smart house for people with dementia goes one stage further and if the user goes to go out of the bedroom, the house makes an initial assumption that they probably want to go to the toilet. It then fades up the toilet lights and fades down the bedroom lights. In this way, it provides guidance to the toilet for the user. Finding the toilet at night can be a particular problem for people with dementia. When the user has finished in the toilet and begins to go out of the bathroom, the house reverses its response, fading up the bedroom light again and fading down the toilet one. In this way, the house can provide guidance to the user moving around the house in addition to providing illumination.

There are many other ways that smart house technology can provide support to the occupant (see Figure 5). Several examples are discussed later. A common usage is to provide safety and security support. The house can detect if something a little dangerous has been done, say in the kitchen, and then provide prompts and support. In a similar way, the use of other domestic appliances such as the bath and the kitchen sink can be backed up by keeping water temperatures safe and turning off taps as described above. For people with dementia, the house can keep an eye on wandering tendencies and try to discourage going out of the house and calling for help if it occurs. The house can also provide prompts for activities that need to be carried out such as taking medication, or provide a form of day diary to remind people of visitors or mealtimes or even a favorite TV program. In many ways the house acts like an extra carer, but one that acts for 24 hours a day without becoming tired or frustrated. But of course it can never supply the qualities of personal human care, and it is crucial that installers bear this in mind and do not just see smart homes as a cheap replacement for normal caring.

APPROPRIATE DESIGN

Simple application of smart home technology can in the ways illustrated provide a lot of support for the user. However, if it is to be effective it has to be designed from a close understanding of the issues that are likely to arise and the way that users are likely to interact with the technology. A very useful rule of thumb that was used in the development of technology within the Gloucester smart house project was to try to design new support equipment that reacted in a way that emulated the behavior of personal carers. The reasoning behind this approach was that in many circumstances a personal carer is likely to be the person who best understands what works in caring for the person they are looking after. If they have developed a strategy that works for them, it is likely that any new technology that reacts in a similar way is likely to be helpful. In the work carried out at Bath for people with dementia, the particular strategies found to work by carers were explored more systematically through a comprehensive survey of personal carers (Jepson and Orpwood, 2000). The survey showed there was a good consensus on the part of carers about the kind of strategies that worked for them. This understanding was a starting point for the new technology developed by the team for use in a smart home. During the design and development work, whenever a situation arose where it was not clear how the technology should react, it was found to be very useful to ask "What would the carer do in this situation?". In this way, the technology is being designed to act as a kind of invisible carer that is ever present, just looking over the user's shoulder, checking that things are okay, and just providing help when needed.

A good example of the use of the "carer emulation" approach is provided by the designs used to control a bath. It would be quite easy to install a bath water level sensor

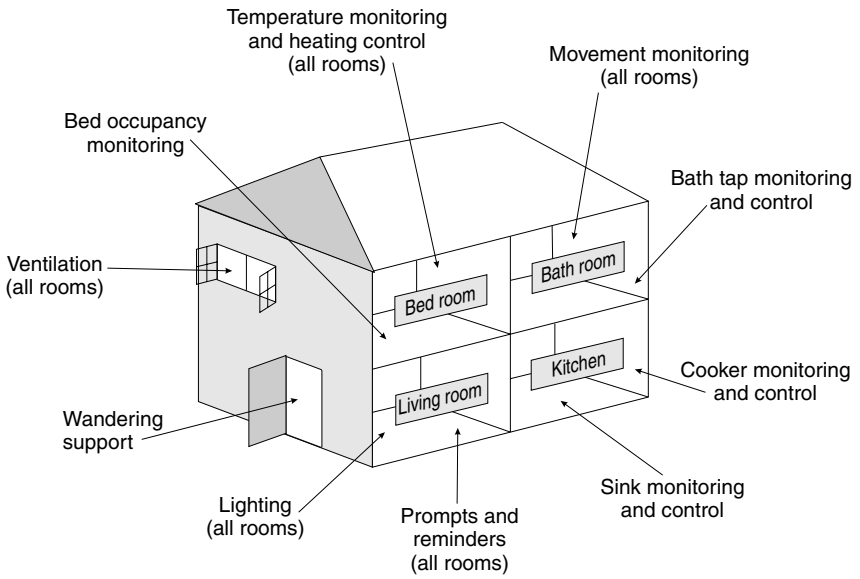

Figure 5 Possible support that can be provided with a smart house installation

that shut off the water supply when the bath was full. Such a facility would ensure that a forgetful user didn't flood the bathroom. However, if they came back to add some more hot water, or they let out the water and wanted to run a bath the next day, they would find the taps didn't work because the water had been shut off. This sense of the house taking control is something that the team were particularly keen to avoid. A key element in maintaining quality of life for someone with a cognitive problem is to enable them to feel they are still in control of their lives, and finding their house is taking that control away from them would be counterproductive. How would a carer react to the problem of someone forgetting they were running a bath? It was found that, in these kind of situations, where the carer would be monitoring the person they were caring for and intervening if they were forgetful, the carer would follow a simple pattern of behavior. They would first of all provide a reminder, "Don't forget you've got the bath running". If that didn't do the trick, they would then intervene to turn off the bath (or the cooker or other appliance). However, they would turn off the tap in the usual way, which would mean it could still be used subsequently. And thirdly, in many cases they would provide some sort of reassuring comment to the user, such as "I've turned off your bath. It's ready now", so that the user knew why something had happened.

If this threefold strategy is to be incorporated within the house, there is a need for some additional technology. There is a need for a means of communicating with the user, to provide prompts and reminders. There is also a need for a means of turning off the bath taps in such a way that the user can still carry on using it themselves. The communication issue is an important one that will be dealt with more fully below. Suffice to say here that the messages were conveyed by voice, and were provided through the radio. The means for shutting off the water was done by redesigning the taps (Figure 6). The taps had their insides removed and a new shaft was provided that was rotated when the tap was turned. The shaft was linked to a sensor that could monitor how far the tap had been turned. So all the new tap did was to sense how far the user had opened the tap. Depending on this information an electric valve would open to let the water through at an equivalent rate. If the house needed to shut off the water it could turn off the electronic water valve and then apply an electric brake to the tap shaft. In this way, as far as the user was concerned, the tap felt like it had been turned off. The house would then reset the rotation sensor back to zero. If the user subsequently came to operate the tap it would first of all feel like someone had turned it off, but it would also activate the sensor in the usual way and the electric valve would supply water. This novel tap design was not just an engineer's good idea about a new tap design, it was completely led by an understanding of the issues involved and the way that the user was likely to respond through emulating the reaction of carers.

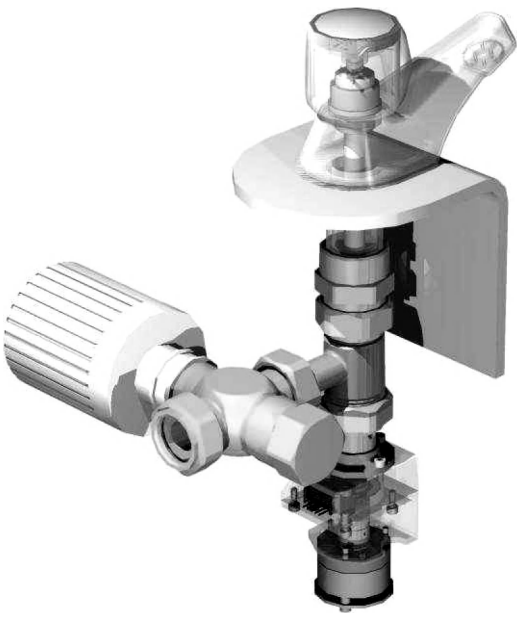

Figure 6 Diagram of the tap developed to enable the water supply to be turned off without taking control away from the user

Other techniques have been used to get a better understanding of what is needed for new designs where there is a very intimate interface with the user. A European Commission funded project, ENABLE, which evaluated the impact of assistive technology on people with dementia and their carers, placed a lot of emphasis on focus groups and other meetings with professional carers (Orpwood *et al.*, 2004b). These sessions were very useful to explore solutions in an interactive manner. The carer could highlight certain problem areas, the engineers could suggest possible design solutions, and the carers could reflect on these and suggest improvements or alternatives. Discussions such as these with professionals from different disciplines can be very constructive and fruitful. Another successful technique pioneered by researchers at Dundee University is the use of actors to provide a bridge between users and researchers (Marquis-Faulkes *et al.*, 2003). The Dundee team explored the issue of falls in the elderly. They used actors to simulate situations where falls occur. These were useful both to communicate with the user and get comments and feedback about situations and strategies, and also as tests for the sensing technology they were developing so that different categories of falls could be detected.

THE DIFFICULTY OF BEHAVIOR MONITORING

The main role of sensors in a smart home environment is to allow judgments to be made about user behavior. Some aspects such as whether someone has just come out of a toilet or not are fairly easy to sense and make judgments about. Most aspects though are surprisingly difficult to judge, even for simple behaviors, where complications can arise from inevitable variations in the way different people act. For example, the work described above on bed-occupancy systems showed that the house cannot just turn the light off as soon as someone gets back into bed. Users were found to

often sit on the bed before getting back in, perhaps to remove slippers or dressing gown. If the lights went out straight away it caused some confusion. A delay was introduced to ensure the user was fully back and settled in bed before turning off the lights. But even this required some careful setting up. The original delay used was five minutes but this proved to be too long and disruptive. If users knew the light would go off automatically many would tend to rely on that facility, or even feel that it must be used. Five minutes can seem to be a long time, lying in bed waiting for the lights to go off. The ENABLE project mentioned above tested a bedside lamp that had the facilities just described. It was interesting that although both people with dementia and their carers knew that the light could be turned off manually in the usual way, they felt they had to wait for it to happen automatically. These may seem like minor points in the use of such technology but they can be major factors in the confidence that their users have in them and therefore their acceptance.

Bed-occupancy sensors would superficially seem to be very straightforward. A weight sensor can tell the difference between whether someone is in bed or out of it. However, such a sensor will also be activated by someone turning over in bed, or moving from one side to the other. It also has to deal with situations that occur such as someone going to stand up from a bed, and then not quite making it and falling back onto the bed before finally getting to their feet. The algorithms (simple computer programs) that use the raw sensor data and make conclusions and judgments based on it have to deal with all these variants of user behavior (Figure 7). To ensure they are effective a lot of raw data has to be collected so that all the variations can be seen to enable an effective algorithm to be developed to deal with them.

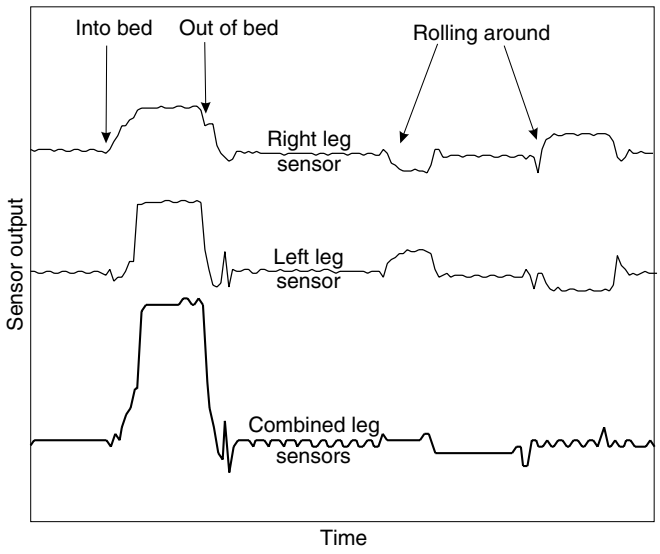

Figure 7 Raw data from a bed-occupancy sensor. The upper traces show the output from the sensors fitted to both legs at the head end of the bed, and the lower shows how the summed output can differentiate between getting in/out of bed and simply rolling around

If the house gets it wrong with a bed-occupancy sensor, it is not so crucial. If it gets it wrong with, say, a gas cooker monitor, then the outcome could be much more serious. Making judgments about human behavior based on simple sensor data is always going to be probabilistic. For example, with the gas cooker monitor developed for the Gloucester smart house, one of the sensors used was a simple infrared temperature sensor that was mounted at the side of the cooker and could detect the temperature of the pan or kettle. The data from the sensor was to be used to detect whether a pan had boiled dry or not. If a pan was boiling water, then its outside temperature would climb to close to 100 °C and stay there until it boiled dry, when the temperature would very rapidly increase. It would appear to be straightforward to detect this sudden temperature increase from the sensor data and initiate a response. However, users do not just leave a pan alone once it is in use on the cooker. They will very likely turn the gas up and down according to how the cooking was going. They may well move a pan around to different rings on the cooker. Such activities can make it very difficult to judge what is going on from the simple sensor data. A lot of cooking activities were monitored until it was felt that for about 80% of the time a pan could be reliably detected as having boiled dry. However, the other 20% of circumstances had to be dealt with in some way. It was decided to try and ensure that any errors were false positives. In other words, the cooker may on 20% of occasions turn off when it didn't really need to. However, these false-positive activations did prove to be quite irritating to users during evaluations. The exercise underlined the probabilistic nature of making judgments about user behavior. The level of errors could be reduced by incorporating information processing systems with learning capabilities, but it would still not reduce them to zero. Clearly in these kind of situations where there is potential danger there has to be some kind of backup. In the case of the cooker monitor, the device had a facility for shutting down the gas supply to the cooker if it continued to sense danger after responding to a danger signal. It also would call for assistance from outside the house in such situations. This is an important conclusion for smart house installations. Some aspects of the support they provide are quite safety critical. In these situations it must be recognized that the house may make a false judgment about the user's behavior and means for providing some kind of backup and a means for calling for outside assistance are essential.

THE IMPORTANCE OF COMMUNICATION

It has already been stressed that communication with the user within the smart house is important. Some systems such as the Brunel Millenium Homes project make much use of voice communication with users. The Bath work also places much emphasis on communication to guide and support the user. The smart house is an intelligent and autonomous care provider and like any other carer it needs to communicate with the person it is caring for. Voice communication is of

course very flexible and has the advantage that it reflects the kind of interactions provided by a human carer. But it does have some disadvantages. The communications it provides are transient. If the user is forgetful, then a message that encourages them, for example, to take some medication may be registered but then forgotten a few minutes later. For users with severe memory problems, such as those with dementia, this problem is exacerbated. In addition, the very fact that voice messages are very anthropomorphic means that users may well treat them emotionally and get angry or irritated when prompted to do something.

Some work has shown the usefulness of voice communication though. The Brunel team have had very positive responses to their system. The Bath group also have had some good responses even though their work was fairly exploratory because it was looking at voice communication with people with dementia. A lot of professional carers felt that this might not work because the person with dementia may well be made more anxious by the use of disembodied voices, particularly people with conditions such as Lewy body disease where they tend to hallucinate and hear voices anyway. The other concern raised was that if the voice was recognised, the person with dementia may well think the owner of the voice was in the building and go looking for them. To try and address the first concern, the designers made sure that any voice messages came from devices that normally had voices coming from them, such as the TV or the radio. The Gloucester smart house project modified radios so that they would be turned on and a message played when necessary, or played instead of the broadcast if the radio was already on. It was argued that the often reported anecdote that people with dementia will personalize the messages they hear from the radio or TV, and feel they are being addressed personally, might well mean they would take good note of any prompt or advice coming from these devices. It was also decided to use a voice that was a warm anonymous one.

Most of our experience of voice prompts has come from the use of a wander reminder for people with dementia. This device sits by the main door and if it detects someone in its vicinity at nighttime it plays a voice prompt that says something like "It is still nighttime Joan. I should go back to bed" (Figure 8). If the user still goes out of the house this is detected, an alarm is sent to a carer to alert them to the fact. Most of the users have been mild to moderate in their degree of dementia. The results have been very positive, with less wandering reported in most cases and no wandering in several. However, some carers have reported that the user just swears at the voice box! The fact that the voice was disembodied does not seem to have been a problem. It would appear that people are quite used to voices coming out of little boxes from their lifetime experience of radio, tape-recorders, and so on, and it seems quite normal. Interestingly, there was some evidence of habituation to the message and the carer was encouraged to change the message frequently. One unexpected outcome from these changes was that it was reported that users seemed to respond better to a voice they recognized. In all the cases so far, the new recording has been done by the personal carer, that is, the person that the user probably trusts. These observations are rather anecdotal at the moment but provide some interesting insight into an area that is an important research topic for smart home installations for elderly people.

Other means for communication are being explored. As mentioned above it would help to use messages that remain for a longer period for people with memory problems or who are a little forgetful. Simple hand written text messages are often used by carers of people with dementia. For example, carers might use Post-Its around the house to remind the user not to touch certain appliances, or to remind them to take medication, and so on. Automated text messages on a small screen on the wall, which can be activated by the house in appropriate situations, are being explored. A further development of this idea that has been successfully tested is the use of simple pictures or graphics in addition to the written message. There is scope for providing these messages on the TV where simple animation or even small video clips can be used.

Figure 8 A wander reminder fitted near an exit door

QUALITY OF LIFE ISSUES

It has been commented that smart home technology has primarily been used to support safety and security issues, and not very much for other activities such as leisure (Marshall, 2001). The technology is ideal for monitoring activities such as cooker, fire, and tap usage, to ensure appropriate temperatures and ventilation, to help prevent wandering or disorientation at night, and so on. The impact that it has on quality of life is less clear, and yet as far as the users themselves are concerned, it is maintenance of or improvement in their quality of life that is all important. Are there ways in which this technology can have an impact on quality of life?

There are a large number of quality of life measures now available, including measures for people with dementia

(Brod *et al.*, 1999). The ENABLE project used a measure of the impact of technology on quality of life as one of its main outcomes. Recently some work has started in the United Kingdom to explore whether it is possible for smart home technology to have an impact as well. This is a collaborative venture with the main academic partners coming from Liverpool, Sheffield, and Bath Universities. The project aims to tease out those aspects of the lives of people with dementia that have an impact on quality of life and then provide designs of smart home technology and built environments that can help improve on them. The work is in an early stage but already it is clear that there are a number of issues that are important. A key issue of course is that of independence, and for the user to have a sense of being in control of their lives. It is for this reason that so much emphasis had been placed in the Gloucester smart house project on empowering the user and not letting the house take control away from them. Another crucial issue is the importance of reducing social isolation. Are there ways in which smart home technology can enable people to feel part of wider society, and still be able to maintain contact and socialize with friends, family, and carers? There is some indication from other work that even simple phone or video conference chats can be of benefit (Monk and Watts, 2000). The often reported habit of TVs being left on in an otherwise empty home to provide a sense of social involvement gives an indication of the complex way that people can interact with technology. Many issues that have an impact on quality of life are very personal to the individual. There can often be some barrier for a given individual that prevents him/her from doing something that may not seem that important to an outsider, such as being able to cook a simple meal for oneself. If such barriers can be identified and removed through the use of some technology, it could provide a big increase in their personal quality of life.

LINKS WITH THE OUTSIDE WORLD

As was mentioned above, the major factor differentiating smart home technology from telecare systems is its ability to act autonomously. However, there is an important need for communication with the outside world. Already mentioned is the need for backup in the event of an emergency. The house needs channels of communication that can alert the carer and others to the fact that the house is not able to cope on its own. The Bath work, for example, used an SMS link to call for assistance. If the gas cooker monitor decided that there was still some danger despite it having turned off the cooker knobs, then it would shut down the gas supply and send a text message to the mobile phones of several carers, advising them to come and check, and to turn the gas back on again. This system worked very well. Such links could be provided via landline phones and perhaps to a call center. It would also be possible to send messages via a web server to appear on a remote monitor. Installations in a sheltered housing scheme in Deptford in London that are an extension of the work carried out in Bath use such a system. Because the Deptford installation is in a care home, any need for backup is initially provided by alerting the warden call system. In addition to the alert, the computer linked to the installation can send text messages via a web server that enables the computers in the warden's office to display messages relating to any need for their assistance.

The external support described could provide details that would enable a care professional to make judgments about the impact of the technology. This is a difficult ethical area that needs much further exploration. On the one hand it might be seen to be useful for an OT to just check on how often one of her clients had used the toilet in case there was evidence of a urinary tract infection, for example. But is such personal intrusion really ethically acceptable? On the other hand it would make sense for the house itself to flag a warning if it detected anomalous behavior that might indicate excessive anxiety, or to let OTs know if the gas cooker had to turn itself off more than 10 times in a week, or if the fridge hadn't been opened for more than a few days. So these links to the outside world seem to make sense if they can be preset to draw attention to some trend in the house, but it becomes much more ethically contentious when it is used as a tool to check and pry.

INFRASTRUCTURE NEEDED FOR INTRODUCTION

A lot of the work carried out so far on the use of smart homes for elderly and disabled people has been on very small-scale installations. They have been more akin to research projects to explore the potential of the technology. As evidence mounts that there are distinct personal benefits to the clients, and as evidence also mounts as to the cost effectiveness of the technology, there is an expectation that the technology can be rolled out to be used throughout the community. However, there are a number of infrastructural requirements that are needed to be satisfied before such a big step.

First of all any such technology can only be used following an extensive assessment of the user's needs by a care professional, probably an OT. The OTs involved need to be knowledgeable about what assistive devices are available and the potential of them to provide support. In this way, they can match the needs of the individual to a prescription of the mix of technology that would best suit the client at that time.

Secondly, there needs to be a knowledgeable set of contractors, either employed by the company manufacturing the assistive technology or able to work for a number of different companies, to carry out the actual installations and configure them according to the results of the assessment process. As with environmental control technology, the commissioning process is complicated because it needs to involve a mix of technical people and OTs.

Thirdly, there needs to be system of operational backup, as described above, in the event of emergencies arising. Such backup may well be provided by call centers, but there is no

reason why this cannot be provided via care professionals directly, or personal carers, particularly through web-based technology.

Fourthly, there needs to be a well thought through system of technical maintenance that can be activated at very short notice. It is clear from the work of projects such as the ENABLE one that users of sophisticated technology can get very anxious when it does not seem to be operating as they expect, and can quite quickly reject the technology if it appears to have gone wrong. Such backup would ideally be provided by manufacturers, but a frontline of quick-reaction local technical support would probably be essential.

All the infrastructures described above would have to be in place before any large scale installation of this technology. Similar facilities are also needed of course for telecare systems and these have been mostly put in place with remarkable efficiency over the last few years in the United Kingdom, mostly through the work of some more visionary manufacturers. The manufacturer involved with the Brunel Millenium homes project has also locally established much of the support needed. So there is every reason to expect such infrastructures can be put in place, particularly once the benefits of using this technology become more widely accepted.

FUTURE TRENDS

There is an important need for much more evaluation of smart home installations to get a better indication of the ways in which it supports users, and indeed the ways in which it does not. Evidence is emerging as to those key features that are of most benefit but much more work needs to be done in this area. In addition, the new support devices developed specifically for the elderly now need to be developed to a more mature state. As has been said, there are a lot of items such as lighting controls that are already available off the shelf. Others such as cooker controllers and reminding devices are less so, and need to achieve the same level of maturity. The one area where there is still a lot of work to do is in terms of the actual physical installations. The logic needed to control even a single home or apartment in a care home can be quite complex, particularly if it has to be able to be configured to suit a range of different users, and deal with power cuts and computer crashes. If installations are to be plug and play, which they need to be, then the logic element that controls the system, and provides the link to the outside world, needs to be plug and play as well. The software needed to configure a system for an individual needs to be developed so that it is very user-friendly and can be used by care professionals.

For installations that are provided in care homes and sheltered housing schemes then, the use of hard-wired communication buses is probably going to be the first choice. Such buses can provide excellent and well-proven reliability, and they can provide the low power needed for many components of an installation. For builders of new housing schemes, it makes sense to install the bus cabling during the build, even if it is not being connected to support installations straight away, because it is very cheap to install at that time. Many housing associations, such as Housing 21, are doing this already. For a retrofit installation, however, especially for those used in people's own homes, the use of hard-wired buses is much less suitable. It is very disruptive and time consuming to install, and therefore expensive. For people who are likely to be anxious anyway, such as those with dementia, such installations can hardly be justified ethically. In these situations, radio-based buses or buses using mains wiring are much more appropriate. A number of radio frequency buses are in use already although an accepted standard does not seem to be agreed yet. Some modern developments such as the Ziggbee radio bus seem to have the right mix of range and bandwidth. It is very likely that an accepted standard will drop out from the various experimental systems currently being explored. Radio-based devices are truly plug and play. They do need battery power and all the backup that that implies for replacements to be provided in a timely manner, but standard replacement times and procedures would probably deal with that. Some of the more modern systems such as the one mentioned above, Ziggbee, have very good power management built-in that provides excellent battery life. There is no doubt that radio-based systems or systems superimposed on normal mains wiring will be the way forward for personal home installations.

There is a need for further work on support devices and sensors, particularly those that can provide support that improves leisure and quality of life more generally. And finally the technology to provide background behavior monitoring, which has been a research topic for some years, is likely to provide added benefits. Such technologies should provide better judgments of complex behaviors that might reflect anxiety levels, or specific issues such as falls. An extra feature incorporated in the Brunel project and one that has been explored by several academic groups (Dewsbury *et al.*, 2004) is to see if the technology can be better tailored to the needs of the individual user by allowing it to learn the typical behavior of the occupant. The house, through its sensors, can acquire a lot of information about the use of various appliances and the patterns of activity within the home. Once this information has been acquired, the house can use this "normal" template to check whether there are major changes that might indicate something is wrong. Such adaptive properties will also enable the installation to adapt to the user's behavior and learn the subtleties of an individual's requirements. All these topics are being researched; some, such as adaptive systems, are being used with clients.

The installations that have been discussed throughout this chapter have been looking at home support technology that can act as a kind of extra care helper. However, the technology also has potential for linking in to other kinds of technological support and may well become integrated with them. For example, the burgeoning developments in telehealth technology could well use some of the same infrastructure as smart homes. If smart homes have appropriate links to the

outside world and can sense user behavior, then there is no reason why they cannot also report health issues resulting from the physiological and other sensors used by telehealth systems. Links between telehealth and telecare have already been made by some companies, so telehealth can certainly be incorporated in smart home installations. There is research also going on looking at telerehabilitation, where home exercises and physiological responses can be remotely monitored in the same way as telehealth systems.

CONCLUSIONS

The application of smart home technology to support elderly and disabled people has developed rapidly over the last few years. Recent work has been much more user-led and aimed at supporting people with a wide variety of abilities, including those with dementia. Evidence is mounting that such systems can provide real benefits to the user, and would also appear to have benefits from a cost point of view. There is still much work to be done, particularly with respect to improving quality of life and leisure activities. However, as long as the relevant infrastructure can be put in place to support the technology, there is no reason why installations in both care homes and people's private homes cannot be a major feature of the support provided to elderly and disabled people in the very near future.

KEY POINTS

- Smart technology has much potential for supporting elderly people, including those with dementia, if it just provides background support and does not rely on user interaction.
- If smart home technology is to be effective, its design must be led by the particular needs of the user.
- Sensors in the home are only going to enable statistical judgments to be made of human behavior, and human backup is needed to deal with mistakes.
- The technology requires an external infrastructure to provide assessment, technical backup, and monitoring.
- Technology can only augment human care, never replace it.

Preventive Geriatrics

Joseph H. Flaherty[1] ***and*** **Antony J. Bayer**[2]

[1] Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA, and [2] Cardiff University, Cardiff, UK

INTRODUCTION

Preventive geriatrics is not an oxymoron. It is, however, a challenging area of medicine for many reasons. (1) When does prevention actually begin? (2) How can guidelines for prevention take into account the increasing variability seen among older persons? (3) How can preventive geriatrics balance the dichotomy between the treatment of populations and the treatment of the individual? (4) How can clinicians handle the unclear areas or "gray zones" of preventive geriatrics? (5) Does early detection or case finding equate with better outcomes?

This chapter presents two models of preventive geriatrics that deal with these questions. The first model is called the *Health Maintenance Clinical Glidepath*, which is primarily for office-based practices. It addresses screening for geriatric-specific areas (e.g. cognition, gait and balance, etc.) as well as screening for common medical illnesses and diseases (e.g. certain cancers, heart disease, etc.). The second model is the British Health Checks, which is community based. It focuses on comprehensive geriatric assessment (CGA) and is intended for all people over 75 years of age.

BACKGROUND

Prevention in medicine has traditionally been divided into primary, secondary, and tertiary prevention. Primary prevention is the prevention of disease before it actually starts. On the basis of this definition, primary prevention of disease that occurs in old age begins at a very young age. Although gene manipulation was in its infancy at the end of the twentieth century, by the end of the twenty-first century, it could prevent, delay, or modify diseases common in old age, such as Parkinson's disease, cardiac disease, diabetes, and even arthritis. Until then, society's obligation to its future elderly is to advocate health promotion over the life span. Although the health promotion guide in Figure 1 does not include all areas of prevention, it is one example of an educational tool that can be used among all ages.

The traditional definition of secondary prevention is the detection of disease at an early stage. This can be detection of asymptomatic diseases by screening tests or identification of unreported problems by case finding. The following cautions need to be added to the definition. Detection should only be done if it is likely to improve outcomes such as mortality, morbidity, function, or quality of life. The priority and importance of outcomes need to be made on the basis of patient preference (Woolf, 1997).

THE HEALTH MAINTENANCE CLINICAL GLIDEPATH

The Health Maintenance Clinical Glidepath answers questions two and three above but also addresses the limitations of two types of clinical decision-making tools: practice guidelines and evidence-based medicine (EBM). Although practice guidelines and EBM have been important in raising the standards of health care in the past decade, their use in preventive geriatrics is limited. Many guidelines do not include older age-groups, and if they do, they are no more specific than "over 65 years of age". EBM emphasizes outcomes of populations, while clinical practice emphasizes the outcome of the individual. One of the reasons EBM may not be so useful is the discrepancy between patients in the EBM studies and in clinical practice (Kerridge *et al.*, 1998). For example, many randomized controlled trials of medication interventions for common diseases such as congestive heart failure, coronary heart disease, and osteoporosis exclude patients who are frail, demented, or at the end of life (Australia/New Zealand Heart Failure Research Collaborative Group, 1997; Pitt *et al.*, 1999; Liberman *et al.*, 1995).

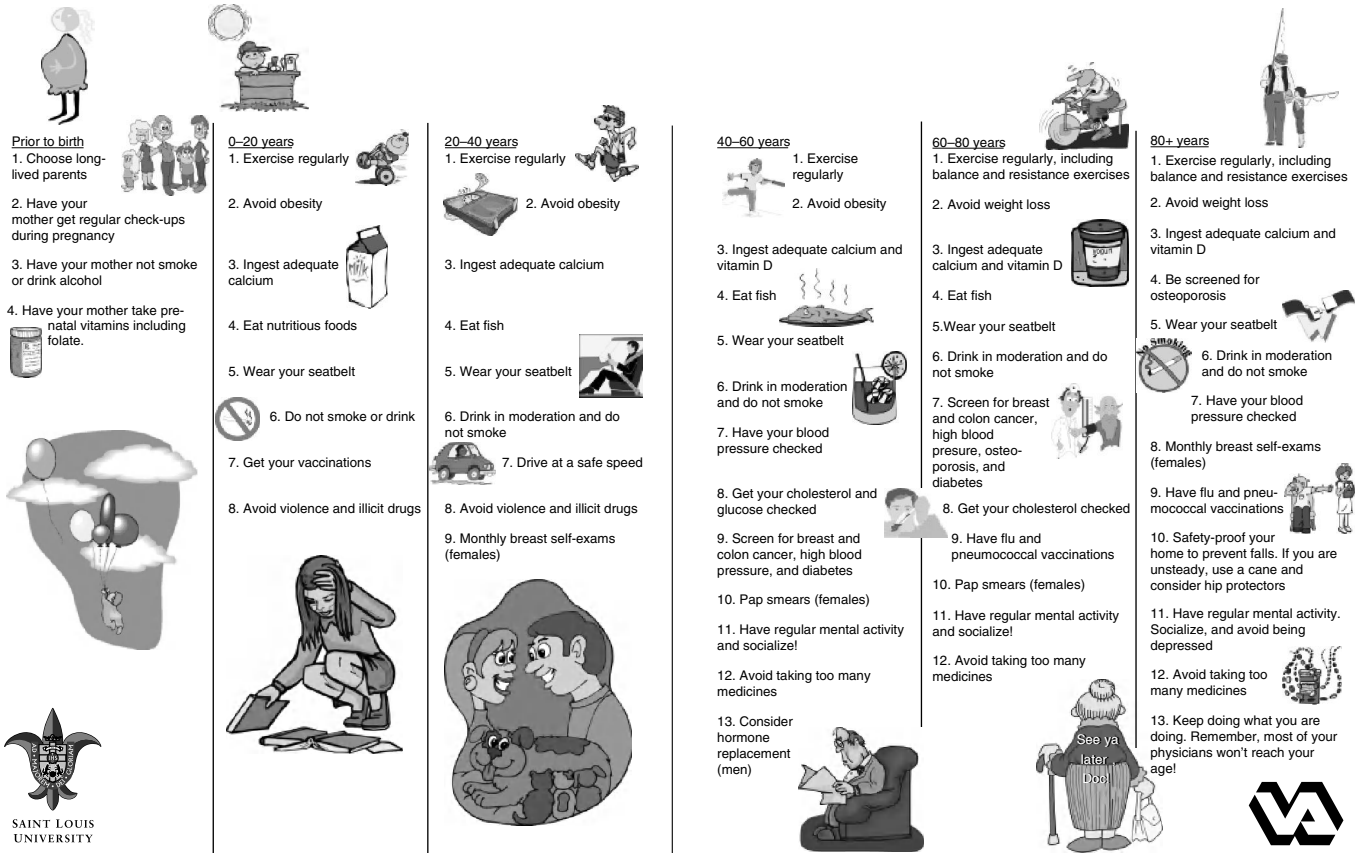

Figure 1 Aging successfully: a guide to health promotion over the lifespan

The older we get, the more unique we become. Chronological age does not equate with physiological or functional age. Guidelines for preventive geriatrics need to take this into account. One approach is to use life expectancy and functional status to help delineate categories of older persons that are more useful than those based on chronological age. Overall health status is a good predictor of life expectancy compared to age alone (Diehr *et al.*, 1998), and functional capacity among older persons has been found to be a predictor of mortality (Corti *et al.*, 1994; Walter *et al.*, 2001). Four categories can be used to help guide decisions about preventive measures. Although overlap exists and functional status may fluctuate, Gillick proposes the following: Robust (life expectancy of greater than 5 years and functionally independent); Frail (life expectancy of less than 5 years and significant functional impairment); and Moderately Demented (life expectancy from 2 to 10 years and may or may not be functionally impaired); End of Life (usually a life expectancy of less than 2 years) (Gillick, 1994).

Preventive geriatrics requires making decisions. Health-care decisions are complex, involving society, health-care workers, and patients. Guidelines for preventive geriatrics need to take into account the following practice principles: (1) patients' expectations and needs, including quality of life, satisfaction, reassurance; (2) physicians' need for diagnostic certainty; (3) physicians' comfort with risk taking and concerns about malpractice; (4) the need for cost-effective medical care; (5) variations in practice patterns, particularly in regard to subspecialty care; and (6) the practical realities of running a practice (Murphy, 1995).

Health-care decisions are not black and white. Thus, four levels of recommendation were developed to allow for decisions to be made on a "graded" rather than an "all or nothing" basis, and to allow for better patient involvement in decision making. The four levels are also based, when available, on the strength or weakness of EBM that exists or does not exist. The four levels are "Do", "Discuss", "Consider", and "∗∗∗∗". "Do" reflects the strongest recommendation. "Discuss" reflects a recommendation that the physician discusses the risk: benefit of the decision with the patient. "Consider" reflects a recommendation that the physician gives consideration, but does not necessarily need to discuss the decision with the patient. "∗∗∗∗" reflects that a particular evaluation or management measure is not recommended, based on these principles.

Table 1 is a shortened version of the original Health Maintenance Clinical Glidepath which details the recommendations for each area of prevention and for each category of Robust, Frail, Moderately Demented, and End of Life. It will be noted in the following paragraphs whether recommendations are based on organizational guidelines, EBM, or expert

Table 1 The Health maintenance clinical glidepath

Recommendations: Highest ↓ Lowest — Do / Discuss / Consider / **** (see text for further explanation)	Robust elderly Life expectancy >5 years and functionally independent	Frail Life expectancy <5 years or significant functional impairment	Moderately demented Life expectancy 2–10 years	Robust elderly Life expectancy >5 years and functionally independent
Office visits	Do yearly	Do 1–4 times/year	Do 1–4 times/year	Do as needed
Blood pressure including orthostatics	Do each visit	Do each visit	Do each visit	Do each visit
Weight	Do each visit. If loss of >5 pounds/year perform MNA[a]	Do each visit. If loss of >5 pounds/year perform MNA[a]	Do each visit. If loss of >5 pounds/year perform MNA[a]	****
Height	Do yearly	Do yearly	****	****
Pain assessment	Do each visit	Do each visit	Do each visit	Do each visit
Medication review including OTCs[a] & herbal medicines	Do each visit	Do each visit	Do each visit	Do each visit
Lifestyle education (exercise, smoking cessation, alcohol, and injury prevention)	Do each visit	Do each visit	Discuss periodically with caregiver	****
Maintain awareness of elder abuse	Do each visit	Do each visit	Do each visit	Do each visit
Assess ADLs[a] and IADLs[a]	Do yearly	Do yearly	Do each visit	Do each visit
Visual acuity testing	Consider yearly	Consider yearly	Consider yearly	****
Auditory testing	Consider yearly	Consider yearly	Consider yearly	****
Ask about urinary incontinence	Do yearly	Do yearly	Do yearly	Do yearly
MALES: Ask about erectile dysfunction and ADAM[a] screen for hypogonadism	Do yearly	Do yearly	Consider yearly	****
Cognitive screening	Do initially; do if symptomatic	Do initially; do if symptomatic	Do initially	Consider if symptomatic
Depression screening	Do initially; do if symptomatic	Do initially; do if symptomatic	Do initially; do if symptomatic	Do initially; do if symptomatic
Screening for gait and balance	Do initially; do if symptomatic	Do initially; do if symptomatic	Do initially; do if symptomatic	Do if symptomatic
Advanced directives	Do yearly and as needed	Do yearly and as needed	Do yearly and as needed	Do yearly and as needed
Influenza vaccine	Do yearly	Do yearly	Do yearly	Do yearly
Pneumococcal vaccine	Do once; consider repeat every 6 years for patients with chronic diseases	Do once	Do once	Consider vaccination once
Tetanus	Do primary series if not vaccinated before and booster every 10 years	Do primary series if not vaccinated before	Do primary series if not vaccinated before	****
Breast exam	Do yearly	Do yearly	Do yearly	****
Mammography	Do every 1–2 years up to 80 years	Consider every 1–2 years up to age 75	Consider every 1–2 years up to age 70	****
Pap smear	Consider 1–3 pap smears if patient has never had pap smears	****	****	****
Fecal occult blood test	Do yearly	Consider yearly	Consider yearly	****
Colonoscopy	Consider every 5 years	****	****	****
PSA[a]	Discuss pros and cons with patient	Discuss pros and cons with patient	Discuss pros and cons with caregiver	****
Osteoporosis	Do at least once; Consider every 2 years	Do at least once	Do at least once	****

consensus. All areas of the Glidepath underwent a Delphi process (Flaherty *et al.*, 2002).

OFFICE VISITS

Although there is no direct evidence available on how often Robust elderly versus Frail or Moderately Demented elderly need office visits, because other screening procedures need to be done, the minimum frequency should be once a year. "Do as needed" is recommended for elderly at the End of Life because of potential limitations or inability on the part of the patient to get to the office. As will be discussed below, yearly British Health Checks are one model that has been recommended for community-dwelling elderly.

BLOOD PRESSURE (BP) INCLUDING ORTHOSTATIC MEASUREMENTS

Doing BP measurements in all age-groups is recommended at each visit. While this pertains to screening for hypertension in all four categories, it also pertains to hypotension (and associated symptoms) in the Frail, Moderately Demented, and End of Life categories. Recommendations for hypertension screening are based on organizational guidelines. Although most organizations agree on the importance of screening for hypertension, they do not agree on how often. For example, the American College of Physicians (ACP) recommends BP screening in all adults *with office visits* at least every 1–2 years (Littenberg *et al.*, 1990). The United States Preventive Services Task Force (USPSTF) recommends *periodic* BP screening, and reports that the current expert opinion is that adults who are believed to be normotensive should have BP measurement at least once every 2 years if their last BP reading was below 140/85 mmHG; and screening should be annual if the last diastolic BP was 85–89 mmHg (United States Preventive Services Task Force, 1996).

Screening for orthostatic hypotension (OH) is based on evidence that OH is prevalent among older patients (13–30%) and that there is an association between OH and adverse outcomes (Hale and Chambliss, 1999; Luukinen *et al.*, 1999; Davis *et al.*, 1987). Although no studies have been done to show improved outcomes if this screening is done, the cost and risk of the intervention is low enough that postural BP measurements are recommended.

WEIGHT

Weight loss in older patients has significant adverse effects on mortality, morbidity, and other unfavorable outcomes (e.g. loss of muscle mass; decreased muscle strength; altered immune function; decreased wound healing) (Morley, 1996). The data on the benefit and outcome of nutrition management is somewhat controversial, but mostly positive. Oral nutritional supplement was shown to improve weight in nursing home elderly, supplementation was shown to improve weight and reduce falls in frail elderly living in the community, and dietary supplementation led to moderate weight gain and improvements in general well-being in homebound elderly (Johnson *et al.*, 1993; Gray-Donald *et al.*, 1995, 1994). However, another study of frail elderly showed that nutrient-dense foods and exercise were not able to improve appetite or sensory perception, and no functional change was found by nutritional supplementation (De Jong *et al.*, 2000).

Since screening for weight loss is very low in cost and risk and the benefits of interventions are mostly positive, it should be done for patients in all categories except End of

Life. In addition to weighing the patient, the Mini Nutritional Assessment (MNA) is a validated nutritional screening tool that can identify patients who are malnourished or at risk for malnutrition (Garry and Vellas, 1999) (Rubenstein, 1998).

HEIGHT

Since measuring height is a low-cost screening intervention, and as bone loss occurs height may decrease, it may be an effective and economical method to identify early osteoporosis of the spine for the Robust and Frail elderly. However, there is no clear evidence to determine what amount of loss is significant (Ismail *et al.*, 1999); (Hunt, 1996); (Ettinger *et al.*, 1994).

PAIN

Pain should now be considered the fifth vital sign and should be checked at every visit for patients in all categories (Anonymous, 1999c). Use of Likert scales (e.g. 1–10) or pictorial scale (e.g. facial expressions) can be useful to quantify pain. Even patients with dementia can be evaluated for pain (Won *et al.*, 1999; Anonymous, 1998b).

MEDICATION REVIEW INCLUDING OTCs AND HERBAL MEDICINES

The risk of adverse drug events, poor compliance, drug–drug interactions, and even the risk of hospitalization are most associated with number of drugs, while underlying comorbidities and to some extent age contribute to this risk (Hanlon *et al.*, 1997; Nolan and O'Malley, 1998; Col *et al.*, 1990; Flaherty *et al.*, 2000). Thus, medication review including OTCs and herbal medicines should be done for patients in all four categories at every visit.

LIFESTYLE EDUCATION

Recommendations about areas of lifestyle education in general apply mainly to the Robust and Frail elderly, with a lower level of recommendation for the Moderately Demented elderly. Activity level should be queried about because a low level of activity is a significant predictor of mortality among older adults (Fraser and Shavlik, 1997). Walking can be recommended to most older persons; sustained walking for 30 minutes a day can result in health improvement. Even small increases in exercise can be beneficial in inactive older persons, including wheelchair and institutionalized elderly. Exercises can include endurance (walking, climbing stairs), strength, balance, flexibility, and posture (Green and Crouse, 1995; Ettinger *et al.*, 1997).

Physicians should ask patients about smoking and should clearly and directly advise all smokers to quit. Patients who want to quit should be assisted with self-help materials, choosing a quit date, and a possible referral to community programs (Rimer *et al.*, 1994).

In order to screen for alcohol problems, either the CAGE questionnaire or the Michigan Alcohol Screening Test can be used (Ewing, 1984; Pokorny *et al.*, 1972). The CAGE questionnaire for alcoholism screening asks the following questions: (1) Do you feel you ought to **C**ut down on drinking? (2) Are you **A**nnoyed by people criticizing your drinking? (3) Do you feel **G**uilty about drinking? (4) Do you have a drink first thing in the morning (**E**ye-opener)?

Areas of education for injury prevention include the use of seat belts, alcohol-related risks in relation to driving, environmental hazards in the home which may aid the prevention of falls and the dangers of firearms (United States Preventive Services Task Force, 1996).

MAINTAIN AWARENESS OF ELDER ABUSE

Physicians and other health-care professionals should maintain awareness at all times for patients in all categories. This is based on the fact that elder abuse and neglect is prevalent, may often be missed, and may be "asymptomatic". The term "awareness" is used because no particular standardized evaluation tool for elder abuse has been shown to be better than others (Lachs and Pillemer, 1995; Joshi and Flaherty, 2005).

ASSESS ADLs AND IADLs

Prevention of functional decline is one of the hallmarks of geriatric care. Loss of function among older persons is associated with long-term care placement, morbidity, and mortality (Corti *et al.*, 1994). Thus, although there is no direct evidence on how often to screen older patients in each of the four categories for functional change, given the importance of this health parameter, it is recommended for patients in all categories at the intervals as noted in the table.

Two commonly used measurements of function are activities of daily living (ADLs) (bathing, dressing, toileting, transferring, continence, feeding) and instrumental activities of daily living (IADLs) (telephone, shopping, food preparation, housekeeping, transportation in the community, taking medications, handling finances) (Katz *et al.*, 1963; Lawton and Brody, 1969).

VISUAL ACUITY AND AUDITORY TESTING

Although both visual acuity and auditory testing are an accepted part of the CGA, the level of recommendation for testing these areas is "consider" for patients in all categories There is evidence that decreased vision is associated with

negative outcomes. However, according to one systematic review of randomized controlled trials, the inclusion of a visual screening component in the assessment resulted in only a small reduction (11%) in the number of older people with improved self-reported visual problems (Smeeth and Iliffe, 1998). Likewise, although there is evidence that decreased hearing is common and associated with negative outcomes, there is a lack of evidence-based medicine that screening will improve outcomes (Murlow and Lichtenstein, 1991).

ASK ABOUT URINARY INCONTINENCE

The level of recommendation is the highest for all categories because urinary incontinence is common among women and may occur in men, is easy to screen for (usually one to two questions), and multiple effective treatments are available (Nasr and Ouslander, 1998; Schmidbauer *et al.*, 2001; Miller *et al.*, 1995).

MALES: SCREEN FOR ERECTILE DYSFUNCTION AND HYPOGONADISM

It is recommended that this be done for males in Robust and Frail categories, but should only be considered in males with Moderate Dementia. Erectile dysfunction is common and multiple treatments are available (Montague *et al.*, 1996). Male hypogonadism is also common and is associated with muscle weakness and osteoporosis (Morley and Perry, 2000). The ADAM (Androgen Deficiency in Aging Males) screen for hypogonadism has high sensitivity and adequate specificity (Morley *et al.*, 2000; *see* **Chapter 121, Ovarian and Testicular Function**).

COGNITIVE SCREENING

Screening for cognitive impairment is part of a CGA and should be done at initial visits for patients in all categories, except for those at End of Life, where it should be considered. The Mini-mental State examination is a commonly used screening tool (Folstein *et al.*, 1975), but may have limited utility if the cut-off score is set too high (White *et al.*, 2002). For elderly with high education levels, the Saint Louis University Mental Status (SLUMS) examination (see chapter on dementia for details) may be used. The term "symptomatic" refers to any complaint given by the patient or caregiver, or any problem observed/illicited by the clinician.

DEPRESSION SCREENING

Depression screening should be done at initial visits for patients in all categories. There is evidence that detection of depression is higher for older patients compared to younger patients when screening data were made available and effective treatments are available. (German *et al.*, 1987). Screening for depression is part of a CGA. There is no strong evidence for one particular screening instrument for depression (Mulrow *et al.*, 1995; Lyness *et al.*, 1997). The Geriatric Depression Scale (GDS) may be one of the easiest to administer (Yesavage *et al.*, 1982–1983). However, the GDS does not maintain its validity for patients with dementia and the Cornell scale (a 19-item clinician-administered instrument) is recommended (Burke *et al.*, 1989; Alexopoulos *et al.*, 1988). Symptomatic refers to any complaint given by the patient or caregiver or any problem observed/elicited by the clinician.

SCREENING FOR GAIT AND BALANCE

The evidence to screen for gait and balance problems at initial visits in all categories except at End of Life is based on the fact that falls are associated with decreased function, increased nursing home admission, and increased morbidity and mortality in populations similar to patients in these categories (Robbins *et al.*, 1989). One of the best "screeners" for gait and balance problems is to ask patients if they have fallen (Tinetti *et al.*, 1986). The "Get Up and Go Test" may quantify functional mobility as well as testing balance, and may also be useful in following clinical change over time (Mathias *et al.*, 1986; Podsiadlo and Richardson, 1991).

ADVANCED DIRECTIVES

Although the evidence is not strong that advance directives make a difference in outcomes (e.g. one study showed that systematic implementation of a program to increase use of advance directives reduced health-care services utilization without affecting satisfaction or mortality) (Molloy *et al.*, 2000), there are ways to increase discussions and completions of advanced directives (Dexter *et al.*, 1998; Rubin *et al.*, 1994). Advanced directives are especially important for patients in the Frail, Moderately Demented, and End of Life categories.

INFLUENZA VACCINE

This should be done yearly for patients in all categories. More than 90% of the deaths attributed to pneumonia and influenza during epidemics occurred among persons aged 65 and older. Influenza vaccination in the elderly has been shown to reduce hospitalization rates, to be cost-effective, and to reduce influenza-associated mortality (Fedson *et al.*, 1993; Foster *et al.*, 1992; Barker and Mullooly, 1980). In the nursing home, while vaccination is only 40% effective in preventing clinical illness, it is more effective in preventing

pneumonia, hospitalization, and death. Vaccinating more than 80% of nursing home residents has been shown to prevent influenza outbreaks (Saah *et al.*, 1986; Gross *et al.*, 1988).

PNEUMOCOCCAL VACCINE

The recommendations about pneumococcal vaccine are based on some evidence and on the probable life expectancy in various categories. Although pneumococcal vaccination increases antibody levels in older adults to a lesser degree than younger adults, and levels decrease more rapidly in the elderly, vaccination has been shown to be effective in reducing the incidence of pneumococcal bactremia in older, high-risk patients who have good antibody response to the vaccine.

Most organizations recommend that one dose of the 23-valent pneumococcal vaccine be given for all adults over age 65. Older patients who received the earlier 14-valent vaccine should be revaccinated with the 23-valent vaccine if they fall into any of those two groups. If patients have had the 23-valent vaccination before age 65, the recommendations for revaccination are controversial (United States Preventive Services Task Force, 1996; American College of Physicians, 1994). The ACP reports that there is currently insufficient data on repeated revaccination every 6 years in healthy elderly, and most other organizations do not provide specific recommendations for revaccination. However, since older patients with chronic diseases may occasionally be "Robust" for other reasons, clinicians should "*consider* repeating" every 6 years (American College of Physicians, 1994).

TETANUS

Recommendations regarding adult tetanus/diphtheria vaccination do not vary for older persons from recommendations for younger adults. Over half of the cases of tetanus occur in persons 60 years or older. All adults should complete a primary series of tetanus/diphtheria toxoid (Td). If an individual had an incomplete series or an uncertain history, it is recommended that the entire primary series be given. Primary series for adults consists of 0.5 cc of Td intramuscularly as the initial dose and at 2 and 6 months later. Booster doses need to be given every 10 years (United States Preventive Services Task Force, 1996; American College of Physicians, 1994).

BREAST CANCER SCREENING

There is no evidence for or against clinician's recommending self-examination, or the clinician doing the clinical breast exam. Given the low cost and low risk (but not zero risk, e.g. a patient with dementia who may misperceive the exam), this should be done on a yearly basis for patients in all categories except for those in the End of Life category.

Levels of recommendation differ for the different categories. This is because of lack of agreement among organizations regarding screening with mammography. For example, the ACP recommends screening up to age 75 (Eddy, 1989). The American Geriatric Society (AGS) recommends that physicians strongly consider recommending annual or at least biennial mammography until age 75 and biennially or at least every 3 years thereafter with no upper age limit for women with an estimated life expectancy of 4 or more years (American Geriatrics Society Clinical Practice Committee, 2000). The USPSTF recommends screening up to age 69, every 1–2 years, mammography alone, or combination of mammography and clinical breast exam. The USPSTF also notes that evidence is lacking to recommend for or against screening women 70 years or older, but doing this for high-risk patients may be made on other grounds (United States Preventive Services Task Force, 1996).

CERVICAL CANCER SCREENING

The low levels of recommendation for Robust (consider) and "Don't Do" for the other categories are based on lack of evidence and organizational recommendations. The ACP and the USPSTF recommend no further Papanicolaou smears for women over age 65 who have had previous regular screening with consistently normal results (United States Preventive Services Task Force, 1996; Eddy, 1990). The AGS position statement says that regular Pap smear screening at 1- to 3-year intervals until at least the age of 70 seems reasonable. Beyond age 70, there is little evidence for or against screening women who have been regularly screened in previous years. An older woman of any age who has never had a Pap smear may be screened with at least two negative Pap smears 1 year apart (American Geriatrics Society, 2001).

COLON CANCER SCREENING

Since the clinician's choice of screening procedure for colon cancer depends on extrinsic factors (e.g. transportation, availability of a gastroenterologist, patient willingness to do one procedure over the other), clinicians can choose to follow recommendations for either fecal occult blood test or colonoscopy. Recommendations for either of these procedures are the lowest level for patients in most categories because they are based on organizational guidelines.

Both the ACP and the USPSTF recommend annual fecal occult blood testing or periodic flexible sigmoidoscopy, or both. The ACP recommends sigmoidoscopy, colonoscopy, or air-contrast barium enema every 10 years from the ages of 50 to 70 years (Annals of Internal Medicine, 1997). The USPSTF recommends sigmoidoscopy, but does not recommend an interval for screening. There is also no upper age limit (United States Preventive Services Task Force, 1996). The American Cancer Society recommends

either one of the following: total colon examination (air-contrast barium enema or colonoscopy) every 10 years or fecal occult blood tests annually and flexible sigmoidoscopy every 5 years. There is no upper age limit (Anonymous, 1999a; Anonymous, 1999b).

PROSTATE CANCER SCREENING

The level of recommendation for prostate cancer screening is to "Discuss the pros and cons" for patients in the Robust, Frail, and Moderately Demented categories, and "Don't Do" for End of Life. The evidence for screening is not strong enough to recommend this routinely (Ilic *et al.*, 2004). Furthermore, there is no agreement among organizations about this issue. For example, neither the ACP nor the USPSTF recommend prostate-specific antigen (PSA) as a screening test for prostate CA (United States Preventive Services Task Force, 1996). However, many urologic organizations tend to recommend it. Digital rectal examination (DRE) has not been demonstrated to be an effective screening test for prostate cancer. The American Cancer Society believes that health-care providers should offer patients the PSA blood test and the DRE yearly for patients over age 50, if they have at least a 10-year life expectancy (Smith *et al.*, 2000; Eyre, 1997). There is insufficient evidence regarding the use of transrectal ultrasonography to consider this a screening tool.

OSTEOPOROSIS

The recommendations to do screening at least once for patients in all categories except End of Life is based on studies that show inadequate rates of diagnosing and treatment. However, there is lack of evidence to show that mass screening of all elderly women and men will be cost-effective or improve outcomes related to osteoporosis (Kanis, 1994).

Bone densitometry studies are accurate screening tools to diagnose early osteoporosis before bone loss exceeds 3%. The dual-energy X-ray (DEXA) absorptiometry and the single-energy X-ray (SXA) absorptiometry provide safe, low-level radiation. These tools are approximately 94% accurate in diagnosing bone deterioration. Both the DEXA and SXA scans are painless and noninvasive procedures that predict patients who are at high risk for developing bone fractures (Yeap *et al.*, 1998; Kanis and Gluer, 2000).

CHOLESTEROL SCREENING

The reason for a low-level recommendation (i.e. consider) and a targeted approach (only for Robust and Frail with additional risk factors) is because the data for primary prevention in this area for many segments of the elderly population is lacking. Some organizational recommendations exist. For example, the USPSTF recommends screening healthy men and women up to age 65, and reports that there is insufficient evidence to recommend for or against routine screening for asymptomatic persons over age 65. The USPSTF also reports that clinicians should consider screening for persons aged 65 to 75 who have additional risk factors (US Preventive Services Task Force, 2001). The ACP recommends screening up to age 65, reports that there is insufficient evidence for or against screening for persons aged 65–75, and advises against screening after age 75 (Annals of Internal Medicine, 1996; Garber *et al.*, 1996). The most appropriate interval for screening is not known.

THYROID-STIMULATING HORMONE (TSH)

Screening all older adults is not currently recommended by the USPSTF, on the basis of lack of data, but notes that screening may be made on other grounds (United States Preventive Services Task Force, 1996). The ACP recommends thyroid function testing in persons aged 50 or over with symptoms suggestive of thyroid disease. The ACP also notes that screening can detect symptomatic but unsuspected thyroid dysfunction (Helfand and Redfern, 1998; Anonymous, 1998a). The yield is highest for women older than 50 years of age. In this group, 1 in 71 women screened could benefit from relief of symptoms. However, evidence of the efficacy of treatment for subclinical thyroid dysfunction is inconclusive. The American Thyroid Association recommends routine screening every 5 years after age 35, but notes that more frequent screening may be appropriate in individuals at higher risk of developing thyroid dysfunction (Ladenson *et al.*, 2000). Many geriatricians advocate screening high-risk population such as nursing home population, frail elderly, and patients with dementia (Mokshagundam and Barzel, 1993). The sensitive TSH assay is probably the screening test of choice.

FASTING BLOOD GLUCOSE

This recommendation is based on organizational recommendations only. Although the USPSTF recommends against routine screening in asymptomatic individuals, it notes that clinicians may decide to screen selected persons at high risk of diabetes on other grounds (United States Preventive Services Task Force, 1996). The American Diabetes Association has recommended fasting plasma glucose measurement every 3 years in adults with one or more of a long list of risk factors (http://www.diabetes.org/for-health-professionals-and-scientists/cpr.jsp, 2005).

SLEEP APNEA

Because of the low cost of screening (in the form of asking about symptoms of sleep apnea during the routine history and

physical or to use a screening questionnaire tool such as the Epworth Sleepiness Scale) (Johns, 1991) and the potential to miss this diagnosis among older patients, it is recommended for robust and frail elderly (Baumel *et al.*, 1997). However, there is no evidence to date that screening for sleep apnea is cost effective or will change outcomes related to this problem.

BRITISH HEALTH CHECKS

The British Health Check model has its origins in the many studies over the past 50 years that have consistently identified high levels of unreported and unrecognized physical, mental, social, and environmental problems among older people living in the community (Williamson *et al.*, 1964; Williams and Wallace, 1993). Thus, repeated annual assessments will detect on average about two new medical problems and one psychosocial problem per person per year (Stuck *et al.*, 2004). The findings have led to numerous randomized controlled trials of general practice-based case finding and intervention, with an emphasis on identifying people with functional loss and dependency, rather than detection of disease. Most of these trials have reported some positive results, for example, with benefits in reduced mortality, fewer nursing home admissions, fewer and briefer hospitalizations, improved functional health status and quality of life outcomes. However, the results have not all been consistent and recent systematic reviews have come to contradictory conclusions (van Haastregt *et al.*, 2000; Elkan *et al.*, 2001; Stuck *et al.*, 2002b). The most effective programs seem to involve an enthusiastic professional (general practitioner or nurse), repeated comprehensive assessment, with the same person responsible for identification of problems and arranging intervention and long-term follow-up.

In 1990, the new contract for general practitioners working in the UK National Health Service established an annual health check to be offered to all patients aged 75 years and over (Freer, 1990). Furthermore, this specified the broad areas that were to be addressed:

- A home visit, at least annually, to see the home environment and to find out whether carers and relatives are available;
- social assessment (lifestyle, relationships);
- mobility assessment (walking, sitting, use of aids);
- mental assessment;
- assessment of the senses (hearing and vision);
- assessment of continence;
- general functional assessment;
- review of medication.

Unfortunately, the policy did not give guidance on appropriate methods or levels of assessment and it was implemented haphazardly, though nearly half the patients who were screened had problems for which some action was taken (Brown *et al.*, 1997).

Table 2 The single assessment process: standardized domains of need (NSF)

User's perspective
- Problems and issues in the user's own words
- User's expectations and motivation

Clinical background
- History of medical problems
- History of falls
- Medication use

Disease prevention
- History of blood pressure monitoring
- Nutrition
- Vaccination history
- Drinking and smoking history
- Exercise pattern
- History of cervical and breast screening

Personal care and physical well-being
- Personal hygiene, including washing, bathing, toileting, and grooming
- Dressing

- Caring arrangements

Safety
- Abuse or neglect
- Other aspects of personal safety
- Public safety

Immediate environment and resources
- Care of the home
- Accommodation
- Finances
- Access to local facilities and services

Those general practitioners who were enthusiastic about the potential benefits of the over-75s checks provided comprehensive screening to all of their patients by invitation, often establishing special clinics and appointing specialist health visitors to help with detailed assessment and follow-up at home. Most general practitioners, however, delegated responsibility to practice nurses. Many adopted a 2-stage targeted approach, using a brief initial screening schedule administered to all the population, to identify the minority thought to justify more detailed assessment. The first stage often used a postal questionnaire, sometimes accompanying a birthday card, while other schemes used volunteers to collect information, or integrated the process into routine care. The latter approach was based on the fact that over 90% of over 75-year olds have contact with their general

practitioner during the year and the nonattenders are generally fit and well (Ebrahim *et al.*, 1984). At worst, this opportunistic method means that only 10% require to be specially contacted. A recent trial involving over 40 000 general practice patients compared the universal versus the targeted approach and subsequent management by a hospital-based geriatric team versus the general practitioner and showed few important differences after 3 years of follow-up (Fletcher *et al.*, 2004). However, the study once again confirmed the high frequency of unreported need amongst the elderly study participants.

The latest General Medical Services General Practice Contract does not include over 75 checks, but the National Service Framework (NSF) for Older People (Department of Health, 2001) envisages that the new Single Assessment Process will incorporate case finding. This aims to provide a more standardized assessment across health- and social-care services so that older people's needs are "assessed in the round" at first contact, using the two-stage targeted approach to explore a wide range of specified domains of need (Table 2). The NSF also aims to ensure that older people have fair access to programs of disease prevention and health promotion, including cancer screening, BP management, smoking cessation, influenza immunization, advice about lifestyle including nutrition and physical activity, and falls prevention.

While the targeting of the older over-75s population will maximize the yield of significant problems, some of these people will be identified too late for effective intervention. Certainly, benefit in terms of reduced mortality associated with preventive home visits in clinical trials appears to be restricted to the younger old. Health risk appraisal combined with reinforcement of recommendations has been suggested to be best suited to those aged 60–75 years, using a self-administered questionnaire to identify potentially modifiable risk factors for functional status decline (Stuck *et al.*, 2002a).

KEY POINTS

- This chapter presents two models of preventive geriatrics that deal with the challenge of heterogeneity seen among older persons, the dichotomy between the treatment of populations and the wishes of the individual, and the unclear areas or "gray zones" of preventive geriatrics?
- The first model is called the Health Maintenance Clinical Glidepath which is primarily for office-based practices, and addresses screening for geriatric-specific areas (e.g. cognition, gait and balance, etc.) as well as screening for common medical illnesses and diseases (e.g. certain cancers, heart disease, etc.).
- Instead of using strict chronological age to tell clinicians when to do certain preventive measures, the Clinical Glidepath helps guide clinicians in their decision making by utilizing four categories of health status based on life expectancy and functional status: Robust, Frail, Moderately Demented and End of Life. The Glidepath also allows for decisions to be made on a "graded" rather than an "all or nothing" basis by using four levels of recommendations: Do, Discuss, Consider, Don't Do.
- The second model discusses the background of the British Health Checks, which is community based, and focuses on comprehensive geriatric assessment for all people over 75 years of age.
- Although the original British Health Checks have historically been effective in identifying unreported and unrecognized physical, mental, social, and environmental problems among older people living in the community, the latest General Medical Services General Practice Contract does not include over 75 checks. The new Single Assessment Process under the National Service Framework for Older People (Department of Health, 2001) aims to provide a more standardized assessment across health and social-care services and access to programmes of disease prevention and health promotion.

Polypharmacy, is this Another Disease?

Oscar A. Cepeda *and* John E. Morley

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Geriatric patients are frequently prescribed multiple drugs in complex dosage schedules. In some instances, this is justified because of the presence of multiple chronic medical conditions, the proven efficacy of an increasing number of drugs for these conditions, and practice guidelines that recommend their use. In many instances, however, complex drug regimens are unnecessary; they are costly and predispose to noncompliance and adverse drug reactions. Many older patients are prescribed multiple medications, take over-the-counter drugs, and are then prescribed additional drugs to treat the side effects of medications they are already taking.

Although persons aged 65 and older comprise only about 12% of the US population, they consume one-third of all prescribed drugs and more than a half of over-the-counter medicines. Overall, more than 80% of all community-dwelling elders use prescription drugs, with the average older person using between 3 and 8 drugs (Morley, 2003).

The devastating consequences of medical errors have been clearly detailed in the book *To Err is Human* by the Institute of Medicine. Medical errors are not uncommon, leading to a number of deaths ranging between 44 000 to 98 000 at a cost to the United States of $17–29 billion a year. A Harvard study done in 51 New York hospitals involving 30 000 patients reported that 3.7% had a treatment adverse event and there was a doubling in the number of undesirable treatment effects in persons over 65 years of age. Most errors are preventable; errors of omission are as important as errors of commission (Morley, 2003).

In addition to concerns about the risks of excessive and inappropriate drug prescribing, there are also concerns about the consequences of underprescribing potentially beneficial drugs. With the increasing numbers of patients surviving to older ages and comprising such a large proportion of drug use, a clear understanding of the risks, benefits, and consequences of drug therapy in older patients is needed.

PHARMACOKINETICS

Pharmacokinetics (the study of the action of a drug in the body over time) changes with age. The physiologic changes that accompany aging alter the pharmacologic processes of absorption, distribution, metabolism, and elimination. The effects of these age-related changes are variable and difficult to predict. Some of these physiologic changes are related solely to aging, whereas others are most likely caused by the combined effect of age, disease, and the environment. Even though increasing age is often accompanied by reductions in the physiologic reserve of many organ systems, independent of the effects of disease, these changes are not uniform; substantial variability exists from individual to individual, which makes some older patients more vulnerable than others (Schmucker, 1985).

Of the four traditional components of pharmacokinetics – absorption, distribution, metabolism, and excretion – only the last three are meaningfully affected by age. In the absence of malabsorptive syndromes, traditional oral formulation of drugs are absorbed as well in old age as in youth, indeed the well-reported changes in gastric motility and blood flow to the gut with aging do not appear to alter the efficiency with which medications move (mainly by passive diffusion) from the gastrointestinal tract into the systemic circulation. More important changes occur from the concurrent administration of several medications at the same time. However, some drugs commonly used for older persons require food for optimum absorption, for example, megestrol acetate which is used to stimulate appetite and weight gain has minimal absorption without food (Table 1).

Unlike absorption, drug distribution is affected by age in clinically meaningful ways. Serum albumin, the major drug binding protein, declines in sick patients due to cytokine excess. Even in healthy patients where there is a small decline, this can substantially increase the amount of free drugs available for action. This effect is of particular relevance for highly protein-bound drugs, especially when they are used simultaneously and compete for

Table 1 Relevant changes in aging and pharmacology

Pharmacological parameter	Age-related changes	Clinical effect
Tissue sensitivity	Alterations in: Receptor number and affinity Nuclear responses Second messenger function	Patients are more sensitive or less sensitive to a given medication
Absorption	Decrease in: Splachnic blood flow Absorptive surface GI motility Increased gastric Ph	Minimal changes associated with aging
Distribution	Decrease in: Total body water Serum albumin Lean body mass Increased fat	Higher concentration of drugs Longer elimination half-life of lipid soluble drugs
Metabolism	Decreased liver blood flow and enzyme activity	Decreased biotransformation and first-pass metabolism
Excretion	Decreased renal perfusion, glomerular filtration rate and tubular secretion	Decreased renal elimination of drugs

GI, gastrointestinal.

protein-binding sites (Schmucker, 1985). In long-term-care residents, diphenylhydantoin toxicity with low serum levels can occur because the decrease in albumin. Thus, measuring a free dilantin level can be essential in these situations.

The relative increase in body fat and decrease in lean body mass alters drug distribution, such that fat-soluble drugs distribute more widely and water-soluble drugs less widely; this fact can potentially lead the health-care professional to the wrong decision due to misinterpretation of serum drug levels. Many assays measure the total amount of drug that is present in serum, both protein-bound and unbound (free). The unbound concentration is more clinically relevant than the total concentration because only unbound drug is pharmacologically active (Grandison and Boudinot, 2000). For a patient with hypoalbuminemia or another deficiency in binding protein, any given serum drug level reflects a greater concentration of unbound drug than the same level would signify in a patient with normal protein-binding capacity. A hypoalbuminemic patient with a normal total serum drug concentration may actually have an unbound drug concentration that is unacceptably high. By contrast, the same patient with a slightly lower than normal total serum concentration may have an unbound drug concentration that is in reasonable range (Grandison and Boudinot, 2000; Table 2).

In evaluating serum drug levels in the older patient, it is also important to recall that the therapeutic range routinely reported on such assays may not be an accurate guide to either efficacy or toxicity in the geriatric patient. Such ranges have typically been defined in nonelderly subjects and cannot take into account pharmacodynamic differences or idiosyncratic aspects of specific agents (Beyth and Shorr, 2002).

Table 2 Volume of distribution for commonly used medications

Decreased volume	Increased volume
Ethanol	Diazepam
Gentamicin	Oxazepam
Digoxin	Prazocin
Cimetidine	Acetaminophen
Phenytoin	Salicylates
Quinine	Tolbutamide
Theophyline	Chlordiazepoxide
Meperidine	Thiopental

Note: If the volume of distribution is higher, drug levels are higher.

The other important aspect is the drug distribution, which varies importantly with age; volume distribution is a virtual space in a given patient which a particular drug occupies. Age-related changes in body composition can prominently affect pharmacology by altering the volume of distribution (Vd); the elimination half-life of a drug varies with the ratio Vd:drug clearance. Thus, even if the same rate of clearance of a drug is unchanged with age, changes in Vd can affect a drug's half-life and duration of action.

Because the total body water and lean body mass decline with increasing age, drugs that distribute in this compartments, such as antibiotics, digoxin, lithium, and alcohol, may have a lower Vd and can, therefore, achieve higher concentrations from given amounts of drugs. On the other hand, drugs that distribute in body fat, such as many of the psychotropic agents, have a large Vd in the geriatric patients. The larger Vd will thus cause a prolongation of the half-life unless the clearance increases proportionately, which is unlikely to happen with age (Beyth and Shorr, 2002).

As a good example of the necessary precautions that needs to be implemented in elderly patients, warfarin is an excellent candidate because it has been used more often in older persons. Warfarin inhibits the 4 vitamin K–dependent coagulant proteins, factors II, VII, IX, X, and it is highly protein-bound (97–99%) which could be a problem in malnourished patients, metabolized in the liver and with a half-life of 42 hours, its onset of action is approximately 36–72 hours, with a peak effect within 5–7 days.

Warfarin has been proven to be effective in prophylactic or therapeutic anticoagulation, but the risk of major bleeding with increasing levels of (prothrombin time/International Normalized Ratio) PT/INR is a major concern; they are increased by the presence of comorbid conditions such as heart failure, liver or kidney failure, or cancer. Warfarin dose should be highly individualized and may have to be adjusted several times, based on laboratory test results depending on the target INR for the patient's condition; strict adherence to the prescribed dosage schedule is necessary and patients should be informed not to take or discontinue any other medications, except on the advice of a physician or pharmacist.

In elderly patients, initial doses of warfarin typically are lower, and INR monitoring should be performed more frequently, and because warfarin possesses numerous drug interactions, some of which increase the effects of warfarin

Table 3 Metabolism of some drugs by the hepatic cytochrome P450 system is altered by aging

	Cytochrome P450				
	CYP1A2	CYP2C9	CYP2C19	CYP2D6	CYP3A4
Substrates	Olanzapine Theophyline	Phenytoin Warfarin	Diazepam Omeprazole Phenytoin	Codeine Desipramine Haloperidol Metoprolol Paroxetine Risperidone	Alprazolam Nifedipine Terfenadine Triazolam Verapamil
Inducers	Omeprazole Smoking		Rifampin		Phenytoin St. John's Wort
Inhibitors	Cimetidine Ciprofloxacin		Amiodarone Fluconazole		Erythromycin

and others that decrease its effects, caution must be observed when any drug, herbal, nutritional supplement or dietary changes are made to existing regimen of a patient receiving warfarin.

METABOLISM AND DRUG CLEARANCE

The liver represents the major site of metabolism for many medications. Hepatic transformations of drugs are categorized into phase I (preparative) and phase II (synthetic) reactions. Phase I reactions include oxidations (hydroxylation, N-dealkylation, and sulfoxidation), reduction and hydrolyses. Phase II reactions involve conjugation of the drug molecule to glucoronides, sulfates, or acetates. There is evidence of decline in phase I reactions with increasing age, and that the decline is more prominent in men than in women. In contrast, the second phase of drug metabolism appears to be less affected by age. There is also evidence that the ability of environmental factors (most importantly smoking) to induce drug-metabolizing enzymes declines with age (Routledge and O'Mahony, 2003).

Significant age-related declines in liver size and in liver blood flow have been described; in terms of absolute hepatic blood flow, reductions of 25 to 47% reported in persons between the ages of 25 and 90. This decrease is clinically important because hepatic metabolism is the rate-limiting step that determines the clearance of most metabolized drugs. This effect is especially relevant for drugs that undergo rapid hepatic metabolism (e.g. propranolol). Also, drugs that undergo extensive first-pass metabolism are likely to reach higher blood levels if hepatic blood flow is decreased.

The cytochrome P450 (CYP) system located in the smooth endoplasmic reticulum of hepatocytes, is the main catalyzer of phase I reactions. Many isoforms of CYP exist; the most important being CYP 3A4, approximately 60% of CYP enzymes are found in the liver and the remainder are found in the intestine, kidney, and brain. Many commonly prescribed medications serve as substrates for these enzyme systems. Phase I metabolism often undergoes a substantial decrease in activity in elderly patients as a result of illness or drug interactions; drugs that are metabolized through phase I enzymatic activity will have prolonged half-lives, but there is no easy way to predict the effects of changes in phase I metabolism in an individual patient or to adjust maintenance doses of drugs that undergo this form of metabolism (Routledge and O'Mahony, 2003; Table 3).

In contrast, phase II hepatic metabolism involves the conjugation of drugs or their metabolites to organic substrates. The elimination of drugs that undergo phase II metabolism by conjugation is generally less altered with age. Thus, drugs that require only phase II metabolism for excretion do not have a prolonged half-life in older people (Beyth and Shorr, 2002).

ELIMINATION AND RENAL EXCRETION

Unlike those of metabolism, the effects of aging on renal functions are somewhat more predictable. The tendency for renal function to decline with increasing age can affect the pharmacokinetics of several drugs (and their active metabolites) that are eliminated predominantly by the kidney. Clearance of drugs from the body occurs more slowly, their half-lives are prolonged, and there is a tendency to accumulate to higher drug concentrations in the steady state (Table 4).

Although blood urea nitrogen (BUN) and serum levels may be useful (albeit crude) markers of renal function, it must be remembered that each is susceptible in its own way to perturbations that can occur with aging but have nothing to

Table 4 Medications with decreased renal excretion

Triamterene	Atenolol
Sotalol	Amantadine
Procainamide	Ampicillin
Ranitidine	Cimetidine
Pancuronium	Cephradine
Phenobarbital	Ceftriaxone
Penicillin	Digoxin
Lithium	Furosemide
Kanamycin	Doxycicline
Hydrchlorothiazide	Gentamicin

do with renal function itself. For example, the BUN reflects the concentration of urea in the blood. However, the origin of much of this urea is ingested protein, so that a malnourished older patient may not consume enough nitrogen to produce an appropriate rise in BUN, even in the face of renal impairment. Similarly, creatinine is produced by muscle, and if a patient has a markedly diminished muscle mass, whether because of chronic illness or any other cause, he or she may not produce enough creatinine to reflect a change in the ability of the kidney to excrete this substance. This, overreliance on normal appearing BUN and creatinine in older patients can severely underestimate the degree of renal impairment. Further decrement in renal function is common in the elderly because they frequently have chronic illnesses that affect the kidney such hypertension, diabetes mellitus, and atherosclerosis.

Early cross-sectional studies of renal function in aging suggested that there is a linear decrease in renal function between young adulthood and old age, amounting on average to a reduction in glomerular filtration rate by nearly a third. The average clearance declines by 50% from age 25 to 85, despite the serum concentration that in healthy adults remains unchanged. Because the serum levels tend to overestimate the actual clearance in older persons, the commonly cited formula devised by Cockcroft and Gault may be used to estimate clearance in older adults (Muhlberg and Platt, 1999). However, it should be recognized that this equation represents a poor approximation of renal function in the old-old.

$$\mathrm{CrCl} = \frac{(140\text{-age}) \times \text{weight (kg)}}{70 \times \text{serum Cr}}$$

(for women, multiply $\times 0.85$)

Altered renal clearance leads to two clinically relevant consequences: (1) the half-lives of renally excreted drugs are prolonged and (2) the serum levels are increased. For drugs with large therapeutic indexes (e.g. penicillin), this is of little clinical importance; however, for drugs with narrower therapeutic index (e.g. digoxin, cimetidine, aminoglycosides), side effects may occur in older patients if a dose reduction is not made. Thus, digoxin is the drug that most often causes side effects in the elderly, especially when doses exceed $0.125\,\mathrm{mg\,day^{-1}}$. To further define dose requirements, therapeutic drug monitoring is useful for doses of drugs with a low therapeutic index (Muhlberg and Platt, 1999).

A common goal of pharmacotherapy in older persons is to achieve and maintain a therapeutic steady-state serum concentration. The steady-state drug concentration is proportional to the medication dosing rate and is inversely proportional to drug clearance. This equality has a number of important ramifications for the prescriber. Although drug clearance is a biologically determined characteristic of each patient over which the prescriber has no control, dose and dosing interval are variables that can be modified. To prevent the excessive accumulation of a drug when its clearance is reduced, one can reduce the dose, increase the interval between doses or both, depending on the situation.

PHARMACODYNAMICS

A proportion of the drug or its active metabolite will eventually reach its site of action. Age-related changes at this point, that is, responsiveness to given drug concentrations (without regard to pharmacokinetic changes) are termed *pharmacodynamic changes*.

Pharmacodynamics has been less extensively studied in older patients than pharmacokinetics. Generalizability is not straightforward; the effect of age on drug sensitivity or the binding of drug to receptor sites varies with the drug studied and the response measured. These differences in sensitivity occur in the absence of marked reductions in the metabolism of the drug and its related compounds (Beyth and Shorr, 2002).

Older persons are often said to be more sensitive to the effects of drugs. For some drugs, this appears to be true; however, sensitivity to drug effects may decrease rather than increase with age. For example, older persons may be more sensitive to the sedative effects of given blood levels of benzodiazepines but less sensitive to the effect of drugs mediated by β-adrenergic receptors; thus, the sensitivity to drug effects may either increase or decrease with increasing age. Other possible explanations offered for these differences are alterations in second messenger function and cellular and nuclear responses.

In general, and because the response of older patients to any given medication is variable, medications should be used with caution to achieve the goal of minimizing risks. This problem could be minimized by knowing the pharmacology of the drugs prescribed, limiting the number of medications used, determining the dosage and preparation on the basis of the characteristics of each individual patient, with downward adjustment for known hepatic or renal illness, and by surveying for side effects (Table 5).

PHARMACOGENETICS

This novel area of research and development in the medical sciences has been defined as the identification of differences in drug effects that have a genetic basis, but also development of simple methods by which susceptible individuals can be recognized before the drug is administered.

Table 5 Examples of adverse drug reactions

Type of drug	Common adverse reaction
Aminoglycosides	Renal failure, hearing loss
Anticholinergics	Dry mouth, delirium, constipation
Narcotics	Constipation, sedation
Diuretics	Dehydration, hyponatremia, hypokalemia, Incontinence
Sedative-hypnotics	Excessive sedation, delirium, increased risk for falls
Antiarrhytmics	Diarrhea, urinary retention
Antipsychotics	Delirium, sedation, extrapyramidal movements

It has been said that the major concern of pharmacogenetics is related to using information about how the effect of variations in the genetic makeup could affect the clinical efficacy of drugs, the required dose of drugs, the choice of the correct agent and the risk for side effects to drugs (David, 2004).

The fundamental theory of pharmacogenetics states that genotype effects expression of genes resulting in a phenotype, and the expression of genes is modified by agents in the environment as well. Conversely, the expression of the gene may influence the efficacy of a drug by effecting its metabolism, availability at its site of action, and by how the drug binds to its target receptors and achieves a desired pharmacologic action. The rapid growth of pharmacogenetics has been helpful in terms of rapid identification and gene sequencing for drug targets, including receptors, transport proteins, ion channels, and enzymes that metabolize drugs (David, 2004).

Current available data on pharmacogenetic research has shown that it will be useful in the near future since the therapeutic-pharmacological approach in many chronic diseases is promising. For example, in chronic conditions or environmental exposures like nicotine addiction, the response of smokers to drugs for smoking cessation differ according to variations in genes encoding several receptors and enzymes. Genetic variation that affects the function and availability of proteins (dopaminergic DRD2-C32806T receptors, and the enzymes dopamine β-hydroxylase DBH-G1368A) could increase the efficacy of drugs for smoking cessation (David, 2004).

In the specific case of Alzheimer's disease, several mutations and polymorphisms, including apolipoprotein E4, have been associated with increased risk for Alzheimer's disease. Furthermore, clinical trials demonstrate that carriers of the APOE E3 allele respond better to cholinesterase inhibitors than those who lack the allele. There is also evidence that treatment response to noncholinergic drugs is affected by the APOE gene and that response to cholinesterase inhibitors is influenced by interactions with other genes involved in drug metabolism.

Another example of how pharmacogenetics is helpful is in the treatment of hyperlipidemia, where genetic variations at the APOE locus has been associated with fasting and postprandial plasma lipoprotein concentrations and with cardiovascular disease. The APOE E2 polymorphism is associated with an increased lipid-lowering response to statin therapy, whereas E4 polymorphism is associated with a decreased response to therapy. However, testing for this genetic variation is not yet part of routine clinical care.

In the near future, pharmacogenetics will give the chance to provide to our patients information about their probability of responding to treatment with a particular medication, given their genotype. Although the discipline is beginning to come of age, only some of pharmacogenetic applications are available currently in clinical settings, whereas many promise to enter the realm of clinical practice in the next few decades (David, 2004).

PRESCRIBING FOR GERIATRIC PATIENTS

The Beers Criteria, a Useful Consensus for Inappropriate Medication Use in the Elderly

The purpose of this initiative was to revise and update criteria for potentially inappropriate medication use in adults aged 65 and older in the United States. The reviewed criteria covered two types of statements: (1) medications that should be avoided in persons older than 65 years and (2) medications that should NOT be used in persons known to have specific medical conditions (Fick and Cooper, 2003).

The Beers criteria identifies 48 individual medications or classes of medications to avoid in older adults and their potential concerns and 20 diseases and conditions and medications to be avoided in older adults with these conditions. Adverse drug events have been linked to preventable problems in the elderly patients, such as depression, constipation, falls, immobility, confusion, and hip fractures.

The 1997 study on adverse drug reactions found that 35% of ambulatory older adults experienced an adverse drug event and 29% required health-care services; some nursing facility residents have one of these events over a 4-year period. In summary, these criteria have been extensively used for evaluating and intervening in medication use in older adults over the past decade. However, owing to the continuous arrival of new medications in the market, increased knowledge about older drugs and side effects from the new ones needs to be updated periodically in order to keep physicians updated on how to avoid undesirable medication side effects in the elderly population (Table 6; Fick and Cooper, 2003).

Clinical Strategies

The quality of life for the older patient can be greatly enhanced with the intelligent use of medications and keeping certain key points in mind. A major problem when facing elderly populations is the fact of prescribing multiple and occasionally unnecessary medications with increased risk of significant drug interactions; establishing a diagnosis is critical to avoid treating a symptom with *hit* or *miss* drugs versus treating a specific condition. Discussions about geriatric pharmacology are frequently centered around age-related changes in drug pharmacokinetics and pharmacodynamics; nonetheless, nonpharmacological factors can play an even greater role in the safety and effectiveness of drug therapy in the geriatric population.

Frequently, neither the patients nor the health-care provider have a clear picture of the total drug regimen. New patients undergoing initial geriatric assessment should be asked to empty their medicine cabinets and to bring all bottles to their first appointment. When asking the patient about their medication, it is important to be specific about prescription medications, over-the-counter products, as needed medications, vitamins, minerals herbal products and home remedies (Cassel and Leipzig, 2003).

Table 6 Inappropriate medication use in older adults: considering conditions and diagnoses

Disease	Drug	Comment
Heart failure	Disopyramide and high sodium content drugs (alginate, bicarbonate, phosphate)	Negative inotropic effect. Potential to promote fluid retention and exacerbation of heart failure
Hypertension	Phenylpropanolamine hydrochloride (removed on 2001), pseudoefedrine, diet pills, and amphetamines	May produce elevation of blood pressure secondary to sympathomimetic activity
Gastric or duodenal ulcers	NSAIDS and aspirin >325 mg per day	May exacerbate existing ulcers or produce new ones. (cox-2 excluded)
Seizures or epilepsy	Clozapine, chlorpromazine, thioridazine	May lower seizure thresholds
Blood clotting disorders, or on anticoagulant therapy	Aspirin, NSAIDS, dipiridamol, ticlopidine, clopidogrel	May prolong clotting time and elevate INR values or inhibit platelet aggregation resulting in increased potential for bleeding
Bladder outflow obstruction	Anticholinergics and antihistamines, GI antispasmodics, muscle relaxants, anticholinergics, antidepressants	May decrease urinary flow, leading to urinary retention
Stress incontinence	α-blockers, anticholinergics, tricyclic antidepressants, and long acting benzodiazepines	May produce polyuria and worsening of incontinence
Arrhythmias	Tricyclic antidepressants	Proarrhythmic effect and ability to produce QT interval syndrome
Insomnia	Decongestants, theophylline, methylphenidate, and amphetamines	Concern to CNS stimulant effects
Parkinson disease	Metoclopramide, conventional antipsychotics	Concern about anticholinergic/dopaminergic effect
Cognitive impairment	Barbiturates, anticholinergics, antispasmodic, muscle relaxants	Concern due to CNS altering-effects
Depression	Long-term benzodiazepine use, sympatholitic agents (methyldopa, reserpine)	May exacerbate depression
Anorexia and malnutrition	CNS stimulants, fluoxetine, methylphenidate	Concern due to appetite suppressing effects
Syncope/falls	Short to intermediate acting benzodiazepines, tricyclic antidepressants	May induce ataxia, impaired psychomotor activity
SIADH/hyponatremia	Fluoxetine, citalopram, fluvoxamine, paroxetine, sertraline	May cause SIADH
Obesity	Olanzapine	May stimulate appetite
COPD	Long acting benzodiazepines, propranolol	May induce respiratory depression
Chronic constipation	Tricyclic antidepressants, anticholinergics, calcium channel blockers	May exacerbate constipation

Source: From Archives of Internal Medicine **163**(22); Dec 2003, pg 2716–24.
NSAIDS, nonsteroidal anti-inflammatory drugs; CNS, central nervous system; SIADH, syndrome of inappropriate ADH secretion; COPD, chronic obstructive pulmonary disease.

Compliance

Compliance is a major problem in all persons, and particularly so in many older persons. Cognitive impairment, depression, decreased hearing, and poor vision can all lead to failure to take a drug or for the drug to be taken inappropriately. Instructions on how to take drugs need to be written in large letters with legible handwriting. The healthcare professional needs to check that the patient understands the instructions. Pill boxes need to be set up for older persons having problems remembering to take their medicines.

When choosing the dose of a medication for an older patient, always remember to *start slow, go slow, and do not stop too soon.* Initially, doses should be modified on the basis of pharmacokinetic predictions, but actual pharmacodynamic responses to the medication should be used to adjust the dose. If the pharmacokinetic information is not available, doses can be initiated at one half the usual dose of adult dose; this can be achieved by splitting tablets or by extending the dosing interval. Minimizing the number of doses per day is easier for the patient and can improve compliance. The use of sustained release dosage forms or taking advantage of prolonged elimination half-lives in older persons can decrease the number of doses per day (Table 7).

Cost is key factor in compliance. Drug costs need to be noted at the time of prescribing. Patients need to be asked if they can afford the drug. It is useful to remember that cheap drugs (e.g. thiazides, β-blockers and reserpine) often perform approximately as well as more expensive drugs. Most pharmaceutical companies have programs to help persons obtain drugs they cannot afford.

There is an increasing recognition that failure to appropriately treat an older person may be as bad as over treating. For example, failure to use β-blockers following myocardial infarction would be a clear error of omission. Most older persons in nursing homes have osteopenia or

Table 7 General recommendations for geriatric prescribing

Source: Reproduced from Fick D *et al.*, 2003. Copyright American Medical Association.

osteoporosis, yet they do not receive calcium with vitamin D, and neither biphosphonates. Many older persons have anemia and chronic renal failure; despite evidence that treatment with erythropoietin or darbopoeitin α improves outcomes including quality of life, they are rarely prescribed. But, the other side of the coin is overtreatment of conditions, for example, there is no evidence for treating blood pressure below 160/90 mmHg in older persons and even less for primary prevention of heart disease by lowering cholesterol in octogenarians (Morley, 2003).

There are many factors that contribute to the underuse of beneficial therapies in the geriatric patient population. Physicians may fail to prescribe potentially beneficial medications to elderly patients owing to the scarcity of data on which to base pharmacotherapeutic decisions or for fear of causing adverse drug events in patients who are already using multiple medications. While some may consider this practice to represent therapeutic nihilism, others may consider this to be prudent prescribing. A fair and balanced assessment of the issue of undertreatment of elderly patients must give consideration to three important areas: (1) the lack of high-quality evidence derived from clinical studies with relevance to treating the older patient with multiple chronic medical conditions; (2) the need for systems of care that improve drug safety and enhance adherence in elderly persons on complex medication regimens; and (3) the persistence of financial barriers to access to medications (Morley, 2003; Cassel and Leipzig, 2003).

The Division of Geriatrics at Saint Louis University has developed many different resources to teach physicians and patients as well in the field of geriatric medicine. The developing of mnemonics, that is the mnemonic developed toward avoiding polypharmacy, has been very successful.

GUIDELINES FOR PROPER MEDICATION PRESCRIBING AND MEDICATION REDUCTION

Alternatives
Vague history or symptoms
OTC (over-the-counter) medications have side effects too
Interactions (drug–drug, drug–disease)
Duration
Therapeutic vs Preventive
Once a day versus twice or four times a day
Other doctors
Money
Adverse effects of other drugs
Need
Yes/No (Is the person actually taking the medication?)

The use of large numbers of medications will always be a key factor of the medical–scientific care of the growing older population around the world. However, there is always a gray area where there is concern about avoiding the excessive use of drugs and providing access to therapeutic guidelines that might have beneficial effects on morbidity and mortality, function and quality of life. The health system should address this issue focusing on including more elderly people in clinical trials, especially patients with multiple comorbidities. The implementation of efforts toward the development of interdisciplinary teams to care for elderly patients and the use of information technology to improve medication adherence and safety should be encouraged.

KEY POINTS

- Older persons take more medications than their younger counterparts.
- The older body does not accommodate drugs in the same manner as the younger body does.
- There is no such thing as an absolutely safe drug.
- Elderly patients are more likely to experience undesirable side effects from drugs than are younger persons.
- Always “start slow, and go up slow”.

The Problem-Orientated Approach to Geriatric Medicine

Cameron G. Swift
King's College London, London, UK

INTRODUCTION

The transitional decades leading into the twenty-first century have seen a period of major organizational change in health-care systems, with a major focus on economic concerns. The health-care needs of aging populations have been economically, if not scientifically, prominent within this process. The compulsion to justify patterns of clinical practice with hard evidence has grown, while this in turn has led to the more widespread development and application of sets of clinical management guidelines and the need for more consistent documentation in clinical practice.

To some extent, the professions concerned with the care of older people have welcomed the impetus to record and quantify their activity in this way, thus to achieve greater consistency, to promote greater recognition of the skilled processes involved (and of the corresponding standards), and to make the case for more appropriate resource provision in the field for services, training, and research. On the other hand, much organizational change (including the growth of documentation) has to some extent generated bureaucracy and impaired flexibility of interaction among the professions and agencies involved. The need, therefore, not only to sustain the best qualities of clinical practice enshrined within geriatric medicine but also to grasp the opportunities presented by a changing organizational climate to categorize and promote those standards is clear.

There has, as a result, been some progress in the development of methodologies to measure activity, but with a distinct slant toward what is required either for cost prediction or cost containment, for the management of defined diagnostic categories, or for modeling the activity of single professions. Examples have included the system concepts of diagnosis-related groups (Goldfarb *et al.*, 1983; Wood and Estes, 1990; Price, 1994), managed care (Wan, 1989; Curtiss 1989) and critical care pathways (Falconer *et al.*, 1993; Bowen and Yaste, 1994; Tallis and Balla, 1995; Anders *et al.*, 1997) – most commonly for application to defined disorders or clinical situations. There is still a need for better methods of scrutinizing the quality and effectiveness of overall service provision for older people–the largest and most rapidly expanding segment of population health-care need.

Categorization is not, however, synonymous with the achievement of standards, although it is a useful instrument in the right hands for service delivery, training, and research. This chapter, therefore, discusses some key principles of problem-orientated decision making in the care of older people (which have not themselves fundamentally altered over this period) rather than pursuing a primary emphasis on measurement methodology, although some measurement tools will be referred to. This somewhat didactic emphasis reflects not only a concern to focus on consensus standards but also the relative paucity of focused evaluative work in this area specific to the health needs of older people. There is a pressing need for comparative trials of delivery models using such standards as end-points, not least because every available indicator suggests that the cost-effectiveness of health services for older people is directly proportional to the expertize and quality of specialist practice achieved.

RATIONALE: PROBLEM ORIENTATION – WHY AND WHAT?

The concept of problem orientation as a practical approach to clinical decision making was elaborated by Lawrence Weed in his system of problem-orientated medical records (POMR) (Weed, 1969). Targeted particularly at clinicians, it was in some respects a precursor of the current fashion

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

for "protocols". The motivating principle was a recognition that the traditional "ideal medical model" (syndrome → pathological basis → etiology → treatment → resolution) is in the real world a gross oversimplification of the decision-making process, based as it is on a single train of thought arising from a single encounter with the patient. In real life clinical practice, the clinician is often faced with several related and/or unrelated problems simultaneously, while the patient is faced with several encounters over a period of time with several clinicians (across a range of professions) before some or all of these problems are properly resolved. There is, therefore, a need for accurate and cohesive documentation. This is to provide a reliable and consistent framework of information on which to base decisions and also to achieve a measure of continuity across periods of time, as well as among different clinicians and departments.

The key components of the original Weed system are:

1. an accurate list of presenting problems;
2. a "defined database" (full coverage of agreed categories, e.g. in case history taking or examination);
3. statements of plans of investigation and/or management related to each presenting problem;
4. progress notes comprising a systematic assessment of progress and a statement of further plans in relation to each problem (McIntyre, 1979).

Historically, the fully developed system of POMR did not find its way into the routine practice of most clinicians, nor into all teaching programs. Opponents claimed that the database was too diffuse, that the "catalog" of problems inhibited diagnostic reasoning, or that the day-to-day implementation of POMR was too unwieldy and heavily structured to be routinely workable (Feinstein, 1973). The advocates maintained that comprehensive patient care, interdisciplinary professional working, and clinical audit were fundamentally advanced by POMR (McIntyre, 1979). It is certainly the case that the system properly implemented is more than a style of medical record keeping and is, in fact, a structured approach to clinical decision making, based on a standardized system of documentation. Information technology advances present enhanced opportunities for using such methods more effectively, both in clinical practice and medical education (Weed, 1996).

The concept of problem orientation still strikes a chord, therefore, with experienced geriatricians, many of whom consider it to be a cornerstone of effective modern clinical practice in the field. The main reasons for this are:

1. *The historical failure of the "Ideal Medical Model" to meet the needs of older people*

The key to resolving any problem lies in its correct initial identification. The agenda presented to the earliest geriatricians was characterized as a *process problem* affecting the health-care system, namely overcrowding in poor law institutions, "blockage" of beds in "acute" hospitals, and waiting lists and delays affecting dependent elderly people in the community. The "geriatric problem" was seen as that of health-care providers facing a seemingly inexorable tide of chronically infirm elderly people, and, as a result, that of angry and frustrated clinical colleagues hampered (as they saw it) in practising "proper" medicine in hospitals and in teaching it to their junior staff and medical students. Thus, the issue was perceived as one of accommodation, not at all as one of diagnosis and intervention.

What in fact took place was a shift in focus and orientation, recognizing the agenda in terms of the *health-care problems of older people themselves*, an emphasis that the clinicians of the day had omitted to address. Skill in diagnosis was combined with systematic identification of the functional and social consequences of ill health and a plan of management agreed in conjunction with an organized team of allied professionals. The success of this changed emphasis is now legendary (Brocklehurst, 1992) and has been replicated and refined many times over, particularly when brought into the arena of early acute intervention.

2. *The complex nature of health-care needs in late life*

- Exacerbation, relapse, recovery: The proportion of medical conditions alleviated rather than eradicated increases with advancing age. Successive clinical encounters thus tend to become the rule.
- Cumulative pathology: Case record folders, best measured in kilograms rather than pages, commonly testify to the numerous departments previously involved in the care of a majority of older patients.
- Masked and/or late presentation of disorders.
- Multidimensional impact: The management of pathology alone is insufficient to achieve a satisfactory outcome in most circumstances. Hence, the scope of the "database" has to encompass the problem of functional autonomy and social relationships arising not only from disease, but from aging itself.
- Multiagency/multiprofessional involvement: Access to reliable information is required by all.
- Orchestration/coordination of multiple assessments and therapeutic objectives.

Problem orientation is thus, to some extent, built into the heart of geriatric medicine. Weed (1969) emphasized the importance of dividing problems into medical and social. For the geriatrician, the overriding objectives of autonomy and self-determination for older people add an additional dimension, that of "function". The definition of a problem thus includes any observation or finding that poses a threat to the health or autonomy of an older individual. The approach does not, of course, supplant the search for unitary diagnosis. It does, however, recognize parallel priorities that may sometimes take precedence.

APPLICATION: PROBLEM IDENTIFICATION AND MEASUREMENT

Assessment as Problem Orientation

The approach to comprehensive patient care adopted within geriatric medicine is commonly given the label "assessment."

(The particular area of functional assessment is elaborated in greater detail in **Chapter 131, Multidimensional Geriatric Assessment**; **Chapter 132, Function Assessment Scales**). Assessment is in essence the preparation of a problem list in the following categories:

1. Problems of medical, surgical, and psychiatric diagnosis.
2. Problems of autonomous function or competence.
3. Problems of relationships.
4. Problems of living conditions and environment.

Successful assessment should be factual, prompt, efficient, and dynamic (i.e. subject to regular review as a health problem pursues its clinical course, or as new information becomes available). Its components should take place simultaneously, and from the moment of presentation. Assessment as an afterthought to acute medicine is far too late. In the context of emergency hospital admission, the process may well be initiated by ambulance personnel.

Preparation of the "database" will incorporate a thorough scrutiny of previous case records and a highly systematic review of a patient's functional and social background. The latter may entail the acquisition of information from many sources, more closely resembling a piece of journalistic research than a consultation. Weed (1969) advocated the inclusion of a "personal patient profile" in the database. This is desirable in all branches of medicine, but is mandatory in geriatric medicine. The whole process is likely to take considerable professional time and effort; thus, any sense of day-to-day inertia in a unit caring for older people indicates that the work is not being covered.

All clinical professionals, especially physicians, need to adopt this comprehensive, multidimensional approach in a systematic way. In order to achieve this, it is highly probable that an acceptable structured form of documentation will be required.

Problem Identification and the Multidisciplinary Team

The composition of a more or less typical multidisciplinary team is indicated in Figure 1. This core team composition has so far stood the test of time as reflecting the blend of competence required to provide information, expertize, and advice in the four problem domains itemized earlier. It is sufficiently small to achieve consensus and make efficient decisions, but depends on *ad hoc* contributions from many other professionals, including dietitians, clinical pharmacists, home-help organizers, prosthetists, transport and portering staff, housing and environmental officers, residential home and sheltered housing supervisors, as well as from various informal supporters and voluntary organizations. Within the team, each professional retains his or her traditional competence, but there is sometimes modification of that function, and invariably heightened awareness of the competence of others arising from cross-fertilization and the team context. The multidisciplinary team is the mandatory core unit central to both problem identification and to decision making and to efficient therapeutic management. (The respective roles of some of its constituent members are considered briefly in the following).

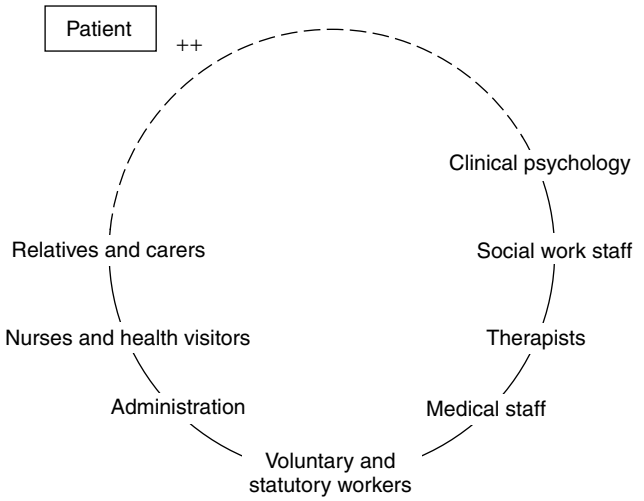

Figure 1 The multidisciplinary network

Objectives and Pitfalls

Problem identification with no prospect of constructive intervention is an academic and largely pointless exercise. Conversely, efficient "management by objective" distinguishes a *problem* from a mere *observation* by the existence of at least some possibility of resolution. Successful problem orientation recognizes and avoids the following well recognized pitfalls, which are more or less common themes across the professions:

Diagnostic overindulgence: Consultant physicians rely heavily on their junior staff to sharpen both their knowledge base and their diagnostic acumen: they have, however, a time-honored duty to protect patients (particularly older ones) from the overzealous pursuit of diagnosis with no prospect of therapeutic benefit. Similarly, for therapists, preoccupation with the use of a "perfect" functional assessment tool to quantify an impairment, the clinical or potential therapeutic relevance of which is dubious, should be avoided.

Therapeutic overindulgence: This is the targeting of some isolated "ideal" therapeutic objective for an individual at the expense of the broad aim of that individual's overall recovery of autonomy. Examples might include total abolition of extrasystoles on a 24-hour ECG, or the relentless pursuit of impeccable gait symmetry before hospital discharge after stroke.

Collective introspection: There is considerable scope in an interdisciplinary context for lengthy in-depth case analyses of individual patients, consisting of a sequential series of explanations from every conceivable discipline as to why

no help can be offered with the particular problem. "Case conferences" in this mold have more to do with professional self-interest than patient well-being and should not be held.

Bureaucracy and delay: The notion that ill older people are less "acute" and that waiting lists for services are "acceptable" has compromised the effectiveness of clinical and social services for decades. A night sitter in 3 months' time is of no use to a caring spouse facing a crisis of sleep deprivation. A waiting list of 8 weeks for the installation of stair rails may do untold damage to the resettlement program of a stroke sufferer. Thus, the 2001 England National Service Framework for Older People correctly set standards for prompt and integrated community equipment supply (Department of Health, 2001a). Successful problem-orientated assessment promotes anticipation, planning, interaction, and flexibility of response among professionals and agencies. Timing may be critical, both to the individual and to the service, and its mastery is a hallmark of effectiveness in the care of older people. A central agenda item for multidisciplinary teams is therefore the agreement of a finite and preferably rapid timetable for the individual care plan.

Inappropriate expectations: Consumer choice in medical care is a topical political issue. It is also a proper objective for physicians, but there is a compelling obligation to identify the choices correctly. A clinician may, for example, have a hard battle to persuade an older person or her relatives that recovery of autonomous function and a return to community living are among the options! Conversely, it may be necessary to dispel unrealistic expectations of miracle recovery, wonder drugs, or costly biotechnology. The clinician's advisory role may be the less popular one of offering limited (but important) improvement through persistence with clear, if modest, objectives. A frequent further element is an appropriate culture of risk taking, without which no rehabilitative program can proceed.

CONTENT: PROBLEM CATEGORIES

The modifying effect of age on the presentation of many specific disorders is covered elsewhere in this volume. In addition, the medical, functional, and social aspects of the health of older people are in a continuous state of dynamic balance and interaction. A problem in any one category seldom exists in isolation without impact on one or both of the other two. Presentation may be functional when the root cause is medical; for example, reduced mobility or falls may result from infection or adverse drug reactions. Conversely, stasis leg ulceration or venous thromboembolism may be caused by impaired function (loss of mobility). Poor housing may be responsible for osteomalacia or hypothermia, while problems of continence or pressure sores may be the culmination of intolerable stress on a caring relative. Exclusion of any one dimension of concern from the assessment is therefore to invite failure.

Medical Problems

Geriatric medicine is rightly concerned with a whole range of clinical situations, including acute life-threatening illness, acute exacerbations of chronic disease, subacute, or chronic health problems, disabling disorders of high prevalence among older people, the assessment and management of special clinical problems (e.g. the "geriatric giants" of cognitive impairment, immobility, and incontinence) and the preventative medicine of old age. Both the importance and the difficulty of careful and accurate diagnosis are well recognized.

Principles of diagnosis: The opposing extremes of academic interest and diagnostic apathy, therapeutic overoptimism and therapeutic nihilism, are unacceptable pitfalls in clinical practice from which older people have suffered extensively. Thorough investigation may be justified on the grounds of (1) therapeutic potential, (2) practical management, and (3) (under certain circumstances) prognosis. In considering any investigation, particularly if at all invasive, the question "how will the results influence management"? is always legitimate, but interpreting the answer for an older patient increasingly requires careful review of recent advances and should invariably be a flexible and sensitive exercise.

Therapeutic potential: It is now clear for many interventions, both medical and surgical, that conservatism based on chronological age alone has no foundation in scientific evidence. Large-scale clinical trials have shown for a whole range that results and cost-effectiveness are at least as satisfactory in older as in younger patients. Examples include:

- effective control of hypertension (SHEP Cooperative Research Group, 1991; Amery *et al.*, 1986; Lever and Brennan, 1993; Dahlof *et al.*, 1993; Julius *et al.*, 2004),
- antithrombotic agents in atrial fibrillation (Ezekowitz *et al.*, 1993; Stroke Prevention in Atrial Fibrillation Study, 1991; Connolly *et al.*, 1991),
- thrombolytic agents and aspirin in myocardial infarction (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico, 1990; ISIS-2 (Second International Study of Infarct Survival) Collaborative Group, 1988; ISIS-3 (Third International Study of Infarct Survival) Collaborative Group, 1992; The GUSTO Angiographic Investigators, 1993),
- angiotensin converting enzyme inhibitors and angiotensin-2 antagonists in left ventricular dysfunction and after myocardial infarction (ISIS-4 (Fourth International Study of Infarct Survival) Collaborative Group, 1995; Granger *et al.*, 2003; Pfeffer *et al.*, 2003),
- lipid lowering agents in cardiovascular risk (Shepherd *et al.*, 2002),
- bone antiresorptive agents and calcium and Vitamin D in fracture prevention (Chapuy *et al.*, 1994; Larson *et al.*, 2004).

Persuading surgical colleagues of therapeutic potential from surgery in older people is now far less often a problem

than formerly, as a result of advances in anesthetic and surgical techniques and of rapidly expanding experience of surgery in the age-group. An excellent example is carotid endarterectomy after stroke (Alamowitch *et al.*, 2001; Aune *et al.*, 2003).

Logistics: In view of the above, there can be no justification for the organization of services in such a way as to exclude older people from sophisticated diagnostic and treatment facilities, or to undertake their care in less technically well supported environments (Working Party of the Royal College of Physicians, 1994). Equally, the role in interdisciplinary practice of physicians trained in the care of older people is clear. The difficulties of prompt diagnosis are well recognized. Symptomatology is notoriously unreliable. The "presenting complaint" frequently bears no relation to the real problem. Occult disease and presentation as stereotypes of aging pose a constant challenge. Physical signs may be modified, unreliable, or absent. As suggested earlier, any unexplained change in function in an older person should prompt the search for a medical diagnosis.

The place of structured models of clinical decision making in medicine is yet to be established and would require specific evaluation for older patients. The relative merits of different processes of diagnostic logic have been considered (McCartney, 1987). Problem orientation has been criticized as having some affinity with the "blunderbuss" approach (uncritical listing of clinical observations and ordering of every conceivable test). This criticism arises mainly from a perception of the database as a cataloguing process to prevent missing any abnormalities. This is unfair to the original concept. It also assumes that the database is totally prescribed rather than flexibly determined for different categories of patient. There is no evidence that problem orientation has a negative effect on diagnosis in the elderly. Other approaches (e.g. the hypothetico-deductive model, algorithmic diagnosis, and league-table diagnosis or its mathematical equivalent, Bayesian probability analysis) (McCartney, 1987) are all potentially compatible with a problem-orientated approach.

The traditional systematic enquiry taught to medical students may be a sterile exercise in real life diagnosis (Hoffbrand, 1989), especially with older patients, for whom its verbal content requires considerable adaptation. Conversely, with the comparative rarity of single problems, the clinician will probably always need to explore a fairly large problem space both in history taking and physical examination to be sure of picking up the important points (Harrington, 1989). Common omissions from the medical assessment include failure to elicit abnormalities of mental status and their timescale, impairment of the special senses, scrutiny of drug therapy, dietary intake and alcohol consumption, examination of the locomotor system (especially the hip joints) and gait, problems of continence and their timescale, and detailed examination of the feet and hands. Important components of functional and social status (see following text) are also commonly overlooked.

Practical approaches to the application of these principles within geriatric medicine are discussed in other chapters in this text and elsewhere. The justification for a structured medical record as an absolute minimum seems incontestable.

Functional Problems

A detailed interest in levels and components of function is a strong distinguishing feature of modern geriatric medicine. It is unusual for health problems to have no short- or longer-term impact on an older person's range of activity. Measurement tools for the assessment of function are discussed in **Chapter 132, Function Assessment Scales** and the more difficult issues of their relative merits will not be considered here. There are considerable differences of opinion as to how broad functional status should be measured and documented and how change should be quantified. Largely because of this difficulty, the tendency both in service delivery and in health services research has been to opt for an increasingly widely accepted core set of "lowest common denominator" scales for the measurement of change, such as the Barthel Index, the Instrumental Activities of Daily Living scale or (in psychiatry) the Clifton Assessment Procedure for the Elderly (Pattie and Gilleard, 1975). Such tools are clearly not intended for more specialized measurement of impairments, or very specific disabilities, for which they lack sensitivity. Instead, they cover a key range of abilities, including, for example, the special senses and continence and/or their consequences for an individual's range of activities.

In principle, there are analogies in this field with the medical model; overemphasis on "diagnostic" categorization should not stand in the way of pragmatic problem-orientated assessment, but those measures that are required should be applied alongside it. The technical skills within the multidisciplinary team for specialized functional assessments reside predominantly with physiotherapists, occupational therapists, speech and language therapists, and clinical psychologists, but other team members, including medical and nursing staff, require a level of competence in the assessment and recognition of functional problems, for which the capacity to use a minimum set of more globally applicable instruments is necessary.

An example of a shorthand form of operational documentation for multidisciplinary decision making is shown in Figure 2, the essence of which is its problem-orientated emphasis. The domains covered are in common with a most general functional assessment scales, but each category of function is graded on a five point scale, the components of which attempt to quantify problems in terms of requirement for assistance or supervision from a third party, that is, "to what extent is the dysfunction an active problem requiring outside intervention?" Thus, if an individual is able independently to travel from point A to point B using a wheelchair, then "ambulatory function" is classed as unimpaired. Similarly, if he or she has an indwelling catheter, which is independently managed without difficulty and with

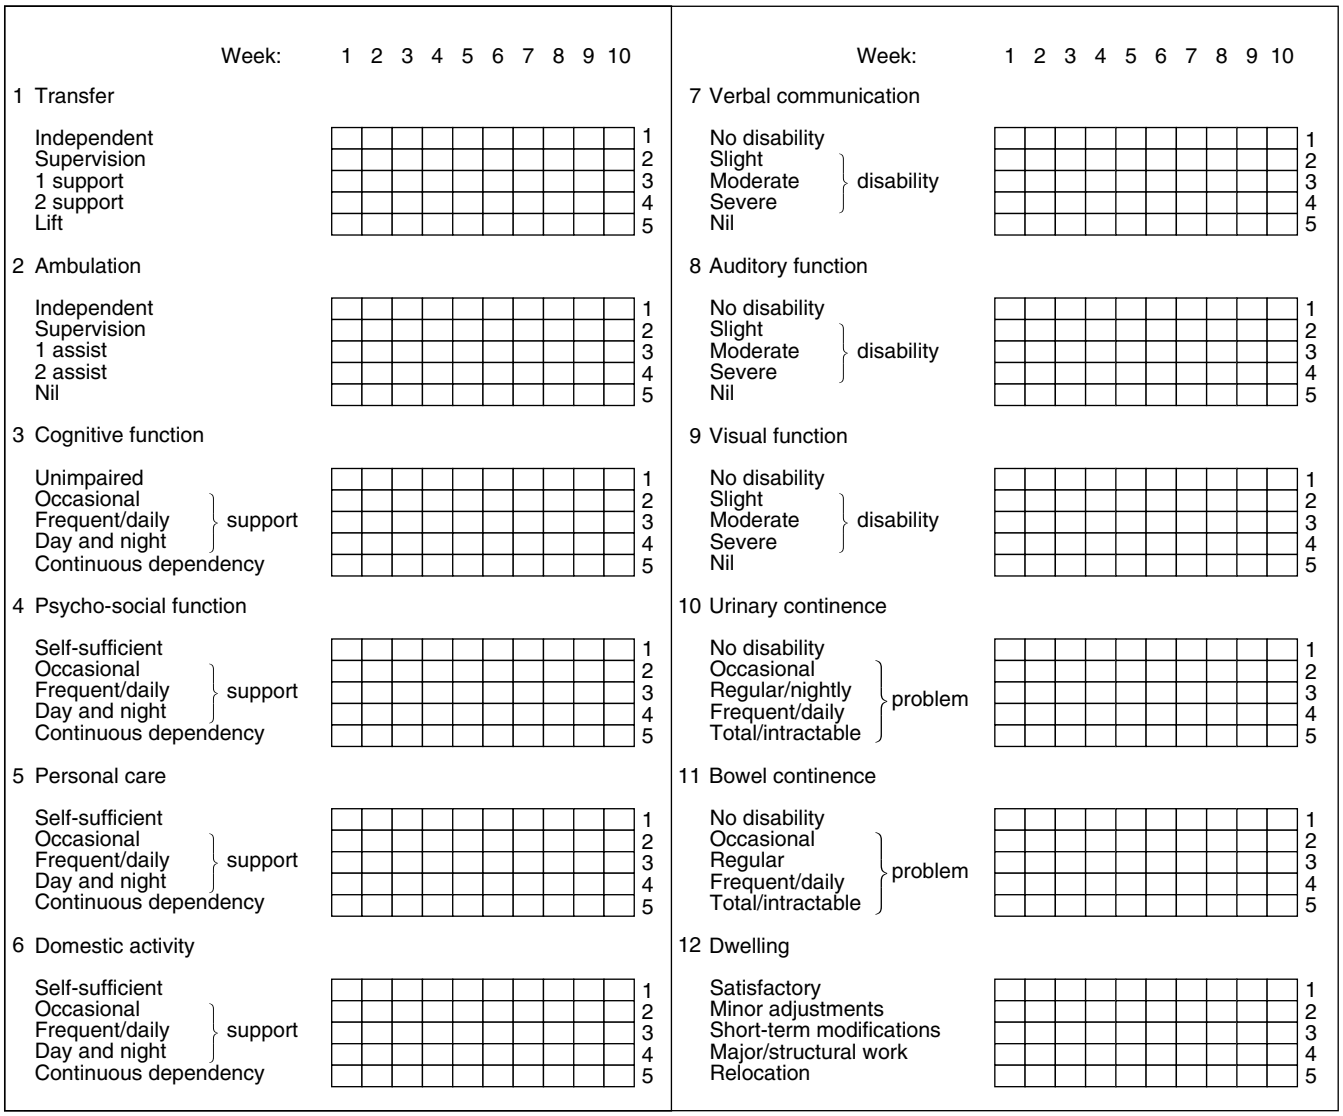

Figure 2 A shorthand operational chart for interdisciplinary decision making

no problems of bypassing or spillage, then urinary continence is classed as unimpaired. Where the criterion of extrinsic assistance is less clear-cut (e.g. in the case of auditory dysfunction), but the category of function is considered to be of major importance, then it is also included. The display and content are designed to be visual and operational rather than quantitative and specific, allowing any member of the team a rapid impression of a patient's functional status, as well as an indication of change over time.

Similar pragmatic and operational approaches to multidimensional assessment, decision making and documentation have been elaborated elsewhere, for example, in the context of community care (Donald, 1997) and rehabilitation (Turner-Stokes and Nyein, 1999; Nyein and Turner-Stokes, 1999).

As with medical diagnosis and treatment, functional assessment and the resulting rehabilitative strategies should be clearly linked to finite and time-limited objectives.

Relationship Problems

Although in this context the skills of social workers and clinical psychologists are vital, the cumulative information to be obtained from all professionals who interact with patients and/or their relatives is indispensable. It is salutary to observe how often the "social prognosis" is good. This reflects the phenomenal contribution to patient care (including "continuing care") made by the army of spouses, relatives, friends, neighbors, and other informal carers who provide governments with major annual savings. Contrary to popular perception, most families in the majority of countries in both the developed and the developing world still consider it the norm to be involved in the care of their older people and as a result, constitute the best possible target for the investment of money, manpower, and time by governments. The health-care services should be their enablers.

Presenting problems in these categories can often be traced to changed circumstances or failure of adequate provision. For older people on their own, the difficulties are often those of isolation or bereavement. Where others are involved, the problems include loss or withdrawal of support, carer stress, rejection (root causes of which may be simple, e.g. remediable disability, incontinence or sleep disturbance, or more complex, such as a long-standing failure of marital relationship) or relocation. Health-related events in older people commonly precipitate an acute imbalance in a fragile structure of family and social relationships. Failure to recognize and address these problems successfully contributes substantially to poor clinical and functional outcome and to health-care costs.

Environmental and Housing Problems

Poor quality: Responding successfully to problems of environment and housing remains a major difficulty in the health care of older people. Some of the more common problems are itemized in an earlier chapter. Housing design for late life has been inadequately addressed in the past and is still at a comparatively rudimentary stage (Frain and Carr, 1996). In addition, the capacity to carry out significant adaptations to existing homes is typically fraught with delay, lack of financial commitment, and bureaucracy. Although, in the United Kingdom, older people are more likely than their younger counterparts to occupy housing that lacks basic amenities, is unfit, old, and in poor repair (Department of the Environment, 1988) (especially private sector housing), adaptations can make a profound difference to the prospects for even the very disabled to remain in their own homes or return there after illness (Statham *et al.*, 1988). Unfortunately, the scale and nature of an individual's need for reorganization or adaptation of their home often cannot be determined until some time after the acute phase of illness, when a "plateau" of functional recovery has been reached.

Assessment: A common and important practice for older people undergoing hospital treatment is the home assessment visit prior to discharge. The work of the occupational therapist is paramount in this, both in assessing the individual's performance and advising on what changes, if any, are required. Not infrequently, the needs for rearrangement are minor inexpensive additions, such as grab rails or stair rails, but where there are problems of access, structural alterations may be necessary.

Relocation: Relocation to another area takes place among very elderly people more often than is commonly realized (Graham and Livesley, 1986). This may or may not be for good reasons (such as proximity to family, particularly where the latter have moved out of inner-city areas to the suburbs). Relocation at any time of life is known to be a stressful event and brings its own range of problems, such as loss of previous social contacts and difficulty in establishing new circles. The same may well be true of rehousing within the district or relocation into an institutional setting, although there is evidence that relocation between institutional settings well managed need not be deleterious (Harwood and Ebrahim, 1992).

Individual choice: Some older people are extremely reluctant to consider moving to new housing, even though the "ancestral" home may be falling around their ears. They may also be reluctant to consider structural alteration or even minor adaptations. The writer recalls an octogenarian double amputee, staked out in an ancient caravan heated by a paraffin stove in the middle of a farmer's field in the South West of England; he developed substantial cortical blindness as the result of occipital lobe infarctions. In spite of everyone's best efforts, he could not be persuaded to relocate and accepted the installation of a new electric mains cable and a safer form of heating, only with the greatest reluctance. In functional terms, however, his abilities within the caravan, the layout of which he knew well, proved to be superior to those within the hospital department, and the decision to support him in his endeavors was subsequently shown to be the correct one. The patient's wishes and preferences are commonly pivotal in housing and environmental matters and should be respected. Having identified the problems, a general rule of thumb is to err on the side of supporting an individual in his or her wish to take certain risks, provided everything possible has been done to minimize their scale.

The option of institutional care may appear at first sight highly preferable when environmental problems are identified, and there is commonly a range of pressures to pursue a "custodial" course under the pretext of greater safety. If other options are open, however, even to those with severe disability, there is a responsibility to identify these and to ensure that the choice which an individual makes is fully informed (Wanklyn, 1996). Too often, older people feel under constraint to "go into a home" because they have no apparent choice. The decision may subsequently be regretted for many years – life with no problems may not be life at all!

The institutional environment: Although there are improvements, institutional design has far to go before optimal standards are universally available. Many old converted premises are totally unsuitable for disabled people and carry their own hazards. There is a very high incidence of falls among elderly people living in institutional settings (Askham *et al.*, 1990) and it is simplistic to equate the institutional environment with "safety". Thankfully, very large numbers settle comfortably and happily into residential and nursing homes, but such a radical decision for an older person should never be made without careful consideration of the alternatives in the framework of a comprehensive problem-orientated assessment. Housing and environmental problems should be addressed in detail and resolved wherever possible, rather than compounded by ill-founded decisions in the direction of institutional care.

Social and environmental issues often require skilled counseling of older individuals, their relatives, and their supporters. This, like all other aspects of successful care,

should be an informed and coordinated team effort. All professionals involved in the medical care of older people should acquire counseling skills. It is well known that many complaints addressed to hospital administrators and managers can be traced back to inept communication.

IMPLEMENTATION: PROBLEM MANAGEMENT – ORGANIZATIONAL IMPLICATIONS

Information and Communication

Records: A central function of POMR is to make available to the clinician the necessary information for decision making more or less at a glance. Such information will be factual, reliable, and relevant, and presented in a format that can be quickly digested. Because of the complexities of a program of investigation and treatment for an older person with multiple problems, this facility is indispensable to the practice of geriatric medicine. The records departments of many large district general and teaching hospitals have so far been unsuccessful or incompletely successful in achieving this objective.

A major problem has been to achieve a synthesized account of functional assessments. The generation of a centralized, multidisciplinary problem-orientated patient record in a variety of formats is a practice that is becoming more widespread. The ideal objective is to have information sited with the individual and available for scrutiny by all professionals, whether in an inpatient setting (i.e. at the end of the bed) or in the community (i.e. with the individual in his or her home). This is one of the aims of the "Single Assessment Process" recommended in the England National Service Framework for Older People. (Department of Health, 2001b) The capacity to make such information available in electronic format (e.g. as "smart cards") presents significant opportunities for improved continuity of care of older people and warrants further evaluation in a service context.

Communications base: It is a common practice of many departments of geriatric medicine to run their own liaison offices. These serve as a central communication point for all enquiries and decisions requiring access to recent patient information. They commonly contain hard copy of recent discharge summaries and outpatient letters, together with other information such as day hospital discharge information or domiciliary assessment correspondence. Contact between professionals (such as a general practitioner-to-hospital telephoned referral) can thus be supported by instant access to a large body of recent summarized patient data on diagnosis, treatment and progress, medication, support services, social and environmental data – in fact, the components of a good problem-orientated record. This arrangement permits rapid decisions on assessment and practical management (including decisions on hospital admission) to be fully informed, thus, reducing the scale of misplacement, duplication of investigations, and delay in diagnosis.

Liaison office staff (normally trained administrative and clerical officers) progressively acquires the skills of handling enquiries and of interprofessional contact, and find a combination of such activity with record keeping both challenging and rewarding. Computerization of patient records has brought further advances allowing access (including out-of-hours access) for designated staff from remote terminals on wards and elsewhere. This contrasts sharply with the situation in some emergency departments and receiving wards, where older people, whose complex background is unknown and who are too ill or incapacitated to provide the necessary information themselves, undergo numerous (often duplicated) investigations and sometimes inappropriate treatment strategies, before the true nature of their underlying problems comes to light some days later.

Whatever organizational structure is adopted, the advantages of a coordinated single entry point to geriatric services are clear, particularly where such services are diverse.

Written interagency exchange: Such access to information is a cardinal requirement of problem-orientated clinical practice. Equally important is the quality and content of information exchanged between different treatment settings. An adequate medical discharge summary, for example, should incorporate a clear problem list, a short narrative section on presentation, progress, and management, a list of ongoing drug therapy with dosages, a clear statement of functional ability, relationships, environmental setting and any aids, adaptations or appliances, a list of domiciliary support services, and a clear statement of the future program of monitoring and follow-up. It should be brief, readable, and accurate.

Multidisciplinary Work Patterns

The multidisciplinary team is the nucleus not only of problem identification but also of management and implementation. Precise work patterns vary between departments, but every mainstream setting for the medical care of older people (e.g. the acute general hospital ward or day hospital) requires the support of a multidisciplinary team to be successful. It is common practice for the team to convene in association with every ward round or day hospital review. The meeting should be no more than a focus for ongoing and continual communication between team members.

A program of mobilization for a patient will, for example, go badly wrong if nursing staff and physiotherapists fail to maintain an effective dialogue and to agree identical approaches around the clock. If medical and social work staff are at cross-purposes in discussing options with patients and their relatives, then irreparable damage may be done to any strategies for return to the community. In the best departments, strong team identity develops with the recognition of mutual interdependence, flexibility over "demarcation" between disciplines, clear lines of accountability and not

uncommonly a little healthy interprofessional rivalry. Direct dialogue is one of the major strengths, for which written referrals or communications are no substitute.

Medicine: The physician within the team, who will require both training, experience, and specific skills in interdisciplinary practice, exercises the traditional functions of diagnostician, therapeutician, and prognostician, but recognizes that none of these can be satisfactorily achieved without substantial input from team colleagues. Their trained observations are crucial in diagnosis. The physician's knowledge and experience of the natural history of disease processes in late life are essential, particularly in assessing prognosis. In most settings, the physician carries the ultimate clinical and medicolegal responsibility for the admission and discharge of patients and has therefore a critical role in holding an overview, in realistic goal setting, and in timing the various stages of assessment and management.

Nursing: The nurse is in the best possible position to acquire a comprehensive day-to-day understanding of the problems confronting individual patients, because of the continuity of contact entailed (McGovern, 2002). He or she is best able to make the close and detailed observations on which correct diagnosis may depend and to obtain an understanding of psychological and emotional problems. The nurse will acquire first-hand awareness of a patient's personal care capacity and motivation and will have an enabling role in communication with the individual, with visitors and with all other professional staff involved. The "key worker" concept is often most readily applicable to the nurse and underlies modern approaches to primary nursing (McGovern, 2002).

The therapies: The expertize of therapists is paramount in defining and assessing problems of functional disability. They have the skills, necessary equipment, and measurement techniques to quantify the challenges involved in regaining autonomy, to present an accurate picture of performance capacity and to determine the strategies, facilitated relearning programs and therapeutic procedures required.

Social work: The role of the social worker in defining the contribution of problems of relationships (or lack of relationships), economic, and environmental problems, is critical. The wealth, variety, and fascination of casework in the field of geriatric medicine make it one of the social work's most exciting challenges. Recent organizational changes leading to a preoccupation with the division of costs between health and social services have in some cases placed this key interdisciplinary function in jeopardy to the extent that social work staff have become caught up in a cost-driven bidding process for "packages of care" and perceive themselves to have little or no time for "family work". Any suggestion that social work for older people requires fewer professional skills or presents fewer intellectual and clinical challenges than other areas of practice, but rather entails the dispensing of aids and support services is supremely outdated and uninformed. A skilled operator in the field regularly transforms the perception of a patient by the multidisciplinary team and radically alters its decisions.

Liaison: Specialist liaison health visitors or nurses have historically played a valuable part in bridging the hospital-community interface. Feedback from follow-up visits of older people resettled in their homes after illness is invaluable self-audit for the hospital-based team. It maintains an indispensable community perspective and frequently enables early troubleshooting where errors or omissions may have occurred, or where aspects of the assessment may have been miscalculated. This function has latterly been undertaken by a variety of personnel, including case managers or discharge coordinators, but the basic concept is the same – a coordinating role among other professionals and agencies, based in the community rather than the hospital. Many holders of the newer posts have a professional background in nursing.

In summary, effective teamwork is fundamental to problem-orientated practice in the medicine of old age. Even the most successful teams get it wrong some of the time, but in clinical settings where team work is underdeveloped or present only in token form the error rate is substantially greater.

Clinical Care Settings

In the United Kingdom the most efficient structural unit containing all the necessary facilities for investigation, treatment, access to other specialties, exchange of information and the presence of on-site multidisciplinary staff is the general hospital. There is ample evidence that the effectiveness of district geriatric medical services depends on the degree of access to acute general hospitals available to competent clinicians in the field (Evans, 1983). Many new technologies, for example, in noninvasive organ imaging and surgery, have particular applicability and effectiveness in the management of older people. Access to these techniques (always assuming careful stewardship) and to other specialties such as vascular surgery, is accepted as necessary and appropriate for the practice of geriatric medicine (Evans, 1983). This degree of "centralization" is an economic necessity, since many of the facilities cannot be cost-effectively dispersed across the community. Provided the service is clearly targeted at the local population, the advantages generally outweigh the disadvantages (e.g. those of transport). Ready access for older people to technically sophisticated and comprehensive medical care is a strong imperative, for which quality "care in the community" should never be perceived as a substitute (as distinct from a parallel partnership).

The need to generate cohesive specialist teams immediately available to ill older people constitutes a strong argument for the positioning of acute assessment units within the acute hospital. Where the acute medical care of older people is wholly integrated (i.e. older patients receiving care in a common pool of general acute beds alongside their younger counterparts) then specific arrangements are necessary to

ensure their prompt access to a fully accountable multidisciplinary process (for example, a team attached to a medical "firm" and incorporating that firm's physician with specialist responsibility for the medicine of old age) (Evans, 1983). The need to position specialized acute assessment and/or rehabilitation facilities in acute hospitals lies in the development of a "tailored" inpatient environment for older people and the maintenance of a clear focus for standards, for training, and for the dissemination of clinical and interdisciplinary skills.

The potential for these disciplines to extend into an increasingly wider range of settings is now being evaluated, with a strong impetus from the desire to reduce costly hospital bed-days. In addition to established practice within geriatric medical rehabilitation units and day-hospitals, the application of different models of the team (problem-orientated) approach, for example, to early or supported hospital discharge and "hospital-at-home" schemes (Hyde *et al.*, 2000) continuing care in the community and strategies for stroke rehabilitation (Kalra *et al.*, 2000) have been investigated. Such applications have potential in so far as they build on established standards and expertize, can be shown to make a measurable, equivalent contribution to the total service (or core need), do nothing to delay or prevent ready access to mainstream medical care and are not primarily "cheaper," unsustainable, short-term alternatives. In terms of cost-benefit and cost-effectiveness, such questions are so far unresolved.

Risk Taking

As already implied, the restoration of autonomy to an older person invariably implies the taking of at least some risk. The concept of restrictive custodialism has now thankfully become unacceptable in most developed and developing societies, but in the past has been the cause of much fear and apprehension among older people. Specific initiatives have been undertaken to minimize or abolish the use of the various forms of restraint, both physical and pharmacological (Dunbar *et al.*, 1996; Brooks, 1993). There is in any case ample evidence that such practices are not only ineffective, but generate their own risks (Frank *et al.*, 1996).

Positive approaches to rehabilitation have instead come of age. Within these, the aim of the problem-orientated approach is to identify and quantify the risks correctly, to take all reasonable treatment and preventative measures to minimize them, and to set a high premium on an individual's successful return to autonomy – in her or his own home wherever possible. Where some risk is entailed, an individual's choice should weigh substantially against the anxieties of others and (perhaps even on occasions the attentions of the legal profession).

The success rate of this approach is high. Modern departments of the medicine of old age have become increasingly interventionist, with a substantial relative decline in their custodial role. Those aspects of the organization of facilities and of clinical practice discussed earlier are a direct consequence of this orientation.

EVALUATION: PROBLEM RESOLUTION – SUCCESS OR FAILURE?

The capacity for activities associated with health care to become self-perpetuating means that this interventional approach, like any other, should have its effectiveness tested. Given that the problem-orientated approach finds its expression predominantly in interdisciplinary practice, the following questions are pertinent:

1. What are the short-, medium-, and long-term benefits for patients?
2. What is the wider impact on older populations at an epidemiological level?
3. How can the standard of practice be assessed?
4. What are the effects on the service in terms of efficiency and cost?

These areas of enquiry broadly reflect the Donabedian categorization of audit criteria – structure, process, and outcome (Donabedian, 1980). Although "health care–technology assessment" is an expanding discipline, the earlier questions remain to be comprehensively answered with respect to Geriatric Medicine. "Outcome measures", in particular, are the subject of much ongoing debate and the health economic aspects are extremely complex. Such answers as exist so far have emerged sporadically in the context of service development rather than as a result of any clear research strategy.

A number of UK departments of Geriatric Medicine providing comprehensive services (and adopting problem-orientated interdisciplinary service patterns) published reports (mainly in the 70s and 80s) showing substantial changes in hospital-based activity consequent on their development (Hodkinson and Jeffreys, 1972; Bagnall *et al.*, 1977; Rai *et al.*, 1985; Mitchell *et al.*, 1987). The changes included substantial increases in patient throughput per year, with concurrent reductions in total bed numbers, duration of patient stay and hospital bed occupancy. It was also possible to demonstrate a facilitating effect of this pattern of service on other areas of clinical activity, most notably acute general medicine, in which the numbers of patients treated also grew as a result of the resolution of "bed blockage". The descriptive content of these models included elements of structure (notably provision of inpatient and day patient places, of places in homes in the community and also the levels and skill-mix of available multidisciplinary staff) and process (notably clear definition of operational policy, patterns of interdisciplinary practice, community and social-services links and specific geriatric service components, e.g. respite care, dementia caseload). Their reports demonstrated the capacity to translate the principles of problem-orientated practice and interdisciplinary activity into viable services, with a measurable positive impact on adjacent clinical services (Swift and Severs, 1997). Detailed conclusions concerning clinical outcome, with the exception of mortality statistics, were by inference, although it is unlikely that service viability would have been sustainable had the clinical

consequences been broadly unacceptable to patients and to the local communities concerned.

Such process data are a fundamental component of evaluation, even though the need for more information on clinical outcome is accepted. The published models have to some extent set standards for resource use efficiency and bear careful scrutiny with respect to this. The delivery of a service will invariably require some balancing of benchmark criteria of practice with the availability of finite resources. There is little point in setting up the "perfect" model if it can only be available to a small proportion of those who need it. The concept of a service entails its ready accessibility to the total population served in relation to need.

More recent health care–technology research has allowed prospective experimental evaluation of the problem-orientated/interdisciplinary approach in randomized controlled clinical studies.

A good example is a study of the efficacy of stroke units (as a model of focused interdisciplinary practice) (Figure 3) (Kalra *et al.*, 1993). This work, using a stratified design based on a validated prognostic scale of severity, showed that assessment and rehabilitation in stroke units versus dispersed wards resulted in more rapid discharge from hospital to community, a reduced requirement for long-term institutional care and an improved and more rapid functional outcome (for those with intermediate stroke severity) as well as a reduction in late mortality (for those with more severe stroke). These operational and clinical outcomes were achieved without the requirement for increased therapy staff or total therapy time. It is important to stress that the findings were set in the context of a comprehensive district geriatric service with corresponding specialist leadership. They do not constitute a carte blanche for the universal deployment of stroke units, but rather provide evidence of the effectiveness of focused problem-orientation and interdisciplinary practice. This leaves the way open for a range of alternative strategies based on these principles, ranging from well-run generic geriatric medical units to peripatetic teams bridging the hospital–community interface (Kalra *et al.*, 2000) and strengthens the case for investment in this general approach to the care of all patients with complex need.

A further example is the application of interdisciplinary assessment strategies in the prevention of falls among older people. In a controlled study, consecutive older people presenting to a London accident and emergency department were randomized to existing discharge and communication procedures or to a subsequent single bi-disciplinary, problem-orientated risk identification and referral protocol comprising a full medical examination and an occupational therapy assessment at home (Close *et al.*, 1999). In only 16% of the assessments was no further action considered necessary. Analysis showed that the odds of a fall in the 12 month follow-up period were reduced in the intervention group by a factor of 2.5 (95% CI; 1.5–4.3) relative to the control group after adjusting for differences in Barthel and AMT scores at baseline and number of falls in the 12 months prior to the index fall (Figure 4). The odds of recurrent falling (3 or more falls) were reduced in the intervention group by a factor of 3.0 (95% CI; 1.5–6.1). There is now a substantial literature indicating the capacity for falls prevention at population level using multidimensional, multidisciplinary approaches (Chang *et al.*, 2004).

There is much discussion about measuring the broader epidemiological impact of the problem-orientated approach. One of the difficulties is getting consensus on the most appropriate measure of achieved autonomy or health over a given time span. One proposal is to develop the concept of measuring Healthy Active Life Expectancy (HALE) within served populations (Evans, 1993).

The proliferation of guidelines may prove to be of limited or little value in the scrutiny of services if no account is taken of the degree of expertize and competence applied. The mere presence of an operating theater, a team of individuals, and a textbook of operative surgery gives no guarantee of the outcome of a series of surgical procedures. The same principal holds in the health care of older people for the existence of a defined service structure, organized "teams" and agreed guidelines. Effectiveness requires the work to be underpinned by good training, professional commitment, research and development, and well-developed career structures. There have been a number of instances where schemes put in place

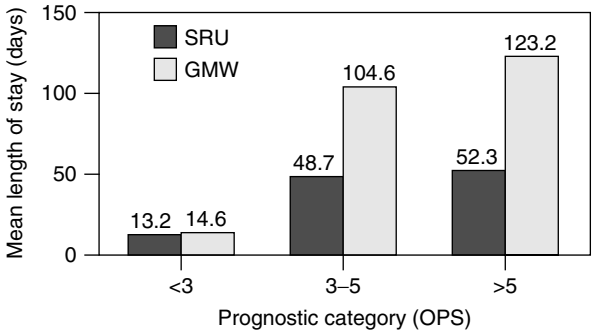

Figure 3 A randomized prospective study showing the effect of stroke-unit based interdisciplinary practice (SRU) compared with care on dispersed general wards (GMW) on duration of hospital stay after stroke (From data of Kalra *et al.*, 1993)

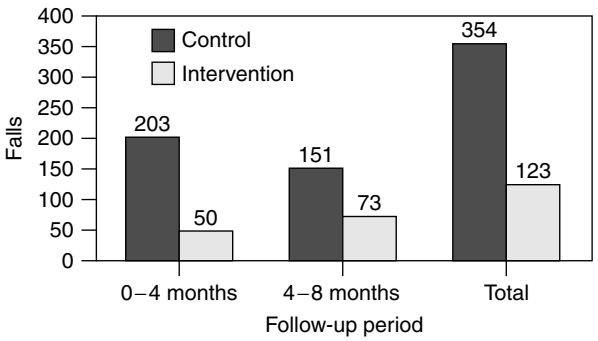

Figure 4 Reduction in the incidence of falls in older people in a randomized prospective study of an interdisciplinary assessment protocol (Reproduced from Close *et al.*, 1999). Copyright Elseveir

(e.g. for community care) have achieved short-term results, but have proved unsustainable in the medium term because of difficulties of professional recruitment and gradual de-skilling. In this context it is gratifying that Geriatric Medicine (where well developed) is no longer a shortage specialty. It is probably correct that success or failure of continued professional recruitment is an invaluable, if indirect, service audit criterion.

In conclusion, the skilled application of a system of problem orientation substantially defines decision-making expertize in the practice of Geriatric Medicine, perhaps more than in any other speciality. The evidence underpinning its effectiveness continues to grow, but on the whole too slowly in relation to the explosion of population need. There is still insufficient consensus among geriatricians on the best measures of effectiveness, minimum datasets and comparative standards of service performance to enable the necessary comparison of "like with like". This remains an urgent and major challenge for clinical age research. In the meantime, it is incumbent on clinicians concerned with the care of older people to ensure that they have well defined and well-used systems in place to optimize and monitor their own practice.

KEY POINTS

- The accurate identification and documentation of "problems" and the resulting application to multidisciplinary decision making constitutes the core method of clinical practice in geriatric medicine. It may be well or badly implemented and the potential pitfalls should be recognized and avoided.
- The four interdependent problem domains fundamental to effective practice are those of diagnosis and treatment, functional autonomy, human relationships, and living environment. The level of skilled practice and experience within each domain and the capacity of multidisciplinary teams to collaborate successfully are the principal determinants of outcome for patients.
- Pragmatic problem-orientated decision support tools (as distinct from solely measurement and assessment instruments) may enable best practice.
- The success, efficiency, and cost-effectiveness of health-care systems for older people are directly proportional to the extent to which they are organized to promote, support, and facilitate such activity rather than constrain and inhibit it. A major presence in the acute general hospital and dedicated communication/liaison systems have both been found to be pivotal.
- The effectiveness for patients and for health systems of implementing the approach within organized service models is now well proven both by audit of routine data and in randomized controlled prospective studies.

Oral Health

Janet E. Griffiths
University Dental Hospital, Cardiff, UK

INTRODUCTION

Healthy teeth and oral tissues and the need for oral health care are as important for older people as any other section of society. Tooth loss can have a profound impact on quality of life (Davis *et al.*, 2000), whereas good oral health has real health gains in that it can improve self-image and social interaction, and contribute to general health and quality of life (Fiske *et al.*, 2000). Older people perceive oral health as being important to quality of life in a variety of ways (McGrath and Bedi, 2002). However, priority must be given to the elimination of disease, and abnormality; comfort, mastication, and aesthetics are paramount in helping the individual to maintain an overall perception of self-esteem and dignity, and generate confidence in making regular use of the services that are available.

DEMOGRAPHIC POPULATION CHANGES AND ORAL HEALTH CARE

Improvements in life expectancy in developed countries have led to an increase in an aging population (*see also* **Chapter 9, The Demography of Aging**). In the 2001 United Kingdom (UK) census, over 12 million people were aged 60 and over, approximately 20.8% of the population (ONS, 2002). The proportion of people aged 65 and above in 2001 is predicted to rise from 16.9% to 19.3% in 2020 (GAD, 2002). Population projections based on declining fertility may need to be revised in the light of migration, and medical advances in the treatment of conditions such as dementia may reduce the burden of care (Tinker, 2003). Nevertheless, there will be an overall increase in the numbers and percentages of older people, of very old people, and of older people from black and ethnic minority groups, and a continued preponderance of older women. Similar increases are noted in other industrialized societies. This will have an impact on most forms of health care provision and will place increasing demands to develop systems that cater for all aspects of health care, including dental services. Future development of oral health care services will need to consider the diversity of demand and need within this aging population (BDA, 2003).

IMPAIRMENT AND DISABILITY

In discussing the oral health needs of older people and their use of services, the self-evident increase in impairment and disability with age must be considered. The 2001 UK census estimates that almost 9.5 million people in England and Wales have some form of disability (ONS, 2002), significantly higher than previous estimates. Of these, 18.2% reported a long-term illness, a health problem or disability that limits their daily activities. Over a third of respondents aged 65 to 74 and approximately a half aged over 75 reported long-term illness that limited their lifestyle (ONS, 1999).

Physical and mental health influence access to services, including oral health care. Loss of mobility increases with age, with the greatest decline in people aged 75 and above (ONS, 1999). Immobility is a frequent pathway by which many diseases lead to further disability (Walsh *et al.*, 1999) (*see also* **Chapter 112, Gait, Balance, and Falls**). Sensory impairments are more common with advancing years (*see also* **Chapter 101, The Older Patient with Down's Syndrome**; **Chapter 104, The Epidemiology of Hearing in Aging Population**; **Chapter 105, Auditory System**; **Chapter 106, Disorders of the Vestibular System**). Approximately 80% of the population over 60 have some form of visual impairment, 75% have a hearing impairment, and 27% experience both visual and hearing impairment (Living in Britain, 1994). Cognitive impairment increases sharply with age affecting 1 person in 20 over the age of 65 and 1 in 5 over the age of 80, and this is predicted to increase Alzheimer's Disease Association (ADS, 2004) (*see also* **Chapter 94, Mild Cognitive Impairment**;

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Chapter 95, Vascular Dementia; **Chapter 96, Other Dementias**).

Older people are distinguished by functionality in the National Service Framework (NSF) for Older People, which refers to the functionally independent and the frail or functionally dependent regardless of age (DoH, 2001a). This classification is used by the British Dental Association (BDA) in addressing the diverse oral health needs and demands of older people for the next two decades (BDA, 2003). This chapter primarily addresses the needs of the frail and functionally dependent older population.

ORAL AND DENTAL STATUS

Tooth loss is irreversible although stem cell research still in its infancy offers future potential for implantation of the patient's own cells to grow and replace missing teeth. Prevalence of edentulousness (total tooth loss) in the general population over time and dental status, together with patterns of dental attendance, can be used to predict dental service needs. Comparison of the UK national surveys confirm a steady decline in tooth loss in adults (Table 1). In 1988, the dental status of older people in the United Kingdom was primarily one of edentulousness. However, the number of older people who are edentulous is declining. In 1968, 79% aged 65 to 74 were edentulous as compared to 36% in 1998, and in people aged over 75, edentulousness fell from 88% to 58% over the same period (Todd and Lader, 1991; Kelly *et al.*, 2000). Retention of some natural teeth is sufficiently common amongst the "younger–old" population; nearly two-thirds (64%) in the 65 to 74 age group and almost half of all the people of "pensionable" age in the United Kingdom (54%) have some natural teeth (Steele *et al.*, 2000).

Age is highly correlated with dental status. Other factors include sex, social class, region of residency, ethnicity, and dental attendance. Social class differences in total tooth loss were much greater among men than women, and particularly noticeable amongst older men compared with older women; it is suggested that differences arise from social values attributed to appearance (Steele *et al.*, 2000). Women from unskilled working backgrounds were most likely to have the lowest proportion of natural teeth. Regional differences in social class structure may account for regional differences in total tooth loss but the highest proportion of retained natural teeth is still in the South of England. Despite a trend toward retaining some natural teeth into later life, a small but varied group of people will continue to become edentulous and these are more likely to be in the older age groups. Similar trends of tooth retention are recorded in other developed societies. Variability is strongly influenced by place of residence, geographic region, and cultural factors; however, edentulousness is more frequently associated with lower socioeconomic status.

Table 1 People aged 45 and over with no natural teeth (1968–1998)

Age group	England & Wales	England & Wales	United Kingdom	United Kingdom	United Kingdom
Year	1968	1978	1978	1988	1998
45–54	41%	29%	32%	17%	6%
55–64	64%	48%	56%	37%	20%
65–74	79%	74%	[a] 79%	57%	36%
75+	88%	87%	[a]	80%	58%

(Based on data from Todd and Lader, 1991; Kelly *et al.*, 2000)
[a]No separate data for age groups in 1978.
In 1978, 79% over the age of 65 had no natural teeth.

Not only has the number of dentate adults in older age groups increased, the number of undiseased and filled teeth have increased (Nunn *et al.*, 2000). It is suggested that increased experience of dental treatment among older people is largely reflected by a lower experience of dental extractions. In older people, a significant proportion of the caries burden falls on exposed root surfaces although there is also an increase in coronal caries often recurring around existing fillings. Prevalence of toothwear increases with age, affecting 89% of the dentate population aged over 65. In 1998, older people had more restored teeth, often large and complex restorations requiring time and advanced professional skill to maintain them. Fifty percent of the teeth of dentate adults aged 45 years and over are filled and crowned, and many will retain their teeth for life (Pine *et al.*, 2001). It appears that regular dental attenders benefit in real terms over a lifetime in terms of tooth retention (Kelly *et al.*, 2000).

Periodontal disease is a major concern in the older dentate population. Seventy-eight percent of dentate adults over 65 had visible plaque and 83% had visible calculus, which can only be removed by professional dental treatment (Morris *et al.*, 2001). Depth of pocketing around teeth is also an indicator of periodontal disease but gingival recession is likely to be a common feature in older age groups, reflecting a lifetime's disease history. The high prevalence of periodontal disease needs to be viewed in the context of larger numbers of dentate older people who are now potentially at risk. Control of periodontal diseases, whether mild or moderate, will be a central issue if large numbers of teeth are to be retained into old age.

It seems that older people are now more concerned with preserving their natural dentition (Kelly *et al.*, 2000). In 1998, dentate adults over 55 were the most likely to say that they attend regular checkups; the proportion reporting this has more than doubled over the last 20 years (Bradnock *et al.*, 2001). A greater proportion aged over 55 have expectations of retaining some or all of their natural teeth for life, and older age groups would consider having more extensive restorative treatment such as crowns and bridges in order to achieve this expectation. Dental attendance does appear to be of substantial benefit in retaining teeth (Steele *et al.*, 2000). Greater awareness of oral and dental health measures together with a greater desire to remain dentate will create an increasing demand for dental services.

In the older UK population, three broad cohorts in relation to oral health are described:

- *People who are old and very old, of whom a large proportion are edentulous,*
- *Those now entering old age, who have retained much or most of their natural dentition, but in a condition that requires a lot of maintenance,*
- *Those in middle age and younger, who are retaining a sound dentition, and assuming the status quo, are unlikely to need complex oral health care, but who may opt for cosmetic dentistry* (BDA, 2003).

Whereas the "new older" health consumer will be more informed and more demanding, for a significant proportion of older people, the maintenance of an aging dentition will pose significant challenges to the dental profession. It is the frail and functionally dependent that have a significant normative treatment need and that pose even greater challenges to their identification and service delivery.

It is generally agreed that poor standards of oral hygiene and lack of access to professional dental care contribute to poor oral health amongst the frail and functionally dependent population (Fiske *et al.*, 2000). Surveys within nursing and hospital care report high levels of oral disease, heavy deposits of plaque and debris, oral mucosal pathology related to inadequate denture hygiene and inadequate support to maintain oral health or access services (Frenkel *et al.*, 2000; McNally *et al.*, 1999; Simons *et al.*, 1999). Poor oral health is also identified in the frail and housebound living in the community (Chalmers *et al.*, 2002).

The dental profession is concerned about the oral health of this client group, and in particular, those who rely on professionals for personal care and activities of daily living (BDA, 2003; Frenkel *et al.*, 2001; Fiske *et al.*, 2000; Simons *et al.*, 1999). Oral health does not have a high profile in the context of personal care. Lack of training for health professionals in oral health care is reported (Longhurst, 1998; Travers *et al.*, 1997). Gaps between theory and practice are noted in pre and postregistration nursing practice and education (White, 2000; Frenkel, 1999; Longhurst, 1998). This has led to a range of initiatives to address the issues and raise standards of oral health care for this client group (BDA, 2003; WAG, 2003; DoH, 2001b; Fiske *et al.*, 2000).

BARRIERS TO ORAL HEALTH CARE

Many older citizens face barriers to oral health care. These include attitudes developed in early life that place oral health as a low priority in the context of other factors such as past dental experiences, dental attendance patterns, lack of information, in addition to practical and financial barriers. Lack of perceived need is an important barrier.

Social problems that influence perceived need are related to age, socioeconomic factors, and residence. The presence of natural teeth, residential status, and age were statistically significant independent variables for the time since the previous reported dental visit (Lester *et al.*, 1998). There is a trend toward decreased perceived need in older populations; this was found to be a barrier to care for 86% of frail and dependent older adults (Lester *et al.*, 1998) although the new elderly have significantly more favorable attitudes to dental care. Uptake of dental care is greater among patients of higher socioeconomic status. Cost, lack of perceived need, and transport were the most frequently quoted barriers by housebound subjects although the true implications of cost were poorly appreciated (Lester *et al.*, 1998). Removal of the examination charge as a financial barrier to screening and, if possible, care is recommended (Walls and Steele, 2001; BDA, 2003). Legislation in Wales has removed the fee for a dental examination for the population aged 60 and over; it remains to be seen whether this alone will increase the uptake of care.

Lack of perceived need and inability to express need are identified within residential care facilities and housebound persons in the community (Lester *et al.*, 1998; Fiske *et al.*, 2000). Fewer dental attendances in this population are in part attributed to the inadequacy of carers' perception of their clients' oral health needs and lack of knowledge of the benefits of oral health and access to dental services. The prevailing management culture that gives oral health a low priority reported in residential care may be a contributory factor. A dental emergency rather than a routine dental check was the usual reason for requesting a dentist's services for a resident (Frenkel *et al.*, 2000).

Fear and anxiety are commonly cited as reasons for irregular dental attendance. Over 12% of older people in the United Kingdom express dental anxiety associated with their use of services and self-reported oral health status (Bedi and McGrath, 2000). This must be viewed in the context of past dental experiences prior to the foundation of the National Health Service (NHS) when the practice of extracting teeth and replacement with dentures was considered to be the most effective form of treatment as opposed to the current philosophy of maintaining and restoring the dentition.

Impaired mobility, access to transport, and ability to reach services have implications for access to dental care for housebound and disabled persons. Inequalities in the distribution of general dental services pose problems for availability of care. This is particularly true of rural areas where transport difficulties and costs create disincentives. Difficulties registering for NHS dental treatment are being widely encountered by the general population. Older people with mobility problems may experience even greater difficulty in accessing NHS care owing to poor physical access to premises that do not comply with the requirements of the Disability Discrimination Act (1995) (Griffiths, 2002). Domiciliary dental care services are not widely known about and yet frail and functionally dependent older adults expressed a preference for treatment in their own home (Lester *et al.*, 1998). Illness and impairment only become disabling if dental services fail to take them into consideration. The provision of adequate domiciliary dental services will be essential to provide professional advice and treatment to residents in care facilities and increasing numbers of frail people living at home or in sheltered accommodation (BDA, 2003).

Figure 1 Loss of vertical dimensions in a 68-year-old female who had been edentulous for more than 20 years

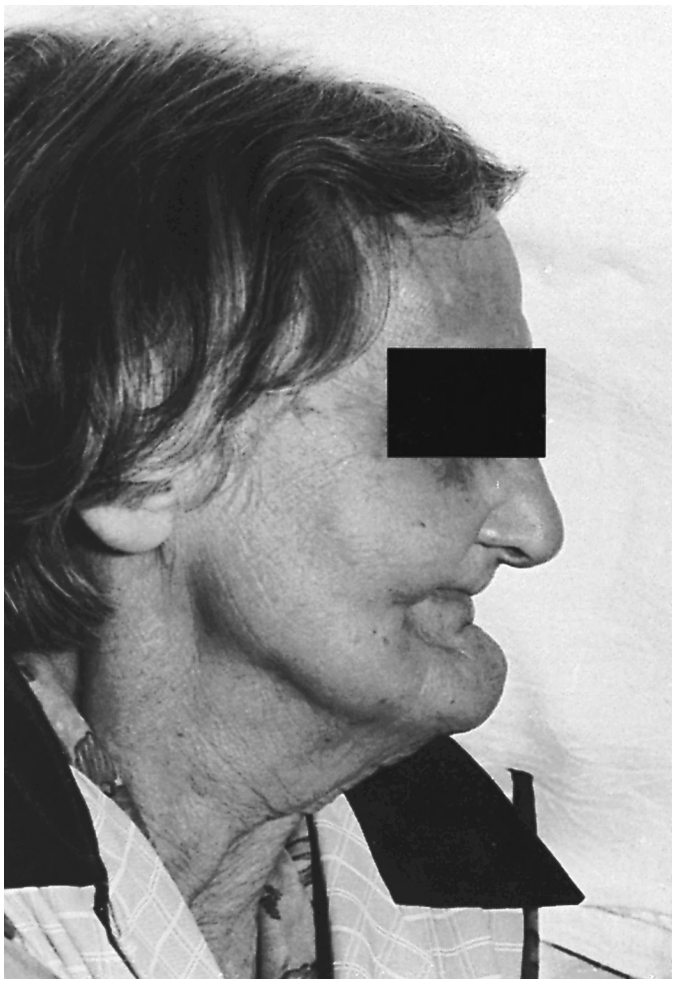

Figure 2 Loss of vertical dimensions in a 68-year-old female who had been edentulous for more than 20 years

Beliefs about lifespan and expectations of dentures may contribute to reasons for low levels of dental attendance among the edentulous. Inadequate advice following the provision of dentures may contribute to this. Misconceptions exist about the management and lifespan of dentures, even though denture-induced stomatitis and mucosal lesions are known to be associated with old, worn, and ill-fitting dentures. Lifespan of dentures is variable and depends upon individual changes in hard and soft tissues. Resorption of alveolar bone and occlusal wear can occur gradually with resultant reduction in vertical dimensions which may be associated with unsatisfactory aesthetics, an overclosed facial appearance, problems with mastication, cheek-biting and possibly tempero-mandibular joint dysfunction (Figures 1 and 2). Gradual adaptation and muscular control allow many people to compensate for loss of dentition. With gradual oral changes and habituation to changing oral status, it comes as no surprise that worn and ill-fitting dentures are perceived as functional and cosmetically acceptable. This, combined with an exaggerated expectation of the lifespan, may contribute to a fall in dental attendance with advancing age, particularly among the edentulous.

Carer-related barriers include deficiencies in knowledge of basic oral hygiene among health care professionals and carers, chronic inadequate oral hygiene practices, and limitations of workloads on long-term care staff (Fiske *et al.*, 2000; Frenkel *et al.*, 2000; Longhurst, 1998). Lack of information on how to access dental services and difficulties in arranging dental care are reported (Lester *et al.*, 1998).

Professional barriers are also identified (BDA, 2003; Fiske *et al.*, 2000). Older patients are less likely to receive restorative treatment than younger patients. Lower socioeconomic groups are less likely to receive advanced dental care, and previous dental attendance patterns influence treatment patterns. Negative stereotypes of older people and lack of confidence in treating older patients with more complex medical histories may contribute to limitations in treatment planning and reluctance to provide dental care. Reasons given for not providing dental services for people with impairments are that it is too time consuming in relation to remuneration, and lack of experience and training (Oliver and Nunn, 1995). The level of dental remuneration for NHS dental care is increasingly being regarded as financially

nonviable and many dentists are opting out of providing NHS coverage (Walls and Steele, 2001). Therefore, vulnerable groups who are frail and functionally dependent are likely to be the most disadvantaged by reduced access to NHS dental care.

Barriers to oral health and dental behavior are complex. The mechanisms by which these barriers may be lowered should be investigated in order to address the unmet oral health care needs and demands of older people (Lester *et al.*, 1998). Good oral health and access to dental care should be available to all older people on the basis of clinical need regardless of age, geography or home circumstances (BDA, 2003).

CLINICAL ORAL HEALTH CARE

The principle underlying oral health care for older people is to provide a service and standard of care that is qualitatively and quantitatively equal to that available to the population at large. This is acknowledged by the BDA in its policy document for the next two decades (BDA, 2003). Provision of oral health care requires a sound knowledge of clinical and preventive dentistry in the adult. Understanding of the aging processes associated with normality and disease, cognitive and attitudinal changes that may accompany aging, and socioeconomic influences in later life are fundamental in providing appropriate care. Knowledge of the effects of organic disease, treatments, and tissue changes on physical and mental well-being is essential. Functional changes that accompany the aging process and an increasing tendency toward organic disease are well documented (Walsh *et al.*, 1999). Deteriorating oral health should not be accepted as an inevitable consequence of aging, and the benefits of good oral health as a contribution to holistic health are recognized.

Oral changes that occur with age are frequently the consequences of earlier disease, wear, and habits. Muscle activity may decline and is hastened by early tooth loss. Speech may be affected by tooth loss and taste perception may be reduced. Xerostomia and a subjective feeling of dry mouth are receiving increasing attention. Age and medication are significant risk factors for xerostomia but medication is a better predictor of risk than age (Field *et al.*, 2001). Xerostomia is more prevalent among institutionalized populations and those on multiple prescribed medications (Locker, 2003). Onset of xerostomia is usually associated with other oral symptoms, problems with eating, communication, and social interaction.

Saliva has an important role in preserving oral health. Its functions include

- lubrication of soft tissues in speech and mastication;
- mechanical flushing of food and debris;
- neutralization of acids created by breakdown of sugars by bacterial plaque;
- remineralization of enamel surface;
- bacteriostatic and bactericidal effect;
- denture adhesion and retention.

A reduction in salivary secretion therefore increases the potential for dental caries, periodontal disease, oral infections, and problems with the retention and comfort of dentures. Composition of saliva with age appears to have fewer protective properties and combined with xerostomic side-effects of medication can have a significant negative impact on oral health status and quality of life (Locker *et al.*, 2002a; Locker, 2003).

Masticatory ability may be reduced by opposing tooth loss, lack of posterior teeth, poor or ill-fitting dentures, or even the absence of dentures (Figures 1 and 2) (*see also* **Chapter 24, Epidemiology of Nutrition and Aging**). While the loss of teeth does not conclusively lead to malnutrition, lack of masticatory efficiency does lead people to modify or adapt their diet to avoid material which is tough and fibrous. Poor diet and impaired food choice is associated with declining number of teeth and increasing age (Daly *et al.*, 2003). Edentulous subjects and those with poor oral health are more likely to report limitations in chewing ability (Locker *et al.*, 2002b).

Surveys of frail and functionally dependent older people report high levels of oral pathology, high levels of plaque, and moderately severe gingivitis in dentate subjects unable to perform their own oral hygiene (Frenkel *et al.*, 2000; Simons *et al.*, 1999; McNally *et al.*, 1999). Much oral pathology in edentulous subjects is associated with inadequate denture hygiene (Figure 3), denture misuse, and loose or ill-fitting dentures and is significantly related to clinically diagnosed denture stomatitis (Simons *et al.*, 1999) (*see also* **Chapter 23, Oral Disease**).

The incidence of oral cancer is increasing in Europe and throughout the developed world. It is primarily a disease of older age groups with a mean age of diagnosis of approximately 60 years (*see also* **Chapter 23, Oral Disease**; **Chapter 128, Cancer and Aging**). Incidence in males is around twice that in females although rates in women are rising. Smoking is a major risk factor (*see also* **Chapter 14, Smoking in the Elderly**). Pipe smoking has been linked to lip cancer, and chewing tobacco to intra-oral cancers. Alcohol also features as a risk factor and acts synergistically with tobacco (*see also* **Chapter 15, Alcohol Use and Abuse**). Chewing betel nut products and quat, practices that occur in certain ethnic minority groups, are implicated in oral malignancy. Long exposure to sunlight is also linked with lip cancer.

Cancerous and precancerous oral lesions are frequently painless until the more advanced stages of disease. Signs and symptoms include persistent oral ulceration, warty lumps and nodules, and red, white, speckled or pigmented lesions (*see also* **Chapter 23, Oral Disease**). Onset of symptoms may be associated with difficulty with speech or swallow and enlarged cervical lymph nodes. Early diagnosis and treatment improve prognosis and therefore regular oral examination is recommended as a screening strategy, which should target people who are not in regular contact with dental services. The dental team is in a unique position to screen for oral cancer and premalignant conditions. However, other health professionals should be trained to distinguish between

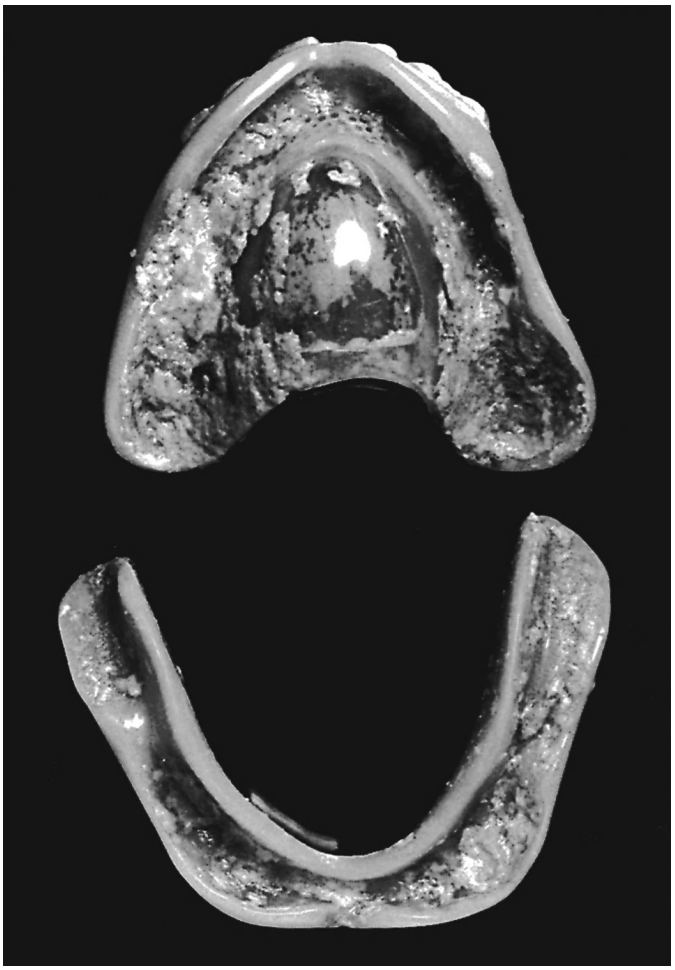

Figure 3 Fresh and old food deposits and bacterial plaque present on the fit surface of dentures being worn by a frail and dependent older patient in continuing hospital care

healthy and diseased tissue and screen for abnormalities as part of routine oral assessment, with a care pathway for referral when abnormalities are noted.

CLINICAL DENTAL CARE

Older people are not a homogenous group and treatment planning must take account of subjective need and demand and the individual's mental and physical health in order to achieve a successful outcome that is acceptable to the patient.

A detailed medical and social history is essential, and when appropriate, information on care and support services is desirable. Advice and support from family, carers, and the multidisciplinary team should be sought for patients with cognitive impairment in order to clarify the individual's capacity for informed consent to the proposed treatment plan. It is the clinician's responsibility to assess the patient's capacity for informed consent, to consult widely, and to act in the best interests of the patient (BSDH, 2004). Detailed referrals help reduce unnecessary ambiguity or inconvenience at initial assessment, and reduce the stress to patient or carer associated with dental care.

It may be difficult to assess the benefits of treatment to improved quality of life; however, relief of pain and discomfort is a priority and treatment plans may be modified as a result of physical and mental illness, and pharmacology. The individual's ability to maintain oral hygiene and cooperate in the provision of clinical dental care are factors that influence treatment planning. Lengthy clinical techniques may be contraindicated and the retention of decayed teeth advised. Dentists unfamiliar with the socio-medical factors associated with aging may find difficulty in adjusting their normative assessment to the needs and abilities of the individual. However, the overall physical and psychological well-being of the patient must be a constant consideration.

Restorative Care

The principal features associated with the aging dentition are attrition, erosion, and abrasion. Increased length of clinical crowns as a consequence of long-standing periodontal disease and gingival recession, over-eruption of unopposed teeth, tooth mobility, and exposed root surfaces make oral hygiene measures more complicated and increase susceptibility to caries and periodontal disease.

Restoration of the dentition can pose problems due to structural changes in dentine, which becomes harder and more brittle with age. Sclerosis may cause narrowing of the root canals with consequences for the success of endodontic treatment. Provided that roots and periodontal tissues are relatively sound, preservation of the dentition is recommended. Partial dentures should be designed before restoring teeth so that features for retention can be incorporated into tooth restoration. Complex partial dentures are generally contraindicated for patients with impaired comprehension or manual disability. The decision to render someone edentulous is not taken lightly. Older people exhibit a reduced learning ability, which influences adaptation to dentures. If complete dentures are proposed, gradual transition via partial dentures assists the process of adaptation and learning. The advantages of tooth and root retention lie in preserving the periodontal membrane, which provides proprioceptive feedback in chewing and helps to maintain alveolar support for dentures or over-dentures.

Age-related oral changes require extra clinical care in extracting teeth. Soft tissues are more fragile and exhibit slower healing. Teeth are more brittle and more prone to fracture if heavily restored. Extraction of maxillary roots close to the maxillary antrum may lead to the development of an oro-antral fistula. Chronic periodontal disease leads to hypercementosis, which increases risk of fracture during extraction, and osteoporosis poses risks of pathological fracture. Surgical extraction may therefore be necessary except when teeth are mobile through periodontal disease. The extraction of asymptomatic retained roots may be contraindicated in the presence of other risk factors; however, pain relief remains a priority.

Extractions must be considered in the light of medical complications and pharmacology, and are best carried out under local anesthesia with a sympathetic and reassuring approach. Mild sedation may be necessary to relieve anxiety and increase cooperation. If multiple surgical extractions are indicated in anxious or uncooperative patients, treatment should be provided under sedation or general anesthesia, with due assessment of the medical history and associated risks.

Generally, simple rather than complex restorations are more successful; the final assessment must be based on the individual's choice, their ability to receive treatment, and standard of oral hygiene. New materials and atraumatic restorative techniques (ART) require minimal tooth preparation. More complex restorative techniques need to be considered in relation to the number of visits, the duration of clinical time, and the potential for deterioration in self-care with impairment or disability.

If minimal intervention and clinical time is indicated, partial dentures may be the choice to restore occlusion. They should be designed for ease of insertion and removal, and incorporate design features for cleanliness and plaque reduction. Keeping gingival margins free from food residues reduces the risk of plaque accumulation (Figure 4). Clasps should be designed or modified to ensure atraumatic insertion and removal. Reduced dexterity or manual disability may require further design modifications so that the denture can be inserted and removed by wearer or carer.

Recurrent coronal caries and carious activity at the margins of existing restorations are prominent features in the neglected dentition. Large intracoronal restorations are avoided due to brittleness of dentine. Rather than replacing and extending existing restorations, it is better to add to them, repairing marginal deficiencies as necessary. For more advanced restorative treatment, the patient must be capable of maintaining good oral hygiene.

Cervical and root caries are significant problems in the presence of gingival recession and poor oral hygiene. Restoration may be complicated by erosion or toothbrush abrasion (Figure 5). Amalgam is not the material of choice for aesthetic restoration of anterior teeth. Restorative techniques for cervical caries have improved with new materials that bond directly to enamel and dentine, and require less invasive tooth preparation. However, they do have limitations in their bonding capacity.

Attrition due to excessive wear may be the result of earlier tooth loss placing abnormal loads upon the remaining teeth (Figure 5). Sensitivity may develop as a result of loss of occlusal or incisal enamel surfaces. Reduction in vertical facial dimensions gives an overclosed appearance. Preventing further tooth wear is a priority, although the level of attrition must be considered in relation to the person's age and ability to accept treatment (Figures 5 and 6). Slight wear does not necessarily merit treatment; moderate wear is usually treated conservatively. In extreme cases, attrition is repaired by crowning or with adhesive filling materials. If bruxism is a

Figure 5 Self-caring 85-year-old male with attrition and abrasion. Attrition (wear of the incisal and occlusal surfaces) caused by loss of posterior teeth. Abrasion at the cervical margins caused by horizontal toothbrushing

Figure 4 Gingival hyperplasia associated with nifedipine therapy, and complicated by a poorly designed denture with the clasp lying too close to the gingival margin and encouraging plaque accumulation

Figure 6 The same 85-year-old male with no denture experience, successfully wearing a partial upper cobalt chrome denture to restore the loss of posterior teeth. Denture design keeps gingival margins as free as possible

feature, a soft vinyl occlusal guard worn at night may prevent further wear and interrupt the habit.

With excessive loss of vertical dimension, it is advisable to acclimatize the patient gradually to the increased vertical height by providing a removable bite-raising appliance to cover occlusal surfaces. An over-denture retained on existing teeth or a cast cobalt chrome splint covering occlusal surfaces may be an alternative to multiple crowns (Figure 7). Major restorative measures are contraindicated if the patient cannot accommodate to increased vertical dimensions.

Erosion caused by excessive intake of acidic food, recurrent vomiting or reflux may cause sensitivity. Medical history and dietary analysis should establish the cause, although it may more rarely be related to previous occupational exposure to acid aerosols. Topical fluoride preparations to remineralize enamel surfaces and relieve sensitivity, and dietary advice, and protective splints may be required.

Figure 7 A cobalt chrome bite-raising appliance which fits over the lower teeth to prevent further occlusal attrition

Figure 9 After treatment: upper anterior teeth restored with porcelain veneers and a partial acrylic denture (By courtesy of A. Ali)

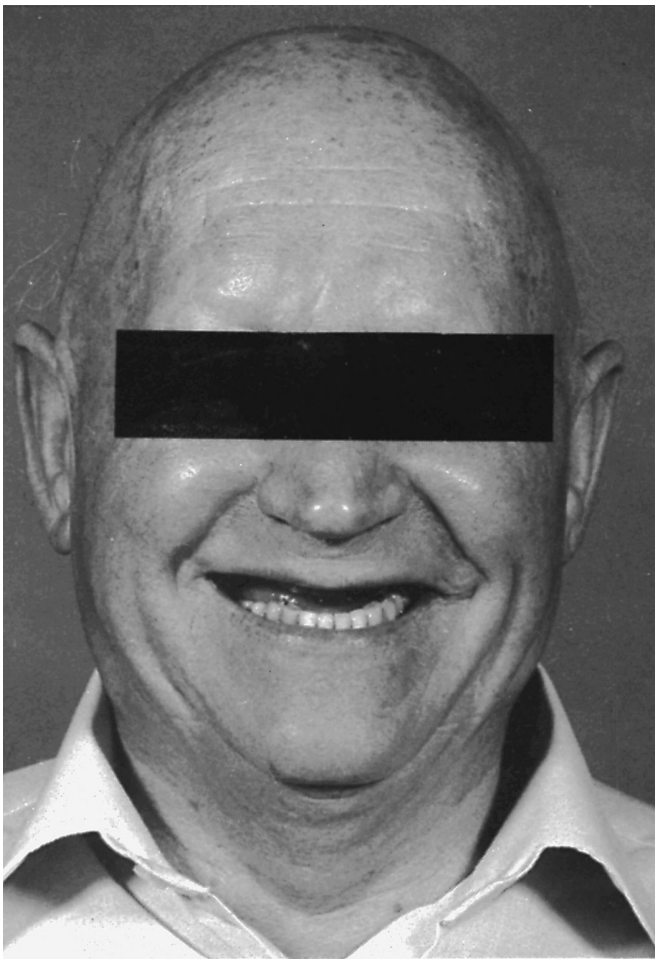

Figure 10 Male aged 68 with fractures and worn maxillary incisors (By courtesy of A. Gilmour)

Abrasion caused by vigorous or incorrect toothbrushing action creates distinctive cavities in the cervical area (Figure 5). Abrasion superimposed on cervical caries may

complicate restoration, and tooth-brushing techniques need to be modified to prevent further damage. Porcelain veneers are effective in cosmetically restoring labial enamel surfaces (Figures 8 and 9). The technique is less destructive of coronal tissue than conventional crowning and the veneer is bonded or cemented to the labial surface. The technique does not produce very aesthetic results with excessive gingival recession.

Teeth and roots may be restored or crowned and retained beneath an over-denture (Figures 10 to 15; the figures provide a case study to illustrate an over-denture in a 68-year-old male). Endodontic treatment may not be necessary and unsuccessful if root canals are sclerosed. Modification of coronal tissue to support a partial denture or the construction of crowns to receive precision attachments retaining a partial denture are accepted and useful methods of improving denture stability and distributing occlusal forces (Figure 16).

Complex bridge work is more rarely indicated. Tooth preparation involves lengthy clinical procedures and supporting teeth will need to withstand the extra occlusal load. Oral hygiene requirements are more stringent and may be difficult for the individual with limited dexterity or diminished self-care. Adhesive bridges require minimal tooth preparation and less destruction of abutment teeth; they provide an acceptable method of replacing one or two missing teeth (Figures 17 and 18) although problems of adhesion to enamel occur in older agegroups. Bonding the crown of an extracted tooth to adjacent teeth acts as a temporary solution (Figure 19); however, the bond must be secure to reduce the risk of displacement and accidental inhalation.

Figure 11 Porcelain crowns in the lower jaw and loss of posterior teeth have contributed to the excessive wear of the upper anterior teeth (By courtesy of A. Gilmour)

Periodontal Treatment

Periodontal health is maintained by effective tooth brushing to control bacterial plaque. With diminished ability for self-care, oral hygiene tends to deteriorate, and coupled with a

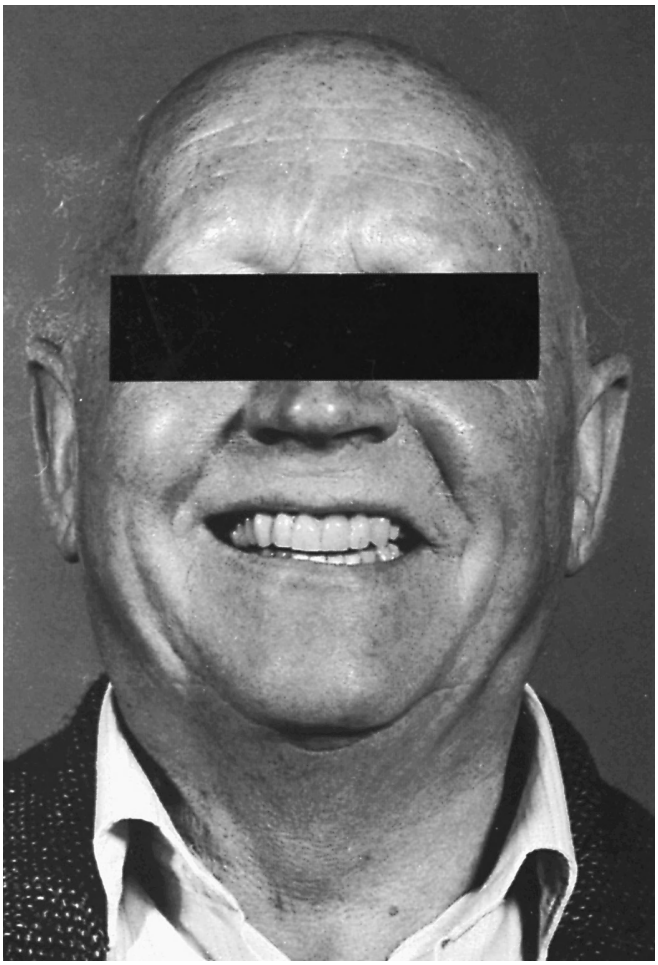

Figure 15 Completed treatment with upper over-denture and lower partial denture to replace missing posterior teeth (By courtesy of A. Gilmour)

Figure 16 Partial upper cobalt chrome denture retained by precision attachments to canine and premolar crowns (By courtesy of A. Ali)

lack of dental health education and a belief in the inevitability of tooth loss, can lead to a significant deterioration in periodontal health. Pain or sensitivity due to recession, periodontal disease or gross sepsis may result (*see also* **Chapter 23, Oral Disease**). The prevalence and severity of periodontal disease increases with age; however, there are problems of differentiating between the aging process and the effects of disease. Since periodontal health can be maintained by good plaque control, it is a matter of concern that older people who are dependent for personal care do not receive appropriate assistance with oral hygiene (Frenkel *et al.*, 2000).

Resorption and gingival recession lead to an increase in the interdental space and a tendency to greater plaque accumulation, pocketing, and ultimately tooth mobility unless plaque is controlled effectively. Ill-fitting or poorly designed partial dentures increase the tendency for plaque accumulation (Figure 4). These areas are more difficult to clean by conventional brushing methods. Individual oral hygiene advice and instruction is essential.

Figure 17 Before: malocclusion and tooth loss causing problems for construction of an aesthetic partial denture

Figure 18 After: Maryland adhesive bridges which are bonded to the palatal surfaces of maxillary incisors and canines, and to the labial surfaces of mandibular incisors. The patient's high lip line concealed the visible metal attachments of the bridge in the lower jaw and produced an acceptable aesthetic result

Figure 19 The crown of an extracted tooth used as a temporary bridge, cemented to adjacent crowns with composite resin (By courtesy of A. Ali)

Thorough and regular prophylaxis may be preferable to extensive periodontal surgery. Professional removal of plaque and calculus, and oral hygiene instruction is best delivered by a dental hygienist with good communication skills, and carried out under the written prescription of a dentist. It is essential that hygienists receive appropriate training to provide care for older people.

Toothbrush modification may be necessary for people with impaired dexterity; simple adaptations and commercial aids are described (Griffiths and Boyle, 2005a). Interdental brushes may be more effective for cleaning isolated areas. Electric toothbrushes with a wide grip may be more acceptable. Flossing is a technique requiring manual dexterity, and gauze or tape may be easier to handle and more effective for cleaning around isolated teeth.

Chlorhexidine gluconate has a specific effect in inhibiting the formation of dental plaque and is an effective adjunct to plaque control, particularly if oral hygiene deteriorates and mechanical cleansing is inadequate. Commercial brands are available as mouthwash (0.2%), mint flavored mouthwash (0.12% and 0.2%), gel (1%), and spray (0.2%); spray delivery is useful when access is limited, and gel for dysphagic patients. Long-term use of Chlorhexidine stains teeth and in rare cases produces idiosyncratic mucosal irritation but the benefits in reducing plaque far outweigh the side-effects.

Effective mechanical plaque control and dietary control of sugar intake are the most effective methods for prevention of periodontal disease and dental caries. COMA (1992) recommends that "*elderly people should restrict the amount and frequency of consumption of non-milk extrinsic sugars because their teeth are more likely to decay due to exposure of tooth roots and reduced salivary flow*". It is important that dietary advice for oral health does not jeopardize the health and well being of the individual. A significant energy intake is derived from sucrose and fats, foods with little or no nutrient density. Guidelines for putting oral health into the context of healthy eating for older people can be adapted for particular client groups and care settings (Fiske and Lewis, 1995).

Prescription of sugar-based medicines for dentate persons is also a matter of concern, and of even greater concern if taken with xerostomic medication (Field *et al.*, 2001). Sugar-free alternatives should be considered. Food supplements taken orally to ensure adequate nutritional intake are a risk factor for dental caries in dentate persons of all ages as many of the these products contain cariogenic sugars and carbohydrates. In order to encourage intake, cartons may be sipped at frequent intervals throughout the day, thus increasing the tooth–food contact time. Aggressive preventive measures are therefore essential for dentate persons on xerostomic medication, long-term sugar-based medication or cariogenic food supplements.

Toothpaste containing fluoride or monofluorophosphate is advocated routinely to remineralize and strengthen surface enamel, increasing its resistance to decay. Sensitivity due to recession can be relieved by toothpastes containing strontium chloride hexahydrate or formalin. However, oral hygiene products may appear expensive and have a low priority for people managing on reduced domestic budgets.

Topical fluorides confer significant resistance to decay and reduce dentine sensitivity but should not be prescribed without prior reference to the fluoride content of the local water supply; fluoridation is currently confined to approximately 10% of water supplies in the United Kingdom (West Cumbria, West Midlands, and the North East). Fluoride varnish is applied professionally. Fluoride mouthwashes (sodium fluoride 0.05% daily and 0.2% weekly) are available as pharmacy medicines. Concentrated fluoride mouthwash (sodium fluoride 2%) is not recommended for people who have difficulty preparing the correct dilution. Brush on fluoride gel (0.4% stannous fluoride) may be more suitable for self-administered prevention. The older dentate person who is medically compromised or at risk of caries or periodontal disease due to diminished self-care or reduction in salivary flow, will benefit from preventive measures which include topical fluorides, chemical plaque control and saliva substitutes. Oral care procedures and a guide to assessment for the dependent patient are summarized (Tables 2 and 3) (Griffiths and Boyle, 2005b; Griffiths and Lewis, 2002). It is important to ensure that toothpaste residue is removed after brushing because of the drying effect.

Prosthetic Treatment

Normative prosthetic need is high; however, demand is considerably lower. Denture replacement will be concentrated more and more in the elderly population, and adults needing a full clearance will be increasingly elderly. Treatment should aim to eliminate pathology and provide comfort, improve aesthetics and masticatory ability, but with due consideration of the individual's needs, previous denture experience and ability for self-care.

Table 2 Summary of oral care for the dependent patient (Griffiths and Boyle, 2005b)

NB: Gloves should be worn for all oral hygiene procedures
Prepare appropriate oral hygiene materials
Place the patient in a sitting or semi-fowler's position to protect the airway
Protect the patient's clothing
Remove dentures or other removable appliances

- *Dentate patient*
  If necessary insert a mouth prop to gain access
  Floss interproximal surfaces of teeth, taking care not to traumatize gingivae
  Brush all surfaces using Fluoride toothpaste or Chlorhexidine gel. (Remember that traditional foaming agents in toothpaste inactivate chlorhexidine so use one or other or alternate their use, at different times of the day).
  Rinse or aspirate to remove saliva and toothpaste
- *Dentate and edentulous patients*
  Gently retract cheeks and brush inside surfaces with soft, gentle strokes
  Using gauze to hold the tongue, gently pull the tongue forward and brush surface gently from rear to front
  Gently brush palate
  Towel or swab mouth if toothbrushing is not possible
  Aspirate throughout procedures if airway is at risk
- *Dentures and removable appliances*
  Brush vigorously with unperfumed household soap
  Pay particular attention to clasps
  Rinse well in cold water
  Saliva substitute may be required before replacing denture in the mouth
- *Intubated patients*
  Reposition tube frequently to prevent lip soreness
  Ensure tube is secure before proceeding with oral care
  Proceed with oral care as appropriate

Successful restoration of occlusion with partial or complete dentures will depend upon patient motivation and the ability to learn the skills necessary to control and use them. Aesthetics may be of more importance to some patients than function. Improved aesthetics and masticatory ability should be stressed and may be effective in improving motivation. Previous successful denture experience is a useful indicator of likely success with new dentures; the main difficulty is in making an accurate assessment of the patient's motivation and adaptability. It may be necessary to approach this through the multidisciplinary team and enlist the advice and support of relatives and carers, particularly if the patient is confused or cognitively impaired.

Learning to wear dentures is more difficult for the older person as muscular patterns are established and learning ability is decreased. Gradual rather than sudden changes in the dentition make adaptation easier. Failure of partial dentures is frequently due to overloading abutment teeth and plaque accumulation leading to periodontal disease, but patient motivation and regular recall are as important as design in determining success rates. With poor motivation, extraction and the provision of dentures may be contraindicated.

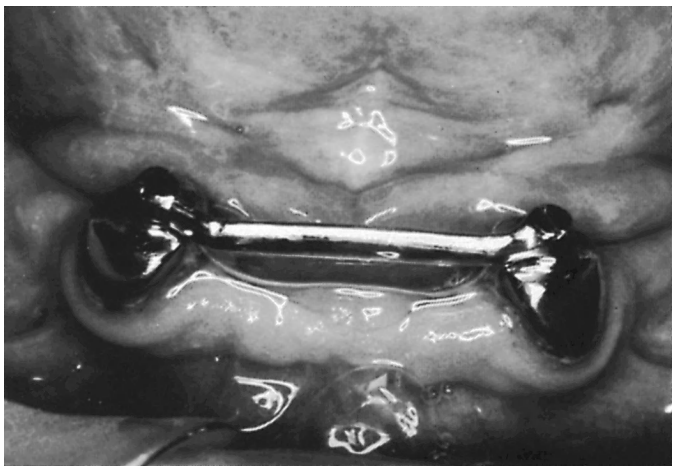

Figure 20 Dolder bar anchoring the crowns of mandibular canines (By courtesy of A. Ali)

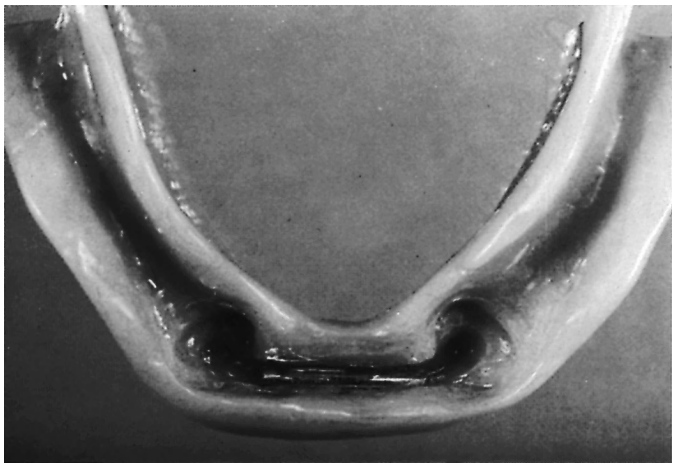

Figure 21 The fit surface of the lower denture which is anchored by the Dolder bar and helps to maintain denture stability (By courtesy of A. Ali)

Over-dentures that cover retained roots and suitably adapted crowns are beneficial in retaining proprioceptive feedback and tactile sensation. Modifications or attachments to the existing teeth help locate the denture and improve stability with obvious consequences for patient satisfaction (Figures 20 and 21). Good oral hygiene must be maintained particularly at the fit surface of the over-denture. If extraction and progression to full dentures is proposed, it should, if possible, be carried incrementally by first providing a training appliance to allow gradual acclimatization before progressing to the edentulous state and complete dentures (Figure 22). Immediate addition of teeth to the training appliance when natural teeth are extracted can provide uninterrupted function and gentle adaptation. If a more rapid transition is required, extractions followed by insertion of immediate complete dentures may be indicated. Pre-extraction models permit a more accurate copy of the previous dentition both in terms of anatomical position of teeth and appearance.

Table 3 Oral Assessment Guide (Griffiths and Lewis, 2002)

Figure 22 Clear acrylic partial training appliance constructed for a 58-year-old male with cerebral palsy and intellectual impairment

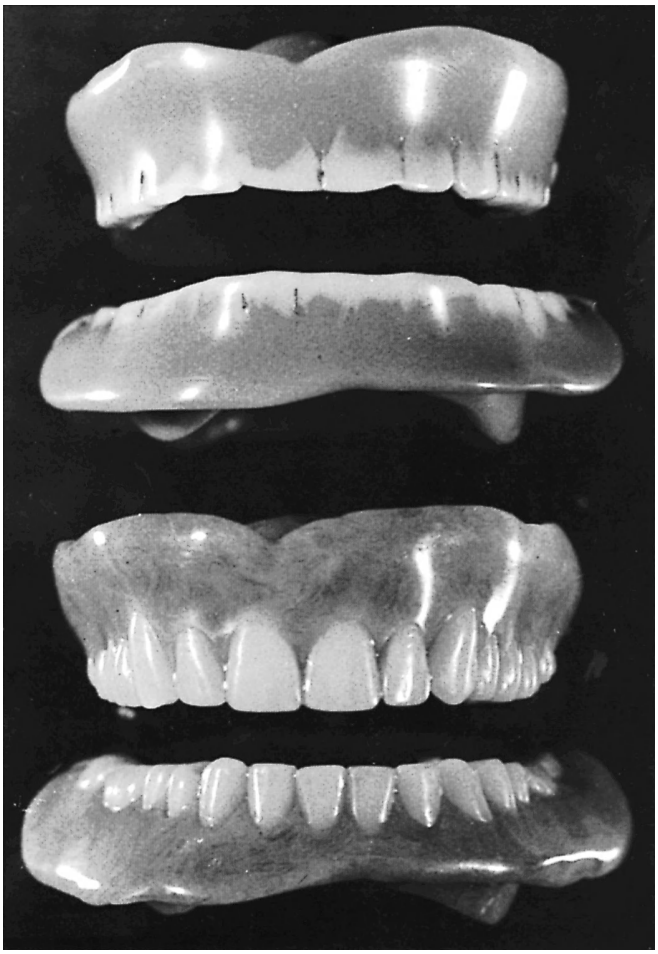

Figure 23 Old worn acrylic resin dentures showing gross occlusal wear and abrasion (above) and new dentures (below)

For the edentulous patient, complete dentures can restore function and aesthetics. Patients frequently do not complain about ill-fitting dentures because of gradual adaptation to progressive oral changes; therefore, it may be difficult for the older denture wearer to adapt to new dentures (Figure 23). In the absence of major defects, ill-fitting dentures can be relined. Temporary linings allow a more even distribution of occlusal forces and allow damaged soft tissue to recover before permanent reline or replacement. Permanent soft linings of silicone or plasticized acrylic resin may improve comfort if the mandible is atrophic. However, these materials lose their plasticity and should be replaced at regular intervals.

Contrary to popular belief, denture construction requires considerable skill and a significant level of cooperation. Impression taking can be distressing and requires compliance to obtain an accurate functional record. The copy technique provides a less invasive method of replacing dentures, while maintaining the contours to which the patient has become habituated but eliminating unsatisfactory features such as wear, poor occlusion or loss of fit due to alveolar resorption. It involves taking an impression of an existing denture. Therefore, a previous set of dentures, however old or unsatisfactory, is essential. Denture retention relies upon the size and shape of alveolar ridges. Gross alveolar resorption reduces retention and stability. Anatomical features that interfere with retention can be eliminated with preprosthetic sulco-plasty or surgical removal of the mylohyoid ridges and benefit healthy patients who can tolerate the procedure. Assessment of the patient's motivation to wear dentures is essential before considering surgery.

Reduced salivation impairs retention and causes discomfort; saliva substitutes provide symptom relief and may improve retention. Pilocarpine is effective in stimulating salivary flow post irradiation and may provide relief for drug-induced xerostomia. However, some patients fail to adapt to new dentures in spite of good anatomical features for success. An upper "social" denture may satisfy the needs of patient or family in restoring appearance and speech. Older people who lose teeth in later life and have difficulty retaining and controlling dentures may benefit from implant-supported dentures provided that wound healing is not compromised by other medical problems.

Denture hygiene is a significant problem. Many denture wearers do not clean their dentures effectively. Nurses lack information on effective methods for denture hygiene (Barber *et al.*, 2002). Denture-related stomatitis may resolve with good denture hygiene, removal at night, and by ensuring adequate oral lubrication. Candidal infection is the most common pathogen in denture stomatitis (*see also* **Chapter 23, Oral Disease**); antifungal therapy may be necessary in conjunction with the above measures. When immediate or new dentures are fitted, patients are advised to wear them continuously for a limited period but with regular removal to allow scrupulous cleaning. After a period of acclimatization, patients should be advised to routinely remove dentures at night.

Denture cleaning procedures should be simple, consistent, and carried out after meals and at night. Cleaning over a sink of cold water reduces the risk of accidental fracture. Recommendations are summarized in Table 4; with the exception

Table 4 Care of dentures (Gloves should be worn when handling a patient's dentures)

Denture hygiene techniques	Acrylic resin (plastic)	Metal and acrylic resin	Temporary soft linings	Permanent soft linings
Rinse after every meal with cold water	√	√	√	√
Remove debris by brushing with soft brush using	Unperfumed household soap and water	Unperfumed household soap and water	Do not brush. Rinse well in cold water	Unperfumed household soap and water

Soak in alkaline peroxide solution (Steradent) using hand hot warm water	15 min	15 min. Do not use acid cleaners	Do not use alkaline peroxide cleaners	
Rinse well with cold water before insertion	√	√	√	√
Store in cold water over night	√	√	√	√

of temporary soft linings which are easily damaged, brushing is the most effective method of cleaning dentures. Effervescent cleaning tablets can be confused with sweets and were implicated in the accidental death of an elderly inpatient (Mackenzie, 1982). Hard calculus deposits cannot be removed by brushing and require professional attention. Immersion in an ultrasonic cleaning bath is effective but care must be taken to ensure dentures are labeled to avoid possible confusion (Figure 24). Clear advice about denture management and hygiene, both verbal and written, should be provided to patient and/or carer. Advice should cover expectations, limitations and lifespan, pain management, problems with speech and salivation, denture hygiene, and labeling.

Soft tissues need oral care in the dentate and edentulous (Tables 2 and 3). Gentle brushing with a soft toothbrush will remove plaque and food debris which tend to accumulate mainly in the buccal sulci. A sweeping action with a gauze-covered finger using chlorhexidine gluconate gel or mouthwash may be substituted if brushing cannot be tolerated. There is little scientific value in the use of foam mouth sticks except for uncooperative and terminally ill patients (Bowsher *et al.*, 1999).

Recommendations are made for routinely naming dentures particularly on admission to residential or continuing care (Barber *et al.*, 2002; Fiske *et al.*, 2000). Few dentures are marked in construction despite long-standing recommendations; when asked, patients are generally in favor of having them *named*. There are additional benefits in identification at postmortem or of unconscious or amnesic persons. In the author's experience of working in acute and continuing care hospital services most referrals for replacement of lost dentures are from acute wards. The emotional distress of being without dentures for several weeks while new dentures are being made cannot be quantified. Denture construction is both labor intensive and costly; it involves a minimum of five visits and presupposes the patient's mental and physical ability to cooperate with treatment. In a number of cases, this is a contraindication to treatment.

Naming dentures is a cheap and simple procedure using a proprietary marking kit. Results are not as durable as laboratory methods and renaming should be carried out at regular intervals. If carried out on admission, it can reasonably be assumed that the dentures are the patient's property. It would help reduce the problem of confused patients wearing the wrong denture or when dentures have been erroneously collected "en masse"' for cleaning. The British Society for Disability and Oral Health (BSDH) recommends a policy for denture care that includes labeling and responsibility for the cost of replacement dentures (Fiske *et al.*, 2000). Naming dentures does not prevent loss, but if found, they can be returned to the owner (Table 5).

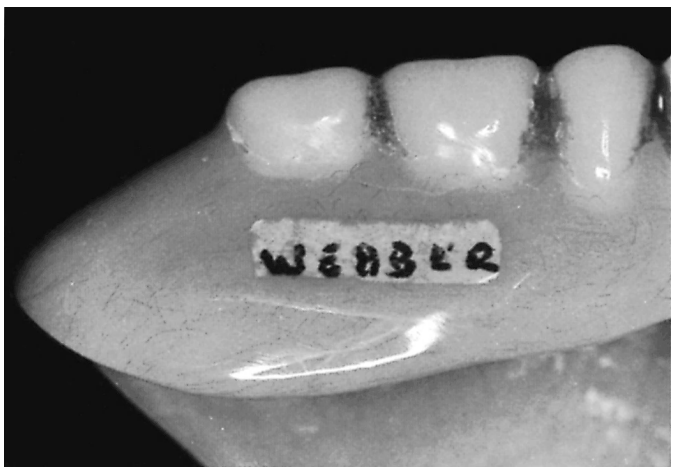

Figure 24 Labeled denture

PEOPLE REQUIRING SPECIAL CARE

Functionally independent healthy adults make up the majority of the older population; they will have increasing expectations about maintaining good oral health and appearance, and many will have the resources to take advantage of advances in cosmetic dentistry (BDA, 2003). However, frail and functionally dependent older people will largely fall within the remit of special care dentistry, which is evolving as a speciality concerned with the oral health needs of specific groups. Special care is defined as

"*those who by virtue of illness, disease and/or its treatment, disability, lifestyle or cultural practices, who are at greater risk of poor*

Table 5 Recommendations to develop local standards for oral health in residential and continuing care

1. Liaison between health, social, and voluntary agencies to identify residential and continuing care establishments without a dental service or with inadequate access to dental services.
2. Screening programs to identify baseline data for dental service planning and oral health promotion strategies appropriate to residents' needs.
3. Oral assessment criteria on admission to identify
   (a) risk factors for oral health;
   (b) individual oral care needs and develop an oral care plan;
   (c) appropriate oral hygiene equipment;
   (d) preventive and palliative measures;
   (e) need for and access to dental services.
4. A policy on the care and safe-keeping of a resident's dentures to include
   (a) denture labeling on admission with the resident's consent;
   (b) responsibility for the cost of replacement dentures if lost or mislaid.
5. Dental input to multi/inter-disciplinary assessment where appropriate including
   (a) procedures for access to pain relief, appropriate general and specialist dental services, oral hygiene advice, and support;
   (b) support for health professionals and carers in oral care;
   (c) procedures for ensuring continuity of dental care on discharge.
6. Training for health care professionals in
   (a) the scientific basis of oral health and disease;
   (b) oral assessment criteria and tools for oral assessment;
   (c) identification of risk factors and stressors for oral health;
   (d) current oral care practices appropriate to individual needs;
   (e) practical oral care to motivate, encourage, support, and assist residents to carry out oral, dental, and denture hygiene;
   (f) eligibility for free or partial exemption for the cost of NHS dental care;
   (g) accessing local dental services.
7. Oral health advice and support for residents, family, and carers, appropriate to their needs.
8. Oral health education and promotion for residents, carers, and health professionals which address
   (a) the oral health needs of residents;
   (b) dietary issues in the context of healthy eating for oral and general health.
9. Facilities for privacy, dignity, and comfort for personal oral hygiene and on-site dental screening, assessment, and treatment.
10. Negotiated standards and procedures for oral health which promote structure and process for putting theory into practice and which can be monitored/audited (Fiske *et al.*, 2000)

oral health, for whom the management of dental care poses other health risks or who experience barriers to the access and receipt of dental care" (Griffiths, 2000).

Gerodontology is a well-established specialty developed in response to the oral health needs and provision of care for older people with chronic debilitating physical or mental illness, pharmacology, and psychosocial problems. Both specialities are raising awareness of the oral health needs of frail and functionally dependent older people in residential care and in the community. Identification of those in the community presents the greatest challenge and it is therefore essential that the dental profession works closely with statutory and voluntary agencies to ensure people are aware of oral health care services available to them, and address the training needs of personal and professional carers.

A comprehensive assessment is essential at the start of any health intervention. Oral assessment is necessary at the first episode of care to identify existing oral health needs, risk factors, and appropriate preventive measures. During an acute phase of illness, the need for oral care requires monitoring and later during the phases of recovery and rehabilitation. There is no single assessment tool that weighs the different factors, quantifies risk status and subsequently translates into the degree and type of intervention required. Assessment tools which alert health professionals to problems can be adapted to different client groups and assist in the development of an oral care plan (Table 6) (Griffiths, 2002). More complex assessments require training to recognize the signs and symptoms of oral pathology. Furthermore, assessment facilitates the identification of individuals who might benefit from services.

Key areas that give an indication of oral health status and point toward objectives for care include

- *presence of existing symptoms and signs of oro-dental disease including early changes to dental and soft tissues;*
- *current mouth care practices and preventive behaviour, including dental service attendance patterns;*
- *presence of risk factors including systemic disease, medication, impairment, and disability;*
- *presence of key stressors for oral health* (Griffiths and Boyle, 2005c).

Oral assessment with consideration of the likely prognostic course of the disease at an early stage will help alleviate later problems and permit gradual adjustment to changes in dental status. Oral health assessment should be incorporated into routine assessment. It need not be confined to

Table 6 Oral health assessment by health professionals provides a mechanism for opportunistic identification of clients who have oral and/or dental problems, are not receiving regular dental care and/or are at risk of poor oral health. Subjective indicators include the ability to speak, smile or eat without pain or discomfort. This example of an Oral Health Assessment may be adapted to suit any client group or adapted for self-assessment. It is recommended that risk assessments are used in collaboration with local dental services in order to facilitate access to an appropriate dental service. The Community Dental Service is best placed to fulfill the role of facilitator. A response in a highlighted area signifies a need for further investigation or action (Griffiths and Lewis, 2002)

professional carers but should be incorporated into wider assessment by members of the multiprofessional team. Organizational links between health professionals and the dental profession facilitate the provision of appropriate dental care and preventive measures at the earliest opportunity to the benefit of patient and carer. These objectives can be best achieved by including dentistry within the multidisciplinary team (Fiske *et al.*, 2000).

There is a need to establish dental fitness at diagnosis for people with continuing health care needs, particularly when cognitive faculties deteriorate. Most oral and dental problems in Alzheimer's disease result from a progressive diminution in self-care (*see also* **Chapter 93, Clinical Aspects of Alzheimer's Disease**). The same principles apply to stroke and other neurological disorders which cause physical disability, and in particular, conditions which affect oro-facial musculature causing paralysis or sensory loss, impaired oropharyngeal reflexes, and a reduction in neuromuscular control (Griffiths, 2002) (*see also* **Chapter 71, Acute Stroke**; **Chapter 81, Muscle Disorders**). The dental team can make a significant contribution to the process of rehabilitation and quality of life. The effect of early advice and support should help to alleviate the stress and psychological morbidity among carers.

Advice on the potential oral side effects of medication, methods of overcoming manual limitations in oral hygiene techniques, instruction in techniques, which overcome disability and modifications to toothbrushes before the onset of poor or deteriorating oral hygiene, may help to motivate patient and/or carer. Information on chemical plaque control and preventive measures is essential. The dental hygienist is best qualified to deliver this under the guidance and prescription of a dentist who has examined the patient.

Oncology patients are at risk of distressing and potentially life-threatening symptoms and oral side effects (*see also* **Chapter 128, Cancer and Aging**; **Chapter 129, Oncological Emergencies and Urgencies**). Oral tissues are more prone to inflammation and infection. Patients may complain of disturbance of taste, dysphagia, soreness, and dry mouth. Xerostomia due to irradiation of the salivary glands encourages excessive plaque formation, which leads to characteristic decalcification of the enamel encircling crowns (Figure 25); this is particularly difficult to restore. Reduced salivary flow on thin and atrophic mucosa creates greater susceptibility to irritation. Dentures may cause discomfort or trauma. Detailed guidance for the oral care of oncology patients receiving radiotherapy, chemotherapy or bone marrow transplantation may ameliorate the serious oral side effects associated with treatment (Fiske and Lewis, 2001). A high standard of oral hygiene should be maintained together with necessary preventive or palliative measures. To maximize comfort, oral assessment, oral hygiene instruction, and preventive measures should be provided at diagnosis and

Figure 25 Post-radiation cervical caries encircling the teeth

repeated at intervals during treatment. Information on the anticipated oral side effects of treatment may be helpful to enable the patient to cope with discomfort and encourage greater attention to oral hygiene and acceptance of routine preventive measures.

Severely or terminally ill patients require increased daily attention to oral care and comfort (*see also* **Chapter 170, Management of the Dying Patient**). Standards of mouth care in professional care settings are inadequate and are based on the use of inappropriate tools and materials (Rawlins and Trueman, 2001; Fiske *et al.*, 2000; McNeill, 2000; Bowsher *et al.*, 1999). A high prevalence of oral symptoms and denture-related pathology affect the quality of life in terminally ill patients (Aldred *et al.*, 1991). Denture wearers experienced difficulties and more than half wore dentures at night. Candidal carriage is higher in terminally ill subjects; a clinical diagnosis of oral candidosis was made in 70% and isolated in 79% of the sample. More than half complained of oral dryness, which must be viewed in the context of pain relief by opiate derivatives that exacerbate xerostomia. Improved denture hygiene to reduce microbial contamination, removing dentures at night, temporary relines, and maintaining oral lubrication provide some relief. The dentist, hygienist, and nursing staff should collaborate to establish appropriate individual oral hygiene to minimize oral discomfort in acute illness and the final stages of life. However, it is the day-to-day responsibility of nursing staff to deliver appropriate oral care. An oral assessment guide for patients who are dependent, dysphagic, or critically ill will facilitate the identification of appropriate oral care (Table 3) (Griffiths and Lewis, 2002).

DENTAL SERVICES

Provision and improvement of dental services for the older population has been a matter of professional concern for many years. There have been major changes in the delivery of dental services in recent decades and changes in the organizational structure of the NHS. There will continue to be major changes in the delivery of primary dental care due to the current pace of legislative changes. Clinical governance, clinical guidelines, and new care pathways will also impact on how dental services are delivered within all dental services.

Responsibility for dental services has devolved from central government to Primary Care Trusts and Local Health Boards. As a result of local commissioning, traditional differences between general dental services and salaried services are likely to change. The role of the Community Dental Service (CDS) in monitoring levels of dental health in all sections of society and in identifying and providing services to patients requiring "special care" dentistry is being eroded by pressure to provide care for the general population who are unable to access NHS dental care. One in five adults in Britain claim that they experience difficulty finding an NHS dentist (McGrath *et al.*, 2001).

The BDA monograph makes comprehensive recommendations for dental services to meet the needs and requirements of the growing population of older people in the United Kingdom (BDA, 2003). The supply of dental services will need to change and be more accessible to people with restricted mobility. Local commissioning of dental services will need to be fully integrated within the NHS. While general dental services will be at the heart of providing primary dental care, health authorities will need to provide support for dental services to frail older people in residential care and within the community. It is essential that the role of the CDS is protected and developed as a provider of specialist care and advice for older patients in order to deal with the increased complexity of treatment demands. It is likely that responsibility for demanding contracts for dental services for older people will continue to lie with the dental profession and relevant pressure groups. Barriers to dental care need to be researched in the light of changes in the organization of NHS dental services and the availability of dental care.

Initiatives to increase service utilization by frail older people are recommended. People in residential care settings can be identified with relative ease as compared with those within the community. Assessment of risk factors can be carried out by nondental personnel. Functional assessment by health care teams is well recognized, particularly for people aged over 75 (*see also* **Chapter 132, Function Assessment Scales**; **Chapter 74, Stroke Rehabilitation**). Implementation of the "Single Assessment Process" and "Unified Assessment" provide an opportunity to include a basic oral health risk assessment into a comprehensive holistic assessment process (DoH, 2001a; WAG, 2002). An oral health care assessment is now a fundamental requirement in all health and social care settings in Wales (WAG, 2003). A simple questionnaire can highlight risk factors and alert professional carers to oral and dental needs (Table 6) (Griffiths, 2002). Liaison between hospital and CDSs provide a mechanism for coordinating and ensuring that older people have access to dental services on discharge. Access to dental care should be included in hospital discharge policy with the CDS acting as a facilitator in this process (*see also* **Chapter 159, Systems of Health Care: the United Kingdom, the United States, and Australia**).

Within long-term care facilities, numerous problems mitigate against routine provision of oral health care and encourage neglect (Fiske *et al.*, 2000; Frenkel *et al.*, 2000). Many institutions do not support a policy for oral health care. Guidance on the wide ranging issues of the needs and demands of residents, knowledge and skills of care staff, screening and oral assessment, diet and nutrition, oral health education and promotion, and access to oral hygiene equipment and dental services is designed to develop local standards for oral health care (Fiske *et al.*, 2000) (Table 5). Changes in nursing practice are slow to be addressed nationally although there is increasing interest in oral hygiene in the nursing press. Changes at a local level require the support of the relevant manager (Griffiths and Boyle, 2005d). Standards for oral health care in residential care facilities must be included in registration criteria by the Social Services Inspectorate.

Dental care in hospital is generally the responsibility of the hospital dental service; however, variation exists in service delivery throughout the United Kingdom. Where dental surgeries exist on hospital premises, quality of care also depends upon the adequacy of the facilities and equipment. A controlled area such as a clear treatment room can satisfy basic requirements. Procedures that generate aerosol droplet infection should not be carried out at the bedside because of the risk of aerosol spread of medically resistant bacteria and proximity of patients vulnerable to infection. Self-drive mobile dental units have been advocated but they are quite unsuitable for patients who are very frail or dependent. Acceptance of the dental team as recognized members of the multidisciplinary team serves to increase oral and dental health awareness with a potential for improved oral health for patients.

Domiciliary dental care has been available for many years for "*patients whose condition precludes attendance at a dental surgery*". Whereas most housebound patients have medical or mobility problems, there may be other social or psychological reasons for providing care at home. Domiciliary care is not widely known, neither is it offered routinely by general dental practitioners. Demand for this service is increasing as a result of demographic population changes, greater awareness of legislation to support equal opportunities for disabled people, increasing public awareness and the increase in the dentate population. Treatment usually comprises typically inexpensive, short duration procedures such as examination, hygiene procedures, denture provision and simple extractions. The development of atraumatic restorative techniques and materials have widened the scope of treatment that can be provided.

Limitations to providing dental care out of a clinical environment include health and safety issues such as manual handling and cross-infection control, the scope of dental procedures and lack of diagnostic radiography. Most of the current need is prosthetic, is noninvasive and requires very little in the way of complex equipment so can be provided in the home environment with minimal difficulty. Invasive procedures require portable equipment and the quality or complexity of care may at times be affected by the "unusual clinical circumstances". Cost of domiciliary equipment is prohibitive and purchase is generally confined to CDSs. Once dental fitness has been established or treatment completed, patients may be transferred to general dental practitioners for periodic domiciliary assessment, continuing care and prevention; withdrawal from NHS coverage makes this increasingly unlikely. Dentate patients may need domiciliary advice and support from a hygienist to maintain oral hygiene.

Surgical procedures carried out at home are confined to simple uncomplicated extractions. The support of family, carer or a medical ancillary worker may be required to provide after care for patients who have little support or live alone. The decision to proceed with any surgical procedures must include a thorough appraisal of the medical history and suitability of the domestic environment. Practicalities of cross-infection control must be evaluated before proceeding with surgical techniques. A mobile dental unit overcomes some of the disadvantages, permitting more complex restorative care while avoiding the stress of traveling to a dental surgery. The drawbacks of the initial expense must be weighed against the flexibility that a self-drive mobile unit provides in reaching a variety of isolated populations who might otherwise not receive treatment.

Domiciliary dental care is time consuming and the cost of purchasing portable equipment may be a financial disincentive to the general dental practitioner. The CDS is currently the major provider of domiciliary dental care in the United Kingdom. Liaison with local medical and dental practitioners, and health care professionals in developing a time efficient service is a function that the CDS is best able to provide. Screening, diagnosis, and advice at home may, in many cases, reduce inconvenience to the housebound, particularly if care cannot be provided at home and referral is necessary. The limitations and disadvantages for clinicians must be weighed against the advantages and benefits for the patient. The role of the CDS in providing domiciliary care must be protected and developed together with financial incentives to encourage general dental practitioners to provide domiciliary care. If these issues are not addressed, older frail or disabled people living in nonresidential settings will be at risk of being denied access to continuing oral health care services.

ORAL AND DENTAL HEALTH PROMOTION

Improvements in dental services will not alone improve the oral health of older people. Oral and dental health education programs that address the specific needs of the target group are more effective. A participative approach that encourages self-empowerment with an emphasis on informed decision-making is advocated. Programs need to be designed specifically for older people and adapted to address the needs of people who are physically or mentally impaired.

Key messages include dietary control of extrinsic sugars, effective plaque control, benefits of fluoride, care and use of dentures, smoking cessation, and regular dental attendance. This might, where relevant, include the use of sugar-free medicines and oral side effects of medication, and any other oral problems associated with specific conditions. Chair-side oral health information is considered to be more effective than mass media campaigns, and should be backed up with written information. However, this relies on dental attendance. For those who are not in regular contact with dental services, other mechanisms must be evaluated to deliver the key messages and provide advice on the local availability of dental services. Daytime television is suggested as an effective communication medium (BDA, 2003). Information must be provided in accessible formats and in a range of languages.

All health personnel should receive additional training to support the concept of primary oral health care (*see also* **Chapter 149, Geriatric Medicine Education in Europe**; **Chapter 157, Nursing (UK)**). This includes care providers in voluntary and social care settings. Training

programs need to stress how poor standards of oral hygiene can pose a serious health threat in relation to general health and aspiration infections (*see also* **Chapter 60, Aspiration Pneumonia**; **Chapter 61, Respiratory Disease in the Elderly**). With adequate training, there is no reason why people without nursing qualifications would be any less proficient in the identification of oral health problems and dental needs than the nursing professionals; however, high staff turnover and accommodating shift patterns can make this type of training difficult to organize successfully (BDA, 2003). There are conflicting reports of the effectiveness of oral health education programs. Improvements in the knowledge of care staff are reported (Frenkel *et al.*, 2001) but evaluation of a carers' training program after a year demonstrated that there had been no changes in practice and no measurable improvement in residents' oral health (Simons *et al.*, 2000). Local standards for oral health care and cascade training may help to overcome this serious barrier to promoting the oral health of frail or dependent older people. Pre and postregistration nurse training must address this historical lack of oral and dental health education.

Individual oral hygiene instruction, and continued supervision should be allocated to a dental hygienist, who is trained in communication skills, and has a major role to play in residential and community settings in educating patients and their carers. The attachment of a hygienist to continuing care facilities enables direct support to improve oral health and hygiene at a local level, reinforce standards for oral health and facilitate earlier identification of oral pathology.

Oral health should not be considered in isolation from general health but integrated into general health promotion and include strategies to facilitate contact with dental services. It should be an essential part of the curriculum for all health professionals as well as members of the dental team.

PROFESSIONAL TRAINING

Changing clinical needs and demands of the older population require changes in training for the whole dental team (BDA, 2003). Following guidance from the General Dental Council, gerodontology is receiving greater attention in the undergraduate curriculum (Thompson *et al.*, 2001) (*see also* **Chapter 150, Education in Geriatric Medicine in the United Kingdom**). The dental profession will need increased clinical skills to deal with the challenges of restorative care. Greater attention to communication skills will be essential, particularly for patients with cognitive impairment. Effective postgraduate and postregistration training programs are essential for dentists and professions complimentary to dentistry (therapists, hygienists, and dental nurses). It is recommended that by the time age discrimination legislation is put into effect in 2006, all members of the dental team will have received awareness training as it applies to patient care, as part of their curricula (BDA, 2003).

The paternalistic model of care is being challenged. Exposure to different client groups does not alone change attitudes or negative stereotypes. Appropriate teaching and experience of services for frail older people may help to overcome negative attitudes and the evolution of a five-year curriculum which is taking place in many dental schools may provide a focus for structured changes in undergraduate education. Dental public health, behavioral science, and special care dentistry in the undergraduate curriculum provide a further focus for addressing the sociological and behavioral aspects of aging, and perhaps help to promote a multidisciplinary and patient-centered approach to dental care. Through experience and familiarity with the problems, the rewards of working with and for older people may be enjoyed. While the debate into specialist training continues, postgraduate and vocational training programs will continue to be necessary to meet the challenges of an aging population.

SUMMARY

Dental services must address the problem of a large and diverse older population with a variety of dental needs. While current treatment needs are primarily associated with edentulousness, increasing numbers in the upper age range, greater levels impairment and disability, and lower rates of edentulousness will pose new challenges to the dental profession to provide more complex restorative care and satisfy expectations. Key issues are covered in depth in the BDA monograph (BDA, 2003).

KEY POINTS

- Universal access to NHS oral health care with free NHS oral health risk assessment from the age of 60.
- Development of dental services that address the needs of the frail and functionally dependent older people, including greater availability of domiciliary dental care.
- Proper resourcing of the CDS to provide specialist services and clinical leadership in providing care for older people.
- Undergraduate, postgraduate and postqualification training for the dental team in gerodontology and special care dentistry.
- Recognition of special care dentistry as a specialty.
- Mandatory oral health education for all professionals involved with health or social care for older people.
- Dissemination of information in a variety of formats to facilitate informed choice and access to appropriate oral health care.

Oral Disease

Donald Murray Walker

University of Sydney, Westmead, New South Wales, Australia

INTRODUCTION

Many people now retain most of their natural teeth into the later decades of life. Once they become edentulous and wear complete dentures, the habit of regular attendance at their dentist is broken. Doctors rather than dentists, therefore, may have the opportunity of regularly examining the mouths of this group of elderly patients who often first consult their doctor rather than their dentist about oral symptoms. Gloves and mask should be worn for the oral examination. A better source of light than the average battery pencil torch is recommended – a headlight or a dental unit light are ideal. A pair of dental hand mirrors serves both to illuminate the oral cavity (by reflected light) and retract the cheeks, lips, and tongue. Subtle changes in the oral mucosa are better detected by drying the surface with a gauze square or with a dental air syringe.

A systematic examination of the lips, cheeks, sulci, teeth, gingivae, retromolar triangles and floor of the mouth, the ventral and dorsal surfaces of the tongue, palate, and oropharynx in turn will ensure that early lesions are not missed. Dentures should be removed and their fit and cleanliness checked and the mouth examined for denture stomatitis (see below), traumatic ulceration, or mucosal hyperplasia at the denture periphery. Any facial swelling or restriction in mouth opening should be noted and the masseter, pterygoid, and temporalis muscles examined for spasm or tenderness. The neck should be palpated for enlarged lymph nodes.

Age changes alone in the teeth, oral mucosa, and salivary glands have little effect on oral health, but the common microbial diseases, such as caries, periodontal diseases, and thrush, remain prevalent with advancing age. Oral ulceration, leukoplakia, and carcinoma are important diseases in the elderly.

Age Changes in Teeth

The enamel becomes increasingly cracked ("acquired lamellae") with age and the surface concentration of fluoride builds up. Attrition, abrasion, and erosion are common (see below). Owing to the deposition of secondary (posteruptive) dentine, teeth become yellower and less sensitive, the pulp recedes from the crown and the root canal becomes narrow and threadlike. Starting at their periphery, the dentinal tubules become progressively obliterated by deposition of calcified peritubular dentine by the odontoblast processes. As a result, the teeth become less sensitive and their roots become translucent and more liable to fracture during extraction.

The odontoblast layer lining the pulp chamber becomes irregular and discontinuous. The pulp tissue is less vascular and cellular (Murray *et al.*, 2002) and undergoes a patchy fibrosis, or features pulp stones composed of dentine and fine calcific deposits. The layer of cementum on the roots becomes progressively thicker.

Tooth Wear

Excessive wearing away of the teeth is commonly the result of a combination of accelerated attrition, abrasion, or erosion.

Attrition

The incisal edges and cusps, and to a lesser extent the approximal surfaces, of the teeth are worn away during chewing. On the usual soft Western diet, the loss of tooth tissue is not clinically significant, unless the teeth are habitually ground together or clenched, often during sleep (nocturnal bruxism).

Abrasion

Misdirected and overenthusiastic horizontal toothbrushing produces substantial grooves at the necks of the teeth and sometimes gingival recession. Dentine exposed by this

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

abrasion is often sensitive, toothbrushing may be inhibited, and a plaque-caries sequence initiated. A soft toothbrush with a small head should be used and the technique corrected, with a demonstration by a dentist or dental hygienist (*see* **Chapter 22, Oral Health**).

Erosion

Excess consumption of grapefruit, lemon juice, or other soft drinks of low pH may demineralize the surface of the enamel and the underlying dentine. Eventually, shallow concavities appear on the labial surfaces and incisal edges of the maxillary incisors and the characteristically imbricated enamel surface becomes smooth and thin. By contrast, oral regurgitation of gastric acid due to repeated vomiting or in gastroesophageal reflux will progressively dissolve the palatal surfaces of the teeth. The margins of fillings appear raised above the adjacent eroded tooth surface.

Dental Caries

Older people in good general health generally enjoy better dental health than dependent chronically sick patients living in institutions, who may have more missing teeth or denture problems. People remain at risk from tooth decay in later life, often occurring at the margins of fillings and particularly on root surfaces exposed by receding gums. Xerostomia resulting from medication or other factors (see below) or a failure of toothbrushing or dental flossing or cleaning of partial dentures may also contribute to root caries. Sucrose-containing drinks, sweets, or snacks between meals or last thing at night may be a factor in caries susceptibility at all ages. Regular toothbrushing with a fluoride toothpaste and flossing and application of a topical fluoride gel by a dentist or a hygienist can have surprisingly good results in preventing or arresting caries in this situation. A 0.2% chlorhexidine mouthwash is an effective adjunct to mechanical measures in prevention of the accumulation of dental plaque.

GINGIVAE AND PERIODONTAL LIGAMENT

Age Changes

The gingivae (gums) recede slowly in adult life with minor loss of the periodontal ligament attaching the teeth to the alveolar bone, even in people with good dental plaque control. The changes are slight and do not usually cause tooth loss and "getting long in the tooth" may be regarded as a physiological aging process (Burt, 1994; Streckfus *et al.*, 1999).

Even in old age, only a minority of the population with risk factors such as poor dental hygiene, tobacco smoking, or diabetes mellitus have inflammatory periodontal disease severe enough to cause tooth loss (Burt, 1994) (see the following text).

Localized Gingival Swelling (Epulis)

The fibrous epulis, a localized chronic inflammatory hyperplasia of the gingiva, is a common reactive lesion, a response to an irritant such as dental plaque, calculus, or a cavity margin. The cause should be eliminated, followed by excision of the swelling.

Generalized Gingival Enlargement

Generalized enlargement of the gingivae may represent a chronic inflammatory hyperplasia induced by dental plaque. Medication is an important cause of a generalized swelling of the gingivae, associated with antiepileptics such as phenytoin (dilantin) or sodium valproate, the immunosuppressive cyclosporine, calcium channel blockers (nifedipine, diltiazem, nitrendipine, felodipine, verapamil), or tranexamic acid (Scully and Cawson, 2002).

Leukemia

Leukemic infiltration of the gingivae results in a dramatic enlargement in a matter of weeks, in contrast with the insidious increase in other types of swelling. This clinical feature of leukemia is more characteristic of the acute monocytic or myelocytic varieties.

There are gingival hemorrhages, which are spontaneous, free, and generalized, unlike the localized and limited bleeding typical of chronic gingivitis, which occurs only after eating or toothbrushing. In leukemia, mucosal purpura, and ecchymoses are also commonly found, or occasionally ulceration of the interdental gingival papillae resembling an acute necrotizing ulcerative gingivitis (Vincent's infection) may occur.

Scurvy

The hemorrhagic and erythematous gingivae in scurvy is an uncommon cause of enlarged gingivae. The body stores of vitamin C are often marginal ($<23\,\mu mol\,l^{-1}$) or as low as those found in clinical scurvy ($<1\,\mu mol\,l^{-1}$). Only dentate subjects show this scorbutic gingivitis, and the institutionalized elderly and alcoholics are most at risk.

Chronic Gingivitis and Periodontitis

Chronic periodontal disease may be more important than root caries as the major cause of tooth loss in older people. This commences as a gingivitis initiated by the accumulation

of dental plaque (biofilm) at the necks of the teeth. The gingivae, which are normally pink and stippled and firmly applied to the teeth, become dark red, edematous and glazed, and bleed easily. Only a minority of people are susceptible to progression to periodontal disease associated with specific anaerobic bacteria. The gingival sulcus becomes pathologically deepened to form a pocket from which an inflammatory exudate seeps, causing an offensive taste, halitosis, and bleeding. Gradually, the collagen fibers of the periodontal membrane are destroyed and the alveolar supporting bone resorbed. Eventually, the teeth may become loose, making eating difficult. Less commonly, an acute periodontal abscess may supervene.

In some older patients, there is a good response to instruction in toothbrushing and flossing to remove plaque, and to a course of scaling and polishing of the teeth. A dental hygienist, the patient's relatives or health carers, can be involved in supervising or even giving this home care. Loose, painful, useless teeth should be extracted. For teeth, particularly with deep residual periodontal pockets, regular scaling combined with root planing under local anesthesia can be beneficial in selected elderly patients. Discomfort from exposed root dentine is an indication for application of topical fluoride by a dentist or dental hygienist, or home use of a desensitizing toothpaste containing fluoride or strontium chloride (Sensodyne).

AGE CHANGES IN THE ORAL MUCOSA

Studies of the oral epithelium have not consistently shown any changes with age, when hematological, nutritional or other systemic factors have been carefully discounted (Mackenzie *et al.*, 1996). Fibroblasts in the lamina propria may synthesize less collagen with age and the collagen fibers are thicker and coarser. No loss of functional capacity of the gingival or oral mucosa to withstand normal masticatory forces has been shown, however. Similarly, the sense of taste to sour or sweet substances remains remarkably intact with advancing years (Bartoshuk and Weiffenbach, 1990).

The ectopic sebaceous glands become more prominent in the mucosa of the lips and cheeks of old people (Fordyce's spots).

Multiple varicose veins resembling caviar on the ventral surface of the tongue ("caviar tongue") or lips are also common. The foliate papillae representing leaflike folds of the mucosa covering accumulations of lymphoid tissue (lingual tonsil) situated bilaterally on the posterolateral margins of the tongue may concern elderly people who fear cancer. Owing to the atrophy of the adipose tissue of the cheeks and lips, the minor labial salivary glands become palpable to the alarm of elderly ladies with cancerophobia.

The vermilion border of the lower lip is subject to solar irradiation and may become irregularly mottled (actinic cheilitis), due to alternating atrophy and hyperkeratosis. There is actinic "elastotic" degeneration of the collagen and lamina propria. Crusted nodules representing actinic keratoses or early invasive squamous cell carcinomas may subsequently develop and require excision and, occasionally, the whole of the unstable vermilion border may need to be removed, in a "lip-shave" operation.

To summarize, the morphological changes in the epithelium or lamina propria of the oral mucosa with advancing age, are insufficient to account for the dry, burning sensation of the lips and tongue which troubles some elderly women (see below).

INFECTION OF THE ORAL MUCOSA

Candidosis

Candidosis is the only common oral mucosal infection in older patients. The most important systemic factors promoting oral candidosis in patients over 70 years of age are listed in Table 1. Local factors are also important. The wearing of complete dentures, particularly continuously day and night, boosts oral candidal populations. Smoking significantly increases the candidal carrier rate (Arendorf and Walker, 1980) and most patients with chronic hyperplastic candidosis have had a history of cigarette smoking.

Salivary flow is a further local factor that limits proliferation of candida. Patients with xerostomia due to Sjögren's syndrome have high oral candidal populations (Tapper-Jones *et al.*, 1981) and are susceptible to thrush.

Oral candidosis takes the following forms:

Thrush (Acute Pseudomembranous Candidosis)

The creamy white plaques, resembling milk curds, on the oral mucosa with an inflammatory surround, can be easily wiped off (Figure 1), a point of distinction from leukoplakia.

Denture Stomatitis (Chronic Atrophic Candidosis)

Denture stomatitis is a symptomless inflammation of the palate caused by candida, and possibly anaerobic bacteria, in the microbial plaque on the fitting surface of the upper denture (Figure 2). Continuous night-and-day denture wearing is a key factor.

Table 1 Factors in oral candidosis

A. *Systemic*	
1. Dehydration	
2. Diabetes mellitus	
3. Drugs	– steroids or other immunosuppressives
	– cytotoxic agents
	– antibiotics
4. Malignant disease	
5. Anemias, iron deficiency, neutropenia	
6. Postoperative states	
7. HIV (uncommon in this age group)	
B. *Local*	
1. Denture wearing (particularly continuously)	
2. Tobacco smoking	
3. Xerostomia	

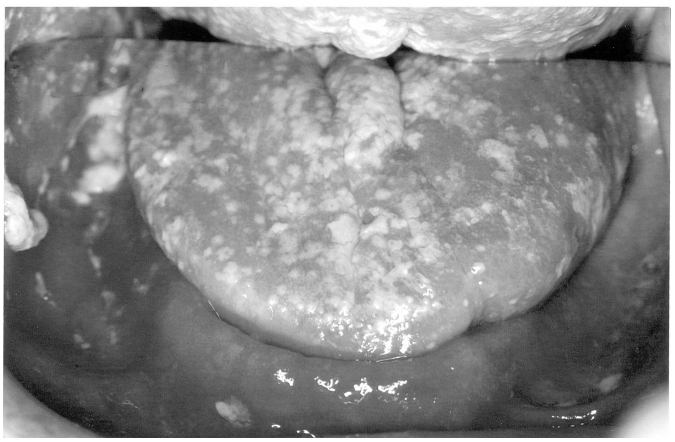

Figure 1 Acute oral pseudomembranous candidosis (thrush). The white plaques could be easily detached

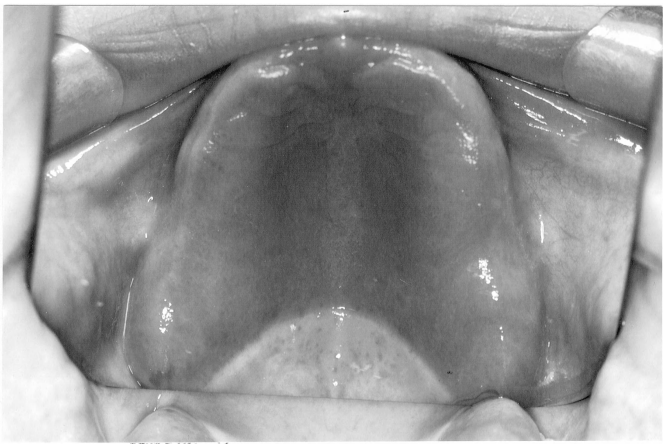

Figure 2 Denture stomatitis in an edentulous patient wearing her dentures continuously day and night. A heavy growth of *Candida albicans* was cultured from the fitting surface of the upper denture

The yeast is carried in the saliva to the other sites, where it may also initiate an angular stomatitis (cheilitis). Dentures should not be worn overnight but instead be immersed in a dilute hypochlorite solution such as dilute Milton or Dentural. Miconazole 2% gel (Daktarin) oral gel may be applied to the fitting surface of the upper denture. Allergy to the acrylic resin of the denture base is only very rarely a cause of denture stomatitis.

Antibiotic Sore Mouth (Acute Atrophic Candidosis)

After broad-spectrum antibiotic therapy the tongue becomes sore, red, and the filiform papillae are lost, whereas the remaining fungiform papillae become prominent.

Chronic Hyperplastic Candidosis (Candidal Leukoplakia)

This appears as chronic nodular or speckled white plaques on the mucosa of the tongue, cheeks, or palate (see below).

Figure 3 Bilateral angular cheilitis secondary to candidal denture stomatitis

Angular Cheilitis

The skin lateral to the commissures is erythematous, fissured, or eroded (Figure 3). This is commonly due to candida, secondary to a denture stomatitis which should be managed as described above. Old dentures in which the vertical dimension has been substantially reduced owing to excessive wear of the teeth may contribute to angular cheilitis and a dental opinion is advisable. Angular cheilitis may be a feature of iron deficiency anemia, when papillary atrophy of the tongue is usually also present, sometimes as part of the Patterson-Kelly (Plummer-Vinson) syndrome.

Median Rhomboid Glossitis

An elliptical depapillated red area of mucosa, often irregularly keratinized, develops in the midline of the dorsum of the tongue, in its middle or posterior third. It may cause intermittent soreness or more commonly is an incidental finding. It appears to be an acquired chronic oral candidosis rather than, as was previously supposed, a developmental anomaly. Tobacco smoking and denture wearing, and HIV infection in younger patients, have been found to be associated factors.

Amphotericin lozenges (10 mg) dissolved orally three times a day will relieve any symptoms but the condition is otherwise harmless.

Management of Candidal Infections of the Mouth

Attention to local factors such as denture hygiene and continuous denture wearing, tobacco smoking, and predisposing systemic factors (see above) is essential.

Topical antifungal agents such as amphotericin lozenges (10 mg) or suspension (100 mg/ml) or 2% miconazole oral gel are well tolerated. Systemic antifungals such as fluconazole or itraconazole are reserved for profoundly immunocompromised patients with neutropenias or HIV-AIDS (Zegarelli, 1993).

Black Hairy Tongue

The filiform papillae in the posterior third of the tongue become longer and discolored by pigment-forming bacteria and possibly by tea and tobacco and other dietary constituents. The long "fur" may prove nauseating or alarming.

Antibiotics, poor oral hygiene, smoking, alcohol, and mouthwashes have been blamed for black hairy tongue. However, the cause is essentially unknown but reassurance that it is not a serious infection, is important. Recently, oral retinoids have been used to treat the condition. Most simply, the patient can scrape off the long papillae with a stiff toothbrush or spoon.

ULCERATIVE AND BULLOUS LESIONS OF THE ORAL MUCOSA

The range of ulcerative and erosive conditions of late onset to affect the mouth is relatively narrow (see Table 2). Failure to recognize erosive lichen planus, mucous membrane (cicatrizing) pemphigoid, or pemphigus presenting as recurrent "mouth ulcers", delays instituting the appropriate treatment.

Recurrent Oral Ulceration

Traumatic Ulcers

Traumatic ulcers are the most frequent. They arise in the sulci at the periphery of ill-fitting dentures or in the buccal mucosa as a result of cheek biting. The ulcers are typically shallow and shelving with an irregular or linear outline, and once the local cause is eliminated, healing is swift. A chlorhexidine gluconate mouth rinse is helpful. Leaflike hyperplastic folds (denture-associated hyperplasia) at the periphery of the denture result from denture trauma in the long term.

Table 2 Ulcerative and bullous conditions of the oral mucosa in the elderly

Recurrent oral ulceration
Traumatic ulceration
Lichen planus
Drug-induced ulceration
Hematological
Neutropenia
Leukemia
Iron, B_{12} or folate deficiency
Behcet's syndrome
Associated with inflammatory bowel disease
Chronic ulcerative stomatitis
Persistent oral ulcer
Squamous cell carcinoma
Bullous disorders
Mucous membrane (cicatrizing) pemphigoid
Herpes zoster
Pemphigus vulgaris and pemphigus vegetans
Angina bullosa hemorrhagica

Lichen Planus

In oral lichen planus, the characteristic lesions are white striae or papules forming a reticular lacelike pattern on the buccal mucosa or lateral margins of the tongue, often with a bilaterally symmetrical distribution (Figure 4). These may cause a burning sensation or discomfort. Only a minority of patients may have skin lesions.

Atrophic changes in lichen planus present as red areas. Confluent white plaques may be a feature on the tongue. The gingivae may become red and atrophic (desquamative gingivitis). Bullous lichen planus may present as recurrent oral ulceration.

The ulceration or erosive form of lichen planus may have a protracted course, sometimes taking 10 years or more to remit. There may be an association with hepatitis C infection or liver disease. Occasionally the lesions heal as a white

Figure 4 White striae and papules in a reticular pattern on the buccal mucosa in oral lichen planus

mucosal plaque or as localized areas of depapillation of the tongue. The keratinized white margins of the erosions usually serve to distinguish lichen planus from those due to mucous membrane cicatrizing pemphigoid. A biopsy of the intact keratinized margin will confirm the diagnosis and exclude any epithelial dysplasia. A subgroup of women with lichen planus affecting the gingivae, vulva, and vagina has been delineated.

In most cases of oral lichen planus, no cause can be isolated. Drugs may, however, induce a lichenoid reaction that may be clinically and histologically indistinguishable from lichen planus. These include gold salts, beta-blockers, captopril, thiazide diuretics, oral hypoglycemics, antimalarials, antituberculous drugs, antidepressants, and nonsteroidal anti-inflammatory analgesics.

Lichenoid reactions to the mercury content of dental amalgam fillings may occur, particularly in cases when the lesions are restricted to mucosal surfaces in the cheek in contact with the fillings. In such selected cases, replacement of amalgams with alternative materials may be rewarded by resolution. An oral lichenoid reaction may be a feature in graft-versus-host disease.

Topical corticosteroids will help relieve any burning sensation or soreness of the involved mucosa. These involve 0.05% clobetasol or 0.05% fluocinonide or 0.1% triamcinolone acetonide in an adhesive paste: Topical tacrolimus (Vente *et al.*, 1999) has been under trial recently. A tetracycline mouth bath used three times daily for 3 days will relieve symptoms due to secondary bacterial infection in the erosive form. For this, a 250-mg tetracycline capsule is opened and the powder contents dissolved in 15-ml warm water, and this mouth bath held in the mouth for 2 minutes and then spat out.

In severe forms, where eating and swallowing have become intolerable to the point of weight loss and the patient's life has become miserable, a limited course of systemic corticosteroids is justified, for example, prednisone, 5 mg four times a day for 1 month, reducing gradually to a maintenance dose of 5–10 mg daily. Usually the systemic therapy can then be tailed off and discontinued within 3 months.

Cyclosporine mouthwashes, retinoids, or tacrolimus have also been used more recently (Chan *et al.*, 2004). Patients with oral lichen planus of long standing, usually of 10–15 years duration have a slightly increased risk of oral cancer with an estimated incidence of 1–4%.

Drug-induced Ulceration

Aspirin ill-advisedly held in the cheek to relieve toothache results in an erosion covered by necrotic epithelium. Cytotoxic agents regularly cause ulceration, either directly by their effect on the oral epithelium or indirectly as a result of neutropenia.

Gold salts, nonsteroidal anti-inflammatory analgesics and occasionally other drugs (Scully and Cawson, 2002) have occasionally been implicated in mouth ulceration. Neutropenic ulceration occurs regularly in bone marrow transplant recipients and usually resolves when the blood neutrophil count rises above 0.5×10^9 cells/l. Recombinant human granulocyte-colony-stimulating factor (rHuG-CSF) elevates blood neutrophil counts with a reduction in oral ulcers (Dale, 1995) in a variety of neutropenias, especially due to chemotherapy but also in congenital and idiopathic and cyclic neutropenia.

Behcet's Disease

The oral ulceration in Behcet's disease may persist into later life. Clinically these ulcers are similar to minor or major aphthae or herpetiform ulceration. To fulfill the current diagnostic criteria for Behcet's disease, the patient should also have two of the following four changes: eye lesions, skin lesions, genital ulceration, and a positive pathergy test (International Study Group for Behcet's Disease, 1990). Topical steroids (see above) or a tetracycline, mouthwash can give some relief for the mouth ulcers. Thalidomide (not to be used for women who could become pregnant) or colchicine 0.5 mg twice daily can control more severe ulceration. Many patients with extraoral manifestations will need corticosteroids such as prednisolone with or without azathioprine (*see* **Chapter 135, Skin Disorders in the Elderly**).

Mouth Ulceration Secondary to Inflammatory Bowel Disease

Mouth ulceration of aphthous type may infrequently be an oral manifestation of inflammatory bowel disease, such as Crohn's disease, ulcerative colitis, or coeliac disease. Diffuse thickening of the lips, cheeks, and lower face may also be a feature of Crohn's disease, with characteristic noncaseating granulomas. Malabsorption of iron or other hematinics may be a factor in this type of mouth ulceration. Pyostomatitis vegetans (Ficarra *et al.*, 1993) or the oral equivalent of pyoderma gangrenosum are other occasional associations.

Persistent Oral Ulcer: Squamous Cell Carcinoma

A solitary enlarging oral ulcer with indurated raised margins in the elderly, persisting for more than 3 weeks despite treatment, particularly in a patient with risk factors for oral cancer (see below) should be regarded as a squamous cell carcinoma until proved otherwise and a biopsy is mandatory.

Bullous Lesions

Mucous Membrane Pemphigoid (MMP) (see Chapter 135, Skin Disorders in the Elderly)

This is a chronic autoimmune blistering disorder with a target antigen in the lamina lucida of the basement membrane. Junctional separation of the epithelium from the lamina propria results in a bulla. It tends to occur in older

people, usually women. The oral mucosa is almost invariably affected, together with the nasal mucosa and conjunctiva in most cases.

Subepithelial bullae arise on the maxillary gingivae, hard and soft palate, and buccal mucosa. The bullae are generally clear, measuring a few millimeters to a centimeter in diameter, and take some hours to rupture, leaving painful erosions (Figure 5). Atrophic erythematous sore gingivae (desquamative gingivitis) in patients whose natural teeth are still present is a typical finding. In severe forms, lesions of the pharynx and esophagus may cause dysphagia, and hoarseness may result from laryngeal involvement. The anus, penis, vulva, and skin may occasionally be affected. An association with rheumatoid arthritis has been reported. The buccal and labial sulci become reduced in depth, due to scarring. As a consequence, dentures become unstable and need frequent adjustment.

Mucous membrane pemphigoid (MMP) is now recognized to be a heterogeneous group of subepithelial blistering disorders involving mucous membranes, particularly of the mouth and eyes. At least five subsets of MMP have been distinguished by their clinical features and the antigenic specificity of the autoantibodies detected in biopsies and serum by direct and indirect immunofluorescence (Scully *et al.*, 1999).

The milder forms of MMP can be treated with topical corticosteroids, such as fluocinonide 0.025% in Orabase or a 5 ml mouthrinse of dexamethasone 0.1 mg ml^{-1} held in the mouth for minutes and then spat out, three times daily. In more severe forms, or where there is eye involvement, a short systemic course of prednisone, 1–2 mg kg^{-1} day^{-1}, tapering to a level just sufficient to retain control. Dapsone and azathioprine have been used in combination with prednisone for their steroid sparing effects (Fine, 1995) but each has potent adverse effects. Topical antifungals such as amphotericin B lozenges can be useful in preventing thrush with such regimes. The tetracycline minocycline, sulphapyridine, and cyclosporine mouthrinses (very expensive) have also been used.

Figure 5 Mucous membrane pemphigoid in an 82-year-old man presenting with "mouth ulcers"

Herpes Simplex

Recurrent herpes simplex may be severe on the lips (herpes labialis) in elderly patients receiving chemotherapy for leukemia or other malignancies and its incidence can be reduced by prophylactic aciclovir.

Herpes Zoster (see Chapter 145, Infectious Diseases; Chapter 148, Infections of the Central Nervous System Chapter 135, Skin Disorders in the Elderly)

Reactivation of varicella zoster virus infection affects middle-aged and elderly patients, in particular, and may involve the sensory ganglion of the trigeminal nerve.

After a prodromal phase of severe facial pain, which may be mistaken for toothache, cutaneous hyperesthesia, erythema, and unilateral grouped mucocutaneous vesicles appear in a dermatome distribution on the skin of the cheek, lower eyelid, and lip in maxillary nerve lesions, with erosions on the ipsilateral mucosa of the upper lip and palate as far as the midline. In mandibular division involvement, the rash is commonly situated on the chin in the distribution of the mental nerve, and on the buccal mucosa and ipsilateral half of the tongue. Trigeminal zoster may occur without vesicles (sine herpete). Geniculate ganglion involvement manifests as a lower motor neurone facial nerve palsy, vesicles in the external ear and fauces, loss of taste on the side of the tongue (Ramsay-Hunt syndrome). Aciclivir, valaciclovir, and famiciclovir are effective and limit postherpetic neuralgia.

Pemphigus Vulgaris and Pemphigus Vegetans (see Chapter 135, Skin Disorders in the Elderly)

This serious bullous eruption, appears in the mouth on average 4 months before the skin is affected, although occasionally it remains restricted to mucosal surfaces. Its onset is commonly in middle age, but the geriatrician will see patients in whom pemphigus first occurs in later life. It is an autoimmune disorder with IgG_1 and IG_2 autoantibodies against the desmosomal glycoprotein, desmoglein-I, the major antigen (or Dsg-3) producing intraepithelial blisters. The oral blisters usually rupture quickly, leaving erosions. To confirm the diagnosis, biopsies of the intact oral lesion or perilesional mucosa are needed (a) a formalin-fixed specimen for light microscopy (b) an unfixed specimen for direct immunofluorescence, and (c) a blood sample (no anticoagulant).

If pemphigus vulgaris can be recognized at an early stage, where the lesions are confined to the mouth, it can usually be controlled with a relatively lower dose of systemic steroids such as 40–60 mg prednisolone daily (Harman *et al.*, 2003). Paraneoplastic pemphigus should also be considered. Regular toothbrushing with a soft toothbrushing and a chlorhexidine gluconate (0.2%) mouthrinse is essential and any thrush treated. In the oral lesions of pemphigus vegetans, the mucosa heals with a granular surface, men are more frequently affected and the clinical course is generally milder than in pemphigus vulgaris.

Angina Bullosa Hemorrhagica

Young or middle-aged women are mainly affected. During meals, a subepithelial hemorrhagic bulla forms rapidly in the subepithelial region of the mucosa of the soft palate or cheeks. Occasionally the palatal swellings may enlarge to the point where the patient fears asphyxiation. The extravasated blood soon ruptures spontaneously, forming a painful erosion. A tetracycline mouthbath made up freshly by dissolving the powder contents of a 250 mg capsule in a 15 ml warm water and held in the mouth for 5 minutes three times daily, relieves soreness from secondary bacterial infection. Rarely, similar oral lesions can be a marker of thrombocytopenia.

DENTURE-INDUCED HYPERPLASIA

This is a benign mucosal hyperplasia seen as leaflike folds of tissue at periphery of a denture, with sometimes superimposed traumatic ulceration. The dentures need to be trimmed back and, if necessary, replaced.

WHITE LESIONS OF THE ORAL MUCOSA

Most white mucosal patches are due to the irritant effect of tobacco smoking or friction from the teeth, often in combination, and these changes are usually reversible and nondysplastic. A leukoplakia has been defined as a predominantly white lesion of the oral mucosa that cannot be characterized as any other definable lesion; a minority of leukoplakias will transform into cancer (Axell *et al.*, 1996). A number of white lesions of thrush, lichen, planus, and aspirin burns, and so on (Table 3) are thus excluded by this definition. Malignant change is more frequent in speckled (nodular), red, or verrucous leukoplakias.

Tobacco-associated Leukoplakia

Many patients presenting with oral white mucosal lesions are pipe or cigarette smokers. In a pipe smoker there are umbilicated white papules on the soft palate due to thickened palatal epithelium at the openings of minor salivary glands. There is no epithelial dysplasia and this is not a premalignant lesion. If the patient stops smoking, the mucosa generally returns to normal within a year.

Table 3 White lesions of the oral mucosa

Benign	***Potentially malignant***
Ectopic sebaceous glands	Dysplastic leukoplakia
Thrush	Tobacco-associated leukoplakia
Aspirin burn	Lichen planus
Frictional Keratosis	Oral submucous fibrosis
Oral epithelial nevus	Chronic hyperplastic candidosis
Leukedema	Discoid lupus erythematosus
Oral hairy leukoplakia	Tertiary syphilis
Darier's disease	
Red lesion of the oral mucosa	
Erythroplasia	

Frictional Keratosis

A frictional keratosis is a linear white lesion where the upper and lower teeth meet in the cheek mucose, lips, or lateral margins of the tongue. Sharp teeth or faulty dentures may be responsible. Smoking often seems to be a coirritant. If the causes are eliminated, the mucosa returns to normal.

Tertiary Syphilis

Syphilitic glossitis, one of the oral manifestations of tertiary syphilis is now rare. The tongue is blunt and fibrosed with keratosis and atrophy of the anterior dorsum. Syphilitic leukoplakia of the tongue or elsewhere in the mouth carries a significantly increased risk of oral cancer.

Chronic Hyperplastic Candidosis

Chronic hyperplastic candidosis appears as speckled white plaques on the buccal mucosa, tongue, or palate. A biopsy is needed to show the candidal hyphae in the superficial epithelial layers, with occasionally epithelial dysplasia. Topical or systemic steroid therapy or immunosuppressive medication, diabetes mellitus, or iron deficiency, are predisposing factors. Tobacco smoking and denture wearing, particularly continuously day and night, may be local promoting factors. The management will include attention to predisposing factors, a course of antifungal therapy of fluconazole, often for several months, and excision of any residual dysplastic white plaques. The risk of cancer is now thought to be low.

Oral Hairy Leukoplakia

This was first described in North American homosexuals with HIV infection. White plaques with a corrugated surface on the lateral margin of the tongue are the usual presenting factors. Histologically, koilocytes in the upper spinous epithelial layer are markers of Epstein-Barr virus infection. Oral hairy leukoplakia has since been reported in transplant recipients receiving immunosuppressive therapy. Some lesions respond to acyclovir but there is no dysplasia and oral hairy leukoplakia is not potentially malignant. It is uncommon in the elderly.

Sublingual Keratoses

There are supple, wrinkled, well-demarcated white plaques on the ventral surface of the tongue, or on the floor of the

mouth, often symmetrically distributed about the midline. A report that the lesions frequently underwent malignant change has not been subsequently confirmed.

Oral Epithelial Nevus

Oral epithelial nevus (white folded gingivostomatosis) is a rare disorder due to a cytokeratin gene mutation, usually of autosomal dominant inheritance. The mucosa of the gingivae, cheeks, lips, and sometimes the soft palate has a white shaggy appearance, and sheets of the surface epithelium are easily wiped off. Vaginal or rectal mucosa may also be affected. The biopsy findings are diagnostic. There is no dysplasia and this is a harmless condition.

Erythroplakia

The bright red velvety mucosal plaque is an uncommon but sinister lesion, which is disproportionately frequent in older patients. Severe dysplasia or carcinoma *in situ* are common biopsy findings. It is often asymptomatic and detected during a routine examination of the mouth. Up to half the patients may develop oral carcinoma.

Management of White and Red Lesions of Oral Mucosa

Tobacco smoking, betel quid use or trauma from the teeth or dentures or thrush should be attended to. Any remaining white patches should be biopsied to confirm the diagnosis and to identify any epithelial dysplasia and its severity. The correlation between the assessment of different pathologists on the presence and severity of oral epithelial dysplasia has been shown, however, to be poor. This subjective variation in histological evaluation of leukoplakia has prompted alternative methods such as ploidy analysis of DNA content which promise to provide a more objective and reliable way of predicting the risk of cancer (Sudbo *et al.*, 2001). In the future, DNA analysis of mutations or other molecular methods will probably prove a more accurate guide to malignant potential. The place of other diagnostic techniques, such as exfoliative cytology, brush biopsy, or vital staining with tolonium chloride mouth rinses, remains uncertain.

Leukoplakias with biopsy-proven moderate or severe dysplasia are generally excised where clinically practicable. However, no random controlled trials are available of the effectiveness of surgery, laser, or cryotherapy in preventing oral cancer developing in these lesions (Lodi *et al.*, 2002). A careful follow-up, therefore, is essential.

ORAL CANCER

Although oral cancer accounts for only 2% of malignant tumors registered in developed countries, approximately 50% of the patients still die from intraoral tumors (all stages, all grades) such as cancer of the tongue. The incidence of oral cancer rises steeply after 50 years, and 70% of patients presenting with the disease are over 65 years. Rather more men are affected than women.

Etiology

Tobacco (smoked, chewed or used as snuff) and heavy alcohol drinking, are the major risk factors for mouth cancer in most industrialized countries and interact with a supermultiplicative effect (Johnson, 2001). In the Indian subcontinent, betel quid containing areca nut and slaked lime and often tobacco, or areca nut (betel) chewing alone, are carcinogenic. Areca nut is also important in the etiology of oral submucous fibrosis, a potentially malignant condition. Lip cancer is usually due to excessive exposure to ultraviolet light, particularly in outdoor workers.

Dietary Deficiency

A low intake of fresh fruit and vegetables carries an increased risk of oral cancer. Prolonged iron deficiency leading to the Patterson-Kelly (Plummer-Vinson) syndrome predisposes to cancer of the pharynx and the mouth (Walker *et al.*, 2003).

Other Factors

Oncogenic types of HPV-16 and 18 virus have been implicated in a small subset of oral cancers, particularly tumors of the posterior tongue and tonsils. The evidence for a link between herpes simplex and oral cancer is less convincing. Syphilis is now only rarely implicated in oral cancer. Dental sepsis or trauma from teeth or dentures have not been convincingly shown to be etiological factors. Genetic polymorphisms controlling the metabolism of tobacco and alcohol or DNA repair may explain the predisposition to lip and oral and pharyngeal cancer in some families but concordance studies in twins indicate that environmental exposure to carcinogens is more important.

Clinical Appearances of Oral Cancer

On the lower lip, a persistent crusted lesion at the vermilion border, often superimposed on a diffuse solar cheilosis, should be regarded as a squamous cell carcinoma until proved otherwise, and the diagnosis established by biopsy.

Within the oral cavity, the cancers arise in a horseshoe-shaped area on the lateral margins of the tongue, floor of the mouth, mandibular alveolus, and lower buccal sulcus. The carcinomas may appear as a raised nodule, an ulcer

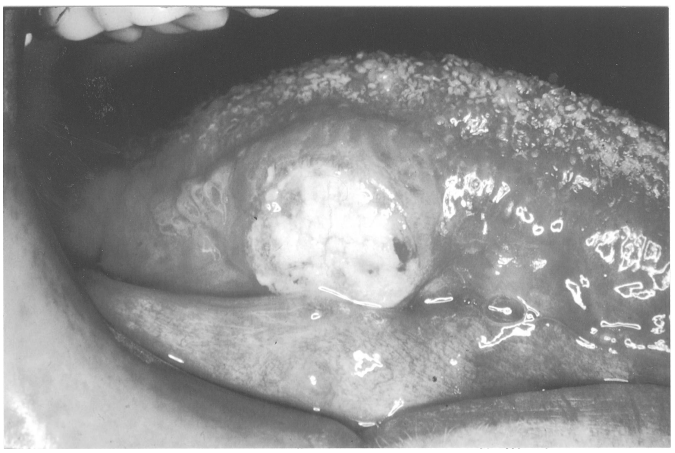

Figure 6 Squamous cell carcinoma with a raised indurated margin on the ventral surface of the tongue

with indurated margins (Figure 6), or an indurated or fissured white plaque. Limitations of tongue movements, severe pain, restricted mouth opening and lymph node involvement are all late signs.

A biopsy is essential. Unrecognized oral cancers are still treated with topical medicaments or antibiotics for long periods with distressing consequences. The stage of the disease is the most important prognostic factor. Metastatic involvement of even a single lymph node is associated with a 50% reduction in survival rates. With improved control of loco-regional disease, distant metastases are becoming clinically more important.

The site of the cancer also affects the outcome. In contrast to lip tumors, which are usually curable, most intraoral cancers in the elderly are advanced at presentation with 5-year survival rates only approximately 50%. Other prognostic factors such as patient gender, tumor grade, and modality of treatment are less important. Poor general health has an adverse effect on outcome.

Treatment

Oral cancer is usually treated by surgery including in some cases neck dissection or radiotherapy or a combination. The place of adjuvant chemotherapy remains to be established. With advances in ablative and reconstructive surgery, better control of the primary tumor and neck nodes is now possible. Distant metastases or a second primary tumor in the upper aerodigestive tract, often also associated with tobacco and alcohol are further problems.

THE JAWS AND MUSCLES OF MASTICATION

Age Changes

The structure and the size of the alveolar processes of the jaws are dependent upon the presence of the teeth which they support. The alveolar bone forms as the teeth develop and erupt and is resorbed after extractions, and the resultant loss of facial contour and height accentuates the appearance of aging. As in other bones, the jaws of the elderly are subject to generalized osteoporosis, and the thickness and bone mass of the mandibular alveolus becomes reduced. Progressive periodontal disease results in inflammatory resorption of alveolar bone which is accelerated in women with generalized osteoporosis (Geurs *et al.*, 2003) and conversely may be retarded by biphosphonates.

Atrophy of the edentulous alveolus after extractions may make dentures unstable, particularly in the lower jaw. Modern surgical procedures, such as insertion of subperiosteal osseointegrated titanium implants can stabilize removable dentures or even retain single teeth, but such preprosthetic surgery in patients aged over 70 years is not to be undertaken lightly. The muscle mass and maximal biting force of muscles of mastication such as masseter and medial pterygoid muscles, is reduced in elderly people (Newton *et al.*, 1993) and is further reduced in the edentulous, but most complete denture wearers do not have problems in chewing the average Western diet.

Swellings of the Jaws

Unerupted Teeth, Roots, and Cysts

A dental abscess from a nonvital tooth is the commonest cause of a sudden swelling of the jaw, irrespective of age. In the elderly subject presenting with a swelling of longer duration, sometimes causing a loss of fit of dentures, radiographs will often reveal a residual dental cyst or an unerupted tooth, sometimes with an associated dentigerous cyst. Unerupted teeth may become more superficial (and then infected) due to resorption of the overlying alveolar bone. Frequent hot salt water mouth baths, a chlorhexidine mouthwash twice daily, analgesics and an antibiotic such as amoxicillin prescribed, for example, 500 mg together with metronidazole 200 mg three times daily or in patients allergic to penicillins, clindamycin 300 mg 6 hourly and the patient instructed not to wear dentures meanwhile. Fluctuant collections of pus need to be incised. After an interval of at least 2 weeks the tooth or cyst should then be removed.

Retained roots may become infected and require removal, but asymptomatic roots buried deeply in the jaws are common radiographic findings and can be safely left, unless a cyst has formed.

Ameloblastoma

This is the commonest odontogenic neoplasm. It arises centrally in the jaws, particularly in the third molar region or the angle of the mandible. It may present as a jaw swelling, loss of fit of a denture or loosening of teeth. A multilocular radiolucency is the characteristic X-ray appearance, although some tumors are monolocular. Ameloblastoma typically presents in about the fifth decade but older patients can

be affected. The tumor is locally invasive and resection with a margin of uninvolved bone with bone grafting is needed.

Paget's Disease

This osteodystrophy involves the facial skeleton in a minority of cases and the maxilla is more affected than the mandible in both the polyostotic and also the rare monostotic form. The vault of the skull is a frequent site for Paget's disease and the deformity imparts an inverted triangle shape to the head.

In the jaws, pain and facial deformity are the usual presenting features. The maxilla is usually diffusely enlarged with a tendency to obliteration of the vault of the palate, or loss of fit of dentures.

A craggy hypercementosis of teeth may make extractions difficult. Severe infection of the sockets may follow extractions where the bone is sclerotic in elderly patients, whereas postextraction hemorrhage is a feature of the vascular osteoporotic phase. Calcitonin injections or bisphosphates may give some relief of pain. Sarcoma, as a complication, is very rare in the jaw lesions.

SALIVARY GLAND DISORDERS

Age Changes in Salivary Glands

With age, an increasing proportion of the secretory acini of the major and minor salivary glands tissue are replaced by fat and fibrous tissue. The cytoplasm of some of the epithelial cells becomes granular and eosinophilic. Ultrastructurally, this oncocytic change is due to many swollen mitochondria. Most investigations, however, have not shown a corresponding drop in salivary flow rates with age (Baum, 1996).

Dry Mouth

A complaint of a dry burning mouth is not uncommon in older people but is not due to age changes in salivary glands. Patients presenting with a complaint of dry mouth can be grouped into those with normal salivary flow and those with reduced salivation (Table 4). Salivary flow rates (unstimulated) can be assessed most simply by asking the patient to first swallow and then drool into a plastic preweighed cup over 5 minutes. The stimulated salivary flow rate is assessed similarly while the subject chews paraffin wax. Values of $<0.1\,\mathrm{g\,min^{-1}}$ unstimulated salivary flow rates and $<0.5\,\mathrm{g\,min^{-1}}$ stimulated flow rates are suggestive of a dry mouth, allowing for the wide range found in asymptomatic healthy people.

In true xerostomia, there may be difficulty in swallowing, speaking, or a taste disturbance. Angular cheilitis, often a marker of chronic candidosis, a smooth tongue with a fissured "cobblestone" appearance, adherent glazed buccal mucosa, widespread cervical dental caries at the gum margins (Figure 7) and an absence of the usual pool of saliva in the floor of the mouth are characteristic findings.

Table 4 Causes of complaint of dry mouth

A. With reduced salivary flow

1. *Salivary gland disease*
   - Radiotherapy
   - Sjögren's syndrome
   - Sarcoidosis
   - Amyloid
   - Hemochromatosis
2. *Generalized disorders*
   - Diabetes mellitus
   - Dehydration
     - Fluid deprivation or loss
     - Prolonged diarrhea, vomiting, HIV, hepatitis C
3. *Medication*

Atropinics	Clonidine
Benzhexol	Opiates
Benztropine	Orphenadrine
MAO inhibitors	Ipra troprium
Phenothiazines	Antihistamines
Selegiline	Amphetamines
L-dopa	DDI
Lithium	Fluoxetine
Retinoids	

B. With normal salivary flow

Psychological
- Anxiety
- Depression

Figure 7 Recurrent dental caries at the necks (cervical margins) of teeth in a patient with a profound xerostomia in Sjögren's syndrome

A dry burning feeling (burning mouth sensation) of the lips or mouth (see below) is a distressing complaint in elderly people, predominantly in women but the salivary flow rates usually prove to be normal and the oral mucosa is clinically healthy.

Dehydration

This may occur in senile dementia when patients no longer drink enough fluid.

Drug-induced Xerostomia

Medication rather than age changes is an important factor in dryness of the mouth in the older person and elderly patients can be particularly sensitive to the anticholinergic action of drugs.

Antidepressants, antihypertensives, or antidepressants are relatively commonly incriminated in drug-induced xerostomia, but a wide spectrum of medication is said to reduce salivary flow (Sreebny, 1996).

Sjögren's Syndrome

Sjögren's syndrome is a chronic slowly progressive autoimmune destruction of exocrine glands, particularly the salivary and lacrimal glands, resulting in dryness of the mouth and eyes. The xerostomia and xerophthalmia may occur in isolation (primary Sjögren's syndrome) or associated with rheumatoid arthritis, systemic lupus erythematosus, scleroderma, primary biliary cirrhosis, vasculitis, or chronic active hepatitis (Moutsopoulos, 1998). Middle-aged women are predominantly affected.

The diagnostic criteria are listed in Table 5.

Autoantibodies: Ro (SS-A), La (SS-B), antinuclear factor, and rheumatoid factor are diagnostically useful. Fodrin and muscarinic acetylcholine receptor antibodies are now claimed to be both more sensitive and specific.

For the minor salivary gland biopsy, minor glands are removed under local anesthesia via an incision in the mucosa of the lower lip. More than 1 focus of 50 or more lymphocytes and plasma cells per 4-mm gland sectioned is diagnostic for Sjögren's Syndrome.

Fatigue is a general complaint. The oral changes of xerostomia are as detailed above. The major salivary glands, most noticeably the parotid glands, may be persistently enlarged in half the patients. Typically the swelling is firm, diffuse, and bilateral. Intermittent painful swellings of the parotid gland may be due to retrograde bacterial infections of the ducts. A B cell lymphoma in the parotid gland is another complication.

Table 5 Diagnostic criteria for Sjögren's syndrome

Eye symptoms	Dry eyes everyday for >3 months, gritty sensation, or use of tear substitutes >3 times daily
Eye signs	Positive Schirmer test (<5 mm per 5 min) positive Rose-Bengal score of >4
Oral symptoms	Daily symptoms of dryness
Minor salivary gland biopsy: >1 focus score per 4 mm^2	
Salivary gland function	Positive result in one or more of the following tests: Salivary scintigraphy, parotid sialography, reduced salivary flow (<1.5 ml per 15 min)

Oral Effects of Radiotherapy and Chemotherapy: Xerostomia, Mucositis, and Osteoradionecrosis

The xerostomia due to the salivary gland atrophy and fibrosis induced by radiotherapy may result in caries affecting the roots and crowns of the teeth. There are effective cariostatic topical fluoride regimes (see below) (Dreizen *et al.*, 1977).

In the mucositis which may follow 12–15 days after radiotherapy or 7–14 days after chemotherapy, the oral mucosa becomes ulcerated, with or without a pseudomembrane on an erythematous base (Scully *et al.*, 2004). A bland soft diet and avoidance of smoking, alcohol, tea, and coffee is advised. Lozenges containing polymyxin E, tobramycin, and amphotericin B can be helpful. For pain control, nonsteroidal anti-inflammatory analgesics or in severe cases opioids may be needed. Topical lignocaine (lidocaine) before meals and benzydamine mouthrinses are useful. Granulocyte-macrophage colony-stimulating factor has been administered subcutaneously for chemotherapy mucositis.

The jaws, particularly the mandible, gradually become hypovascular, hypocellular, and hypoxic after radiotherapy and extractions or even trauma from a denture, may be complicated by osteoradionecrosis. This is difficult to treat and the emphasis should be on prevention, getting the patient dentally fit before radiotherapy. A dentist is a valuable member of the multidisciplinary team managing head and neck cancer patients.

Management of Dry Mouth

The problem of replacing the normal 1500 ml or so daily salivary secretion for a patient with severe xerostomia has not yet been solved. Diabetic sugar-free chewing gum or pastilles help stimulate salivary flow. Saliva Orthana (Nycomed) aerosol spray containing mucin and xylitol, available with fluoride ($4.2\,mg\,l^{-1}$) or in pastille form and Glandosane (Fresenius) spray are approved for the relief of dry mouth in Sjögren's syndrome but are relatively expensive and many patients resort to frequently lubricating their mouths with tap water (should be fluoridated) from a small plastic spray bottle. Pilocarpine 5 mg orally three times daily may increase salivation but palpitations, sweating, flushing, or abdominal cramps may limit patient acceptability.

Sodium fluoride gel (1.23%) applications to the teeth and regular scaling, polishing, and instruction in effective toothbrushing with a standard fluoride tooth paste twice daily and a neutral high concentration toothpaste (5000 ppm F-) once daily are important for caries prevention in profound xerostomia. Topical antifungal preparations, such as amphotericin suspension (Fungilin) or miconazole oral gel (Daktarin), should relieve the discomfort due to chronic candidal infection, which is frequently present.

HYPERSALIVATION (PTYALISM)

Hypersalivation may occur transiently as a response to local causes, such as wearing dentures for the first time

or oral ulcers or wounds. Prolonged ptyalism may be an adverse reaction in iodism or medication with a parasympathomimetic effect, or in poisoning by mercury or other heavy metals (Table 6).

In most patients complaining of "too much saliva," the measured salivary flow rates are within normal limits. The affected individual seems to have become overaware of what is in fact a normal volume of saliva but does not swallow it as usual. This may be an obsessional trait and explanations and reassurances are usually unavailing. Lack of coordination between (normal) saliva production and swallowing seems also to be responsible for the "hypersalivation" in Parkinsonism and in Down's syndrome. Drooling from one corner of the mouth is a feature of unilateral facial paralysis.

Table 6 Causes of hypersalivation

A. With increased salivary flow	
Local	
	New dentures
	Oral ulceration
Medication	
	Anticholinesterases
	Iodides
	Pilocarpine
	Buprenorphine
	Haloperidol
	Niridazol
B. With normal salivary flow (False ptyalism)	
	Psychogenic
	Parkinson's disease
	Facial paralysis
	Bell's palsy or other lower motor neurone lesion
	CVA

CVA, cerebrovascular accident.

FACIAL PAIN

Dental Causes

As in younger patients, a dental cause such as a carious tooth is the commonest explanation for facial pain (Table 7). Exacerbation of the pulpitis by hot or cold drinks is characteristic. A transient hypersensitivity to hot, cold, or sweet substances can be due to dentine exposed at the necks of the tooth by toothbrush abrasion or by periodontal disease. A transient pain produced by biting on hard food can be due to a filled tooth whose crown has cracked more or less vertically. An orthopantomogram radiograph is useful for screening the jaws in facial pain.

The pain of an infected socket may be very severe and continuous. On examination the usual blood clot is missing and the alveolar bone lining the socket is exposed. The surrounding gingiva is inflamed and tender. Syringing the socket with warm chlorhexidine 0.2% solution, insertion of an obtundent dressing Alvogel, and adequate analgesics (e.g. paracetamol-codeine) usually give relief. Unerupted teeth, jaw cysts, and retained roots are painful in the event of secondary bacterial infection.

Table 7 Causes of facial pain

1. Dental causes	
	Dental caries and periodontal disease
	Cracked tooth
	Infected socket
	Retained roots, unerupted teeth
	Infected jaw cyst
2. Temporomandibular joint pain	
3. Trigeminal neuralgia	
4. Postherpetic neuralgia	
5. Periodic migrainous neuralgia	
6. Giant cell arteritis	
7. Myocardial ischemia	
8. Ocular causes	
9. Atypical (psychogenic) facial pain	
10. Burning mouth sensation	
11. Trotter's syndrome	

Temporomandibular Joint Pain

Significant pain from the temporomandibular joint pain is uncommon in old people. Although erosions, lipping, flattening, and other degenerative changes of osteoarthritis have been identified histologically or radiologically in surveys of older people, most patients remain symptomless. Temporomandibular joint pain dysfunction is characterized by pain, clicking, limitation of movement, tenderness, and spasm of the pterygoid and masseter muscles but the temporomandibular joints are radiographically and histologically normal. Young women are predominantly affected and the condition is distinctly uncommon in older people. Patients should be reassured that they do not have arthritis, any abnormal biting or jaw posturing habit corrected and satisfactory dentures provided as necessary. An occlusal acrylic splint fitting over the existing teeth is usually helpful.

Arthritis as part of rheumatoid arthritis, psoriasis, gout, or ankylosing spondylitis may rarely involve the temporomandibular joint with destruction of the condylar head and marked restriction of mouth opening.

Trigeminal Neuralgia (*see* Chapter 64, Neurological Signs of Aging)

The patient is usually over 50 years of age at presentation. The diagnosis of idiopathic trigeminal neuralgia is made on the history in the absence of any physical signs. More females are affected than males. The patient complains of a paroxysmal pain of frightening intensity, arresting any activity. The pain is usually brief (<2 minutes) and confined to one or more divisions of the trigeminal nerve, most commonly both the maxillary and the mandibular divisions. It is almost invariably unilateral, particularly affecting the right side of the face. The pain may be provoked by washing or toweling the skin of the face or eating. It may occur several times daily for weeks or months and then remit spontaneously, only to recur with greater severity with increasingly brief remissions. A dental cause of pain

must always be excluded first by a detailed clinical and radiographic examination.

Medical management with carbamazapine, phenytoin, or baclofen is usually successful. A minority of patients will need ablative procedures such as peripheral neurotomy or cryotherapy, Gasserian ganglion injected or trigeminal nerve root decompression (*see* **Chapter 64, Neurological Signs of Aging**).

Usually some years after the onset of the disease, 3–4% of patients with multiple sclerosis will develop trigeminal neuralgia. A similar pain, secondary (symptomatic) trigeminal neuralgia, may be caused by intracranial tumors or other lesion but the pain rarely resembles primary trigeminal neuralgia. In unusual cases, Paget's disease of bone may also cause pain simulating trigeminal neuralgia.

Postherpetic Neuralgia

This can be particularly troublesome for the elderly patient who may become severely depressed as a result. It is a common sequel to herpes zoster reactivation in the trigeminal nerve. On examination there may be atrophic scars from the eruption with a segmented distribution. The skin is hyperesthetic or dysesthetic. Topical 0.075% capsaicin cream or lignocaine gel may give relief. Early treatment with amitryptiline is effective. Adequate analgesics should be prescribed, together with a reassurance that the pain will usually remit in time.

Periodic Migrainous Neuralgia (Cluster Headache)

The pain is usually unilateral and felt in or around the orbit. Young males are predominantly affected. The pain lasts from 15 minutes up to 3 hours. It tends to occur late at night or in the early hours of the morning, in a regular manner, daily for several weeks or months, and then remits for months, only to recur. There may be an ipsilateral lacrimation, conjunctival injection, rhinorrhea, and nasal stuffiness. The management is discussed in **Chapter 64, Neurological Signs of Aging**.

Giant Cell Arteritis

Middle-aged or elderly patients are affected (*see* **Chapter 64, Neurological Signs of Aging**; **Chapter 65, Headache in the Elderly**). They usually present with a headache but alternatively pain confined to the face may be a symptom of involvement of the superficial temporal or facial arteries. The pulses are typically absent and tender nodular thickenings may be palpable along the course of the vessel. Alternatively, the lumen of the affected artery may be merely narrowed and pain during mastication results from the ischemia of masseter and temporalis muscles. There is a good response to systemic prednisone therapy. Sudden blindness, which is sometimes bilateral, can follow ophthalmic artery involvement and an early ophthalmic opinion is advisable in all cases of giant cell arteritis.

Myocardial Ischemia

Although anginal pain may radiate to the mandible, it is only rarely confined to the jaw.

Ocular Causes

In acute glaucoma, the pain is felt in the globe of the eye itself and visual disturbances, photophobia and lacrimation are frequent. The eye is characteristically red, hard, and tender to palpitation.

Psychogenic (Atypical) Facial Pain

The patients are usually elderly or middle-aged women. Often there is a history of recent bereavement or retirement from a busy job, when for the first time the patient is alone in the house for long periods. The complaint is of a continuous diffuse pain affecting both jaws, spreading across the midline (unlike toothache) and the pain is not confined to the territory of any of the branches of the trigeminal nerve. The pain, however, does not usually keep the patient awake or interfere with daily activities and can be described by the patient with a composed or even cheerful facial expression. Often, previous dental treatment such as extractions is blamed. Mastication or taking cold or hot sweet foods have no effect on the pain in contrast to that from pulpitis. Clinically and radiographically, there are no abnormalities in the mouth, teeth, or jaws. Frequently, the patient has had previous dental extractions because of the pain. In many patients there are features of anxiety and depression or of an obsessional trait. Analgesics are unhelpful. Treatment with a psychotropic drug, particularly antidepressants, for example, prothiaden or amitryptiline, is beneficial in some patients but the relapse rate is high. Requests for the extraction of sound teeth should be resisted.

Burning Mouth Sensation

Middle-aged or elderly women are usually affected. They complain of a diffuse, dry burning sensation of the tongue, cheeks, and lips. Local causes such as faulty dentures should be excluded. Candidal infection or lichen planus (see above) or a true xerostomia should be excluded. Glossitis, stomatitis, or mucosal ulceration may be indicators of iron, folate, or vitamin B_{12} deficiency, even in the absence of symptomatic anemia (Field *et al.*, 1995). Lack of other nutritional factors or perimenopausal estrogen deficiency have been suggested, but not substantiated, as causes of burning mouth syndrome,

and a "scalded mouth" sensation is an occasional adverse effect of ACE inhibitors such as enalapril or lisinopril.

However, no such local or systemic organic causes can be identified. Psychological factors such as depression or anxiety or obsessional traits seem to be common in this group. Cognitive behavior therapy, but not antidepressants or hormone replacement therapy, has been found to be effective.

Trotter's Syndrome

Pain from a nasopharyngeal carcinoma can be referred in the mandibular or maxillary divisions of the trigeminal nerve. An ipsilateral conductive deafness and immobility of the soft palate and an enlarged cervical lymph node are characteristic.

DENTAL CARE OF THE ELDERLY (*see* Chapter 22, Oral Health)

General Consideration

A lot can be done to prevent and relieve pain from the teeth and mouth in older people. Retaining at least some natural teeth into middle and old age is becoming the norm but many people aged 65 or more wear partial or complete dentures. Prostheses are often erroneously regarded by their wearers as permanent life-long fixtures. Once patients are rendered edentulous, the habit of regular dental attendance is usually lost and thus many oral malignancies in old people are unfortunately advanced, and early detection of oral cancer in this group is the exception.

Since mastication with dentures is considerably less efficient than with natural teeth, older complete denture wearers living independently may choose a diet significantly lower in most nutrients, fruit, and vegetables (Sheiham and Steele, 2001).

The dental treatment of old people poses particular problems. Brittle, broken down teeth, often with gross abrasion and attrition, are more difficult to restore satisfactorily, the more so because few elderly patients can tolerate lengthy sessions in the dental chair. A significant proportion have difficulty in visiting a dentist because of transport problems, or because they are bedridden or confined to a wheelchair or cannot manage the stairs of a dentist's premises. Some dentists, however, will provide treatment on a domiciliary basis. The expense involved is another reason why some old people may not seek dental care. Others are simply afraid of dental treatment. Institutionalized, house-bound or dependent patients, particularly those in poor general health, are known to be, in particular, dental need (Peltola *et al.*, 2004).

Elderly patients living independently and retaining some natural teeth may have difficulty in keeping their teeth clean. Root caries and periodontal disease are common but may cause surprisingly few symptoms. The zealous eradication of all dental disease may not be appropriate. Root caries can be arrested by topical fluoride application, using either a 1% sodium fluoride gel in a customized applicator tray provided by the dentist or hygienist, and in toothpaste used at home by the patient professionally instructed in efficient toothbrushing.

DENTAL TREATMENT OF THE MEDICALLY COMPROMISED

Cardiovascular diseases, cerebrovascular disease, asthma, and obstructive airways disease are common in older people, and local anesthesia for dental treatment is always preferable to general anesthesia where possible. Effective sedation is important before dental treatment for the anxious cardiac patient. Patients at moderate or high risk of infective (bacterial) endocarditis should have antibiotic prophylaxis before dental procedures likely to cause a bacteremia. The indications and recommended antibiotic regimes are detailed elsewhere (Dajani *et al.*, 1997; Ramsdale *et al.*, 2004).

Dental treatment is also complicated by concurrent medication. Patients who have taken corticosteroids over the previous 2 years may have adrenocorticortical suppression, and a booster intramuscular injection of hydrocortisone immediately prior to dental treatment is advisable, even in patients on low doses of steroids.

Elderly patients receiving cytotoxic or immunosuppressive therapy are at increased risk from infections following surgical procedures in the mouth. A full blood count and platelet count should be performed immediately prior to any oral surgery to exclude a drug-induced anemia, neutropenia, or thrombocytopenia, and most dental surgeons prescribe antibiotics prior to extractions or other surgical procedures in the immunocompromised. In patients taking anticoagulants who need extractions, the dose will have to be stopped or reduced until the International Normalized Ratio is 2–2.5 to avoid a postextraction hemorrhage (Scully and Cawson, 2002). A close liaison between the patient's physician and dentist is essential.

Systemic Effect of Oral Disease

Bacteremias of oral origin may result in bacterial endocarditis in patients with prosthetic heart valves, valvular heart disease or other cardiac disorders carrying an increased risk of endocarditis (see above). Recent evidence also indicates that periodontal disease is a risk factor for cardiovascular disease (Desvarieux *et al.*, 2003), and in pregnancy for premature low birth weight babies. Glucose control in diabetes may be adversely affected. Other confounding factors such as smoking, hypertension, hyperlipidemia, and diabetes may explain this apparent association (Tuominen *et al.*, 2003) and more research is needed. Oropharyngeal (including periodontal) pathogens can be aspirated into the lungs to cause pneumonia in the elderly (Shay, 2002).

KEY POINTS

- Although age changes do occur in otherwise healthy teeth, gingivae, oral mucosa, jaws, and salivary glands they do not cause any functional problems.
- Candida is the commonest cause of oral mucosal infection and successful management involves attention to systemic and local factors
- A systematic examination with a good light source of the whole mouth is needed if potentially malignant epithelial lesions are to be detected at an early potentially curable stage.
- Dryness of the mouth is not a symptom of aging but usually due to medication or salivary gland disease in older people.
- There is growing evidence of the systemic adverse effects of oral disease.

Epidemiology of Nutrition and Aging

Wija A. van Staveren *and* Lisette C.P.G.M. de Groot
Wageningen University, Wageningen, The Netherlands

INTRODUCTION

According to WHO (2002), population aging is one of humanity's greatest success story. It is also one of the greatest challenges to cope with it in social-economic and health policies. Worldwide, the proportion of people 60 years and over is growing faster than any other age-group. In addition, it is foreseen that decreasing fertility rates and increasing longevity ensure the continued "graying" of the world's population. The extra years are not always spent in good health; therefore, often the question is raised, "How do I get old healthy?"

Analyses of the major causes of death clearly show that the burden of noncommunicable diseases has rapidly increased. In 2001, these noncommunicable diseases accounted for almost 60% of 56.5 million deaths annually and for 47% of the global burden of diseases. Figure 1 shows the 20 leading risk factors for disease disability and death in developed and developing countries. Only few of these risk factors – underweight and unsafe sex (Human Immunodeficiency Virus (HIV)) – explain the much lower life expectancy in developing countries. This differs from developed countries, where the most important risk factors are associated with noncommunicable diseases and include high blood pressure, high concentrations of serum cholesterol, low intake of fruits and vegetables, being overweight, alcohol and tobacco use. Five of these global risk factors are closely related to diet and inactivity and may lead to cardiovascular disease, type 2 diabetes and certain types of cancer. Other diseases also related to diet and physical inactivity, such as dental caries and osteoporosis, are widespread causes of morbidity. These global epidemiological data have prompted WHO (World Health Organization) and Food and Agriculture Organization (FAO) to set up a Joint WHO/FAO Consultation on Diet Nutrition and the Prevention of Chronic Disease. The recent report of this group provides an update of dietary recommendations including the following guidelines (WHO, 2003):

- limit energy intake from fat and shift consumption away from saturated fats and trans-fatty acids toward unsaturated fat;
- increase consumption of fruits and vegetables as well as legumes, whole grains, and nuts;
- limit the intake of "free" sugars;
- limit salt (sodium consumption from all sources) and ensure that salt is iodized;
- achieve energy balance for weight control.

The guidelines are evidence based for younger adults and may not have the same impact in older adults. In old age, frailty is likely to develop as a consequence of the aging processes, combined with one or more chronic conditions. There are numerous factors that may lead to frailty (Figure 2). These factors make that in old age the role of nutrition may expand from the prevention of diseases to the supply of specific nutrients and the maintenance of food intake (Schürch and Scrimshaw, 2000). This food intake should be sufficient to combat frailty and to maintain quality of life. Frail is defined here as an age-related physiologic vulnerability resulting from impaired homeostatic reserve and reduced capacity of the organism to withstand stress. In view of a desired adaptation of the dietary guidelines to health priorities in older adults, we will discuss in this chapter epidemiological evidence for this age-group on:

- body weight, body composition, and health;
- changes in dietary intake: differences within and between populations;
- risk nutrients;
- healthy diet scores, all-cause mortality, coronary heart disease (CHD), and cancer mortality;
- nutrition supplements and health indices;
- dietary guidelines in old age.

BODY WEIGHT, BODY COMPOSITION, AND HEALTH

Epidemiology of Body Weight Change, Changes in Body Composition, and Usual Aging

In cross-sectional studies, the prevalence of high body weight or obesity (Body Mass Index (BMI) $>30\,\mathrm{kg\,m^{-2}}$) increases with age up to about age 60 years, remains stable until about 70 years and then declines (Baumgartner *et al.*, 1995; Seidell and Visscher, 2000). These studies indicate that both weight loss and weight gain are associated with adverse health outcomes, such as decreased functional status, institutionalization, and increased mortality (Newman *et al.*, 2001; De Groot *et al.*, 2002).

In considering changes in body mass and health, changes in body composition have to be included. A decline in lean body mass occurs already in the third decade (Baumgartner *et al.*, 1995). This loss in lean body mass, much of which may

be due to a sedentary lifestyle, tends to be offset by gains in fat mass that continues until age 65 to 70. At any given BMI, older people will be considerably fatter, than younger adults of similar body weight because the fat-free mass diminishes by as much as 70% between the ages of 30 to 70. Studies in very healthy elderly people indicate that only very small decrements in weight ($0.1-0.2\,kg\,year^{-1}$) appear to occur in association with normal aging. Therefore, weight loss should never be dismissed as part of the aging process.

Most of the studies on BMI in the aged have been conducted in the United States (Baltimore Longevity Study; New Mexico Study and the older age-group of the NHANES III (National Health and Nutrition Examination Survey)) or in Europe (SENECA (Survey in Europe on Nutrition and the Elderly a Concerted Action)). Available data indicate that demographic changes are even more dramatic in the less developed countries (Solomons, 2000). One study including other demographic groups is the International Union of Nutrition Societies (IUNS) cross-cultural study on "Food Habits in Later Life." In this study, people of 70 years and older from communities in Australia, Greece, China, Japan, the Philippines, and Sweden were involved. The results show that on average BMI for Caucasian men and women is about $25\,kg\,m^{-2}$, with the highest for the Greek women ($30\,kg\,m^{-2}$). Filipino and Chinese had average BMIs between 20 and $22\,kg\,m^{-2}$. The estimated fat mass showed as expected: a large gender difference with on average 43 to 50% for women and 25 to 35% for men, but differences in fat mass between ethnic groups were less striking (Wahlqvist *et al.*, 1995).

Aging and the Association between BMI, Weight Loss, and Health

Many studies have documented that the relative risks of a high BMI may become less pronounced with aging. Several explanations for this phenomenon have been forwarded, such as selective survival, cohort effects, and/or a ceiling effect of mortality rates (Seidell and Visscher, 2000). Also, it might be possible that an excess of fat mass is less detrimental at old age. The most important explanation might be that BMI is not a good indicator of body composition. The U-shaped relation between BMI and mortality in younger adults may be the result of a positive association between body fat mass and mortality and an inverse linear association between fat-free mass and mortality. As stated above, the ratio between the two compartments changes with aging and the BMI does not measure this. Finally, kyphosis in old age makes it difficult to measure height and, therefore, may result in unreliable estimates of BMI.

At the other end of the scale reflecting body weight, prospective studies have shown that weight loss, a decline in BMI, can be both a marker of and an independent contributor to adverse health outcomes (Wallace and Schwartz, 2002). Weight loss in elderly subjects is likely to reflect sarcopenia, a loss of lean body mass and particularly muscle mass. The latter may contribute to the increased mortality, especially if the initial body weight is relatively low. Incidence rates of 5 to 15% have been reported in studies of involuntary weight loss in community-dwelling older adults (Wallace and Schwartz, 2002; De Groot *et al.*, 2002). In frail elderly people, often dependent on professional care, rates of over 25% up to 40% have been observed. The degree of weight loss used to define "weight losers" has been variable in the different studies. Although no clear consensus exists in practice, mostly involuntary weight loss of 5% or more in one month or 10% and more in 6 months is applied to clinical diagnoses of malnutrition based on weight loss (Dempsey *et al.*, 1998).

It is considered helpful to inquire if weight loss was voluntary, nevertheless, two studies have suggested that intentional or not intentional, weight loss was similarly associated with increased mortality (Wallace and Schwartz, 2002). Suggested explanations for this finding are that weight loss per se is due to loss of lean body mass with all consequences of impaired function. Further, nutritional deficits are associated with low energy intake as is shown in Figure 3; (De Groot *et al.*, 1999).

Central Adiposity and Health

Redistribution of body fat with aging further limits the applicability of BMI as risk indicator in older adults. There is evidence in younger adults that those who have the majority of their adipose tissue around their waist (high waist-to-hip ratio) have a higher prevalence of diabetes mellitus, hypertension, and coronary artery disease than those who have predominantly hip adiposity. Folsom *et al.*, (1993) examined the role of body fatness on mortality in a random sample of 41 837 Iowan women aged 55 to 69 years, followed for 5 years. Waist-to-hip ratio was positively correlated with mortality, also after correction for smoking, alcohol, and estrogen use. Waist-to-hip ratio is, however, increasingly difficult to interpret with advancing age. Whereas the waist measures abdominal fatness, hip circumference may reflect also variation in pelvic width and gluteal muscle. In elderly people, narrow hips may reflect peripheral muscle wasting, which may correlate with chronic conditions (Seidell and Visscher, 2000; Visscher *et al.*, 2001).

Comparative data on the impact of abdominal fatness on mortality in younger and older adults come from the Baltimore Longitudinal Study on Aging. This study showed that increased abdominal depth (sagittal diameter) was related to increased all-cause mortality and CHD in men aged 55 and younger, but the same diameter was not related to either endpoint in older men. Explanations include again selective survival and cohort effects, but it may also be that the increased abdominal fat mass is less hazardous in older than in younger men (Seidell and Visscher, 2000).

The question arises, how useful in addition to BMI a measurement is of the waist-to-hip ratio, or waist circumference only. Visscher *et al.*, (2000) used data from the seven-country

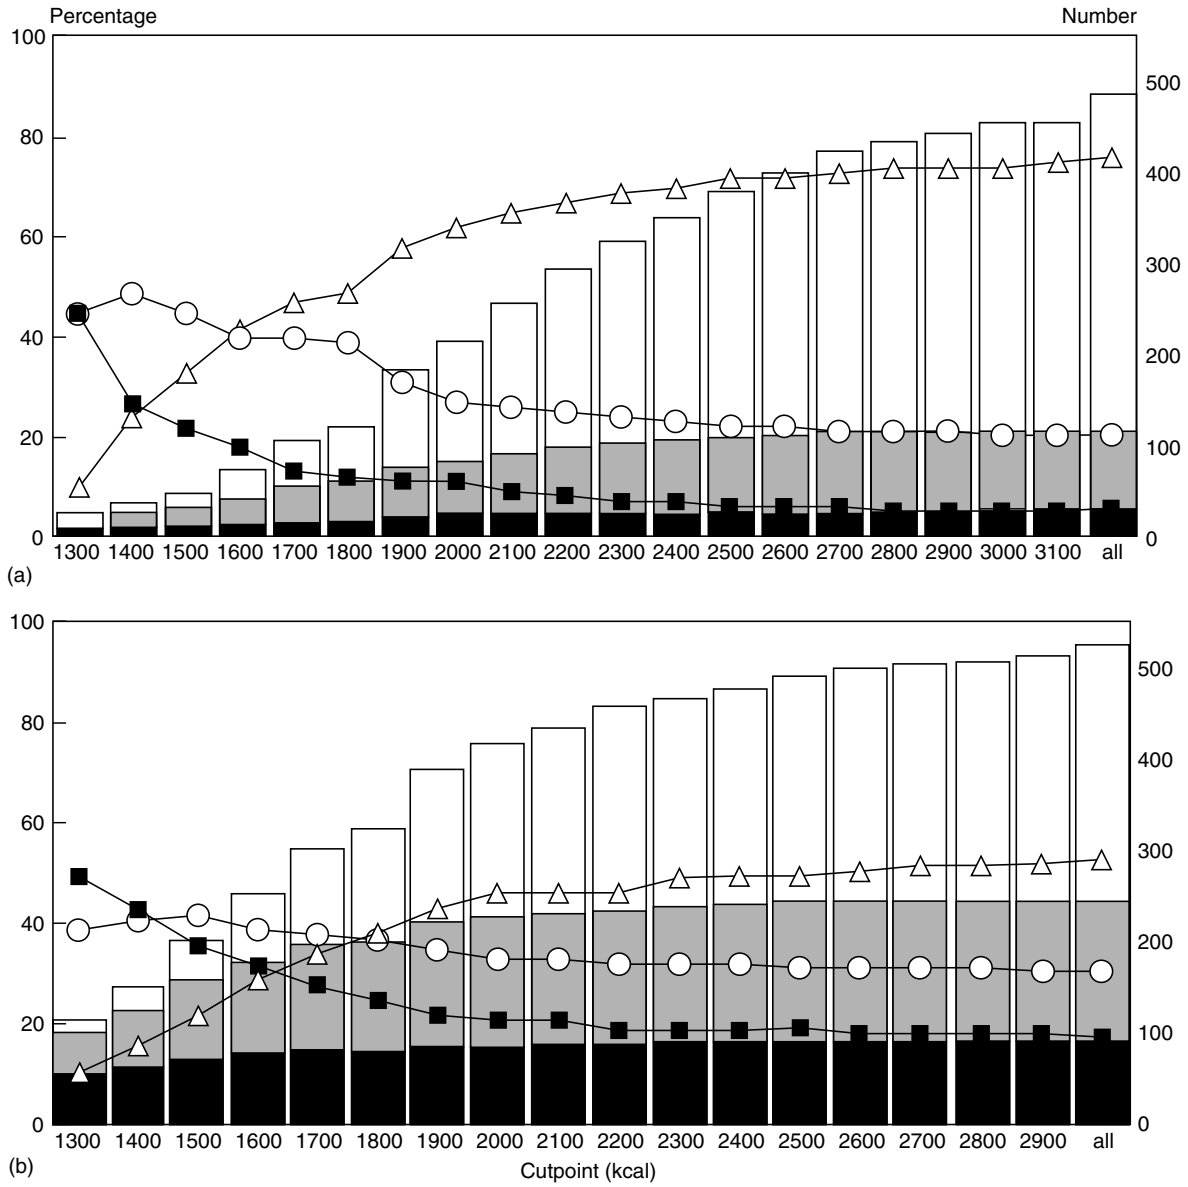

Figure 3 Number and percentage of **a** men and **b** women with an inadequate intake of no nutrients (□ and △), one nutrient (■ and ◯) and at least two nutrients (■ and □) for groups with energy intakes under different cut points (Reproduced from De Groot *et al.*, (1999) by permission of Oxford University Press)

study and showed that a large waist circumference was a better predictor of higher 5-year mortality than waist-to-hip ratio or BMI. Low BMI was a better predictor of mortality than low waist circumference. It is very likely that low lean body mass is better reflected by a low BMI, whereas increased fatness is better reflected by increased waist circumference.

The Importance of Weight Stability and the Need for Data on Body Composition

Weight stability within acceptable range as described above, or even a slight increase in weight seems to result to the lowest mortality (De Groot *et al.*, 2002). However, a stable weight or BMI may mask loss of lean body mass replaced by fat mass. There is a greater need for body composition data in epidemiological studies. How far waist circumference as an indicator of body fatness is of practical use in clinical situations should be studied further.

Fluid Status and Dehydration in the Elderly

Older adults are at risk for dehydration because of both reduced fluid intake and increased fluid losses (Weinberg and Miraker, 1995). Even in healthy, successful aging, there is a reduction in thirst in response to water deprivation, which is evidenced both in a lower self-reported thirst score during

dehydration and ingestion of less water after the dehydration period. Dehydration is a common and potentially lethal problem in both institutionalized and community-dwelling elderly people. In the United States, about 1.5% of community-dwelling people are hospitalized with dehydration each year (Reyes-Ortiz, 1997), but a British study found lower rates of 0.3% (Long *et al.*, 1991). The most common causes of dehydration were infection, altered level of consciousness, cognitive impairment, and use of diuretics. In hospitals, mortality rate was 54% in those older adults with dehydration (Long *et al.*, 1991). In a recent review, Allison and Lobo (2004) concluded that dehydration is a common problem in nursing homes often due to failures in detection of dehydration and appropriate management. They point to the fact that overload of water and salt is also common and may result in impaired recovery from surgery or perioperative mortality and morbidity. For the elderly, it is advised to take about 1.51 fluid per day.

Aging, Bone Loss, and Nutrition

Bone loss commences around the age of 40 years and is on average between 0.5% and 1% per year in men, and in women, the rate of bone loss accelerates around the menopause to about 2% per year. When bone density falls below 2.5 SD of the mean bone mineral density (BMD) of young adults, WHO (1994) speaks about osteoporosis. Osteoporosis is a multifactorial disease and defined also as "a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fractures" (Consensus, Osteoporosis, 1993). Biological, environmental, and genetic factors as well as lifestyle factors may play an important role in the onset and development of osteoporosis. Incidence of osteoporosis varies widely between countries and between and within ethnic groups. For instance, the NHANES III (Broussard and Magnus, 2004) showed that low BMD is most common among elderly non-Hispanic white women (21% osteoporosis) and among Mexican American women (20% osteoporosis) and lower in non-Hispanic black women (18%). Prevalence data are lower depending on diagnostic criteria applied.

Although a low percentage of the bone mass can be explained by nutritional factors (less than 20%), it can still have a large impact on bone health. Dietary therapy of vitamin D and calcium, and especially the combination of these two, is promising, as most of the times supplementation of both nutrients shows beneficial effects on BMD, bone turnover, and a reduced risk of fractures without side affects. Vitamin D requirement may be higher in regions where calcium intake is low. Vitamin D also has a beneficial effect on the risk of falling, explained by improvement of muscle function. Evidence for associations between optimal protein intake and bone mass is diverse, whereby positive, negative, and no associations have been found. Other dietary factors such as vitamin K, vitamin A, caffeine, fluoride, phosphorus, and zinc are subjects of current bone research as well, and are under debate whether important and truly associated with bone health.

CHANGES IN DIETARY INTAKE: DIFFERENCES WITHIN AND BETWEEN POPULATIONS

Changes in Energy and Macronutrients over Time

Population-based nutritional surveys have shown a gradual decline in energy intake at old age (De Groot *et al.*, 2000; (Figure 4 NHANES III)). Cross-sectional studies and longitudinal studies starting at middle age suggest that this decline in intake is accompanied by an increase in the percentage of energy from carbohydrates, whereas relative contributions

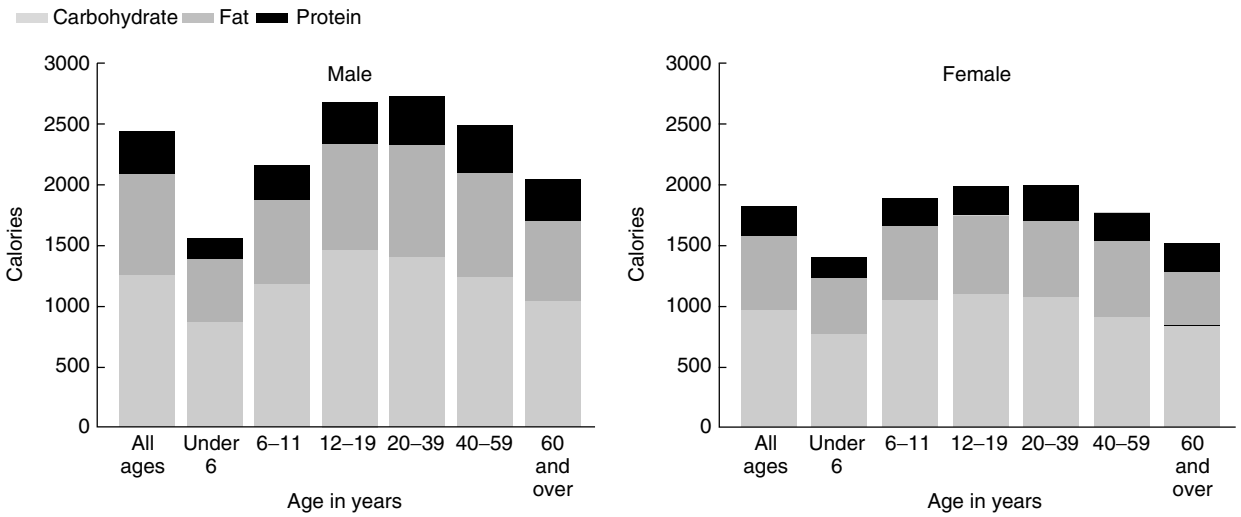

Figure 4 Total calorie intake and major sources of calories for US population, NHANES 1999–2000. (*Source*: http://www.cdc.gov/nchs/nhanes.htm U.S. Department of Health and Human Services Centers for Disease Control and Prevention National Center for Health Statistics)

of fat to energy intake decrease (Morley, 1997; Wakimoto and Block, 2001). In the SENECA (Survey in Europe on Nutrition and the Elderly, a Concerted Action) study in relatively healthy elderly people, thus starting at older age and covering shorter time spans, such shifts in macronutrient intakes did not emerge, despite the tendency of a reduction in total energy intake (Table 1, Moreiras *et al.*, 1996). This suggests that changes related to aging are small after the age of 70 years.

The macronutrient composition appears to vary considerably between populations. Across studies, intakes range from 12 to 18% energy from protein, from 20 to 42% energy from fat, and 38 to 65% of energy from carbohydrates. Low percentages energy from fat and high from carbohydrates are especially found in the Japanese and Chinese older communities (Wahlqvist *et al.*, 1995; Stookey *et al.*, 2000, Moreiras *et al.*, 1996).

The implication of macronutrient composition of the diet for health has been studied less than that of insufficient energy intake. One study that related macronutrient composition with survival revealed that decreasing protein and fat intake were increasingly related with mortality, while carbohydrates show a threshold effect on frail elderly patients (Frisoni *et al.*, 1995).

Table 1 Contribution of protein, fat, and carbohydrates (energy %) to daily energy intake in SENECA's follow-up study and longitudinal changes (1993 vs 1989)

	Men ($n = 155$)		Women ($n = 585$)	
	1993	Change	1993	Change
Energy (MJ day^{-1})	8.9 ± 2.4	-0.6 ± 2.5	7.0 ± 2.1	-0.4 ± 2.0
Energy % from:				
Protein	14.5 ± 2.8	-0.1 ± 2.8	15.4 ± 3.2	0.0 ± 3.3
Fat	35.8 ± 8.4	0.6 ± 7.6	38.1 ± 9.7	0.7 ± 8.6
Carbohydrates	45.0 ± 8.7	-0.2 ± 8.4	46.2 ± 9.5	-0.4 ± 8.9

Meal Patterns

As part of the culture, there are numerous factors that may influence the share of energy in the diet coming from various energy sources. These include, for example, the meal pattern and the use of food between meals. In Europe, large differences exist in the number of meals eaten per day; the median ranges from six in Denmark to three in the South of France. Meal-based nutrient intake data suggest that the cooked meal in the South of Europe mediates the beneficial effects of the Mediterranean diet (Schlettwein-Gsell *et al.*, 1999).

Vulnerable Groups

Within older populations, there are some subgroups, such as the socially isolated, the lonely, the institutionalized, or the economically deprived people, more likely to be consuming an imbalanced diet. Regarding the socially isolated, there are hardly any data, however, food consumption data of elderly *people living alone* show an adverse impact neither in the United States nor in Europe (Gerrior *et al.*, 1994; Pearson *et al.*, 1998).

Institutionalized elderly people tend to have a lower energy intake – mainly due to a lower fat intake – and a lower protein intake. Furthermore, nutrient inadequacy was more prevalent in the institutionalized elderly than in the community-dwelling groups as is shown in Table 2 (Van der Wielen *et al.*, 1996; Nowson *et al.*, 2003). At the same time, no clear differences in food patterns were observed. Therefore, the main cause of the higher prevalence of nutrient inadequacy in the dependent elderly people is most likely the low level of total food intake. An exception might be the group with a *poor state of dentition*. In the NHANES III as well as the SENECA, a lower quality of the diet was observed due to avoidance of food groups such as meat, fruit, and vegetables (Fontijn-Tehkamp *et al.*, 1996; Sayoun and Krall, 2003).

Table 2 Percentage of elderly people in different categories receiving *less* than the recommendations (RDA)[a] or less than the mean minimum requirements (Minimum need)[a] from diet alone

		Females			
		Nursing homes		Free-living	
Nutrient	Reference value	Resident $n = 40$	Admission $n = 11$	SENECA $n = 68$	4-day marches $n = 32$
Thiamin	RDA 0.12 mg MJ^{-1} and >1.0 mg day^{-1}	88^{A}	91^{AB}	71^{AB}	44^{B}
	Minimum need 0.07 mg MJ^{-1} and >0.8 mg day^{-1}	55^{A}	45^{A}	31^{A}	6^{B}
Riboflavin	RDA 1.3 mg day^{-1} (females); 1.5 mg day^{-1} (males)	62^{A}	45^{AB}	26^{B}	12^{B}
	Minimum need 1.1 mg day^{-1}	45^{A}	36^{AB}	19^{B}	9^{B}
Vitamin B6	RDA 0.02 mg g^{-1} protein[b]	90^{A}	91^{AB}	66^{B}	38^{C}
	Min. need 0.015 mg g^{-1} protein and >1.0 mg day^{-1}	58^{A}	45^{AB}	31^{B}	6^{C}
Vitamin C	RDA 70 mg day^{-1}	72^{A}	64^{A}	16^{B}	3^{B}
	Minimum need 50 mg day^{-1}	48^{A}	45^{AB}	12^{BC}	0^{C}

[d]For calculations of the score see Haveman-Nies *et al.*, (2001).

Institutionalized people are often frail and suffer from functional as well as *cognitive impairment*. In addition to an overall inadequate food intake, several studies have pointed to more specific nutrients and cognitive decline. Examples are increased serum homocysteine levels, as a result from a shortage of folic acid, vitamin B12, or B6 (Morris *et al.*, 2001; Eussen *et al.*, 2002), vitamin C and E as antioxidants, and specific fatty acids (Kalmijn, 2000). However, up till now, studies regarding these relations are either contradictive or valid trials are lacking.

Economically deprived people also may consume an unhealthy diet. In the United States, 21% of the older independently living people below the poverty index had a poor diet based on the Healthy Index (for description see Table 3), while amongst those above the poverty level, this was 11% (Federal Forum, 2000). In the SENECA study, those subjects who reported difficulty in budgeting for their food purchases were found to have a significantly lower intake of three out of five nutrients analyzed, than those subjects who reported no such difficulty. It should be added that the former subjects also reported four times more often to have poor health as the SENECA participants without budget problems (Schlettwein-Gsell *et al.*, 1999).

Park *et al.*, (2003) reviewed dietary intake data in *rural and urban elderly people* in Korea. She observed that urban elderly people with a low income had energy intakes about 400 kcal or 1.7 MJ below the all-income (no separation between low and high income) elderly groups, and this resulted for the low income group in an inadequate supply of micronutrients. The low energy intake was related to a lower body weight and BMI ($24\,kg\,m^{-2}$ vs $22\,kg\,m^{-2}$). In the rural elderly group, BMI was also rather low ($22\,kg\,m^{-2}$), but their energy intake was as high as the all-income group. Similar results were obtained in a Chinese study (Stookey *et al.*, 2000).

HIGH-RISK NUTRIENTS

Even with an apparently adequate food intake, an adequate supply of some nutrients is hard to achieve. Below we discuss some specific high-risk nutrients not directly related to a low energy intake.

Atrophic gastritis reduces the absorption of several nutrients, which leads, especially for *vitamin B12,* to a deficiency state. Van Asselt *et al.*, (1998) found in the Dutch SENECA cohort a prevalence of 24%, which only partly could be explained by dietary intake or atrophic gastritis. As yet, there is no evidence that vitamin B12 is handled differently in old age once the vitamin is absorbed. Therefore, other factors responsible for the cobalamin deficiency need to be sought.

Low *vitamin C* levels have been associated with increased risk for coronary artery disease and senile cataract (Nyssonen *et al.*, 1997). Nevertheless, based on current knowledge, requirements for vitamin C in older people do not differ from those of younger people ($60-100\,mg\,day^{-1}$). Unfortunately, vitamin C is readily lost from foods during storage and preparation. For Dutch and Danish diets, such vitamin C losses amounted to approximately 45% of vitamin C content of the diet, and consequently, about 30% of the subjects had too low intakes. Results from the NHANES III study showed that average intake serum levels were normal in the Americans, but smokers, those not taking supplements, and non-Hispanic black males had higher risks. Low serum levels for the latter group were mainly due to low intakes of fruits and vegetables (Hampl *et al.*, 2004).

Vitamin A is of worldwide concern as a risk nutrient, but probably due to lower requirements in old age (Russell, 1997), has not been observed as a specific problem for the elderly people. An exception might be the observation of very low intakes in Korea (Park *et al.*, 2003).

Approximately one-third of the *vitamin D* requirements can be obtained from the diet. The rest is synthesized in the skin under the influence of sunlight. As a result of limited sunlight exposure and a fourfold reduced capacity of the skin to produce vitamin D, deficiencies may occur in homebound elderly people (Lips, 2001). However, also in relatively healthy older people, low vitamin D levels are often observed (Van der Wielen *et al.*, 1995; Newmark *et al.*, 2004). Surprisingly, in the SENECA Southern survey towns, lower values were found than in the Northern towns. This could be explained by reduced sunlight exposure and

by problems performing activities of daily living. Using sunlamps and/or vitamin D supplements was particularly prevalent in the Northern SENECA towns, and such use was associated with a higher serum 25-hydroxyvitamin D concentration.

Calcium is a risk nutrient in elderly people with no or little dairy products in their diet. This might happen within many cultures and was particularly observed in some Asian centers (Park *et al.*, 2003; Wahlqvist *et al.*, 1995).

DIETARY PATTERNS, HEALTHY DIET SCORES, AND SURVIVAL

Healthy Diet Scores

In addition to single dietary components or nutrients, measures of overall dietary patterns are important in investigating diet and health status (Kant, 1996 and Trichopoulou *et al.*, 1995). To make dietary patterns operational, two common methods are cluster analysis and calculation of diet scores. Cluster analysis explores the categorization of persons into groups on the basis of similarity in food intake (e.g. alcohol drinkers or fish and grain eaters). Diet scores are based on dietary guidelines and are applied to identify groups with good or poor nutritional status. In the United States and Europe, existing measures of overall dietary quality include the Healthy Eating Index (HEI), Mediterranean diet score, and the healthy diet indicator. These diet scores differ in diet components, scoring rates, and definition of cut-off values (Table 3). In spite of these differences, diet scores as well as cluster analysis have been shown to be useful tools to identify groups with different nutritional status. Haveman-Nies *et al.*, (2001) evaluated dietary quality of European and American elderly subjects using cluster analysis, the healthy diet indicator, and two versions of the Mediterranean diet scores MDS. These measures were tested for associations with lifestyle and nutritional status in an elderly population, aged 70 to 77 years from the Framingham study and from the SENECA. Table 4 shows food group intake and results of the scores by the five dietary pattern clusters observed. In general, Southern European Centers and Framingham had better mean diet scores than Northern European Centers. Cluster analysis revealed that the meat, eggs, and fat pattern coincided with significantly lower average dietary quality, as measured with all three scores, compared to all other clusters except the alcohol cluster. The cluster characterized by a relatively high fish and grain intake had a significantly better MDS than all other clusters. High-quality diets were associated with less body fatness, greater physical activity, and nonsmoking.

Healthy Diet, Other Lifestyle Scores, and Mortality

As a next step, Haveman-Nies *et al.*, (2002) examined the relationship between three modifiable lifestyle factors and 10-year survival in the SENECA study. The factors included the quality of the diet as measured with the MDS, smoking, and physical activity. The results are shown in Figure 5. Even at age 70–75 years, the unhealthy lifestyle behaviors having a low-quality diet, smoking, and being physically inactive were singly related to an increased mortality risk (hazards

Table 4 Mean (s.d.) food group intake of 70–77 years elderly of the Framingham Heart Study and SENECA's baseline study, by dietary pattern cluster

	Sugar $n = 526$	Fish and grain $n = 307$	Meat, eggs, and fat $n = 659$	Milk and fruit $n = 525$	Alcohol $n = 93$
Northern center (n) (total = 782)	101	18	511	129	23

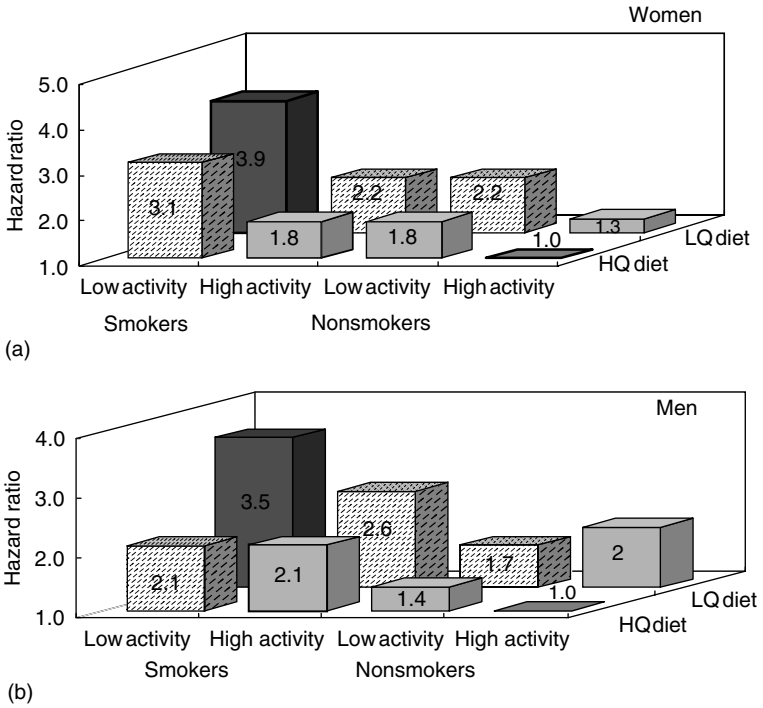

Figure 5 Hazard Ratios for single and combined effects of the lifestyle factors diet, smoking, and physical activity in European women (5a) and men (5b) born between 1913 and 1918, The SENECA Study, 1988 to 1999 (Reproduced by permission of Oxford University Press)

ratios ranged from 1.2 to 2.1). The risk of death was further increased to a three- or fourfold risk for all combinations of an unhealthy lifestyle. Numbers in the SENECA study were too low to examine associations with cause-specific mortality. Therefore, Knoops *et al.*, (2004) merged the data set of SENECA with three centers of the seven-country study (centers in Finland, Italy, and the Netherlands). Since important features of design and methods were similar, the merging of data did not lead to spurious results. Preliminary data show that, also in these groups (1507 apparently healthy men and 832 women aged 70–90 years), adherence to a Mediterranean diet and healthy lifestyle is associated with >50% lower rate of all-cause mortality; similar results were obtained for mortality of CHD, cardiovascular disease, and cancer. The results regarding the diet score confirm earlier data published by Trichopoulou *et al.*, (1995) for the Greek population and by Kouris-Blazos *et al.*, (1999) for Anglo–Celts and Greek Australians.

EFFECT OF NUTRITIONAL SUPPLEMENTS ON HEALTH INDICES IN ELDERLY PEOPLE

There are many ways to improve the nutritional situation in old age, mostly aimed at improving nutrient intake either in terms of quantity and or quality. In order to assess the efficacy of nutrition-related interventions, a number of studies have been conducted. A literature review (Wouters-Wesseling, 2002) examining the literature between 1985 and 2002 divided the studies into multinutrient supplements and single nutrient supplements. Studies conducted in the elderly with specific diseases such as Alzheimer disease were excluded.

Regarding the multiple nutrient studies, only nine were found with a placebo-controlled double-blind design. Six studies were carried out in institutionalized elderly and three studies in home-dwelling elderly. The number of participants varied between 30 and 130, and the duration of the studies between 1 month and 1 year. One study had a duration of 2 years and included a large number of 180 patients (Girodon *et al.*, 1999). The supplements varied in composition and also outcome measures varied. Nevertheless, the results of the studies are more or less in the same direction: improvement of body weight and biochemical parameters of the nutritional status such as serum vitamin levels and functional biochemical parameters, for example, serum homocysteine. Beneficial effects were more convincing when the intervention was conducted during a longer period and when the patients had more serious functional impairments. Studies also showed improvement of the immune status; especially humoral response improved after supplementation with both trace elements and antioxidants, meanwhile, antioxidants only had no effect (Girodon *et al.*, 1999).

Twelve placebo-controlled studies with a single nutrient intervention were found; three in institutionalized elderly people and nine in home-dwelling elderly. The nutrients included selenium, zinc, β-carotene (2 studies), vitamin D, E (4 studies), C, B1, and folic acid. The amount and duration

of the supplementation varied according to the multinutrient intervention. The supply of these single nutrients resulted in improvement of indices of the status related to the single nutrient supplement. Furthermore, the recommended daily doses of either a zinc or selenium supplement improved the immune status according to some, but not all immune status parameters. This occurred also with a high dose (400–800 mg) vitamin E, on the other hand, such an intervention also has shown an unfavorable effect on respiratory infections (Graat *et al.*, 2002).

The literature search shows that in frail elderly people, a combination of macronutrients and micronutrient (enriched or fortified foods) might be preferred. Such an intervention affects several aspects of the nutritional and health status of this group. Again, the doses should not exceed the recommended daily intakes, because adverse affects of such doses on organ systems have been reported (Palmer *et al.*, 2003).

In addition, other types of intervention studies provided evidence for improvement of the nutritional status and quality of life with different approaches to increase food intake. These are, amongst others, (van Staveren *et al.*, 2002):

- stimulation of physical activity,
- improving meal ambiance, and
- flavor enhancement of the cooked meal.

In sum, intervention studies have shown that in frail elderly, dietary interventions improve the nutritional status and that combining these interventions with other interventions such as extra physical activity give complimentary effects on health outcome variables.

DIETARY GUIDELINES

In this chapter, we started with the dietary guidelines for the prevention of chronic diseases of WHO (2003).

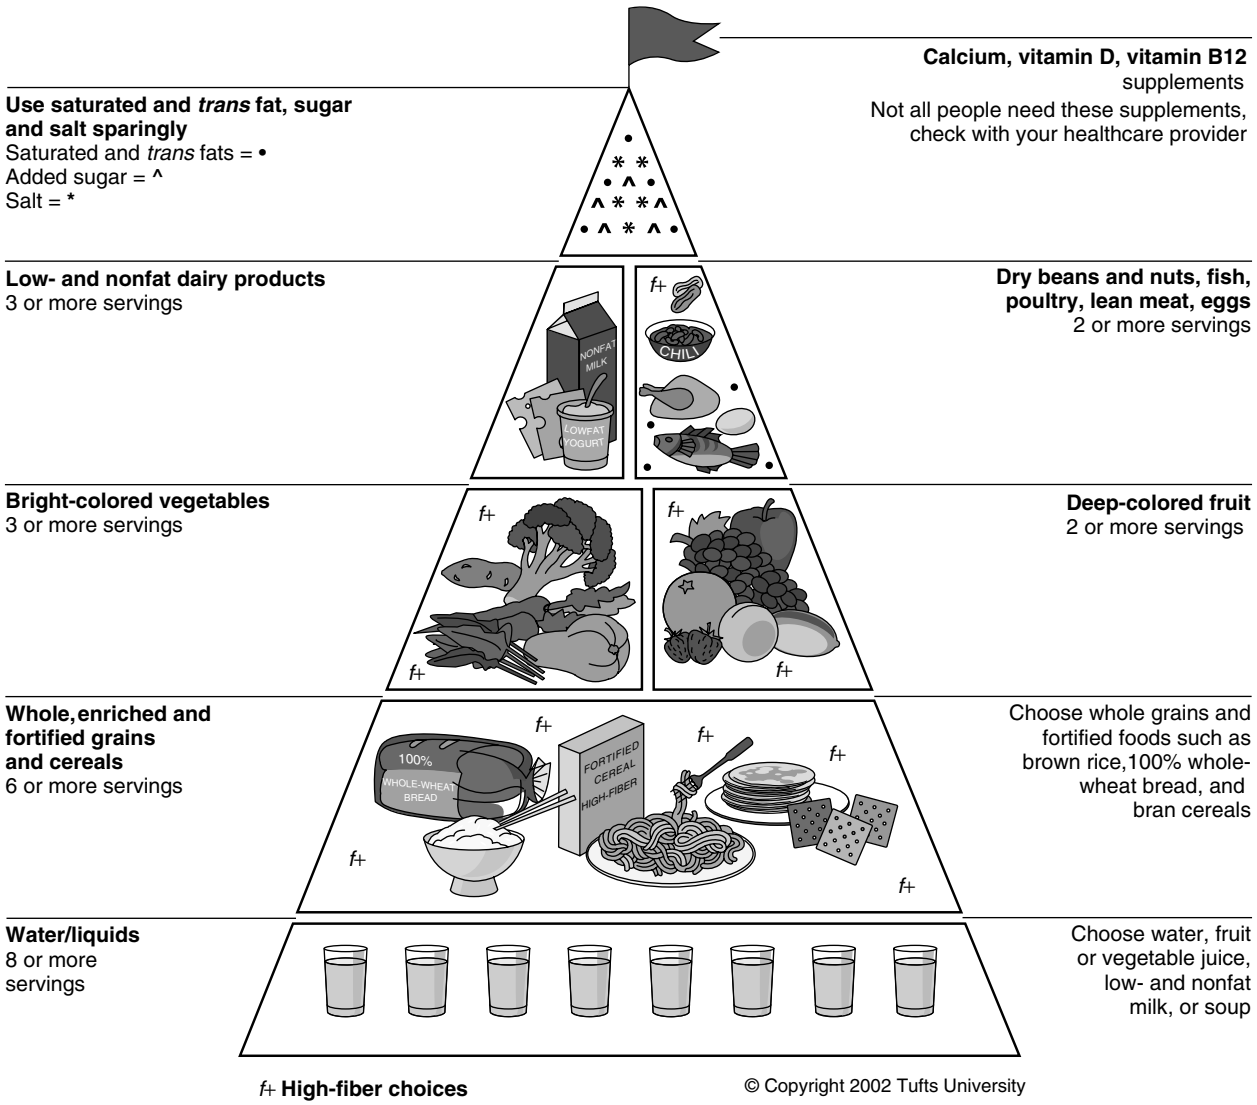

Figure 6 Food guide pyramid for older adults (Copyright Tufts University, Boston, USA)

Epidemiological studies on nutrition and aging show that the guidelines for elderly people are very similar to those formulated for younger adults. However, the priorities should be different. In the first place, it is recommended to aim for stable body weight and maintenance of fat-free mass by sufficient physical activity. Dietary recommendations are nicely depicted in the pyramid for elderly people (Figure 6). The healthy foods in the pyramid are the same foods that comprise the MDS. In addition, there is a basis of sufficient fluid (although the amount recommended is rather a maximum than an average), and attention is given to some supplements. For vitamin D, there is sufficient evidence that a supplement is required for groups of elderly people. Homebound elderly people are most at risk. Further, as explained above for elderly people with insufficient intake of dairy products, extra calcium is required and elderly people suffering from atrophic gastritis may benefit from a vitamin B12 supplement.

Frail elderly people with a very low energy intake may need enriched or fortified foods with vitamins and minerals added according to the dietary recommendations.

Finally, we like to conclude that although there are still many questions in the relationship between dietary patterns and health and in the effectiveness of supplement use, the epidemiology of nutrition and aging supplies us with sufficient evidence on the importance of adequate nutritional care and a healthy diet in old age.

KEY POINTS

- The relative risks of a high BMI become less pronounced with aging. A decline in BMI may reflect sarcopenia, which is related to decreased survival time.
- A low energy intake (<6.3 MJ/1500 kcal) goes together with an insufficient supply of micronutrients.
- High-risk nutrients independent of sufficient energy intake are vitamin B12 and vitamin D and for specific groups vitamin A, vitamin C, and calcium.
- Also in an elderly population, healthy dietary patterns are related to decreased total mortality and disease-specific mortality.
- Adequate nutritional care includes care for sufficient fluid intake.

Absorption of Nutrients

Akeeb Adedokun

Saint Louis University, St Louis, MO, USA

INTRODUCTION

Since the evolution of the first unicellular microorganisms, absorption of nutrients has been a challenge, that is, the ability to process and transfer energy from complex nonabsorbable forms stored in food to simpler and more usable forms across semipermeable biological membranes. In lower organisms this was generally easier as the unicellular organisms were bathed in the medium of nutrients they lived in. As more advanced multicellular organisms evolved, and as organisms were now living in environmental media that were outside of their food, it then became necessary to evolve a more complicated internal digestive and absorptive systems, with the various parts, that is, teeth, jaws, stomach reservoir, digestive enzymes, large absorptive surface areas in the intestine, and so on, all functioning as a system. Digestion of nutrients then became coupled to absorption of nutrients.

The small intestine is the most important site of nutrient absorptions. Structurally, it is constructed to provide maximum absorptive surface area within a limited space. The presence of Kerckring's folds, villi, and microvilli result in a 600-fold increase in surface area, compared to the surface area of a simple cylindrical tube. In humans, the surface area of the small intestine available for absorption is about 100 times larger than the human body surface area (Caspary, 1987).

Absorption of nutrients occurs across the plasma membranes of the intestinal epithelial cells. Nutrient molecules penetrate by various mechanisms that include simple passive diffusion, facilitated (carrier-mediated) diffusion, active transport, and pinocytosis (Caspary, 1992).

REGULATION OF NUTRIENT ABSORPTIONS

The amount of nutrients that is eventually absorbed into the body depends on several factors. Some of these are mechanical factors such as the amount of food ingested, masticating activities of the teeth, peristaltic activities of the gastric emptying and intestinal transit. Others are neuronal and hormonal factors, which control the secretions of digestive juices from the glands in the mouth, stomach, pancreas, and intestines. Still others are mucosal (especially of the small intestines) and intraluminal factors, which alter how nutrients are able to move from the intestinal lumen into the intracellular and interstitial spaces.

It has long been suspected that the composition of the food we eat, especially during our early days of formation may have effects on how we digest and absorb nutrients later on in life, that is, the phenomenon of intestinal adaptation and critical-period programming. Karasov *et al.* (1985) defined this as a biological mechanism, which is turned irreversibly on or off once during an individual's lifetime, in response to conditions prevailing at some critical stage.

Studies in rodents with hormones or peptides such as glucocorticoids, polyamines, growth hormone, insulinlike growth factors, proglucagon derived peptides, or by changing various components of the baby's diet have shown some acceleration of the rate of maturation of intestinal absorption (Tiesen *et al.*, 2000).

COMPOSITION OF DIET

The average diet consists of macronutrients (such as carbohydrates, proteins, fats), micronutrients (such as Vitamins B_{12}, C, A, E, D, K, niacin, thiamine, riboflavin, pantothenic acids, minerals), nonabsorbable fibers (such as hemicellulose, pectins), and water. Carbohydrates, especially polysaccharides account for at least 50% of the daily calories of adults living in western industrialized countries (Elsenhans and Caspary, 1987).

ABSORPTION OF MACRONUTRIENTS

After ingestion of carbohydrate, the enzyme alpha amylase acts on the polysaccharides of starch to convert them to

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

short chain oligosaccharide. These are then acted upon by the membrane-bound enzymes of the epithelium of the small intestines to convert them into the monosaccharides of primarily glucose, galactose, and fructose, which are the absorbable forms of carbohydrates. The monosaccharides are then absorbed via transport routes that are both specific (e.g. sodium-dependent active transport and facilitated diffusion) and nonspecific (e.g. passive diffusion) (Elsenhans and Caspary, 1987) into the portal venous system. The main events of protein digestion occur with cleavage of polypeptides by pancreatic proteases such as trypsin, chymotrypsin, elastase, and carboxypeptidase. Large polypeptides are converted to oligopeptides. At the intestinal brush-border membranes, there is hydrolysis of oligopeptides into tripeptides, dipeptides, and some free amino acids, with subsequent transport by different specific amino acid and small peptide carrier systems into the cytoplasm of the intestinal epithelial cells where most dipeptides and probably all tripeptides are rapidly hydrolyzed to their constituent amino acids before they finally appear in the portal venous system (Caspary, 1992). About 90% of dietary fats consist of triglycerides, while the rest is made up of phospholipids, cholesterol, fatty acids, and fat-soluble vitamins (Glickman, 1983; Stremmel, 1987). Digestion of dietary fats begin with activities of upper gastrointestinal (GI) tract secretions, which bring about emulsification of fats into particles (mainly by bile salts), hydrolysis of lipid esters (mainly triglycerides by pancreatic lipase) converting them to fatty acids and monoglycerides. A water-suspension of mixed micelles consisting of bile acids, fatty acids, monoglycerides, cholesterol, lysophospholipids, and fat-soluble vitamins is presented to the intestinal mucosal cells (Stremmel, 1987; Carey *et al.*, 1983). Permeation of fatty acids through the microvillus membrane of the mucosal cells occur by a specific carrier-mediated energy dependent transport process driven by a transmembranous sodium gradient (Stremmel, 1987). Following absorption, intracellular, long chain fatty acids are reesterified into triglycerides. Then together with cholesterol, cholesterol esters, fatty acids, and fat-soluble vitamins, the lipids are reconstituted with apolipoproteins to form chylomicrons and very low density lipoproteins. These are then released into the interstitial spaces via a process of reversed pinocytosis or exocytosis and eventually into the lymphatic system and then the systemic circulation. Medium chain triglycerides are absorbed much more easily. They do not require bile salts for absorption and are not reesterified intracellularly. For this reason they do not require incorporation into chylomicrons, and are transported directly to the liver via the portal venous system (Caspary, 1992).

ABSORPTION OF MICRONUTRIENTS

Vitamins and minerals are readily absorbed from the gastrointestinal tract. Iron is mainly absorbed in the upper gastrointestinal tract and the absorption is enhanced in the presence of acid from gastric secretions. An acidic medium also enhances the absorptions of folate and calcium. Vitamin B_{12} is mainly absorbed in the terminal ileum. Malabsorption of fats will affect the absorptions of fat-soluble vitamins (A, D, E, K). Vitamin D is produced endogenously from the skin following exposure to sunlight (Moore and Iber, 1998). However, this amount is reduced with aging, making gastrointestinal absorption more important.

EFFECT OF AGING ON NUTRIENT ABSORPTION

The aging gastrointestinal tract has very few changes that substantially influence digestion and absorption of nutrients. The changes that do commonly occur have greater impact on the activity and pleasure of eating (Moore and Iber, 1998). The taste threshold for recognition and detection of flavors becomes elevated with aging (Stevens *et al.*, 1984). Medications and cigarette smoking can markedly alter taste thresholds. Similarly, zinc deficiency, which can occur in persons with diabetes mellitus or diuretic users, can cause an increase in taste thresholds. This means greater concentrations of substrate must be presented to the taste buds before they are detected. Loss of smell is also common with aging especially after the age of 80 years. Salivary flow is often diminished with aging, but it is usually related to disease or medications (Russell, 1992). Salivary volume secretion does not appear to be affected by aging per se (Baum, 1981). Chewing activities may be affected by aging because of loss of effective dentition, leading to restriction of food, malnutrition, and undernutrition. Reduced gastric acid production is common among the elderly. In one US population-based study, it was found to be about 31% in those over the age of 60 years (Samloff *et al.*, 1982). This was attributed to the high prevalence of Helicobacter pylori infection and atrophic gastritis in the elderly population.

Impaired gastric emptying and impaired esophageal motility are occasionally encountered with aging but they have little or no effect on nutrient absorption (Kupfer *et al.*, 1985). With aging, the blood flow to the gastrointestinal tract declines both absolutely and as a fraction of cardiac output (Blender, 1965). For a 65-year-old man, cardiac output decreases by 30% compared to young adults. This translates to a 50% decrease in gastrointestinal blood flow (Richey and Blender, 1977).

The liver size decreases with aging, and the portal blood flow also decreases significantly with aging. The activities of many glucuronyl transferase enzymes are diminished with aging (Iber *et al.*, 1994). The sensitivity of gallbladder contractions to cholecystokinin stimulation has been shown to be diminished in older people (Khalil *et al.*, 1985). Pancreatic enzyme secretions are slightly diminished with age. It is unclear if these changes have any significant effect on nutrient absorption under physiologic conditions. Morphological changes in the gastrointestinal tract such as number of crypts and villi, diverticulosis, intestinal brush-border membrane and its enzymes that occur with aging have been studied but there is no consensus if age-related changes

Table 1 Effect of aging on nutrient absorption

Nutrient	Age-related changes
Carbohydrates	Slightly reduced absorption at high doses
Protein	Slightly reduced absorption at high doses
Fat	Slightly reduced absorption at high doses
Thiamine	No change
Riboflavin	No change
Pantothenic Acid	Slightly reduced absorption
Niacin	No change
Folic Acid	Slightly decreased absorption
Vitamin A	Slightly increased absorption
Vitamin B_{12}	Slightly decreased absorption
Vitamin C	Slightly increased absorption
Vitamin D	Decreased skin synthesis
Vitamin E	Decreased antioxidant status
Vitamin K	No change
Calcium	Slightly decreased absorption
Magnesium	No change
Zinc	No change

significantly alter nutrient absorption (Warren *et al.*, 1978; Table 1).

DISEASE CONDITIONS INFLUENCING NUTRIENT ABSORPTION

Although impaired intake due to conditions such as depression and neurological diseases are the most common causes of reduced nutrient intake, a variety of gastrointestinal disorders can influence nutrient absorption. Chronic gastritis especially from Helicobacter pylori infection can lead to atrophic gastritis and achlorhydria with the consequence of malabsorption of iron (due to reduced gastric acid secretions) and of vitamin B_{12} (due to loss of intrinsic factor).

Small intestinal bacteria overgrowth, which is common in patients with long standing diabetes and diverticulosis, can be a cause of malabsorption of fats, vitamin B_{12} and folate, as the overgrown intestinal bacteria deconjugate bile salts and remove vitamin B_{12} from intrinsic factors. In severe cases, there may be extensive damage to the mucosal cells of the small intestine, leading to a more generalized malabsorption of nutrients (Holt, 1992). This condition can also be associated with an excessive gastrointestinal cytokine secretion leading to anorexia.

Celiac disease can result in damage to the intestinal absorptive surfaces due to gluten hypersensitivity with consequence of malabsorption of folate, vitamins A, D. This condition is worsened in the presence of wheat products, and may present with diarrhea. It is commonly associated with diabetes mellitus, and may present for the first time in older persons. Diseases of the pancreas can result in reduction of the exocrine function of the pancreas and pancreatic insufficiency with consequence of malabsorptions of fats, vitamins A, D, E, vitamin B_{12}, and calcium. Diseases of the terminal ileum such as regional ileitis can also result in malabsorption of fats, vitamins A, D, E, vitamin B_{12}, and calcium. Gastrointestinal surgeries that involve gastrectomy or vagotomy may result in malabsorption of iron, calcium, and vitamin B_{12}. Surgical removal of the terminal ileum may result in malabsorptions of vitamin B_{12} and fat. Pancreatic surgeries may also result in malabsorptions of fat, and fat-soluble vitamins. Surgical operations on the liver, gallbladder, or biliary tract generally have no effect on subsequent nutrition if the patient remains free of jaundice (Moore and Iber, 1998).

The work-up for malabsorption includes examining the stool for excess fat and meat fibers, and measuring circulating beta-carotene and vitamin A (Table 2).

DRUG–NUTRIENT INTERACTIONS

Drugs effect nutrient absorption by various mechanisms, among which are direct mechanisms such as drug-induced pH changes in the gastrointestinal tract (antacids), drug-induced changes in bioavailability (e.g. adsorption to drugs like kaolin, pectin), drug-induced retardation of absorption (charcoal), drug binding, or chelation (e.g. anionic exchange resins – cholestyramine, metal ions – iron, calcium). Drugs can also effect nutrient absorptions via indirect mechanisms, such as drug-induced changes in gut motility (e.g. anticholinergics), or drug-induced malabsorption syndromes (e.g. neomycin) (Thomas, 1995). The effect of drug–nutrient interactions are commonly seen in patients taking the same drugs daily for many months or years, as opposed to patients taking short courses of the drugs (Moore and Iber, 1998).

Table 2 Most common diseases modulating nutrient absorption

Disease	Impaired absorption	Mechanism
Chronic gastritis	Decreased vitamin B_{12}, iron	Reduced gastric acid secretion. Loss of intrinsic factor
Partial gastrectomy	Decreased vitamin B_{12}	Loss of intrinsic factor
Bacteria overgrowth	Decreased vitamin B_{12}, folate	Deconjugation of bile salts. Removal of vitamin B_{12} from intrinsic factor
Celiac disease	Decreased folate, vitamins A, D	Damage to intestinal absorptive surfaces
Pancreatic insufficiency	Decreased vitamins A, D, E, and calcium	Malabsorption of fats
Terminal ileum diseases	Decreased vitamins A, D, E, B_{12}, calcium, fats	Loss of absorptive surfaces
Alcoholism	Decreased folate, thiamine, macronutrients	Decreased intake. Damage to intestinal absorptive surfaces
Chronic liver and gallbladder diseases	Decreased vitamins A, D, E, K, fats	Malabsorption of fats

Table 3 Drug–nutrient interactions

Drugs	Effect on nutrient absorption	Mechanism
Methimazole, PTU, formaldehyde, CNS depressants	Decreased macro- and micronutrients	Impaired smell
Penicillamine, tetracycline, flagyl, captopril, cancer chemo, CNS depressants	Decreased macro- and micronutrients	Impaired taste
Erythromycin, digoxin, codeine, morphine, amphetamine	Decreased macro- and micronutrients	Suppressed appetite
Antacids, H2 blockers	Decreased vitamin B_{12}, calcium, iron	Cause pH changes
Kaolin. Pectin, charcoal, drug binder/chelations	Decreased calcium, iron	Impaired bioavailability
Anticholinergics	Malabsorption of macro- and micronutrients	Impaired gastrointestinal motility
Broad-spectrum antibiotics (neomycin)	Decreased vitamin K, folate	Affect intestinal bacteria flora
Anticholinergics	Decreased vitamins A, D, K, macronutrients	Impaired gastrointestinal secretions.

Examples of some commonly encountered clinical scenarios include folate deficiency or megaloblastic anemia in patients chronically on drugs such as phenytoin, phenobarbital, primidone, and phenothiazine. Vitamin B_{12} malabsorption occurs in patients on aminosalicyclic acid, colchicines, and trifluoperazine. Malabsorption of iron is present in patients chronically on antacids. Calcium malabsorption is associated with taking large amount of fibers. Niacin and pyridoxine deficiencies occur in patients chronically on isoniazide and penicillamine (Trovato *et al.*, 1991).

Chronic use of alcohol can result in injuries to the intestinal mucosal cells with resulting malabsorption syndrome that causes impaired absorption of both macro and micronutrients (Table 3).

CONCLUSION

In humans, absorption of nutrient is coupled with digestion of food and is regulated by a complex interaction of factors. Some of these are neurohormonal, while others are glandular, mucosal, and intraluminal factors. Normal aging brings about very few changes that substantially influence digestion and absorption of nutrients. The changes, however, have greater impact on the activity and pleasure of eating. Malabsorption of nutrients is often due to pathological gastrointestinal conditions of which those commonly seen in older adults include atrophic gastritis and achlorhydria, intestinal bacteria overgrowth, celiac disease, pancreatic diseases, previous gastrointestinal surgeries, and drug–nutrient interactions.

In summary the following apply:

KEY POINTS

- Physiological changes with aging have minimal impact on gastrointestinal absorption.
- Lack of production of intrinsic factor and achlorhydria can cause malabsorption of vitamin B_{12} and iron.
- Bacteria overgrowth in the intestine can lead to nutrient malabsorption.
- Medications are an important cause of micronutrient malabsorption.
- Celiac disease and pancreatic insufficiency are common causes of malabsorption in older persons.

The Anorexia of Aging

Ian M. Chapman

University of Adelaide, Royal Adelaide Hospital, Adelaide, South Australia, Australia

THE "PARADOX" OF UNDERNUTRITION IN OLDER PEOPLE

Over-nutrition is the major form of malnutrition in the developed world. A substantial proportion of older people in western countries are overweight or obese according to generally accepted body mass index (BMI weight[kg]/(height[m])^2) criteria. For example, in a 2000 study, 58% of Americans aged $\geq$65 years had a BMI of 25 kg m^{-2} or more (Flegal *et al.*, 2002), the World Health Organization cut-off for overweight. Weight loss is usually recommended for overweight and obese older adults in the same manner as in younger adults and at any given time, a substantial proportion of older people wish to lose weight. Furthermore, there is evidence from studies in species as varied as yeast, spiders, mice, and possibly primates, that long-term restriction of energy (food) intake by 30–60% compared to *ad libitum* intake, prolongs life (Lane *et al.*, 2004). It might seem, therefore, that reduced food intake leading to weight loss would be good for the majority of older people.

This is not necessarily the case, however. The effects of long-term voluntary energy restriction have not been tested in humans and the benefits observed in other species may not apply to ours. Even if such a restriction is beneficial, it may have to be started in childhood, with consequent inhibition of normal growth. Marked energy restriction in older adults is likely to lead to a substantial loss of beneficial lean body tissue as well as fat mass and increase the risk of vitamin, mineral, and other dietary deficiencies.

As indicated in the following text, (1) ideal weight ranges are almost certainly higher in older than young adults; (2) weight loss is often associated with adverse effects in the elderly, particularly if unintentional; and (3) undernutrition manifesting as low body weight and weight loss is common in older people and has significant adverse effects. For these reasons, caution should be exercised in recommending weight loss to people over 70 years and a high level of awareness needs to be maintained to detect unintentional weight loss and undernutrition in this age-group.

"IDEAL" BODY WEIGHT IN OLDER PEOPLE

There is increasing evidence that the adverse effects of being overweight or obese, as defined by standard BMI criteria, are not as great in the elderly as in younger adults. Ideal weight ranges based on life expectancy are higher for older than young adults. For example, in a 12-year study of 324 000 people in the American Cancer Society Cohort, for people under the age of 75 there was a significant and progressive increase in subsequent mortality as baseline BMI increased above 21.9 kg m^{-2}. These adverse effects of increasing body weight diminished, however, with increasing age above 45 years, and were absent altogether over 75 years (Willett *et al.*, 1999). Among 4736 people aged 60 or more followed for an average of 4.5 years in the Systolic Hypertension in the Elderly Program (SHEP) (Somes *et al.*, 2002), those whose baseline BMI was in the lowest quintile ($<$23.6 kg m^{-2}) had the highest subsequent mortality and those within the highest BMI quintile ($\geq$31 kg m^{-2}), corresponding to the conventional criteria of obesity, had the lowest mortality. Recommendations for ideal weight ranges in older people vary, but there is good evidence that BMI values below about 22 kg m^{-2} in people over 70 years of age are associated with worse outcomes than higher weights, and BMIs below 18.5 kg m^{-2} are a particular concern.

While optimum body weight for older people is probably higher than for young adults, they in fact tend to weigh less. The decline in body weight with age, as measured by BMI, has been well documented in population-based, cross-sectional, and longitudinal studies (Schoenborn *et al.*, 2002; Chumlea *et al.*, 1988). For example, in the 1997–1998 US National Health Interview Survey of 68 556 adults, more people aged 75 years and older than those aged 45–64 years were "underweight" (BMI $<$ 18.5; 5 vs 1.2%) and substantially less were "overweight" (BMI $>$ 25; 47.2 vs 63.5% (Schoenborn *et al.*, 2002)).

WEIGHT LOSS IN OLDER PEOPLE

The lower average body weight of older than younger adults is not just because overweight people die earlier from obesity-related diseases, leaving the healthy, thin ones behind. On average, people over 75 years are more likely to lose than gain weight (Wallace *et al.*, 1995; Newman *et al.*, 2001), in part explaining why they weigh less than younger adults. For example, in a study that followed 247 community-dwelling American men aged over 65 for 2 years, on average these men lost 0.5% of their body weight per year and 13.1% of the group had involuntary weight loss of 4% per annum or more (Wallace *et al.*, 1995).

Numerous studies have shown that weight loss in the elderly is associated with poor outcomes, certainly if involuntary, but possibly even when deliberate. The prospective Cardiovascular Health Study (Newman *et al.*, 2001), for example, studied 4714 home-dwelling subjects over 65 years without known cancer. In the 3 years after study entry, 17% of the subjects lost 5% or more of their initial body weight, compared to 13% who gained 5% or more. The weight-loss group had significant increases in total ($2.09 \times \uparrow$ (95% confidence interval 1.67–2.62)) and risk-adjusted mortality ($1.67 \times \uparrow$ (1.29–2.15)) over the following 4 years compared to the stable weight group. The increased mortality occurred irrespective of starting weight and whether or not the weight loss was intentional. The weight gain group had no increase in mortality. In the SHEP study mentioned in the preceding text (Somes *et al.*, 2002), those subjects who had a weight loss of 1.6 kg year^{-1} or more experienced a 4.9 times greater death rate (95% CI 3.5–6.8) than those without significant weight change. Although mortality was also increased if weight increased more than 0.5 kg year^{-1}, the increase was less than that with weight loss (2.4-fold vs 4.9-fold increase). Of particular note, the adverse effects on mortality of weight loss were present even in the subjects who were heaviest at baseline (BMI $\geq$ 31) and were independent of baseline weight.

The combination of initially low body weight and weight loss is especially bad news for older people. In the SHEP study (Somes *et al.*, 2002), subjects with a low baseline weight (BMI $<$ 23.6 kg m^{-2} who lost more than 1.6 kg year^{-1} had a mortality rate of 22.6%, almost 20 times greater than the mortality rate of those with a baseline BMI of 23.6–28 kg m^{-2} whose weight remained stable. This interaction is a particular concern as the tendency for older people to lose weight is variable, with lean individuals probably most at risk (Rumpel *et al.*, 1993). In an older person, unintentional weight loss of 5% or more over 6–12 months is associated with an increased risk of adverse effects, while a loss of 10% or more very likely means protein-energy malnutrition.

There are many reasons why weight loss in older people has adverse effects. It some cases, weight loss is due to an illness, such as a malignancy, which is mainly responsible for the poor outcome and the weight loss is partly an "innocent bystander". Nevertheless, the weight loss and associated undernutrition is itself often a significant problem. This is because loss of body weight after the age of 60 is disproportionately of lean body tissue, that is, sarcopenia (Evans and Campbell, 1993) and individuals lose up to 3 kg of lean body mass per decade after the age of 50. Unlike loss of fat tissue, such a loss of lean tissue has adverse effects. Sarcopenia is associated with metabolic, physiologic, and functional impairments and disability including increased falls, and increased risk of protein-energy malnutrition.

UNDERNUTRITION IN OLDER PEOPLE

Prevalence

Protein-energy malnutrition is common in the elderly. Reported rates vary, in part because of differing methods used to diagnose this condition, but studies in developed countries have found that up to 15% of community-dwelling and home-bound elderly, between 23 and 62%, of hospitalized patients and up to 85% of nursing homes residents suffer from the condition (Morley, 1997).

Adverse Effects

Protein-energy malnutrition is associated with impaired muscle function, decreased bone mass, immune dysfunction, anemia, reduced cognitive function, poor wound healing, delayed recovery from surgery and ultimately increased morbidity and mortality (see Table 1). Epidemiological studies have demonstrated that protein-energy malnutrition is a strong independent predictor of mortality in elderly people regardless of whether they live in the community or in a nursing home, are patients in a hospital or have been discharged from hospital in the last 1–2 years (Cederholm *et al.*, 1995).

The increased mortality rate in elderly people with protein-energy malnutrition is further increased in the presence of other medical diseases, such as renal failure, cardiac failure, and cerebrovascular disease. For example, the 9-month mortality rate of 205 patients >70 years without cancer, admitted to a medical ward in Sweden, was 18% in 164 well-nourished patients without cardiac failure, 44% in 41 malnourished patients without cardiac failure, but 80% in 10 malnourished patients with congestive heart failure (Cederholm *et al.*, 1995).

CAUSES OF UNDERNUTRITION IN OLDER PEOPLE

Reduced Food Intake

Aging is associated with a decline in energy (food) intake. Energy intake decreases by approximately 30% between 20 and 80 years (Wurtman *et al.*, 1988). The elderly people on an average consume smaller meals more slowly, and

Table 1 Effects of weight loss and protein-energy malnutrition on function in the elderly

↓ Muscle function
↓ Muscle relaxation
↓ Muscle mass
↓ Muscle strength
↑ Risk of fracture
↓ Bone mass
↑ Incidence of falls
↓ Functional status
Immune dysfunction

Anemia
Poor wound healing
Fatigue
Pneumonia
Delayed recovery from surgery
↓ Cognitive function
↓ Cardiac output
↓ Intravascular fluid (dehydration)
↑ Incidence of pressure sores
↓ Maximal breathing capacity
↑ Hospital admission and length of stay
↑ Mortality

fewer snacks between meals (Morley, 1997), and consistently report that they are less hungry than young adults (Clarkston *et al.*, 1997). For example, the 1989 cross-sectional American National Health and Nutrition Examination Survey (NHANES III) study reported a decline in energy intake, between the ages of 20 and 80 years, of 1321 calories day^{-1} in men and 629 calories day^{-1} in women (Briefel *et al.*, 1995), a 7-year New Mexico longitudinal study of 156 persons aged 64–91 years, reported a decrease of 19.3 kcal day^{-1} $year^{-1}$ in women and 25.1 kcal day^{-1} $year^{-1}$ in men (Koehler, 1994), while a Swedish 6-year longitudinal study of 98 people found that between the ages of 70 and 76 years, there was a decrease in energy intake of 610 calories day^{-1} in men and 440 calories day^{-1} in women (Sjogren *et al.*, 1994).

The Physiological "Anorexia of Aging"

The age-related decline in food intake is not just due to the effects of illnesses that become more frequent with increasing age. Numerous studies have documented an age-related decline in appetite and energy intake in *healthy, ambulant noninstitutionalized* people (Wurtman *et al.*, 1988). Healthy older persons are less hungry and more full before, and become more rapidly satiated after eating a standard meal than younger persons. Much of this decrease in energy is probably a response to the decline in energy expenditure that also occurs during normal aging. In many individuals, however, the decrease in energy intake is greater than the decrease in energy expenditure, so body weight is lost (see the preceding text). This physiological, age-related reduction in energy intake has been termed *the anorexia of aging* (Morley, 1997).

Loss of Homeostasis

Old age is associated with diminished homeostatic regulation of many physiological functions, including the regulation of energy intake. For example, Roberts *et al.* (1994) underfed 17 young and old men by 3.17 MJ day^{-1} ($\approx$750 kcal day^{-1}) for 21 days, during which time both the young and old men lost weight. After the underfeeding period, the men were allowed to again eat *ad libitum.* The young men ate more than at baseline (preunderfeeding) and quickly returned to normal weight, whereas the old men did not compensate, returned only to their baseline intake and did not regain the weight that they had lost. Older people also have a reduced ability to detect and respond to dehydration.

The combination of age-related physiological anorexia and impaired homeostasis means that older people as well as young adults do not respond to acute undernutrition. Consequently, after an anorectic insult (for example, major surgery), older people are likely to take longer than young adults to regain the weight lost, remain undernourished longer, and be more susceptible to subsequent superimposed illnesses, such as infections.

Pathological Anorexia and Undernutrition in Older People

Protein-energy malnutrition is particularly likely to develop in the presence of other "pathological" factors, many of which become more common with increased age (Table 2). The majority are at least partly responsive to treatment, so recognition is important.

Poverty

One of the social factors that contributes to decreased food intake in the elderly is poverty, which is associated with an increased rate of hunger and food insecurity (Nelson *et al.*, 1998). Many older individuals have limited financial means, which makes it difficult to afford food of good nutritional quality.

Social Isolation

Older people are more likely to live alone than young adults. Social isolation and loneliness have been associated with decreased appetite and energy intake in the elderly (Walker and Beachene, 1991). Elderly people tend to consume substantially more food (up to 50%) during a meal when eating in the company of friends than when eating alone. The simple measure of having older people eat in company rather than alone may be effective in increasing their energy intake.

Table 2 Nonphysiologic causes of anorexia in older persons

Social factors
Poverty
Inability to shop
Inability to prepare and cook meals
Inability to feed oneself
Living alone/social isolation/lack of social support network
Failure to cater to ethnic food preferences in institutionalized individuals
Psychological factors
Depression
Dementia/Alzheimer's disease
Alcoholism
Bereavement
Cholesterol phobia
Medical factors
Cardiac failure
Chronic obstructive pulmonary disease
Infection
Cancer
Alcoholism
Dysphagia
Rheumatoid arthritis
Malabsorption syndromes
Gastrointestinal symptoms
– Dyspepsia
– Helicobacter pylori infection/atrophic gastritis
– Vomiting/diarrhea/constipation
– Parkinson's disease
Hypermetabolism (e.g. hyperthyroidism)
Medications
– Anti-infectives
– Antineoplastics
– Antirheumatics
– Nutritional supplements
– Pulmonary agents
– Cardiovascular agents
– CNS agents
– Gastrointestinal agents

CNS, central nervous system.

Depression

Depression, often associated with bereavement and the deterioration of social networks, is a common psychological problem in older people, present in 2–10% of community-dwelling older people and a much greater proportion of those in institutions (Evers and Marin, 2002). Depression is more likely to manifest as reduced appetite and weight loss in the elderly than in younger adults and is an important cause of weight loss and undernutrition in this group. Undernutrition *per se*, particularly if it produces folate deficiency, may further worsen depression, thus setting up a vicious cycle. Treatment of depression is effective in producing weight gain and improving other nutritional indices (Thomas *et al.*, 2003).

Dementia

Dementia may also contribute to reduced food intake in the elderly, because individuals simply forget to eat. Up to 50% of institutionalized dementia patients have been reported to suffer from protein-energy malnutrition (Sandman *et al.*, 1987).

Physical Factors

Many older people no longer have their own teeth. Poor dentition and ill-fitting dentures may limit the type and quantity of food eaten in older persons. For example, in one study, half of 260 nursing home patients, aged 60–101 years, in Boston, USA, complained of problems with chewing, biting, and swallowing. The patients with dentures were more likely to have poor protein intake than those with their own teeth (Sahyoun *et al.*, 1988). Immobility (e.g. stroke), tremor (e.g. Parkinson's disease), and impaired vision may also affect the capacity of an older person to shop for, prepare, and consume food. Common medical conditions in the elderly such as gastrointestinal disease, malabsorption syndromes, acute and chronic infection, and hypermetabolism (i.e. hyperthyroidism) often cause anorexia, micronutrient deficiencies, and increased energy requirements (Morley, 1997). Cancer and rheumatoid arthritis, which produce anorectic effects by releasing cytokines (see the following text), are also common in older persons.

Iatrogenic/Medications

The elderly are major users of prescription medications, a number of which can cause malabsorption of nutrients, gastrointestinal symptoms, and loss of appetite. For example, digoxin and some forms of chemotherapy can cause nausea, vomiting, and loss of appetite. Other medications can deplete the body's mineral stores; high doses of aluminum or magnesium hydroxide antacids deplete phosphate and potassium stores that can lead to muscle weakness and anorexia, while penicillamine induces zinc depletion that can lead to the loss of taste acuity and decreased food intake. The elderly often take multiple medications that increase the risk of drug interactions that can cause anorexia.

CAUSES OF THE PHYSIOLOGICAL ANOREXIA OF AGING

Declining Senses of Taste and Smell

Taste and smell are important in making eating pleasurable. The sense of taste probably deteriorates with age, although not all studies confirm this. Age-associated changes in taste may influence food choice in the elderly. There is strong evidence that the sense of smell declines with age, particularly after age 50. In one study, over 60% of subjects aged 65–80 and over 80% aged 80 or older exhibited major reductions in their sense of smell, compared to less than 10% of those aged under 50 (Doty *et al.*, 1984). The decline in the sense of smell is a cause of decreased food intake in the elderly because it makes eating food less enjoyable. It may also influence the type of food eaten; several studies have shown a strong correlation between impaired sense of smell and reduced interest in and intake of food. Consistent with this effect of aging on the types of food eaten is the

observation that aging is associated with a less varied, more monotonous diet.

Sensory-specific Satiety

Sensory-specific satiety is the normal decline in pleasantness of the taste of a particular food after it has been consumed. Sensory-specific satiety leads to a decrease in the consumption of a previously eaten food and a tendency to shift consumption to other food choices during a meal. This acts to promote the intake of a more varied, nutritionally balanced diet. Older people have a reduced capacity to develop sensory-specific satiety (Rolls and McDermott, 1991), perhaps because of reduced senses of smell and taste. Reduced sensory-specific satiety may in turn favor the consumption of a less varied diet and the development of micronutrient deficiencies.

HORMONES AND NEUROTRANSMITTERS: A SELECTIVE REVIEW (TABLE 3)

The remainder of this chapter will review, selectively, some of the emerging information about the control of food intake and why it declines with normal aging, with particular emphasis on endocrine factors. Recently discovered hormones with effects on feeding include leptin, ghrelin, and the orexins. At the time of writing, these discoveries had not yet led to evidence-based therapies, which still largely consist of nutritional supplements. The hope is that endocrine appetite stimulants or antagonists of anorexigenic hormones may have a future therapeutic role.

Table 3 Some endocrine factors influencing feeding and their possible contribution to the anorexia of aging

Effect of aging	
Factors that stimulate feeding	
Opioids	↓ activity; not proven in humans
Neuropeptide Y	no good evidence for role
Galanin	circulating levels unchanged sensitivity unknown
Orexins	no good evidence for role
Ghrelin	circulating levels possibly ↓ sensitivity unknown
Testosterone	stimulatory role unconfirmed (?indirect) ↓ activity with age possible effects via leptin, ghrelin and others
Factors that inhibit feeding	
CART[a]	possible ↑ central levels (rodents)
Cholecystokinin (CCK)	↑ circulating levels ↑ CSF levels ↑ sensitivity to satiating effects
GLP-1[b]	few data, possibly ↑ activity
Peptide YY	few data, no evidence for role
Insulin	effect on feeding unconfirmed, no evidence for role
Leptin	situation complex: circulating levels increase in men (↓ testosterone) BUT? leptin resistance
Cytokines	↑ activity likely

[a]CART, Cocaine-amphetamine-related transcript. [b]GLP-1, glucagon-like peptide I.

Overview of Appetite Regulation (Figure 1)

Central

The central feeding system is dependent on the stimulatory effect of neurotransmitters including the opioids, noradrenaline, Neuropeptide Y (NPY), the orexins, galanin, and ghrelin, and the inhibitory effect of corticotrophin-releasing factor, serotonin, cholecystokinin (CCK), and possibly insulin.

Peripheral (Gastrointestinal)

The short-term peripheral satiety system is largely driven by gastrointestinal mechanisms. In the longer term, factors such as leptin and cytokines (see the following text) become more important. Gastrointestinal sensory and motor functions are important in the regulation of satiation. Sensory signals induced by the distension by food contribute to initial sensations of fullness during a meal. These sensations are mediated via vagal mechanisms from mechanoreceptors situated within the stomach wall. In young adult humans, gastric distension, using a barostat, reduces food intake by up to 30%. Distension of the distal stomach (antrum) is related to increased sensations of fullness and is likely to

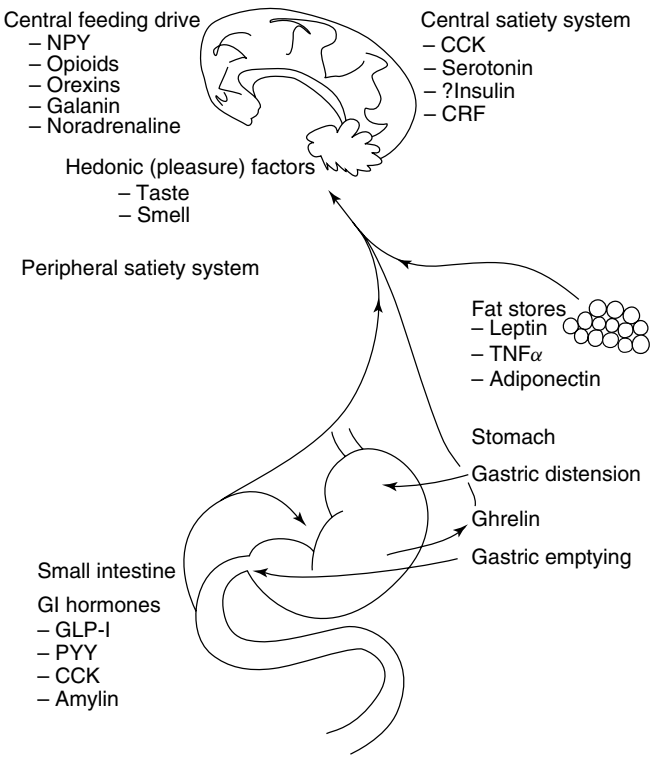

Figure 1 Overview of the mechanisms involved in appetite regulation

be more important than distension of the proximal stomach (fundus). After eating, the stomach relaxes by a process of receptive relaxation, resulting in decreased intragastric pressure and increased gastric volume. This relaxation is particularly marked in the proximal stomach and results in a proximal fundic reservoir where food is retained. Not long before it is emptied into the small intestine, food is propelled distally from the fundus into the antrum. The extent of antral filling and distension relates more closely to feelings of fullness and satiety than does proximal gastric distension.

Studies in animals and humans have demonstrated a relationship between postprandial satiety and the rate of gastric emptying. Slowing of gastric emptying may reduce appetite and food intake by increasing and prolonging antral distension and by prolonging the effect of small intestinal satiety signals. People with gastroparesis often exhibit symptoms of early satiety, loss of appetite, nausea, and vomiting, and studies in both animals and humans have shown that there is a relationship between postprandial satiation and the rate of gastric emptying.

Once food enters the small intestine, mechano- and chemoreceptors relay signals to the hypothalamus, resulting in the cessation of food intake. These signals are mediated by the release of gastrointestinal peptide hormones, including CCK, peptide YY (PYY), and glucagon-like peptide-1 (GLP-1). A number of gastrointestinal (GI) and pancreatic hormones, including CCK, GLP-1, and amylin have feedback effects on the stomach to slow gastric emptying, an effect associated with increased fullness and reduced food intake, by increasing and prolonging gastric distension and prolonging the effect of small intestinal satiety signals. Feedback signals from peripheral fat cells via leptin and, possibly, tumor necrosis factor-α as well as absorption of nutrients from the gut also contribute to satiation.

The Aging Gut

Aging is associated with cell loss in the myenteric plexus of the human esophagus and a decline in conduction velocity within visceral neurones. The consequent reduction in sensory perception may contribute to reduced food intake by inhibiting the positive stimuli for feeding. The elderly frequently complain of increased fullness and early satiation during a meal. This may also be related to changes in gastrointestinal sensory function; aging is associated with reduced sensitivity to gastrointestinal tract distension. If anything, reduced sensitivity to the satiating effects of distension might be expected to increase, not decrease, the food intake in older people. Nevertheless, proximal gastric distension has been found to have similar effects on food intake in healthy older and young adults, and the role, if any, of impairment of gastric sensory function in causing the anorexia of aging is unknown.

Aging is probably associated with impaired receptive relaxation of the gastric fundus. As a result, for any given gastric volume, there is more rapid antral filling and distension and earlier satiety. This impaired gastric accommodation response in the elderly may be because of altered fundic nitric oxide (NO) concentrations. Peripheral NO causes receptive and adaptive relaxation of the stomach, leading to dilation of the fundus and, ultimately, slower gastric emptying. The increase in NO with aging may therefore contribute to the slower gastric emptying observed in the elderly. Most, but not all studies indicate that gastric emptying slows slightly, but significantly, with increasing age. Clarkston *et al.* (1997) found that healthy older subjects were less hungry and more satiated after a meal than young subjects, and that postprandial hunger was inversely related to the rate of gastric emptying. The effects of aging on gastric emptying rate may require ingestion of a relatively large energy content, as small meals have not been shown to have different emptying rates in old compared to young individuals. Delayed gastric emptying in older people may, in part, result from enhanced release of small intestinal hormones such as CCK (see the following text).

In contrast, it seems that age has little, if any, effect on small intestinal or colonic motor function and orocecal and whole gut transit time are not affected in the healthy elderly. Healthy older people do have slower phase III migration velocities and more frequent "propagated contractions" in the small intestine, but no differences in duration of postprandial motility or amplitude or frequency of either fasting or postprandial pressure waves.

Central Neurotransmitters and Hormones

Monoamines

The central aminergic system has effects on feeding, with noradrenaline stimulating, serotonin inhibiting, and dopamine having region-specific stimulatory or inhibitory effects. Aging may be associated with increased satiating effects of serotonin, without apparent effects on dopamine or noradrenaline.

Opioids

Endogenous opioids play a role in mediating the short-term sensory reward response to food. Exogenous administration of opioid agonists increases food intake in animals, and opioid antagonists decrease food intake in animals and adult humans (MacIntosh *et al.*, 2001a). There is evidence that aging is associated with a reduced opioid feeding drive (reviewed; (Horwitz *et al.*, 2002)). Elderly patients with idiopathic, senile anorexia have lower plasma and CSF ß-endorphin concentrations than normal weight, age-matched controls (Martinez *et al.*, 1993). Intraperitoneal (IP) morphine injection increases food intake in young but not old mice, while IP naloxone decreases food intake in young but not older rats. Healthy older men are less sensitive to the inhibitory effects of subcutaneous naloxone on fluid intake than young men (Silver and Morley, 1992), and in one small study of feeding in humans, the suppression of food intake by naloxone was nonsignificantly greater in the older than young adults (MacIntosh *et al.*, 2001a:16 vs 8%).

Overall, these results suggest that the stimulatory effect of endogenous opioids does decline somewhat with advancing age and may contribute to the anorexia of aging. Further work is required to clarify these changes.

Neuropeptide Y

NPY is synthesized in the peripheral nervous system and brain and strongly stimulates food intake. There is preliminary evidence from animal studies that aging may be associated with reduced NPY activity, perhaps more in males than females. Old rats have lower levels of arcuate nucleus prepro NPY mRNA than young rats, and hypothalamic NPY levels decrease with aging in male, but not female rats. Studies in humans, however, suggest, if anything, *increased* NPY activity with increasing age. CSF NPY levels increase with healthy aging in women, and plasma and CSF levels are increased in elderly people with idiopathic anorexia (Martinez *et al.*, 1993). In rats, the feeding response to hypothalamic NPY injections diminishes with aging, whereas the stimulation of feeding by intracerebroventricular NPY administration in mice does not diminish with age. The effects of NPY administration in humans have not been reported. There is currently, therefore, no convincing evidence for an involvement of NPY in the human anorexia of aging.

Galanin

Galanin is a peptide hormone located in the brain and periphery, which stimulates food intake. Available animal evidence does not suggest a decline in galanin levels with aging, and circulating levels do not differ between young and older women (Baranowska *et al.*, 2000). Declining galanin levels are therefore unlikely to contribute to the anorexia of aging, but reduced sensitivity to galanin might. The effect of aging on stimulation of feeding by galanin has not been reported in humans, but older women (not men) display a reduced growth hormone secretory response to galanin compared to young adults (Giustina *et al.*, 1993).

Orexins (Hypocretins)

Orexin A and B (hypocretin-1 and -2) are neuropeptides synthesized in the hypothalamus and involved with feeding and sleep. Orexin deficiency causes narcolepsy in animals and humans and hypophagia and weight loss in animals (Matsumura *et al.*, 2002). Intracerebroventricular orexin injection dose-dependently increases food intake in rodents and orexin antibody reduces food intake (reviewed in Kirchgessner, 2002). Orexin A is the subtype mainly responsible for effects on feeding. The majority of evidence does not support declining orexin activity as a cause of the anorexia of aging. In a cross-sectional study of 82 healthy men and women aged 23–79 years, plasma orexin-A concentrations increased with age in both men and women (Matsumura *et al.*, 2002), which should, if anything, favor *increased* appetite and food intake. Studies in mice have found no changes or increases in total brain orexin levels and hypothalamic orexin-A receptors levels with increasing age, while a decrease in hypothalamic orexin gene expression in aging rats has been described (Kappeler *et al.*, 2003). In humans, the effects of normal aging on the levels of the orexin receptors and sensitivity to the effects of orexin are unknown.

Cocaine-amphetamine-regulated Transcript (CART)

Cocaine-amphetamine-regulated transcript (CART) is a peptide widely distributed in the brain including the hypothalamus. In animals, central CART administration reduces feeding and blocks NPY-induced feeding. Sohn *et al.* (2002) reported that arcuate nucleus CART mRNA levels were higher and NPY mRNA levels lower in healthy old than young, male rats, while testosterone treatment of castrated, older rats significantly lowered CART mRNA levels and increased NPY mRNA levels. This suggests that in males there is aging-related increased central activity of CART and reduced activity of NPY, both mediated by the normal age-related decline in testosterone. This is an intriguing possibility, but the effects of aging on CART in female animals have not been reported, nor have those in humans. The evidence that age-related increases in central CART levels may be a cause of the anorexia of aging is therefore currently derived from one study in male rodents.

"Peripheral" Hormones, Including Gut Peptides

Cholecystokinin (CCK)

CCK is present in the hypothalamus, cortex, and midbrain and is released from the lumen of the intestine in response to nutrients, particularly fat and protein, in the gut. CCK causes contraction of the gallbladder and relaxation of the sphincter of Oddi. Exogenous CCK administration decreases food intake in animals and humans. CCK is probably a physiological satiety hormone as its suppressive effect on food intake occurs with the administration of doses producing plasma CCK concentrations within the physiological range, and administration of CCK antagonists increases food intake in animals and young adult humans (Beglinger *et al.*, 2001). CCK also slows gastric emptying.

The satiating effects of CCK appear to increase with age. Most studies in humans have shown plasma CCK concentrations to be higher in healthy older than young adults (MacIntosh *et al.*, 1999, 2001b). Elderly people with idiopathic anorexia have significantly higher plasma levels and nonsignificantly higher CSF levels of CCK than healthy age-matched controls (Martinez *et al.*, 1993). IP CCK suppresses food intake more in old than young rats and mice. Intravenous CCK-8 administration has been found to acutely suppress food intake twice as much (31% vs 15%, $P = 0.02$) in older versus young adult healthy, human subjects (MacIntosh *et al.*, 2001b). The combination of increased circulating CCK

concentrations and enhanced sensitivity to CCK suggests that CCK may be a cause of the anorexia of aging, and raises the possibility of using CCK antagonists to increase energy intake in undernourished older people.

Glucagon-like Peptide-1 (GLP-1)

GLP-1 is released by the lining of the intestine in response to nutrient ingestion, particularly carbohydrates. It stimulates insulin secretion and, together with gastric inhibitory peptide (GIP), is one of the incretin hormones. It also slows gastric emptying. Administration of GLP-1 to humans increases feelings of fullness and reduces food intake (Flint *et al.*, 1998). Studies on the effects of aging on plasma GLP-1 concentrations have found either no effect or increased levels in older people (MacIntosh *et al.*, 1999). Further studies are needed to determine if increased GLP-1 activity is a cause of the anorexia of aging.

Peptide YY (PYY)

PYY is a peptide hormone present in the brain and released from the bowels in response to presence of fat and carbohydrate in the small intestine. PYY is involved in physiological processes such as memory, pain, blood pressure regulation, appetite, and anxiety (Pedersen-Bjergaard *et al.*, 1996). In rodents, feeding is increased by central PYY administration, but decreased by peripheral administration. Intravenous infusion of PYY to normal weight and obese humans aged less than 50 years, in doses that produce postprandial blood levels, reduces short-term food intake by approximately 30% (Batterham *et al.*, 2003). This suppression may be mediated by the associated suppression of ghrelin levels, whereas leptin, insulin, and GLP-1 are unaltered.

There is currently no evidence favoring alterations in PYY activity as a cause of the anorexia of aging and no difference in plasma PYY concentrations, fasting, and in response to intraduodenal nutrient infusions, between young and older subjects. Because there is a strong negative correlation between fasting plasma PYY levels and BMI in healthy, nonelderly subjects, studies involving accurate body composition analysis are needed to determine the true effect of healthy aging on PYY. The effects of aging on sensitivity to the appetite-suppressant effects of PYY have not been reported.

Leptin

Leptin is produced predominantly in adipose tissue and circulates in amounts directly related to the size of fat stores. It suppresses appetite and food intake. Congenital leptin deficiency in humans is a very rare cause of morbid obesity associated with hyperphagia, and leptin treatment produces substantial weight loss in these people. Most obese people, however, have elevated circulating leptin concentrations consistent with their increased fat mass. Leptin resistance is probably a feature of most human obesity, and leptin administration to obese people has resulted in only minor weight loss.

Although adipose tissue leptin mRNA expression increases with age in mice and rats, studies in rats and pigs have not found an increase in serum leptin with aging. Plasma leptin concentrations in humans often increase with aging, to a large extent because of the increased fat mass that also accompanies aging. Most studies show that adjustment for fat mass removes this effect (Baumgartner *et al.*, 1999). This is certainly so in women, but in men, some but not all studies have shown aging to be associated with an increase in circulating leptin levels, even allowing for fat mass. This appears to be because of age-related decreases in circulating testosterone concentrations. After adjusting for fat mass, plasma leptin levels in men are inversely related to plasma testosterone, while testosterone therapy reduces, and inhibition of testosterone production increases, circulating leptin levels (Hislop *et al.*, 1999).

Little is known about the effects of aging on sensitivity to the effects of leptin. Circulating levels of the soluble leptin receptor do not change with age in humans. Resting energy expenditure and carbohydrate oxidation are predicted by fat-free mass and serum leptin concentration in middle-aged, premenopausal women, but the relationship between fat store size and plasma leptin is much weaker in older adults (Moller *et al.*, 1998). Fasting normally dramatically suppresses plasma leptin concentrations, thus stimulating hunger. Reduced suppression of leptin levels by fasting has been reported in aging rats. Conversely, food intake, fat mass, and insulin action are suppressed less by leptin administration in older than young rats. This suggests that aging may be accompanied by leptin resistance, which would tend to *increase* food intake. The impact of human aging on the effects of fasting on leptin levels, and of leptin administration, has not been reported.

Ghrelin

Ghrelin stimulates feeding and growth hormone release. It is present in the hypothalamus but the main site of production is the gastric mucosa. Circulating ghrelin concentrations increase with fasting and with diet-induced weight loss in obese subjects, and are elevated in underweight, undernourished young and older subjects. In contrast, circulating concentrations decrease after ingestion of food, particularly fat and carbohydrate, and are reduced in obese people. These changes are consistent with compensatory responses to, rather than causes of, these altered nutritional states. It therefore seems unlikely that reduced ghrelin activity contributes significantly to the anorexia and weight loss in markedly undernourished older subjects. Nevertheless, the effects of aging and undernutrition on sensitivity to ghrelin have not been reported, and ghrelin resistance may occur in these states. In support of this, older subjects are less sensitive to the (growth hormone) GH-releasing effects of intravenous ghrelin (iv ghrelin) than young adults (Broglio *et al.*, 2003).

The effect of healthy aging on circulating ghrelin concentrations has not yet been clarified. A possible rationale for a decline in ghrelin levels with age, particularly in men, is the positive association between circulating testosterone and ghrelin concentrations and the increase in plasma ghrelin concentrations that occurs in hypogonadal men in response to testosterone therapy (Pagotto *et al.*, 2003). As normal aging is accompanied by reductions in circulating androgen levels (see the following text), this might have the effect of reducing ghrelin concentrations and thus food intake. One study found a rise in plasma ghrelin concentrations with increasing age, but there was no relationship with age *per se* when a multivariate analysis was performed (Purnell *et al.*, 2003), and the study did not include subjects older than 64 years. Two small studies have reported circulating ghrelin concentrations 20% (Sturm *et al.*, 2003) and 35% (Rigamonti *et al.*, 2002) lower in healthy older (69–87 and 67–91 years respectively) than young adults, the latter reduction statistically significant. However, increasing body fat, as indicated by BMI, is associated with decreasing ghrelin concentrations, and the older subjects had higher BMIs as compared to the young subjects in both studies. Neither study included detailed body composition analysis, so the lower ghrelin levels in older subjects may have been because of differences in body composition. Studies involving body composition analysis are needed to assess the effects of aging *per se* on ghrelin.

Insulin

Human aging tends to be associated with increased fasting and postprandial circulating insulin concentrations (Fraze *et al.*, 1987). Increased insulin activity could, therefore, be a cause of reduced food intake in older people. The evidence for a satiating role of insulin is, however, limited. Suppression of food intake by insulin has only been demonstrated in animals and has required central insulin administration at high doses or high dose, prolonged peripheral administration. Short-term, peripheral, euglycemic insulin infusions have been shown not to affect appetite or food intake in humans (Chapman *et al.*, 1998). Moreover, age-associated increases in insulin concentrations are due mainly to insulin resistance resulting from increased adiposity, and only to a small extent to aging itself. It seems unlikely that insulin contributes substantially, if at all, to the anorexia of aging.

Testosterone and Other Androgens

Circulating androgen concentrations decline with aging. This may contribute to the development of sarcopenia and the decrease in functional status that occurs with aging. While androgen replacement therapy (ART) is advocated for men with marked androgen deficiency, there is no consensus for the use of ART in elderly men with less severe aging-related declines in androgen concentrations, or in elderly women.

Studies of androgen replacement have been performed in healthy, older men with androgen deficiency, but although benefits have been seen in muscle mass and, in some cases, strength, there is, as yet, no agreement that this leads to improvements in functional status (reviewed; (Morley, 2001)). Two small studies have reported functional benefits when testosterone is administered in supraphysiological doses to older, frail men. Amory *et al.* (2002) gave older men with a mean total testosterone within the normal range 600 mg IM testosterone weekly for 4 weeks before elective knee replacement surgery and found significant increases in the ability to stand postoperatively and trends to improvements in walking and stair climbing, compared to placebo-treated men. Bakhshi *et al.* (2000) gave older men in a rehabilitation program with low-normal testosterone levels 100 mg IM testosterone or placebo weekly and found significant increases in grip strength and the Function Independence Measure after testosterone but not placebo.

In women, serum concentrations of testosterone and the adrenal androgens gradually and progressively decline from the decade preceding menopause. Even if testosterone therapy does not increase food intake in older, undernourished people, it may provide functional benefits by treating the associated sarcopenia, and studies to examine this are under way.

Cytokines

Age-associated increases in the production and/or effect of satiating cytokines may contribute to the anorexia of aging (Yeh and Schuster, 1999). Cytokines are secreted in response to significant stress, often because of malignancy or infection. Circulating concentrations of the cytokines interleukin 1 (IL-1), interleukin 6 (IL-6), and tumor necrosis factor alpha (TNF-α) are increased in cachectic patients with cancer or AIDS. They act to decrease food intake and reduce body weight via a number of central and peripheral pathways. Blockade of these cytokines, for example, of TNF in mice with TNF-producing sarcomas, significantly attenuates weight loss in high stress conditions associated with cachexia.

Aging itself may be a form of stress. It is associated with stress-like changes in circulating hormonal patterns; increased cortisol and catecholamines and decreased sex hormones and growth hormone. Increased cortisol and catecholamine levels, in turn, stimulate the release of IL-6 and TNF-α, whereas sex hormones inhibit IL-6. Interleukin 1 and IL-6 levels are elevated in older people with cachexia, while plasma IL-6 concentrations apparently increase as a function of normal aging and correlate inversely with levels of functional ability in elderly people. Increased cytokine levels, due to the "stress" of aging *per se*, or the amplified stressful effects of other pathologies, may thus provide an explanation for some of the decline in appetite and body weight that occurs in many older people.

DIAGNOSES AND TREATMENT OF UNDERNUTRITION IN OLDER PEOPLE

These are covered in **Chapter 24, Epidemiology of Nutrition and Aging** and **Chapter 27, Weight Loss in Older Adults**.

KEY POINTS

- On an average, food intake is about 30% lower in the elderly than young adults, because of a physiological decrease in appetite, the anorexia of aging. This predisposes to the development of protein-energy malnutrition, which is surprisingly common in the elderly.
- The physiological anorexia of aging predisposes to the development of pathological anorexia and undernutrition when factors that become more common with aging, such as depression, dementia, poor dentition, social isolation, medications and various illnesses, are superimposed.
- A number of hormones involved in the control of feeding have been discovered recently and knowledge of the hormonal control of feeding is expanding rapidly. Understanding of the anorexia of aging is in its infancy.
- Current evidence supports the following as causes of the anorexia of aging:
  ↑ activity CCK
  ↑ activity cytokines
  ↓ activity androgens (particularly in men)
  weaker evidence for ↓ activity ghrelin, ↑ leptin

Weight Loss in Older Adults

David R. Thomas[1] *and* Bruno Vellas[2]

[1] Saint Louis University Health Sciences Center and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA, and [2] Toulouse University Hospital, Toulouse, France

INTRODUCTION

Weight loss has devastating consequences in older adults. Weight loss is strongly associated with a 76% increase in mortality risk among home-bound older adults, along with male gender and age. This effect of weight loss persists after adjusting for initial body mass index (BMI, the weight in kilograms divided by height in meters squared), smoking, health status, and functional status (Payette *et al.*, 1999).

A BMI of less than 22 $kg\,m^{-2}$ has been associated with a higher 1-year mortality rate and with poorer functional status among older community-dwelling persons (Landi *et al.*, 1999). The higher mortality risk in men older than 65 years begins at a BMI of less than 22 and increases to a 20% higher risk in men older than 75 years with a BMI of less than 20.5. Similarly, the higher mortality risk in women begins at a BMI of less than 22 in women older than 65 years and increases to a 40% higher risk in women older than 75 years with a BMI of less than 18.5 (Calle *et al.*, 1999).

Involuntary weight loss greater than 4% of body weight is an independent predictor of increased mortality in older community-dwelling male veterans. Over a 2-year follow-up period, mortality rates were substantially higher in the 13% of the population with involuntary weight loss (28%) than in those who did not lose weight (11%). This effect was present after adjusting in baseline age, BMI, tobacco use, and other health status and laboratory measures (Wallace *et al.*, 1995).

Weight loss is also associated with a decline in functional status. Weight loss of more than 5% in community-dwelling women 60–74 years old is associated with a twofold increase in risk of disability over time, compared to women who did not lose weight, after adjustment for age, smoking, education, study duration, and health conditions (Launer *et al.*, 1994).

BMI is an important predictor of mortality among both young and old hospitalized patients. A BMI of less than 20 is a risk factor for in-hospital mortality (Thomas *et al.*, 2005). In hospitalized veterans, a weight loss of greater than 5% in the preceding 6 months was a predictor of life threatening in-hospital complications (Sullivan *et al.*, 2002). BMI less than the 15th percentile is an independent predictor of 180-day mortality following hospitalization after controlling for recent weight loss, serum albumin, severity of illness score, and patient demographics (Galanos *et al.*, 1997).

A 10% loss of body weight over a six-month interval strongly predicted mortality in the ensuing six months in nursing home residents (Murden and Ainslie, 1994). When compared to controls, the 16% of subjects who lost at least 5% of their body weight were 4.6 times more likely to die within 1 year (Ryan *et al.*, 1995). In another study of long-term care residents, a 10-fold increased risk for death was seen for persons who lost 5% of their body weight in any month compared with those who gained weight (Sullivan *et al.*, 2004). For this reason, the Long-Term Care Minimum Data Set defines a loss of greater than 10% of body weight within 180 days or 5% within 30 days as an important clinical threshold for triggering resident assessment protocols (Health Care Financing Administration, 1999). Body weight and BMI are easily obtained clinical measurements that can predict adverse outcomes in older persons.

POPULATION-BASED OBSERVATIONS OF LOW BODY WEIGHT AND MORTALITY

Several epidemiological studies have focused on the relationship of body weight and mortality in older persons. The characteristics of the study and the populations are given in Table 1. In the National Health and Nutrition Examination Survey Epidemiological Follow-Up Study (NHANES I) (Cornoni-Huntley *et al.*, 1991), both race and sex groups in the lowest 15% of the BMI distribution had a statistically significant excess risk of mortality after adjusting for smoking

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Table 1 Representative observational studies of body weight and mortality in older persons

Study	N	Age-group	Follow-up	Comorbidities
NHEFS	3339	65–74	Up to 20 years	Smoking, cholesterol, blood pressure, history of diabetes, cardiovascular disease, bronchitis, alcohol intake, and education
FHS	1723	65 at baseline	Mean 9.5 years	Smoking, cholesterol, blood pressure, and blood glucose
EPESE	6387	70 and older	3–6 years	Self-reported smoking, number of chronic diseases (diabetes, coronary heart disease, stroke, hip fracture, cancer, angina), previous hospitalizations, or nursing home admissions, and measures of disability, function, and mental status
CHS	5201	65 and older	5 years	Coronary heart disease and stroke
Cancer Prevention Study I	324 135	30–74	12 years	Never smoked, no history of heart disease, stroke, or cancer, no history recent unintentional weight loss
Cancer Prevention Study II	1 184 657	Mean 57	14 years	Healthy, never smoked

NHANES, National Health and Nutrition Examination Survey Epidemiological Follow-up Study; FHS, Framingham Heart Study Longitudinal Database; EPESE, Established Populations for Epidemiologic Studies of the Elderly; CHS, Cardiovascular Health Study. For references, see text.

history, and presence of disease. In the Established Populations for Epidemiologic Studies of the Elderly (EPESE) (Losonczy *et al.*, 1995), death rates were higher for those who weighed the least. A low BMI in old age was an additional risk factor, with persons in the lowest quintile having a 40% higher mortality rate in men and women relative to persons in the middle quintile of BMI. In the Cardiovascular Health Study (CHS) (Diehr *et al.*, 1998), women with a BMI of 20 or lower had higher mortality than others, but there was not a significant relationship of BMI and mortality for men or for women whose BMI was greater than 20. This was true with or without controlling for a large number of clinical covariates, including recent unintended weight loss (Diehr *et al.*, 1998).

In the Framingham Heart Study database (FHS) (Harris *et al.*, 1988), the relative risk of death was almost twice as high for those at the lower extreme of BMI. However, most of this increased risk occurred in the years immediately after age 65 compared to later follow-up, suggesting that the increased early death rate was due to disease that was already present.

These observational data demonstrate that a low body weight adjusted for height is clearly associated with higher mortality. However, the effect of coexisting disease and early mortality may confound these observations.

THE RELATIONSHIP OF HIGH BODY WEIGHT TO MORTALITY

Obesity is associated with greater morbidity and poorer health-related quality of life than smoking, problem alcohol drinking, or poverty (Sturm and Wells, 2001), and has been argued to be the number one health problem in the United States. A national campaign has been advocated to reduce body weight by dieting and exercise to reduce the mortality and morbidity. However, body weight increases with age in women, at least until their seventies, and aging is accompanied by body composition changes in both men and women (Thomas and Morley, 2001a). There is evidence to suggest that a higher BMI in older persons may not convey the excess risk observed in younger persons.

In general population studies, the relationship between mortality and BMI has been reported as a J-shaped curve, or a U-shaped curve (Weindruch and Sohal, 1997). Excess risk of death has been observed at both extremes of high and low weight. This relationship is clear in the young and middle-aged population, but becomes more controversial in the older population.

In the Cancer Prevention Study I (Stevens *et al.*, 1998), greater BMI was associated with higher mortality in men and women up to 75 years of age. However, the magnitude of the risk associated with greater BMI diminished with age, as shown in Table 2. For example, an increment of 1 in the body mass index in women was associated with an 8% increase in cardiovascular disease mortality risk in 30–44-year-old women, but only a 2% increase in risk for 65–74-year-old women. In the Cancer Prevention Study II (Calle *et al.*, 1999), a higher BMI was associated with a higher all-cause mortality in women in all age-groups, including those 75 years or older. Again, the relative risk also diminished with increasing age.

There is an increased mortality risk for both men and women at the highest extremes of BMI in the Framingham Heart Study, even when accounting for potential effects of excess weight on serum cholesterol level, blood glucose level, and systolic blood pressure. At the upper extreme, risk of death was twofold higher over the entire follow-up period for persons with BMIs above the 70th percentile at both 55 and 65 years of age.

Data from EPESE demonstrates that mortality risk was approximately 40% higher for persons in the heaviest quintile of BMI at age 50 compared with persons in the middle quintile. In the CHS data, a BMI greater than 34 was associated with an age-adjusted 8% mortality for women and an 18% mortality in men (BMI greater than 32). In the Nurses Health Study (Manson *et al.*, 1995), a 60% increase in relative risk for death began at a BMI of $27\,kg\,m^{-2}$ and continued to about twofold from a BMI greater than 29, using a reference BMI of 19.

Not all studies have shown an increased risk of mortality with higher BMI. A BMI of greater than $27\,kg\,m^{-2}$ has not been significantly related to risk of mortality (Landi

Table 2 Association of mortality and high body weight

Study	Characteristic	RR	95% CI
Cancer Prevention Study I	30–44-year-old men	1.10	1.04–1.16
	65–74-year-old men	1.03	1.02–1.05
	30–44-year-old women	1.08	1.05–1.11
	65–74-year-old women	1.02	1.02–1.03
Cancer Prevention Study II	65–74-year-old men, BMI 26.5–27.9	1.1	1.0–1.3
	>75-year-old men, BMI 26.5–27.9	1.1	0.97–1.2
	65–74-year-old women, BMI 26.5–27.9	1.04	0.9–1.2
	>75-year-old women BMI 26.5–27.9	1.07	1.0–1.2
	65–74-year-old men, BMI 30–31.9	1.4	1.2–1.7
	>75-year-old men, BMI 30–31.9	1.2	1.0–1.3
	65–74-year-old women, BMI 30–31.9	1.3	1.2–1.5
	>75-year-old women BMI 30–31.9	1.3	1.2–1.4
Nurses Health Study	BMI 29–31.9 versus BMI 19	2.1	
	BMI >32 versus BMI 19	2.2	
Framingham Heart Study	BMI >70th percentile	2.0	
EPESE	BMI highest quintile versus middle quintile		
	Men	1.33	1.13 – 1.57
	Women	1.31	1.12 – 1.53

[a]Landi F, Zuccala G, Gambassi G *et al.* Body mass index and mortality among older people living in the community. *Journal of the American Geriatrics Society* 1999; **47**:1072–1076.
NHANES, National Health and Nutrition Examination Survey Epidemiological Follow-up Study; EPESE, Established Populations for Epidemiologic Studies of the Elderly. See text for references.

et al., 1999; Dorn *et al.*, 1997). All-cause mortality among women 55–74 years with a BMI greater than 30 was not higher compared to women with a BMI range 22–30 in the NHANES I data. In older patients, only a slight elevation in mortality rates occurred at a BMI of greater than $35\,kg\,m^{-1}$ (Landi *et al.*, 2000; Diehr *et al.*, 1998). Overall, the data suggest that a BMI $>27\,kg\,m^{-2}$ does not convey the same degree of increased mortality risk in older adults (Thomas and Morley, 2001a).

Current standards have defined overweight for all ages as a BMI of 27.8 or more for men and 27.3 or more for women (Kuczmarski *et al.*, 1994). Andres *et al.* have suggested that a BMI of 24–30 is the desirable range for people aged 60–69 (Andres *et al.*, 1985). Although there is increased mortality at extremes of body weight, this data would seem to support using higher desirable weights for older adults.

THE RELATIONSHIP OF WEIGHT LOSS TO MORTALITY

Weight in the general population is not stable. Twenty-nine percent of men and 44% of women in the United States report that they are attempting to lose weight. Thirty-five percent of men and 34% of women report that they are attempting to maintain weight. The most common strategy among those attempting to lose weight was to consume less fat, but not fewer calories (34.9% of men and 40.0% of women). Only 21.5% of men and 19.4% of women reported using a combination of eating fewer calories and engaging in at least 150 minutes of leisure-time physical activity per week (Serdula *et al.*, 1999).

When observational data for persons with the lowest and highest BMI have been adjusted for weight loss, weight loss rather than current BMI becomes the salient factor (Table 3). The presence of preexisting illness may confound the association between weight loss and death, either because of earlier deaths from noncardiovascular disease or because weight loss serves as a marker for more severe cardiovascular disease. In the NHANES I dataset, risk of mortality was higher for both men and women who lost 10% or more of their maximum lifetime weight within the 10 years before the study, even when controlling for current weight. The effect of preexisting illness was adjusted for, by excluding deaths within the first 5 and first 8 years of the study. This adjustment weakened the association between weight loss and increased risk for death from noncardiovascular disease in women. There was a strong association between weight loss and increased risk for death from cardiovascular disease among men and women even with a maximum BMI between 26 and 29 (relative risks of up to 2.1 and 3.6, respectively) (Pamuk *et al.*, 1993).

In the EPESE, persons who lost 10% or more of body weight between age 50 and old age had a 60% increase of mortality compared with persons with stable weight. Exclusion of participants who lost 10% or more of their weight and adjustment for health status eliminated the higher risk of death associated with low weight. This inverse association of weight and mortality in old age appears to reflect illness-related weight loss from heavier weight in middle age.

In the CHS, the age-adjusted death rate for people who reported an unintended loss of 10 lb or more in the year before evaluation (16.2% for women and 33.0% for men) was much higher than the death rate for those who lost weight through diet or exercise (5% in women and 16.4% in men) or who maintained or gained weight (9.5% in women and 14%

Table 3 Association of weight loss and mortality

Study	Characteristics	Factors	Relative risk	95% CI
NHANES I	BMI 22–26, who lost >10% of maximum lifetime weight within the 10 years before the study	Men	2.1	
		Women	3.6	
EPESE	Lost 10% or more of body weight between age 50 and follow-up	Men	1.69	1.45–1.97
		Women	1.62	1.38–1.90
CHS	Involuntary weight loss of 10 lb or more in the year before baseline	Men (% mortality)	33.0%	
		Women (% mortality)	16.2%	
Community Study	288 frail elders	Weight loss at baseline	1.76	1.15–2.71
	78 ± 8 years, home support services; followed 3–5 years.	Male gender	2.71	1.73–4.24
		Age at baseline	1.40	1.06–1.86

NHANES, National Health and Nutrition Examination Survey Epidemiological Follow-up Study; EPESE, Established Populations for Epidemiologic Studies of the Elderly; CHS, Cardiovascular Health Study. See text for references.

in men). People who had lost 10% or more of their body weight since age 50 also exhibited a relatively higher death rate (15.9% in women and 30.3% in men). The relationship between BMI and mortality disappeared after excluding those who lost weight since age 50. Weight loss between age 50 and baseline was a critical risk factor for higher mortality, rather than being overweight.

From the NHANES I data, an increased risk in women with a lower BMI occurred only among those who had lost more than 8.5% of their reported lifetime maximum weight. Women who had lost weight had a higher risk than women with a low BMI. In fact, women with a low BMI but whose weight remained stable had the lowest risk of mortality. Thus, the effect of weight loss on mortality is more profound than current weight, even when accounting for factors associated with weight loss and increased mortality risk (Rumpel *et al.*, 1993).

A high BMI at both age 55 and age 65 was associated with the highest mortality in the Framingham study. In contrast, CHS found that those with a high BMI at both times had better survival than those with a high BMI at age 50 and a lower BMI at follow-up (Diehr *et al.*, 1998).

The Framingham study, EPESE, and CHS all found little relationship between BMI and mortality when subjects with long-term weight loss were excluded. All of the observational studies have found that weight loss is associated with increased rather than decreased risk for death (Andres *et al.*, 1993; Williamson and Pamuk, 1993; Blair *et al.*, 1993; Lissner *et al.*, 1991) Furthermore, for those persons who have not had a substantial weight change, body weight does not seem to be an important concern.

The data suggest that obesity in older adults may not be a significant clinical target for reducing mortality, and that a preferred public health emphasis for this age-group would be to increase awareness that substantial weight loss after age 50 and unintended weight loss are potential indicators for poor prognosis.

Lifestyle modifications may be more important than weight loss. In an observational study, overweight and obese persons who were at least 35 years of age and who had a body mass greater than $25\,kg\,m^{-2}$, self-reported their intention to lose weight and actual weight change during the past year. Those persons reporting an intentional weight loss had a 24% lower mortality rate, compared with persons not trying to lose weight and reporting no weight change. However, mortality rates were independent of actual weight change. The persons who reported trying to lose weight but who had no weight change experienced a 20% reduction in mortality risk. An unexpected finding was that a decreased mortality rate was also found among those who reported gaining weight but who were not trying to lose weight.

In this study, an attempt at weight loss was associated with lower all-cause mortality, independent of weight change. A higher mortality rate (31%) occurred only in those persons reporting unintentional weight loss. Self-reported intentional weight loss was associated with lower mortality rates, and weight loss was associated with higher mortality rates only if it was unintentional (Gregg *et al.*, 2003).

Prospective studies on the effect of voluntary weight loss have not been done in older populations. Paradoxically, a higher 2-year mortality was found in community living subjects who lost weight by dieting (36%) compared to those who had involuntary weight loss (28%). This data suggests that even voluntary weight loss by dieting may place older persons at risk (Wallace *et al.*, 1995).

The data from these observational studies suggest that weight loss is the chief predictor of higher mortality rates in older adults, rather than the current BMI. Surprisingly, this risk appears to be associated even with voluntary weight loss in older persons. The recommendation that older adults voluntarily reduce body weight cannot be supported by the literature and may be hazardous.

EFFECT OF WEIGHT LOSS ON COMORBID CONDITIONS

Only limited data support the notion that intentional weight loss reduces total mortality. However, mortality is only a small part of the substantial burden of disease caused by obesity-related conditions such as hypertension (Stamler *et al.*, 1978; Reeder *et al.*, 1997), diabetes mellitus (Colditz

et al., 1995; Manson *et al.*, 1992), coronary artery disease (Willett *et al.*, 1995; Hubert *et al.*, 1983; Rabkin *et al.*, 1977; Harris *et al.*, 1997), degenerative arthritis (Sahyoun *et al.*, 1999), and cancers of the breast (Paffenberger *et al.*, 1980; Lubin *et al.*, 1985), uterus (Kelsey *et al.*, 1982), and colon (Phillips and Snowdown, 1985). Short-term reductions in caloric intake (dieting) have favorable effects on blood pressure, cholesterol, and metabolic rate. These benefits require at least a 20% reduction in caloric intake (Velthuis-te Wierik *et al.*, 1994).

Weight loss has been shown to reduce disease-specific risks such as hypertension and type 2 diabetes (Diabetes Prevention Program Research Group, 2002). However, it should be noted that overweight/obesity-related comorbidities, particularly those associated with the insulin resistance syndrome (e.g. hypertension, dyslipidemias, and hyperinsulinemia) can be improved rather independently of weight loss (De Lorgeril *et al.*, 1994; Weintraub *et al.*, 1989). Blood pressure can be lowered in the absence of weight loss by dietary changes (Appel *et al.*, 1997). The effect on blood pressure by nonpharmacological interventions can be maintained for 3–5 years despite significant increases in body weight (Leserman *et al.*, 1989). Other trials in coronary artery disease have shown prevention effects to be independent of weight loss (Gaesser, 1999). The data suggest that improvement in comorbid conditions can be improved with lifestyle changes, but that the effect is independent of whether weight loss occurs or not.

CAUSES OF WEIGHT LOSS

Weight loss can occur from a variety of causes. Weight loss can be either voluntary (a conscious decision to reduce body weight by either restricting calories or increasing energy expenditure) or involuntary (absence of any intention to reduce weight). Voluntary weight loss in older persons may be an unrecognized health risk. Involuntary weight loss generally occurs in association with disease. In this setting, weight loss may occur in the terminal phase of illness, and the association of mortality and weight loss may reflect the underlying disease rather than the weight loss *per se*.

Involuntary weight loss is rarely due to occult disease. A physical cause of weight loss was clinically evident on the initial evaluation in 55 of 59 patients, and in 23 of 32 patients, weight loss was without a physical cause (Marton *et al.*, 1981). The primary cause of undernutrition was found to be treatable in nearly 90% of medical outpatients (Wilson *et al.*, 1998). An algorithm for the approach to the differential diagnosis and management of involuntary weight loss has been published by the Council for Nutrition in Long-term Care (LTC) (Thomas *et al.*, 2000).

INVOLUNTARY WEIGHT LOSS

Involuntary weight loss may result from several conditions. Decreases in appetite (anorexia), ingestion of inadequate calories (starvation), disuse atrophy or hormonal deficiencies (sarcopenia), or the effects of disease (cachexia), or a combination of factors may result in weight loss.

Starvation

Simple starvation is caused by pure protein-energy deficiency. Starvation can be short-term (fasting) or long-term (chronic protein-energy undernutrition). Worldwide, starvation is most often caused by lack of food. In developed countries, starvation is usually associated with disease. Starvation occurring in the presence of adequate food results from inability to swallow, a nonfunctioning gastrointestinal tract, or failure of appetite (anorexia).

Older persons ingest less calories than younger adults. On average, persons over the age of 70 years consume one-third less calories compared to younger persons (McGandy *et al.*, 1966). Sixteen percent to 18% of community-dwelling elderly persons consume less than 1000 Kcal daily (Abraham *et al.*, 1977). Weight loss and undernutrition are related to functional decline (Zuliani *et al.*, 2001).

The decline in energy intakes that accompany aging has been the subject of intensive investigation (Morley and Thomas, 1999). Total energy expenditure (TEE) declines with aging, chiefly due to changes in resting energy expenditure (REE). REE decreases 10–20% with age, primarily due to a decrease in muscle mass (Kendrick *et al.*, 1994; Lipson and Bray, 1986). REE is higher in active older adults compared to sedentary older adults (Poehlman *et al.*, 1990), but a decline in muscle mass occurs in both sedentary and active aging adults (Aniansson *et al.*, 1983; Davies *et al.*, 1985; Larron *et al.*, 1979). A decrease in physical activity largely explains the decline in TEE with age (Westerterp and Meijer, 2001). Surprisingly, there is little correlation between physical activity and fat mass in older persons. Higher physical activity is not associated with a lower body fat mass in subjects older than 60 years (Westerterp, 1998).

Strategies for involuntarily increasing the intake of nutrients include enteral or parenteral feeding. Increasing voluntary consumption of nutrients is more problematic.

Anorexia

Appetite regulation is affected by illness, drugs, dementia, or mood disorders (Chapman and Nelson, 1994; Weinsier *et al.*, 1979; Wright, 1994). Anorexia may be a physiological response to aging, resulting from changes in the physiological regulation of appetite and satiety (Morley and Thomas, 1999). Acute illness is characterized by a spontaneous decrease in food intake despite an increased need for energy and nutrients (Plata-Salaman, 1996). Although seemingly paradoxical, the voluntary suppression of food intake during illness is common to most species (Hedlund *et al.*, 1995). The relationship between hedonic qualities of food, gastrointestinal and central satiation drives, and hormonal relationships may explain this observed difference

(Morley, 2001). The importance of understanding this relationship lies in the hope that pharmacological (Thomas and Morley, 2001b) or dietary interventions (Mathey *et al.*, 2001) may reverse this anorexia of aging.

The reduction in food intake accompanying acute illness occurs both before and during hospitalization. In a prospective study of elderly people, 65% of the males and 69% of the females had an insufficient energy intake in the month before hospitalization (Mowe *et al.*, 1994). This reduction in nutrient and energy intake beginning with acute illness predisposes to a risk for worsening undernutrition during hospitalization.

Inadequate intake of nutrients continues during hospitalization. In 286 general medical subjects, 27% became malnourished after hospital admission (defined as a reduction in mid-arm circumference of 3.6% during admission). These subjects were more likely to consume less than 40% of prescribed food, and were more likely to have lower Mini-Mental Status Examination scores, functional impairment, lower total lymphocyte counts, and lower serum albumin levels (Incalzi *et al.*, 1996).

Cachexia

Cachexia is the cytokine-associated wasting of protein and energy stores due to the effects of disease. Systemic inflammation mediated through cell injury or activation of the immune system triggers an acute inflammatory response. This response is the most common cause of anorexia observed in the acute-care setting (Rote, 1998).

Cytokine-mediated cachexia is almost always associated with anorexia. Cytokines are related to a number of disease conditions, including cancer, end-stage renal disease, chronic pulmonary disease, congestive heart failure, rheumatoid arthritis, and AIDS (Thomas, 2002). In subjects with pneumonia, the admission concentrations of α-1-antitrypsin and α-1-acid glycoprotein are better predictors of hospital morbidity than albumin and C-reactive protein levels (Hedlund *et al.*, 1995). In subjects with end-stage renal disease on hemodialysis followed for 3 years, increased IL-1, TNF-alpha, IL-6, and IL-13 levels were significantly associated with increased relative mortality risk, while higher levels of IL-2, IL-4, IL-5, IL-12, T-cell number and function, and CH50 were associated with improved survival (Kimmel *et al.*, 1998). Although the cancer anorexia–cachexia syndrome is present in 50% of advanced cancer patients and in 80% of terminally ill cancer patients, serum levels of cytokines are not always directly associated with the onset of cancer anorexia–cachexia syndrome (Maltoni *et al.*, 1997).

Cytokines directly result in feeding suppression and lower intake of nutrients and cachexia is nearly always accompanied by anorexia. IL-1 beta and TNF act on the glucose-sensitive neurons in the ventromedial hypothalamic nucleus (a "satiety" site) and the lateral hypothalamic area (a "hunger" site) (Espat *et al.*, 1995). The data suggest that cytokine levels are commonly associated with disease conditions characterized by cachexia, and may play a role in mortality, weight loss, and appetite suppression. In contrast to starvation, cachexia is remarkably resistant to hypercaloric feeding.

Nutritional Interventions

The first response of caregivers to clinical signs of undernutrition, whether due to starvation or cachexia, is to increase nutrient intake. A number of nutritional interventions have been directed toward improving intake. Yet, despite demonstrating an increase in nutrient delivery, clinical trials have shown disappointing results in improving clinical outcome (Atkinson *et al.*, 1998). The poor response of these subjects to hypercaloric feeding suggests that a different mechanism may be operative.

A 20% decline in lean body mass has been shown in critically ill patients, despite aggressive caloric support (Plank *et al.*, 1998). Malnourished or high-risk surgical patients have not had postoperative complications reduced to that of well-nourished patients undergoing similar procedures by enteral or parenteral support (Campos and Meguid, 1992).

Interventions to voluntarily consume adequate calories in the face of anorexia have been marginally effective. In a meta-analysis of 24 randomized, controlled clinical trials of dietary advice with or without nutritional supplements, no difference in mortality was observed. The nutritionally supplemented group, but not the group receiving dietary advice alone, had a small gain in weight at 3 months but no difference was seen at 6 months (Baldwin *et al.*, 2005).

In a trial of nutritional supplementation, 87 consecutive patients were randomized into a trial of a glucose drink containing vitamin A, B1, B2, B3, and B6 supplements or placebo. Compliance with the supplement was poor, with only one-third of subjects consuming more than 50% of the offered drink. Even when the analysis was limited to compliant subjects, there was no beneficial effect observed (Hogarth *et al.*, 1996).

Survival does not appear to be affected by enteral feeding. In 1386 nursing home residents older than 65 years with recent progression to severe cognitive impairment, 9.7% of patients had a feeding tube placed. Survival for a period of 24 months was not different compared to residents who were and who were not tube fed (Mitchell *et al.*, 1997).

The provision of additional calories and protein alone has not been shown to be efficacious in patients with cancer cachexia (Fearon *et al.*, 2001).

Pharmacological Interventions

Various appetite stimulants, shown in Table 4, have been studied. Corticosteroids in randomized, placebo-controlled trials have improved appetite, but have not demonstrated body weight gain (Moertel *et al.*, 1974; Willox *et al.*, 1984;

Table 4 Pharmacological agents for unintentional weight loss

Agent	Condition	Improved appetite	Weight gain
Corticosteroids	Cancer	Yes	No

Bruera *et al.*, 1985; Robusteli Della Cuna *et al.*, 1989; Popiela *et al.*, 1989). Cyproheptadine has been shown to increase appetite in cancer patients without weight gain (Kardinal *et al.*, 1990). Cannabinoids (dronabinol, marinol, and nabilone) have shown promise in improving mood and appetite in cancer patients (Plassee *et al.*, 1991; Nelson *et al.*, 1994) and in AIDS cachexia (Beal *et al.*, 1995), but body weight gain was not seen. Thalidomide, a tumor necrosis factor inhibitor, has produced body weight gain in a small number of patients with human immunodeficiency virus-associated wasting syndrome (Reyes-Teran *et al.*, 1996). Recombinant human growth factors have produced weight gain (mean 1.6 kg vs. 0.1 kg in the placebo group) in patients with AIDS, but at substantially higher than physiological doses (Schambelan *et al.*, 1996).

Sex steroids have shown promise in producing weight gain in ill subjects. The male anabolic hormone, testosterone, declines with age (Morley *et al.*, 1997). This decline is associated with a loss of muscle mass and strength (Baumgartner *et al.*, 1999). Testosterone levels are even lower in ill and malnourished persons (Morley *et al.*, 1979; Rudman *et al.*, 1988). Testosterone replacement leads to an increase in muscle mass (Snyder *et al.*, 2000), and muscle strength (Morley *et al.*, 1993; Sih *et al.*, 1997). Testosterone has been shown to improve function in a rehabilitation center (Bakhshi *et al.*, 2000). For these reasons, testosterone may be an ideal drug to use for malnourished males. The combination of testosterone and megestrol acetate may be particularly useful in the anorectic, sarcopenic older person.

An anabolic-androgenic steroid, oxymetholone, has produced body weight gain in advanced HIV-1 infection (Hengge *et al.*, 1996), but not in cachectic cancer patients (Pengelly, 1973). The weight gain has usually occurred only in patients who were hypogonadal. Medroxyprogesterone acetate has been observed to produce body weight gain when used as a chemotherapeutic agent, independent of tumor response (Work group. Federation of the French Cancer Centres (FNCLCC), 2000).

Dronabinol may be useful not only for treatment of anorexia but also to improve disturbed behavior in patients with Alzheimer's disease. Body weight of study subjects increased more during the dronabinol treatment than during the placebo periods (Volicer *et al.*, 1997).

Of the pharmacological agents demonstrated to produce weight gain in patients with anorexia and cachexia, megestrol acetate has shown the most promise and has been the most widely studied agent used in cachexia (Tchekmedyian *et al.*, 1987; Cruz *et al.*, 1990). An increase in body weight has been shown in 54% (seven of 13) clinical trials (Bruera *et al.*, 1990; Loprinzi *et al.*, 1990; Schmoll *et al.*, 1991; Heckmayr and Gatzenneier, 1992; Feliu *et al.*, 1992; Azona *et al.*, 1996; Mantovani *et al.*, 1995). Other trials with megestrol acetate have shown improvement in appetite, but not shown an increase in body weight (Tchekmedyian *et al.*, 1992; Beller *et al.*, 1997; Bruera *et al.*, 1996; Fietkau *et al.*, 1997; McMillan *et al.*, 1999; Gebbia *et al.*, 1996). When megestrol acetate was directly compared to dexamethasone and fluoxymesterone in patients with cancer cachexia, fluoxymesterone was clearly inferior in producing weight gain. Megestrol and dexamethasone produced an equal nonfluid weight gain, but the rate of discontinuation due to toxicity was higher in the dexamethasone group (Loprinzi *et al.*, 1999).

In a meta-analysis of 26 trials, megestrol acetate was found to increase appetite, produce weight gain, and improve health-related quality of life in oncology patients, compared to placebo. In AIDS patients, increased weight was demonstrated. A significant benefit over dronabinol in improving appetite was apparent, but no statistically significant advantages over other drugs for treating cachexia were observed.

Only edema was significant as an adverse event (Pascual *et al.*, 2004).

Although body weight gain has been shown with growth hormone, thalidomide, oxandrolone, and megestrol in cancer cachexia and AIDS cachexia, very little data is available on whether this effect occurs in geriatric anorexia and cachexia syndromes not associated with cancer or immunodeficiency syndrome.

Megestrol acetate has been evaluated in three long-term care settings. In a prospective trial, 69 patients in a veterans nursing home were randomized to receive 800 mg of megestrol acetate or placebo for 12 weeks. Forty-four patients completed a 25-week evaluation. Weight gain occurred in 68% of treated subjects. The treatment group gained 1.1 kg compared to 0.9 kg in the control group at 12 weeks. By 25 weeks, the treatment group continued to gain weight (3.0 kg) compared to a weight loss (0.5 kg) in the control group (Yeh *et al.*, 2000).

In another study of 13 elderly nursing home residents who were losing weight and refused enteral feeding, megestrol acetate was prescribed. All residents showed improvement in food intake, BMI, and serum albumin. One patient had an exacerbation of congestive heart failure (Karcic *et al.*, 2002). In an unpublished observational trial comparing megestrol acetate with cypoheptadine, weight gain occurred in the megestrol treated group (Diabetes Prevention Program Research Group, 2002). The data are suggestive that megestrol may have some effect in producing weight gain in nursing home residents.

CONCLUSIONS

In older persons, a low BMI is associated with a higher mortality risk. When the observational studies are adjusted for weight loss, nearly all of the higher mortality risk is due to weight loss. The effect of a higher BMI is weakened or disappears when an adjustment for weight loss is made, suggesting that weight loss in older persons is a profound risk factor despite initial body weight. Involuntary weight loss has an intensified effect of mortality risk, and is usually associated with clinical illness. There is some data to suggest that even voluntary weight loss in older person may carry a higher mortality risk. Body weight is an easily obtained clinical measurement and weight loss is a profound marker for adverse outcome. A careful differential diagnostic approach is mandatory, combined with nutritional and often pharmacological interventions.

KEY POINTS

- Body weight and body mass index are easily obtained clinical measurements that are profound markers for adverse outcome.
- In older adults, nearly all of the higher mortality risk is due to weight loss, independent of initial body weight.
- Involuntary weight loss may result from decreases in appetite (anorexia), ingestion of inadequate calories (starvation), disuse atrophy or hormonal deficiencies (sarcopenia), or the effects of disease (cachexia), or a combination of these factors.
- There is some data to suggest that even voluntary weight loss in older persons may carry a higher mortality risk.
- A careful differential diagnostic approach is mandatory, combined with nutritional and often pharmacological interventions.

Dehydration

Margaret-Mary G. Wilson

Saint Louis University Health Sciences Center and Veterans' Affairs Medical Center, St Louis, MO, USA

"Drink and be thankful to the host! What seems insignificant when you have it, is important when you need it."

Franz Grillparzer (1791–1872)

INTRODUCTION

Dehydration is the most common fluid and electrolyte disorder in older adults. Approximately 1.5% of community-dwelling elderly will be hospitalized with dehydration each year. Additionally, over 5% of octogenarians admitted to hospital have significant hypernatremic dehydration compared to younger patients. In the United States, direct health-care costs of dehydration among persons older than 65 years exceeds 1.2 billion dollars annually.

Dehydration is associated with significant morbidity and is often the presenting illness in patients with underlying diseases such as malignancy, diabetes, or stroke (Warren *et al.*, 1996). Approximately two-thirds of older adults with dehydration will have a coexisting infection such as pneumonia, urinary tract infection, or gastroenteritis. Available date indicates that the mortality rate observed during hospitalization among dehydrated patients ranges from 33 to 72%. Untreated dehydration is associated with mortality rates exceeding 50% (Long *et al.*, 1991; Molaschi *et al.*, 1997). Notably, age is one of two major risk factors – advanced age and hypernatremia – associated with exceedingly high mortality rates in dehydrated patients.

Multiple physiological and pathophysiological factors increase the risk of dehydration in older adults. Aging is associated with a disproportionate reduction in the proportion of total body water. In addition, water handling ability is compromised in older adults because of impaired renal tubular concentrating ability and blunted sensitivity to antidiuretic hormone (Kenney and Chiu, 2001; Ritz, 2001). Aging is also associated with physiological hypodipsia that may be further exacerbated by superimposed illness. Hydration status may also be compromised by medications such as diuretics or laxatives, psychosocial factors, and environmental barriers (Morley, 2000).

From the practical perspective, the ultimate goal of all dehydration intervention and prevention strategies is increased fluid intake. Thus, maintaining the integrity of mechanisms underlying thirst and dipsogenesis (thirst provocation) is pivotal to combating dehydration in older adults.

THIRST AND AGING

Contrary to popular opinion, thirst is not the primary driving force behind fluid consumption. In the healthy and nonstressed adult, behavioral and nonregulatory psychosocial factors are the major determinants of fluid ingestion. However, under physiologically stressful or threatening conditions, homeostatic mechanisms are triggered that motivate an active search for fluids and encourage drinking. Thus, under normal circumstances, fluid intake is primarily voluntary and subject to appetitive control. In contrast, the maintenance of fluid balance under physiological or pathological stress is primarily a homeostatic function (Kenney and Chiu, 2001; Rolls, 1998). Thirst mechanisms may therefore be classified as either homeostatic or nonhomeostatic (Table 1).

Homeostatic Thirst Mechanisms

Neural control mechanisms of thirst are highly complex and involve multiple neural interconnecting pathways. Plasma tonicity and intravascular volume are the major homeostatic dipsogenic factors. Osmoreceptor cells are present in the hypothalamus within the *organum vasculosum* and the subfornical region of the *lamina terminalis*. These cells function as tonicity sensors in response to alterations in plasma osmolality. Following stimulation of these osmoreceptors, afferent

signals travel within the nucleus *tractus solitarius* and converge on the supraoptic and paraventricular nuclei. Axonal projections from both nuclei traverse the median eminence and terminate in the posterior pituitary gland. This pathway modulates vasopressin release. An alternate dipsogenic pathway comprises fibers from the nucleus *tractus solitarius* that terminate in the lateral preoptic region of the hypothalamus (Schoorlemmer *et al.*, 2000; Stricker and Verbalis, 1998).

Afferent fibers arising from peripheral baroreceptors located in the carotid sinus, aortic arch, and left atrium also terminate in the *nucleus tractus solitarius*. Decreased intravascular volume stimulates these fibers, resulting in increased plasma renin activity and elevated serum angiotensin and aldosterone levels. Increased plasma renin activity induces dipsogenesis by increasing circulating angiotensin II levels (Stachenfield *et al.*, 1997; Kenney and Chiu, 2001).

Angiotensin II is a very strong stimulus of thirst. Intraventricular injection of angiotensin II induces an immediate and highly motivated search for water that results in the rapid ingestion of large volumes of water far in excess of the animal's daily needs. Elevated circulating angiotensin II has similar, though less marked effects on drinking.

Angiotensinergic nerve endings and angiotensin receptors have been identified in the median preoptic nucleus, *organum vasculosum*, and *lamina terminalis* in the periventricular and subfornical areas. Efferent impulses arising from thirst regulatory centers located in the latter areas allow circulating angiotensin II to exert an effect on other regions of the hypothalamus and brain stem involved in sodium appetite and blood pressure control. Animal studies have shown that Angiotensin II induces vasopressin release when administered intraventricularly. Plasma hypertonicity and intravascular volume depletion both stimulate vasopressin release, thereby inducing a dipsogenesis. Although the precise mechanism is unknown, available data indicates the existence of a separate central renin-angiotensin axis that independently modulates thirst and vasopressin release (Fitzsimons, 1998; McKinley and Johnson, 2004).

Short-term regulation of fluid intake is largely predicated on the act of swallowing and an additional thirst regulatory mechanism described as oropharyngeal metering. Deglutition appears to trigger the afferent arm of a conceptual pathway that determines the appropriate amount of drinking that occurs in response to dipsogenic stimuli. Oropharyngeal metering is most likely responsible for the rapid perception of relief from thirst during drinking, even prior to sensing of restored homeostasis by the osmoreceptors and baroreceptors. Oropharyngeal metering may also play a role in the suppression of vasopressin secretion that occurs during drinking. Although the precise physiology underlying oropharyngeal metering has not been identified, this mechanism prevents excessive ingestion of water in response to thirst and subsequent wide fluctuations in intravascular volume or plasma tonicity (Figaro and Mack, 1997). The effect of aging on oropharyngeal metering is unknown. However, it is plausible that age-related xerostomia, esophageal dysmotility, and blunting of oral chemosensory perception may compromise oropharyngeal metering. Further research is needed in this area.

In the nonstressed person, dipsogenesis is triggered and drinking occurs even in the presence of adequate amounts of total body water. Similarly, in the presence of adequate food and drink, fluid ingestion exceeds the amount strictly required to maintain physiological fluid balance (Kenney and Chiu, 2001). Clearly, drinking is a multifactorial phenomenon that occurs in response to a variety of dipsogenic (thirst provoking) factors. Such factors may be physiological or pathological. Behavioral, psychosocial, cultural, and hedonic cues have all been implicated as triggers.

Overall, available data implicates elaborate and highly coordinated cortical and subcortical neural dipsogenic pathways that are yet to be precisely defined. In older adults, the overlay of age-related changes renders these elaborate mechanisms even more tenuous (Horani and Morley, 1998).

Dipsogenesis

Experimental fluid deprivation observations have yielded useful information on the response of older adults to fluid deprivation under controlled conditions. Compared to younger subjects, older adults exhibit lower thirst ratings and decreased fluid consumption for comparable degrees of thirst. Hypertonic intravenous saline infusion results in relatively higher serum vasopressin levels in older adults compared to younger adults, suggesting heightened sensitivity of central vasopressin osmoreceptors with aging. Aging also results in the loss of the normal circadian rhythm of vasopressin secretion expressed as nocturnal peaking (Phillips *et al.*, 1993; Mack *et al.*, 1994). Thus, quantitative and qualitative changes in circulating vasopressin levels may partially account for age-related attenuation of the thirst response.

Evidence also indicates that aging osmoreceptors may have a higher osmolarity threshold and are less sensitive to changes in osmolarity. Observational studies of older adults undergoing prolonged exercise in relatively high ambient temperatures suggest impaired compensatory fluid balance mechanisms. Results from such studies show that older

subjects fail to drink enough fluid to restore euvolemia. However, fluid loading and thirst suppression studies indicate less suppression of thirst in older adults compared to younger adults following ingestion of equal amounts of fluid. Thus, although older adults are more susceptible to dehydration following water deprivation, there is a paradoxical increase in the risk of fluid overload due to compromised ability to appropriately limit the quantity of fluid ingested in response to dipsogenic stimuli (Mack *et al.*, 1994; Kenney and Chiu, 2001).

Several other hormones have been implicated in the etiology of age-related hypodipsia. Atrial natriuretic peptide (ANP) is a 28-amino acid peptide produced by atrial myocytes in response to volume overload and distension. Angiotensin II induces increased synthesis and release of ANP. Increased circulating ANP exerts a negative feedback effect on renin release, thereby decreasing and regulating angiotensin levels.

ANP is the foremost hormonal mechanism that prevents volume overload. Elevated circulating levels of ANP occur in response to hypervolemic states and induce increased diuresis and natriuresis, thereby reducing intravascular volume. ANP receptors are also located in the atria, hypothalamus, and areas of the brain stem involved in the regulation of intravascular volume and blood pressure. Within the brain, ANP receptors also receive afferent activating impulses from baroreceptors. Angiotensin II antagonizes the effects of ANP. ANP inhibits renin release, thereby decreasing angiotensin II levels (Levin *et al.*, 1998; Kamoi *et al.*, 1991; McKinley and Johnson, 2004).

Norepinephrine (NE) has also been implicated in thirst regulation. Animal studies indicating an antidipsogenic effect of NE suggest a possible role for NE in the pathogenesis of age-related hypodipsia (Izumi, 1991; Racotta *et al.*, 1995).

Adrenomedullin (AM) is a 52-amino acid peptide that has been shown to reduce thirst in fluid deprived rats. AM is similar in structure to calcitonin gene-related peptide (C-GRP) Although the main source of AM is the vascular endothelium, AM is also found in high concentrations in the adrenal glands, hypothalamus, anterior pituitary, kidneys, lungs, gastrointestinal tract, pancreas, heart, skin, salivary, and sweat glands. AM release is enhanced by proinflammatory cytokines. Additionally, both nitric oxide (NO)-dependent and NO-independent pathways have been implicated in the release of AM during inflammation (Bunton, 2004). Little is known about the exact role of AM in human thirst regulation.

Naloxone, an opioid receptor antagonist, has been shown to suppress fluid intake after overnight water deprivation in younger subjects. However, the antidipsogenic effect of naloxone is far less pronounced in older adults possibly because of age-related blunting of opioid receptor sensitivity (Silver and Morley, 1992; Fregoneze *et al.*, 1999).

Nonhomeostatic Regulation of Hydration

Age-related changes in functional status and quality of life threaten independence and socialization. Compromised access to utilities and limited recreational activity invariably affect domains such as nutrition and hydration that are vulnerable to environmental and sociocultural influences. In the young and healthy adult, fluid balance is rarely significantly threatened in the absence of restricted access to fluids or disease. In contrast, older adults are not only subject to adverse pathophysiological events but may also develop dehydration as a result of compromised nonhomeostatic dipsogenic influences.

Observations of ad-lib fluid intake in free-living individuals of all ages highlight the importance of nonphysiological factors in regulation of fluid balance. When a fluid is freely accessible, drinking consistently results in sufficient fluid intake to forestall the development of hypovolemic or hypertonic deficits. Psychosocial and cultural influences are major determinants of the volume and type of fluid ingested (Rolls, 1998). Thus, hedonic factors such as taste preferences, palatability, and culinary presentation affect drinking. Social, cultural, and environmental factors may also trigger dipsogenesis. In older adults, age-related changes in chemosensory perception may detract from the pleasantness of specific drinks and thereby discourage drinking. Health awareness and lifestyle habits also affect the type and quantity of fluid consumed. Health conscious adults are more likely to make an active effort to consume relatively large volumes of fluid. In contrast, elders who participate in religious practices or sociocultural rituals that involve fasting or fluid restriction are more vulnerable to dehydration.

CLINICAL DEHYDRATION AND AGING

Risk Factors for Dehydration in the Older Adult

Common causes of dehydration are preventable and easily treatable. However, early diagnosis and intervention is critical. Prompt clinical detection is facilitated by an increased awareness of the risk of dehydration in geriatric patients. Available data identifies a positive correlation between the amount of food consumed and fluid ingested. Thus, a direct consequence of anorexia of aging from either physiological or pathological causes will be a reduction in fluid intake and an increased risk of dehydration.

Specific pathological syndromes in the aging adult may further threaten hydration status (Table 2). Frailty, depression, impaired cognition, and social isolation may diminish or motivate or compromise the drinking ability. Likewise, functional disability, neurological deficits, and impaired mobility may bar access to adequate amounts of fluid. Neurological diseases such as cerebrovascular disease, Parkinson's disease, and Alzheimer's disease may restrict access to fluids either by compromising the patient's ability to overcome environmental barriers or by disrupting pharyngeal and neuromuscular mechanisms that control drinking. Iatrogenesis is another important cause of dehydration. Polypharmacy in older adults increases the risk of drug-related adverse events. Diuretics, nephrotoxic drugs, and laxatives can compromise

Table 2 Common risk factors for dehydration in the elderly

Institutionalization

hydration and fluid balance. Inappropriate use of nonprescription medications such as calcium supplements may result in dehydration from hypercalcemia-induced polyuria. Institutionalized elders dependent on staff for feeding assistance are also vulnerable to dehydration. Inadequate staffing levels may result in the failure to identify patients at high risk for dehydration. Physical restraints are a recognized cause of dehydration as they increase the dependency of the patient on staff for hydration. Similarly, chemical restraints may result in oversedation or amotivational states that result in reduced fluid intake (Warren *et al.*, 1996; Horani and Morley, 1998; Wilson, 1998).

Clinical Assessment and Diagnosis of Dehydration

Clinical diagnosis of dehydration is unreliable. Symptoms are usually nonspecific such as lethargy, muscle weakness, dizziness, and confusion. Furthermore, patients with hypertonic dehydration may remain asymptomatic until serum sodium levels exceed 160 mmol l^{-1}, at which point they may present with delirium, seizures, or other neurological symptoms. Physical examination may also be unreliable. Reduced skin turgor from dehydration is not easily distinguished from age-related cutaneous atrophy (Adrogue and Madias, 2000; Pals *et al.*, 1995; Weinberg and Minaker, 1995). Axillary moisture assessment has been shown to be a fairly specific, though poorly sensitive, index of hydration in younger adults. However, in older adults, evidence shows that axillary sweating is a reproducible and reliable sign of hydration in ill elderly patients with a high negative predictive value and moderate positive predictive value (Eaton *et al.*, 1994). Dry oral mucous membranes in older patients are not necessarily indicative of systemic dehydration. Similar changes occur with chronic mouth breathing, supplemental oxygen use, pathological xerostomia, or adverse effects of anticholinergic medication.

Cardiovascular responses to dehydration may also be impaired in older adults. Blunted age-related chronotropic responsiveness to intravascular volume depletion confounds early detection of significant fluid deficits, prior to the development of hypotension. Reliability of orthostatic hypotension as an index of dehydration in older adults is also suspect. Confounding factors include medications, age-related vascular changes, and prolonged bed rest, all of which may result in autonomic dysfunction and orthostasis (Gross *et al.*, 1992; Weinberg and Minaker, 1995).

Weight loss is a valuable sign of dehydration. Generally, rapid and acute weight loss in excess of 3% of baseline body weight is most likely due to reduced total body water from dehydration (Weinberg and Minaker, 1995). Dehydration may also masquerade as a variety of nonlocalizing geriatric syndromes due to increased vulnerability of aging organs to stress. Reduced skin integrity due to subcutaneous dehydration may result in xerosis, pruritus, recurrent skin infections, and pressure ulcers in the immobile patient. Cystitis and urinary tract infections may result from the irritant effect of highly concentrated urine on the vesical mucosa. Inspissated oral and gastrointestinal secretions can lead to constipation, impaction, xerostomia, periodontal sepsis, and mouth ulcers. Neurological dysfunction in dehydrated older adults may present as delirium, dizziness, recurrent falls, and subsequent complications such as hip fractures or traumatic brain injury.

Overall, the detection of dehydration is largely dependent on a high threshold of suspicion. Laboratory indices are often relied on to support the diagnosis of dehydration, assess severity, and guide intervention. Serum osmolarity >300, blood urea nitrogen (BUN) >20, or BUN: Creatinine ratio >20 are useful indices of dehydration. However, data shows that biochemical indices, though frequently used as indices of dehydration lack specificity (Wakefield *et al.*, 2002).

Dehydration may be classified as isotonic, hypertonic, or hypotonic. Isotonic dehydration is the more common type of dehydration and reflects loss of water and electrolytes in relatively equal proportions. Serum osmolarity and electrolytes are often normal. Restricted oral intake or diseases manifesting with both diarrhea and vomiting are likely to result in isotonic dehydration. Hypertonic dehydration is most often observed in patients with compromised ability to replace

ongoing free water losses. Thus, functionally disabled or cognitively impaired patients with restricted excess to water are more likely to be affected. Serum sodium and serum osmolarity exceeds 145 mmol l^{-1} and 300 mmol l^{-1} respectively. A general rule of thumb is that hypernatremia in older adults indicates hypertonic dehydration. In hypotonic dehydration, serum sodium is below 135 mmol l^{-1} and serum osmolarity is less than 280 mmol kg^{-1}. Excessive natriuresis, such as may occur with excessive diuretic use or renal tubular disorders, causes a disproportionately excessive loss of sodium compared with free water. Affected patients may present with hyponatremic dehydration.

Available evidence examining urine osmolarity indicates poor correlation between serum and urine parameters. Several bedside tools have been developed to screen urine for dehydration, some of which use colorimetric devices. However, most of these tools are yet to be validated. Biochemical measurements are still regarded as the best laboratory benchmark for the assessment of dehydration.

Fluid balance charts documenting input and output are helpful in determining the risk and characterizing the severity of dehydration. However, charting is often rendered inaccurate because of a variety of factors such as staff errors in documentation, poor patient history, and urinary incontinence (Weinberg and Minaker, 1995; Kim and Berlowitz, 1994).

Management of Dehydration

Ultimately, identification of patients at risk for dehydration and institution of appropriate preventive measures are the most cost-effective strategies to ensure adequate hydration in the older adult. Unlike the pediatric population where fluid requirements are more clearly defined, precise recommendations are not available for older adults. Arbitrary guidelines recommend consumption of at least 2 l (68 oz glasses) of fluid daily. This estimate assumes relatively cool ambient temperature, average body weight of approximately 70 kg, and moderately intense physical exercise of about 20 minutes daily. Nevertheless, available evidence-based data supports the benefits of ingestion of at least 1.5 l of fluid daily. There is no data to show that the consumption of fluid in excess of this amount is of added benefit. Paradoxically, age-related defects in cardiac and renal tubular water handling increase the risk of fluid overload and dilutional hyponatremia with excessive fluid consumption. Providers should therefore ensure that patients are provided with specific hydration recommendations to guide intake (Lindemann *et al.*, 2000).

As a rule of thumb, hemodynamically stable hospitalized patients require at least 30–35 ml kg^{-1} day^{-1}. However, requirements will differ widely in older adults, depending on the underlying illness. Fluid intake may need to be restricted in patients with liver cirrhosis, chronic kidney disease, or cardiac failure. Insensible loss occurs through the skin, respiratory surfaces, and fecal loss. Therefore, during the warmer months and in warm climates, increased ambient temperature should prompt careful attention to fluid intake.

In addition, patients with fevers, extensive burns, persistent vomiting, diarrhea, or draining fistulas may need additional fluid. Similarly, patients with chronic lung disease, decubitus ulcers, excessive tremors, or movement disorders are likely to have increased amounts of insensible fluid loss. Increased daily fluid intake may also be necessary in patients with poorly controlled diabetes mellitus and patients on chronic diuretic or laxative therapy.

Hedonic influences are important, as taste preferences and palatability are an important determinant of fluid intake. Providers often emphasize water intake; however, patients should be made aware that preferred fluid beverages may be substituted for water. Preventive strategies, particularly in institutionalized patients, should include ensuring easy access to fluid. Water fountains should be located at convenient intervals and esthetically pleasing locations. Circulating water or juice carts are other methods by which fluid consumption can be encouraged.

Drinking assistance must be readily available for dependent elders. Cognitively impaired elders need to be frequently reminded to drink. In addition, offering fluid at very frequent intervals (1.5–2 hours) has been found to improve hydration among dependent institutionalized elders. Data indicates that the major proportion of fluid ingestion occurs with medication rounds. Encouraging fluid intake at medication rounds may help maintain adequate hydration (Morley, 2000; Wilson, 1998).

Although the suspicion of impaired hydration status may be notably strengthened by laboratory testing and ancillary data, therapy should not be unduly delayed. Fluid replacement therapy can very often be started empirically. Effective treatment of dehydration mandates due attention to restoration of normal plasma tonicity and replacement of the fluid deficit and ongoing losses. Calculation of the free water and sodium deficit are helpful guides to fluid therapy prescription in younger adults (Table 3). Although the same formulas are used in older patients, aggressive and rapid replacement should be avoided in older persons, unless absolutely necessary, because of the increased risk of fluid overload. Additionally, rapid correction of hypernatremia in patients with hypertonic dehydration may result in neurological complications. This is due to severe cerebral edema arising from the reabsorption of large volumes of fluid due to the osmotic gradient created by the intracellular neuronal accumulation of organic osmolytes during the hyperosmolar period (Adrogue and Madias, 2000; Lien *et al.*, 1990; Gullans and Verbalis, 1993).

Table 3 Helpful formulae for fluid prescription

Free water deficit (l)
(Total body water = [0.6 × body weight (kg)]) × (Sodium/140 − 1)
Na deficit (mEqiv)
(135 − [Na^+]) × (total body water = [0.6 × body weight (kg)])
Plasma osmolality (mOsm kg^{-1})
2[a][mEqiv $l^{-1}Na^+$] + (mg dl^{-1}glucose)/18 + (mg dl^{-1} BUN)/2.8

[a]Do not replace more than 1/2 of fluid deficit in the first 24 hours. Recommended Na^+ reduction rate should not exceed 0.5 mmol l^{-1} $hour^{-1}$.

In patients with a functioning gut, oral ingestion or enteral tube administration are the safest routes for fluid replacement. Although in acutely hospitalized elders the intravenous route is frequently utilized for fluid replacement, complications are not uncommon. These include difficulty with peripheral access, subcutaneous fluid infiltration, local infection, air embolism, bacteremia, and septicemia. Direct intravenous infusion also increases the likelihood of hemodynamic overload with rapid fluid infusions. Peripheral venous cannulation access is much safer than central venous line placement. However, in patients with emergent and life threatening diseases, central access may be unavoidable. Intravenous fluid infusion is a highly effective delivery system in patients who require resuscitation, as this method facilitates delivery of precise amounts of fluid and rapid restoration of intravascular volume.

Hypodermoclysis is an underutilized parenteral hydration method that delivers fluid into the subcutaneous tissue. Hypodermoclysis has been shown to be effective in restoring hydration, especially in mild to moderately dehydrated older adults. This infusion method is often advocated in frail, institutionalized persons. However, this is also a convenient technique that can be used in all geriatric health-care settings, including subacute care and home care. Family members, lay caregivers, and nurses are easily trained to administer hypodermoclysis. Technically, hypodermoclysis is a relatively safe procedure suitable for use in many hospital and home-care situations regardless of the patient's age and is simpler to perform than intravenous cannulation. Emerging research clearly favors hypodermoclysis as an alternative infusion method (Sasson and Shvartzman, 2001; Lipschitz *et al.*, 1991; Hussain and Warshaw, 1996; Ferry *et al.*, 1999).

KEY POINTS

- Dehydration is the most common fluid and electrolyte disorder in older adults. Multiple risk factors for dehydration coexist in the elderly. These include age-related physiological hypodipsia, frailty, polypharmacy, acute and chronic illnesses, and iatrogenic factors.
- Recommended daily intake of fluids in older adults is unclear, but should not be less than 1500 mL/24 hours in order to ensure adequate hydration. Fluid intake and hydration status should be monitored closely, especially in dependent elders.
- Clinical diagnosis of dehydration is unreliable. Thus, multiple assessment modalities should be used to assess hydration status and define therapeutic intervention.
- Aggressive and rapid fluid and electrolyte replacement in older adults may lead to fluid overload and neurological complications.
- Oral and enteral routes are safest for fluid replacement therapy. In patients requiring intravenous infusion, cautious administration is required. Hypodermoclysis is a safe and effective subcutaneous infusion technique that can be used in all health-care settings.

INTRODUCTION

Poor nutritional status is a primary concern for the elderly. Nutritionally inadequate diets can contribute to or exacerbate chronic and acute diseases and hasten the development of degenerative diseases associated with aging (Weimer, 1998).

Undernutrition is one of the most common and devastating conditions in the older population. Thirty percent to 40% of men and women over the age of 75 are at least 10% underweight. Full-blown undernutrition occurs in 5 to 12% of community-dwelling older persons, in 11% of medical outpatients, and in 20% of higher risk community-dwelling populations. In hospitalized older adults, protein-calorie undernutrition reaches epidemic proportions, with a reported frequency of 32 to 50%. In institutionalized, long-term care settings, an even higher prevalence of undernutrition (23–85%) has been reported. The devastating consequences of undernutrition include a higher mortality, greater functional decline, more frequent infections, and higher rates of adverse complications in all settings (Thomas, 2002).

As people age, activity levels and energy requirements tend to decrease. Concomitant decreases in food consumption may cause protein and micronutrient intake to fall below desirable levels. It is well documented that many older persons develop physiological anorexia associated with aging. Additional factors that increase the risk of undernutrition include physiological changes that affect digestion, absorption and metabolism of nutrients, social isolation, chronic diseases, oral problems, sensory impairment, cognitive impairment, depression, multiple and chronic medication use, poverty, and inappropriate food intake (Tripp, 1997; Thomas *et al.*, 2000; Morley, 1998; The Nutrition Screening Initiative, 1991).

The specific requirements for micronutrients in the elderly have not been studied until quite recently. Vitamin and mineral requirements do not stay static over the adult life span. There are several micronutrients for which there is strong evidence that requirements are in fact increased in the elderly compared to younger people such as: vitamins D, B6, and B12 (Russell, 1992; Johnson, 2002a). It is clear that individuals change physiologically during aging and that aging is often associated with the development of chronic degenerative diseases. The roles that various supplements play in these changes appear to be less defined. There is overall lack of evidence on the nutritional needs of the elderly, with particular lack of data from clinical trials. Additionally, there is a critical need for the development of valid and reliable methods to detect undernutrition and the generation of data to determine the dietary reference intakes (DRIs) of individuals 51 to 70 years and >70 years old (*Nutrition Reviews*, 2004).

Vitamin disorders in the elderly usually present atypically or are masked by coexisting diseases or a general failure to thrive (Larry, 1995). Vitamin preparations are consumed on a daily basis by 20–60% of elderly. These supplements are consumed for various reasons including the following: to increase energy, improve health, improve appetite, and to prevent and treat diseases. Older persons may consume potentially toxic amounts of vitamins and minerals by supplementation (Hartz *et al.*, 1988; Subar and Block, 1990; Kim *et al.*, 1993; Kellet *et al.*, 1984; Schneider and Nordlund, 1983; Hale *et al.*, 1982; Read and Graney, 1982). Drug–nutrient interactions are common in the elderly because of the high incidence of polypharmacy, many of which may occur unrecognized (Roe, 1992). Table 1 summarizes drugs with potential for interaction with various vitamins and minerals.

PREVALENCE/SCOPE OF THE PROBLEM

There have been few studies concentrating on the prevalence of vitamin and mineral deficiencies, most studies have concentrated on protein energy malnutrition (*Vitamin*

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

Table 1 Potential micronutrient–drug interaction (Larry, 1995; Warber *et al.*, 2002)

Micronutrient	Drugs
Calcium	Vitamin D, lysine
Chromium	Vitamin C
Copper	Zinc, iron
Folic Acid	Methotrexate, cotrimazole, phenytoin, sulfasalazine, triamterene, zinc, alcohol
Magnesium	B6, calcium
Manganese	Calcium, iron, zinc, copper
Selenium	Vitamin E
Vitamin A	Iron, vitamin E, tetracycline, cholestyramine
Vitamin B1 (Thiamine)	Vitamin B2, vitamin B3
Vitamin B2 (Riboflavin)	Ouabain, theophylline, penicillin, boric acid, probenecid, chlorpromazine, phenothiazines, barbiturates, streptomycin, and oral contraceptives, antidepressants, or probenecid, tobacco, alcohol
Vitamin B3 (Niacin)	Vitamin B1, vitamin B2, anticonvulsants, aspirin, clonidine, hydroxymethylglutaryl (HMG) Coenzyme A reductase inhibitors
Vitamin B6 (Pyridoxine)	Magnesium, anticonvulsants
Vitamin C	Copper, iron, vitamin
Vitamin D	Aluminum hydroxide, corticosteroids, diuretics, rifampin, phenytoin.
Vitamin E	Antacids, cholestyramine, colestipol, mineral oil, sucralfate, iron, vitamin A, tobacco, alcohol, coumarins, anticoagulants or indandiones
Vitamin K	Calcium, anticoagulants
Zinc	Diuretics, copper, *N*-acetyl cysteine, iron, calcium, magnesium

Deficiency, 2004). The prevalence of vitamin deficiency in usual western diets is higher than generally believed, especially in the elderly (Fletcher and Fairfield, 2005). Various studies reveal that up to 20% of community-dwelling ambulatory adults, 37% of home-bound elderly, 30–60% of hospitalized patients and 17–85% of institutionalized patients are malnourished (Morley and Silver, 1995; Abbasi, 1995; Abbasi and Rudman, 1993; Ritchie *et al.*, 1997; Keller, 1993; Guigoz *et al.*, 1996).

According to the National Health and Nutrition Examination Survey (NHANES), up to 16% of Americans over the age of 65 consume less than 1000 calories a day. The reduced caloric intake is incompatible with maintaining adequate vitamin and mineral intakes. Studies on vitamin deficiencies in older individuals reveal that vitamin deficiencies vary from 2.6 to 6.8% for vitamin D in the general population to 35% in the institutionalized patients, while vitamin A deficiency is seen in 1% or less of the older adults. The prevalence for vitamin B deficiency shows marked heterogeneity. The prevalence for vitamin B1 varies from <5% in the nursing home patients to as high as 43% in independent older persons; B12 deficiency is seen in up to 43% of independent older adults and up to 29% of nursing home patients (*Vitamin Deficiency*, 2004; Drinka and Goodwin, 1991; Vir and Love, 1979; Baker *et al.*, 1979; Garry *et al.*, 1984). Table 2 gives the prevalence of vitamin deficiencies. Information on prevalence of trace mineral deficiencies comes from the developing world; zinc deficiency is widely recognized to be a common association with malnutrition. Geographic surveys show trends for selenium deficiency in individuals living in areas with low soil content of selenium (Jacobs and Wood, 2003a,b).

Table 2 Prevalence of vitamin deficiencies in the elderly

Vitamin	Independent	Hospitalized	Nursing Home
Vitamin A	1%	Unknown	Unknown
Vitamin B1 (thiamine)	13–43%	40%	2–5%
Vitamin B2 (riboflavin)	3–42%	12%	1–34%
Vitamin B6 (pyridoxine)	5–56%	19%	21–93%
Folate	2.5–34%	24%	4–24%
Vitamin B12 (cobalamin)	4–43%	Unknown	4–29%
Vitamin C (ascorbic acid)	Unknown	Unknown	0–5%
Vitamin D	2–5%	22%	35%

DIETARY REFERENCE INTAKES

The goal of the Recommended Dietary Allowances (RDA) was to estimate nutritional requirements for preventing basic deficiency diseases. The recommendations were also meant to be applied as general guidelines for groups, not as a gold standard for individuals. Research, led by the American Heart Association in the 1960s, demonstrated the links between diet and disease. It was already known that deficiency in certain nutrients results in disease. Studies went on to show clearly that increased intake of certain nutrients actually helps prevent some chronic illnesses. Because of this research and because the RDAs were being used for purposes other than those for which they were created, new recommendations were in order.

The new guidelines are called *Dietary Reference Intakes* or *DRIs*. They were developed by the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, and published in 1998. These were designed to reflect the latest understanding of nutrient requirements based on optimizing health in individuals. For the first time, the group included data for individuals 70 years and older. They are being developed with individuals in mind. They are also concerned about the prevention of chronic degenerative diseases, such as macular degeneration, heart disease, and osteoporosis. The DRIs are based on several factors. These include the level of a nutrient needed to meet the needs of a healthy individual and the level at which a nutrient will produce harmful side effects. The DRIs also consider the source of the nutrient, for example, the body is often better able to use nutrients supplied in food than by supplements. The new DRIs take age and gender into consideration as well (*Vitamin Deficiency*, 2004; www.nap.edu, 2005; Institute of Medicine, 2000, 2001).

The committee described four categories of reference values:

1. Estimated average requirement (EAR): represents the amount of nutrient intake that meets the requirements of

Table 3 Dietary reference intake for micronutrients (National Policy and Resource Center on Nutrition and Aging, 2004)

	RDA/AI*				TUL

TUL, Tolerable Upper Intake Levels; RDA, Recommended Dietary Allowance; AI, Adequate Intakes; ND, not determined. AI are in ordinary type followed by an asterisk.

50% of the individuals in that group. The EAR serves as the basis for developing the recommended dietary allowance.

2. Recommended dietary allowance (RDA): the daily nutrient intake that meets the nutrient needs of 97–98% of healthy individuals in that group. It is set at 2 standard deviations above the EAR.
3. Adequate intakes (AI): the average observed or experimentally derived intake by a defined population or subgroup that appears to sustain a defined nutritional state, such as normal circulating nutrient values, growth, or other functional indicators of health.
4. Tolerable upper intake level (TUL): represents the maximum nutrient intake by an individual that is unlikely to pose risks of adverse health effects in 97–98% of individuals. It is not intended to be a recommended level of intake.

Table 3 gives the DRIs for vitamins and minerals for individuals aged 51–70 and over 70 years.

FACTORS AFFECTING NUTRIENT INTAKE IN THE ELDERLY

Total energy intake decreases substantially with age; this results in concomitant declines in most nutrient intakes including vitamins and minerals. Despite the common occurrence of protein energy undernutrition in older persons, its presence is rarely recognized. Factors implicated in the decreased nutrient intake in the elderly can be divided into the following categories (Thomas, 2004; Morley, 1995a):

- Social
- Psychological
- Medical
- Age-related

Factors affecting the nutrient intake are summarized in Table 4.

THE ANTIOXIDANTS

One of the leading theories proposed for cellular and organism aging is that damage to cellular mechanisms and tissues occurs because of chronic damage resulting from oxidative stress caused by free oxygen radicals. Endogenous oxidative damage to proteins, lipids, and DNA is thought to be an important etiologic factor in aging and development of chronic diseases such as cancer, atherosclerosis, and cataract formation. The developing recognition that many disease states are caused by oxidative damage and that certain antioxidant compounds may scavenge these damaging free oxygen radicals has resulted in an increased interest in vitamins and minerals as antioxidants. Vitamins A, C, E, and β-carotene, referred to as *antioxidant vitamins* have been suggested to limit oxidative damage in humans. Riboflavin (vitamin B2) and selenium, a trace metal, are also suggested to have antioxidant capabilities (Thomas, 2004; Larry, 1995; Morley, 1992; Christensen, 1993; Sies *et al.*, 1992).

A large body of epidemiological evidence suggests that eating a diet rich in sources of vitamins has a protective effect on development of disease. The strong association of dietary intake of vitamins and disease in epidemiological studies has not been borne out in clinical trials (Larry, 1995). Caution

Table 4 Factors affecting nutrient intake in the elderly

Social
1. Poverty
2. Social isolation
3. Ignorance
4. Problems with meal preparation
5. Inability to shop
6. Lack of recognition of ethnic or other food preferences in institutional settings
7. Monotony of institutionalized food

Psychological
1. Depression
2. Bereavement
3. Alcoholism
4. Dementia
5. Late-life paranoia
6. Late-life mania
7. Anorexia Tardive
8. Sociopathy
9. Overwhelming burden of life

Medical
1. Increased metabolism
   - Hyperthyroidism, phaechromocytoma
   - Movement disorders: Parkinsonism and Tardive dyskinesia
   - COPD.
   - Severe cardiac disease
2. Anorexia
   - Drugs: Digoxin, psychotrophic drugs, theophylline, cimetidine, ranitidine, l-thyroxine.
   - Gallstones, chronic and recurrent infections
   - Malignancy
   - Physiologic anorexia of aging
3. Swallowing problems
   - Esophageal candidiasis
   - Teeth and denture problems
   - Severe tremors and strokes
4. Malabsorption
   - Late onset gluten enteropathy
   - Lactose deficiency
5. Feeding problems
   - Severe tremor
   - Strokes
   - Dementia

Age related
1. Anorexia of aging
2. Decreased olfaction
3. Decreased taste

must be used in interpreting the results of observational studies, as the association of diets rich in fruits and vegetables with reduced risk of cancer and cardiovascular disease may be due to the vitamins themselves, other compounds in fruits and vegetables, or the substitution of dietary meat and fat with fruits and vegetables (Jha *et al.*, 1995).

Vitamin A and β-carotene

Vitamin A consists of preformed vitamin A (retinol) and the carotenoids such as β-carotene. The carotenoids are a diverse group of more than 600 naturally occurring pigments. Natural sources include yellow, orange, and red plant compounds, such as carrots and green leafy vegetables. Humans cannot synthesize carotenoids and depend on dietary intake exclusively for these micronutrients. β-carotene can act as an antioxidant by quenching the unpaired electrons of free radicals and divert free-radical damage toward itself. Vitamin A refers to preformed retinol and the carotenoids that are converted to retinol. Preformed vitamin A is found only in animal products, including organ meats, fish, egg yolks, and fortified milk. More than 1500 synthetic retinoids, analogs of vitamin A, have been developed. Vitamin A intake decreases with age; however, hypovitaminosis A is uncommon even in the very old. The current RDI for vitamin A is $1500\,\mu g\,l^{-1}$ (5000 IU). Except at the extreme ranges, retinol levels correlate poorly with vitamin A status and are affected by many nonnutritional diseases. Hepatic levels of vitamin A appear unchanged in adults. About 50–85% of the total body retinol is stored in the liver. It is also found in many other tissues in much smaller concentrations. (Thomas, 2004; Larry, 1995; Ross, 2000; Harrison, 1993).

Dietary proteins undergo proteolysis to release retinyl esters in the stomach. They then join lipids and bile salts to form micelles for absorption through the intestinal mucosa. Preformed vitamin A is absorbed by the intestinal cell by a carrier-mediated mechanism, however; carotenoids are passively absorbed by the intestinal epithelium. Vitamin A is then transported to the liver via the lymphatics. By means of a receptor-mediated endocytosis on the surface of the hepatocytes, the retinol esters are released and stored as retinyl ester. These are further metabolized to eventually combine with retinol binding proteins (RBP) before storage in vitamin A–containing lipid globules within the hepatic stellate cells. In order for vitamin A to reach its target organs, it binds to RBP molecules for release into plasma as a Retinol-RBP complex (Larry, 1995; Ross, 2000; Harrison, 1993; Pazirandeh and Burns, 2005a).

Vitamin A has a number of biologic actions. In the eye, it is required for prevention of xerophthalmia and phototransduction. Vitamin A is crucial to cellular differentiation and integrity (Pazirandeh and Burns, 2005a; Jacobs and Wood, 2003c).

Vitamin A deficiency is rarely seen in the United States and other industrialized countries. However, it is still the third most common nutritional deficiency in the world. In the elderly, diminished physical activity reduces intake and concentrations may drop, but there is little evidence to support the need for supplementation, and, indeed, toxicity is manifested more readily with age (Ross, 2000; Pazirandeh and Burns, 2005a; Higdon, 2002; Cantorna *et al.*, 1995, 1996). Deficiency can result in

- night blindness, complete blindness, and xerophthalmia;
- Bitot's spots (areas of abnormal squamous cell proliferation and keratinization of the conjunctiva), which can be seen in young children;
- corneal perforation, keratomalacia, and punctate keratopathy, which have been observed in early childhood development;
- nonspecific dermatological problems, such as hyperkeratosis, phrynoderma (follicular hyperkeratosis), and the

destruction of hair follicles and their replacement with mucous-secreting glands;
- impairment of the humoral and cell-mediated immune system via direct and indirect effects on the phagocytes and T cells.

In a majority of cases, vitamin A toxicity occurs because of the ingestion of large amounts of synthetic vitamin A, about 10 times higher than the Daily Value, or about 50 000 IU. In the elderly, diminished physical activity reduces intake and concentrations may drop, but there is little evidence to support the need for supplementation, and indeed, toxicity is manifested more readily with age. Hypervitaminosis can occur both acutely and after chronic ingestion. Symptoms of toxicity include dry skin, nausea, headache, fatigue, irritability, ataxia, alopecia, hyperlipidemia, hepatotoxicity, bone and muscle pain, and visual impairments (Larry, 1995; Pazirandeh and Burns, 2005a; Jacobs and Wood, 2003c; Biesalski, 1989).

Epidemiologic studies of dietary vitamin A on possible cancer chemoprevention appear to primarily represent the effect of β-carotene. Studies of relationships between cancer and vitamin A and carotenoids have provided mixed results. Observational data and clinical trial data have not been consistent.

Two large, randomized, placebo-controlled trials assessed the risk of lung cancer among male smokers or asbestos workers receiving β-carotene supplements. The risk of lung cancer was significantly increased among men receiving supplements. In the α-Tocopherol, β-Carotene (ATBC) Cancer Prevention Study, there was an increase in both prostate cancer incidence and mortality among subjects randomized to β-carotene. The excess risk appears to resolve over time once supplements are stopped (The α-Tocopherol, β-Carotene Cancer Prevention Study Group, 1994; Omenn *et al.*, 1996; Virtamo *et al.*, 2003).

There have been no clinical trials of vitamin A intake and breast cancer. However, observational studies of vitamin A intake and breast cancer have yielded varying results. In a study by Kushi *et al.*, no association between dietary vitamin A and breast cancer was observed (Kushi *et al.*, 1996). In contrast, recent data from the Nurses' Health Study suggest that premenopausal women, particularly those with a positive family history, have significant reductions in breast cancer risk with increasing dietary α-carotene and β-carotene, lutein /zeaxanthin, and total vitamin A (Hunter *et al.*, 1993; Zhang *et al.*, 1999a) Data from the Polyp Prevention Study Group did not show a reduction in adenoma risk in patients randomized to receive either β-carotene, vitamin C and E or both β-carotene and vitamins C and E (Greenberg *et al.*, 1994).

Vitamin A and β-carotene supplements have shown no benefit for primary or secondary prevention of coronary heart disease (CHD) in randomized trials and have been associated with potential harm (Vivekananthan *et al.*, 2003). There is consistent evidence from observational studies that vitamin A intake within the range taken by many people in western societies, is a risk factor for osteopenia and fractures. The Physicians Health Study found that 12 years of β-carotene supplements had no effect overall on the risk of cataract formation, but appeared to significantly decrease the risk among current smokers (Melhus *et al.*, 1998; Feskanich *et al.*, 2002; Michaelsson *et al.*, 2003; Christen *et al.*, 2003).

On the basis of current clinical data and the lack of clinical efficacy with respect to cancer prevention, along with its possible adverse effects, the use of vitamin A and β-carotene supplement use should be discouraged.

Vitamin E

Vitamin E occurs in eight natural forms as tocopherols (α, β, γ, and δ) and tocotrienols (α, β, γ, and δ), all of which possess potent antioxidant properties. Vitamin E was originally found to affect reproduction in rats and was given the name tocopherol derived from the Greek word of *toc* (child) and *phero* (to bring forth) to describe its role as an essential dietary substance in normal fetal and childhood development (Machlin, 1991; Mason, 1980).

Vitamin E absorption depends upon the breakdown of fatty acids and their uptake via enterocytes to the enterohepatic circulation. The synthesis of chylomicrons are required for transport of vitamin E via the lymphatic system to the liver. Within hepatocytes chylomicron, remnants are broken down by lysosomes, and RRR-α-tocopherol is preferentially secreted into the bloodstream, packaged within very low density lipoproteins (VLDL) molecules. The transport protein for α-tocopherol is named *α-tocopherol transfer protein* (α-TTP) (Traber *et al.*, 1990; Cohn *et al.*, 1988a,b).

Vitamin E works as a free-radical scavenger and antioxidant. α-tocopherol is the biologically active form of vitamin E. It protects polyunsaturated fatty acids (PUFA), a major structural component of the cell membranes, from peroxidation. Primary sources of vitamin E are vegetable oil, wheat germ, leafy vegetables, egg yolk, margarine, and legumes (Olson, 1998; Burton *et al.*, 1983). Vitamin E deficiency can be measured by examining serum or tissue α-tocopherol levels (Reuben *et al.*, 1995).

Deficiency of vitamin E is uncommon in humans except in unusual circumstances. In the elderly, conditions resulting in fat malabsorption can cause vitamin E deficiency. The effects of deficiency are widespread throughout the body and include the following (Pazirandeh and Burns, 2005a; Perrig *et al.*, 1997; Johnson, 2002b):

- Neuronal degeneration resulting in spinocerebellar ataxia, decreased deep tendon reflexes or areflexia, peripheral neuropathy, and posterior column destruction with impairment of proprioception and vibratory sense. This can result in gait disturbance, which is a basic manifestation of vitamin E deficiency.
- Degenerative myopathy.
- Ocular impairment such as retinopathy and extraocular muscle paresis.
- Brown bowel syndrome, a result of lipofuscin deposition and oxidative damage.
- Red blood cell life span reduction.

The effects of long-term supplementation of vitamin E are unclear. Some studies caution against the use of vitamin E in patients with an increased propensity to bleeding or those taking oral anticoagulants. Impaired absorption of fat-soluble vitamins A and K with large vitamin E supplements have been seen in animal models. Necrotizing enterocolitis is seen in infants supplemented with high doses of vitamin E. It may impair the hematologic response to iron in children with iron-deficiency anemia (Pazirandeh and Burns, 2005a; Hathcock, 1997; Finer *et al.*, 1984).

There have been several studies examining the role of vitamin E in cancer prevention. The ATBC Cancer Prevention Study observed a 32% decrease in prostate cancer incidence and 41% decrease in prostate cancer mortality among men receiving α-tocopherol compared with placebo (Hennekens *et al.*, 1996) In contrast, observational data from the Health Professionals Follow-up Study showed no association between vitamin E supplement use and all prostate cancers. However, it showed a decrease in risk of metastatic or fatal prostate cancer among smokers who consumed at least 100 IU of supplemental vitamin E daily (Chan *et al.*, 1999). A second report from the ATBC study showed a significant 19% reduction in lung cancer risk associated with higher serum vitamin E levels. The reduction in risk was greatest among men younger than 60 years and among patients with fewer years of cumulative smoking exposure (Woodson *et al.*, 1999).

Vitamin E supplementation has shown no benefit in both primary and secondary prevention of CHD (Vivekananthan *et al.*, 2003). In the ATBC study, daily supplementation with vitamin E had no overall effect on stroke risk. However, a subgroup analysis suggested that vitamin E may increase the risk for subarachnoid hemorrhage and decrease the risk for ischemic stroke, particularly in men with hypertension (Leppala *et al.*, 2000). In the Heart Outcomes Prevention Evaluation (HOPE) trial, daily supplementation with vitamin E had no effect on progression of carotid intimal medial thickness (Lonn *et al.*, 2001). The HOPE-TOO trial (ongoing outcomes) showed that vitamin E at 400 IU was associated with an increase in heart failure (Lonn *et al.*, 2005). The Health Professionals Follow-up Study showed no association between supplemental vitamin E and stroke risk (Ascherio *et al.*, 1999)

Data from observational studies have suggested that increased dietary intake of vitamin E may have a protective effect against the development of Alzheimer's disease. A longitudinal cohort study found that both vitamin E and C supplementation protected against the development of vascular dementia and improved cognitive function late in life (Masaki *et al.*, 2000; Morris *et al.*, 2002; Engelhart *et al.*, 2002). In a randomized trial of selegiline, vitamin E, both, or placebo among patients with Alzheimer's disease showed that both selegiline and vitamin E were independently associated with significant reductions in several outcomes, including functional decline (Sano *et al.*, 1997)

There have been several studies reporting that vitamin E supplementation improves the immune response. However, randomized, placebo-controlled studies have found no reduction in the incidence of respiratory infections in institutionalized or noninstitutionalized elderly patients receiving daily vitamin E supplements (Meydani *et al.*, 1997; Serafini, 2000; Girodon *et al.*, 1999; Meydani *et al.*, 2004; Graat *et al.*, 2002).

A meta-analysis of vitamin E supplementation that did not stratify trials by dose of vitamin E found no significant effect of supplementation on all-cause mortality (Vivekananthan *et al.*, 2003) However, a recent meta-analysis that examined the dose–response relationship between vitamin E and overall mortality in a total of 19 randomized clinical trials found that vitamin E supplementation with a dose $\geq$400 IU/day was associated with a significantly increased risk of all-cause mortality (Miller *et al.*, 2005).

Current evidence for vitamin E supplementation is inconclusive. Data at present suggest that high-dose vitamin E ($\geq$400 IU/day) increases all-cause mortality. Also, individuals taking anticoagulants should be particularly advised against high doses of vitamin E because of the synergistic action of vitamin E with these drugs.

Selenium

Selenium, a trace element, is a component of several enzymes. These include glutathione peroxidase and superoxide dismutase. Both these enzymes are important in the prevention of oxidative and free-radical damage of various cell structures. Evidence suggests that the antioxidant protection conveyed by selenium operates in conjunction with vitamin E because deficiency of one seems to enhance damage induced by a deficiency of the other (Mason, 2004). Selenium is incorporated as selenocysteine at the active sites of multiple selenoproteins. Selenoproteins are also important for thyroid function, muscle metabolism, and sperm function, as well as immune function (McClain, 2002).

Dietary sources include vegetables, grains, brazil nuts, seafoods, and organ meats. The amount of Se in plant food is determined by the amount present in the soil. The mechanism of absorption of Se from the gut is unknown. Dietary Se has a high bioavailability and its absorption from the gut is unregulated (Massey, 2002; Pazirandeh and Burns, 2005b).

The risk of Se deficiency seems to increase in proportion to age. Also, low levels have been documented in type II diabetes (McClain, 2002; Savarino *et al.*, 2001). In China, Keshan disease is seen in areas where the soil is poor in selenium. It is an endemic cardiomyopathy which improves with selenium supplementation. Se deficiency has been reported in individuals on chronic total parenteral nutrition (TPN) (van Rij *et al.*, 1979). Severe deficiency of Se manifests as

- cardiomyopathy
- myopathy

Toxicity can result from excessive intake. The most common manifestations are hair and nail loss. Other manifestations include nausea, emesis, tooth lesions, mental status

changes and peripheral neuropathy (Yang *et al.*, 1983; *Morbidity and Mortality Weekly Report*, 1984).

The potential protective effect of selenium status on the risk of developing cancer has been examined in animal and epidemiologic studies. Low levels of dietary selenium are associated with a greater risk of prostate, esophageal, colon, and antral gastric cancers (Massey, 2002; Clark *et al.*, 1991; Mark *et al.*, 1999; Schulman *et al.*, 2000). There have been studies evaluating the effect of selenium on cancer related chemotherapy. A study assessing the *in vitro* effects of Se on chemotherapy revealed that the addition of selenium enhanced drug-mediated cancer cell death. In another study, the addition of dietary selenium at the beginning of chemotherapy prevented the development of resistance to cisplatin (Vadgamma *et al.*, 2000; Caffrey and Frenkel, 2000).

The antioxidant properties of selenium have been linked to a lower incidence of cardiovascular disease in humans. However, the therapeutic benefit of selenium administration in the prevention and treatment of cardiovascular diseases still remains controversial (Salvini *et al.*, 1995; Neve, 1996).

Se deficiency has been associated with impaired cell-mediated immunity and enhanced activity of natural killer cells (Spallholz *et al.*, 1990; Kiremidjian-Schumacher *et al.*, 1994). Studies done on the coxsackievirus and influenza virus by Beck *et al.* (1994, 2001) have shown that selenium prevented the genomic conversion of a nonvirulent strain into a virulent strain that occurred in the presence of selenium deficiency in mice. These effects of Se may have considerable implications on the elderly population, especially in the institutional setting.

Vitamin C

Vitamin C (ascorbic acid) is a water-soluble vitamin widely found in citrus fruits, raw leafy vegetables, strawberries, melons, tomatoes, broccoli, and peppers. Humans cannot synthesize vitamin C, and a deficiency results in scurvy. The amount in food consumed, however, depends on the season of the year, the transportation time to the store, the shelf time before purchase, the form of storage, and the method of cooking. Boiling can cause a 50–80% loss of vitamin C. Cooking with minimal water or microwaving food reduces losses (Thomas, 2004; Johnson, 2002b).

Vitamin C is absorbed in the distal small intestine through an energy dependent process. Blood concentrations of ascorbic acid are regulated by renal excretion. The greatest concentrations of ascorbic acid are found in the pituitary, adrenal, brain, leukocytes, and the eye. Its absorption does not seem to be affected by age. The bioavailability of vitamin C is inversely related to the amount ingested as well as the form. Sustained release tablets allow higher absorption than standard pills. It is a reversible biologic reductant, and provides reducing equivalents for a number of biochemical reactions involving iron and copper. It therefore functions as a cofactor, enzyme complement, cosubstrate, or a strong antioxidant in a variety of reactions and metabolic processes (Larry, 1995; Jacob, 2000; Schorah, 1992; Kallner *et al.*, 1985; Garry *et al.*, 1987).

Vitamin C has multiple functions. It is an antioxidant and reduces harmful free radicals. It is purported to be an immune enhancer and is known to be crucial to collagen synthesis and to norepinephrine synthesis. The conversion of iron from the ferric (+3) to the ferrous (+2) form requires vitamin C. Without this conversion, methemoglobin could not be converted to hemoglobin, and iron could not be absorbed in the duodenum. Vitamin C is also involved in the reduction of nitrates, a function that possibly is involved in stomach cancer. Vitamin C has a role in prostaglandin and prostacyclin metabolism. It may be capable of attenuating the inflammatory response or even sepsis syndrome (Johnson, 2002b; Willett and Stampfer, 2001; Levine *et al.*, 1999; Pazirandeh *et al.*, 2005).

Vitamin C deficiency is common in many frail elderly populations. Because vitamin C is supplied only by diet, deficiency is caused by insufficient dietary intake (Larry, 1995; Morgan, 1987; Mandal and Ray 1987; McClean *et al.*, 1976). Deficiency primarily affects the musculoskeletal and hematopoietic systems. Deficiency results in the following (Johnson, 2002b):

- Reduced collagen cross-linking and therefore decreased collagen tensile strength, leading to impaired wound healing, and to weakened blood vessels.
- Hemostasis abnormalities occur, producing painful subperiosteal hemorrhages, hemarthrosis, hemorrhagic perifolliculitis, gingival bleeding, ecchymoses, petechiae, and nail bed splinter hemorrhages. Some of these manifestations are common in elderly persons and are usually attributed to age-related physiologic changes and not to vitamin deficiency.
- Structurally abnormal collagen that produces structurally abnormal osteoid, which produces structurally abnormal bone;
- Scurvy: Scurvy is the clinical syndrome produced with deficiency and develops after intake of less than 10 mg/day for 3 to 6 months. Scurvy includes the previously mentioned physical findings plus the development of corkscrew hairs, glossitis, gingival hyperplasia and bleeding, and poor dentition caused by periodontitis and loss of teeth. Iron-deficiency anemia can also occur. Terminal features include icteris, edema, hypotension, and convulsions.

There have been some reports of excessive use of vitamin C as risk factor for calcium oxalate nephrolithiasis. However, a prospective epidemiologic study demonstrated that consumption of high doses of vitamin C lowered the relative risk of calcium oxalate stones compared to 250 mg or less of vitamin C per day. Ingestion of large quantities of vitamin C has been rarely associated with fatal cardiac arrhythmias in patients with iron overload, presumably due to oxidative injury. Vitamin C toxicity has been associated with diarrhea and abdominal bloating. High doses are also associated with false negative guaiac tests and they also alter the results of

glucose measurements (Pazirandeh *et al.*, 2005; Urivetzky *et al.*, 1992; McLaran *et al.*, 1982; Block, 1991).

A large, randomized trial of vitamin C for secondary prevention of CHD found no benefit of supplementation with vitamin C. The Health Professionals Follow-up Study showed no association between supplemental vitamin C and stroke risk. Prospective data from the Nurses' Health Study showed a 45% reduction in the risk of cataract requiring extraction in women using vitamin C supplements for at least 10 years. In contrast, a randomized, placebo-controlled study of high-dose supplementation with vitamins C and E and β-carotene found no reduction in the 7-year risk of development or progression of age-related lens opacities with vitamin C supplementation (Vivekananthan *et al.*, 2003; Ascherio *et al.*, 1999; Hankinson *et al.*, 1992; Age-Related Eye Disease Study Research Group, 2001).

Riboflavin

Riboflavin or vitamin B2 is an important component of the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). It is involved in an array of biochemical reactions. It is important for oxidative phosphorylation, ATP production, and the production of reduced glutathione, which is an antioxidant. Vitamin B2 has been implicated in a signal transduction role for programed cell death and regulation of a number of other important intracellular pathways. Dietary sources include dairy products, green leafy vegetables, whole and enriched grains, meats, liver, poultry, and fish. It is not destroyed by heat, oxidation, or acid but is susceptible to ultraviolet light and alkalis (Johnson, 2002b; Jacobs and Wood, 2003d).

Riboflavin is released by proteolysis from the ingested food and undergoes passive absorption from the intestinal lumen. It then enters the hepatic cells and undergoes conversion to FAD and FMN. Like other B vitamins in this class, stores are minimal, and regulated replacement is necessary through food or supplements.

Vitamin B2 deficiency is regarded as the most common vitamin deficiency in the United States, it is usually seen in conjunction with other vitamin B deficiencies. There is some evidence that the requirements for riboflavin may increase with aging and that the glutathione reductase activity declines with aging. Plasma riboflavin concentrations tend to reflect recent dietary intake. Erythrocyte glutathione reductase assay is a better test for riboflavin deficiency; it is however not valid in individuals with glucose 6-phosphate dehydrogenase deficiency (*Vitamin Deficiency*, 2004; Jacobs and Wood, 2003d; Mason, 2004).

Deficiency may be secondary to inadequate dietary intake or a result of chronic diarrhea, alcoholism, or liver disease. Deficiency may manifest as (Johnson, 2002b; Jacobs and Wood, 2003d; Mason, 2004)

- Cheilosis
- Magenta-colored glossitis
- Inflammation of the oral mucosa
- Seborrheic dermatitis
- Normocytic normochromic anemia
- Corneal revascularization.

Vitamin B2 supplementation helps only in the prevention of deficiency. A small randomized control trial has shown some benefit of supplementation with a very large dose in the prevention of migraine (Johnson, 2002b; Schoenen *et al.*, 1998).

VITAMIN D

Vitamin D, or calciferol, is a generic term, and refers to a group of lipid soluble compounds with a four-ringed cholesterol backbone. Vitamin D is not a true vitamin, because humans are able to synthesize it with adequate sunlight exposure. By photoconversion, 7-dehydrocholesterol becomes previtamin D3, which is metabolized in the liver to 25-hydroxyvitamin D3, the major circulating form of vitamin D. In the kidneys, this is converted to two metabolites, the more active one being 1,25-dihydroxyvitamin D3. It is derived primarily via synthesis in the skin. Dietary sources include fortified milk, milk products, oily fish, egg yolks, and fortified foods (Thomas, 2004; Pazirandeh and Burns, 2005a; Johnson, 2002b).

Vitamin D is absorbed in the form of micelles by the intestinal epithelium to form chylomicrons. Chylomicrons enter the liver via the portal circulation where vitamin D undergoes a hydroxylation process by 25-vitamin-D hydroxylase to form 25-hydroxy-vitamin-D (calcidiol). Further hydroxylation of 25-hydroxy-vitamin-D to 1,25-dihydroxy-vitamin D (1,25(OH)2-vitamin D or calcitriol) occurs in the mitochondria of the proximal tubules of the kidney. Vitamin D from any source and in either form is absorbed into circulation and bound to vitamin D-binding protein. Calcitriol, the biologically active form, has a short half-life of 4–6 hours and thus does not accurately reflect body stores, whereas 25OHD (calcidiol) has a longer half-life of 3 weeks. Thus, 25OHD is more widely used to measure vitamin D status. Laboratory measurements reflect both vitamin D2 and vitamin D3 status. Deficiency is defined as a 25OHD level below 15 mg dl^{-1} (Pazirandeh and Burns, 2005a; Johnson, 2002b; Gloth and Tobin, 1995; Thomas *et al.*, 1998; Gloth *et al.*, 1995).

Increased age is a risk factor for vitamin D deficiency. Several studies have shown that the levels of 1,25dihydroxyvitamin D are lower in older people (Dandona *et al.*, 1986; Russell, 1992). 25-hydroxyvitamin D has been shown to decline with age in a longitudinal study by Perry *et al.* (1999). Factors resulting in low circulating levels in the elderly include:

- inadequate intake of vitamin D due to decreased intake of dairy products in their diets;
- decreased ability to form previtamin D3 in the skin upon ultraviolet light exposure secondary to decreased amounts

of 7-dehydrocholesterol levels in the skin with advancing age;
- decreased synthesis of 1,25-dihydroxyvitamin D by the kidney;
- medications interfering with vitamin D metabolism.

Deficiency of vitamin D can result in the following biochemical and physical manifestations (Johnson, 2002b):

- low calcium and low phosphorus levels and elevated alkaline phosphatase levels;
- secondary hyperparathyroidism;
- osteomalacia;
- fractures;
- neuromuscular irritability;
- proximal myopathy, deep proximal musculoskeletal pain, neuropathy, and hyperesthesia.

Vitamin D excess is associated with hypercalcemia, hypercalciuria, confusion, polyuria, polydipsia, anorexia, vomiting, muscle weakness, and bone demineralization with pain (Pazirandeh and Burns, 2005a).

Vitamin D supplementation results in a decreased bone loss and fracture rate in older men and women. In a study done by Dawson-Hughes *et al.*, vitamin D supplementation in healthy postmenopausal women was associated with a net gain in bone mineral density during the summer-fall period with a significantly lower spinal loss compared to the placebo group during the winter-spring period. In a randomized, controlled trial vitamin D supplementation with calcium, reduced bone loss in several sites and decreased the incidence of nonvertebral fractures by one-half after 3 years. In another study, vitamin D supplementation decreased the risk of falls in the elderly, possibly secondary to improvements in muscle strength (Gloth and Tobin, 1995; Gloth *et al.*, 1995; Dawson-Hughes *et al.*, 1997; Bischoff-Ferrari *et al.*, 2004; Dawson-Hughes *et al.*, 1991). Vitamin D improves muscle strength only in persons with low circulating levels.

The daily intake of vitamin D in older adults should be at least 800 IU with at least 1200 mg of elemental calcium in the diet or as a supplement (Pazirandeh and Burns, 2005a). This is particularly important in the elderly individuals who are unable to expose themselves to sunlight since a large part of the daily requirements are met by skin synthesis.

VITAMIN K

Vitamin K occurs in two naturally occurring forms, phylloquinone found in plants and menaquinones synthesized by the GI flora. Vitamin K produced by the gut flora is thought to provide upto 50% of the requirement in humans. Vitamin K is found in various food sources which include green leafy vegetables, vegetable oils, and liver (Johnson, 2002b; Jacobs and Wood, 2004).

Vitamin K is a fat-soluble vitamin absorbed by the intestinal epithelium in the form of micelles. It is then incorporated in chylomicrons and enters the liver via the portal circulation. Within the body, the stores are relatively small. They are mostly hepatic; however, the trabecular and cortical bone also contain substantial concentrations (Pazirandeh and Burns, 2005a; Jacobs and Wood, 2004).

Vitamin K is an important cofactor for the endoplasmic enzyme γ-glutamylcarboxylase. This enzyme acts as a catalyst for the carboxylation of glutamate to γ-carboxyglutamate. This is an important step for the activation of several coagulation factors within the hepatic cells. It thus plays a central role in blood coagulation, by activating factors II, VII, IX, and X. It is also needed for the activity of the natural anticoagulants proteins C and S (Pazirandeh and Burns, 2005a; Johnson, 2002b; Jacobs and Wood, 2004).

Deficiency of vitamin K in healthy adults is uncommon because of the widespread distribution of the vitamin in nature, its recycling within the cells and its synthesis by the GI flora. Deficiency can be seen in the following conditions (Pazirandeh and Burns, 2005a; Johnson, 2002b; Jacobs and Wood, 2004; Shearer *et al.*, 1988):

- prolonged antibiotic therapy, which disrupts the GI flora;
- parenteral nutrition;
- disorders associated with fat malabsorption;
- medications such as anticonvulsants, high doses of vitamins A and E, warfarin;
- starvation.

Deficiency results in prolongation of the prothrombin time and partial thromboplastin time, signs and symptoms of bleeding such as easy bruisability, splinter hemorrhages, mucosal bleeding, melena, and hematuria (Pazirandeh and Burns, 2005a; Olson, 1998; Johnson, 2002b; Jacobs and Wood, 2004; Shearer *et al.*, 1988). Studies have shown an increase in the incidence of hip fractures in the elderly. There have been studies showing a decrease in bone mineral density in hemiplegic limbs of vitamin D deficit stroke patients (Sato *et al.*, 1999; Booth *et al.*, 2000).

Toxicity associated with excess doses is rare, it can however cause hemolytic anemia and jaundice in infants. Doses greater than 150 μg/day from food supplements can interfere with anticoagulation in patients on warfarin.

FOLATE

Folates represent a group of related pterin compounds. More than 35 forms of the vitamin are found naturally. The term folic acid is derived from the latin word *folium* which means leaf. The pharmacologic form is folic acid; it is more bioavailable and does not exist in nature in this form. The various dietary sources include green leafy vegetables, fresh fruits, yeast, liver, and other organ meats. Folate in foods is destroyed by excessive cooking, as much as 95% may be destroyed (Larry, 1995; Johnson, 2002b; Stabler and Allen, 2004).

Folate is required for the transfer of single carbon groups; it is essential in the *de novo* synthesis of nucleotides and metabolism of several amino acids. It is an important component for the regeneration of the "universal" methyl donor, *S*-adenosylmethionine. In the body, homocysteine is remethylated into methionine. The process of remethylation requires folate and cobalamin (vitamin B12). In the presence of folate deficiency, homocysteine levels are elevated (Johnson, 2002b; Stabler and Allen, 2004).

The luminal enzymes convert the polyglutamate forms of folate present in the dietary sources to the monoglutamate and diglutamate forms. Folate is then absorbed from the lumen of the small intestine by both active and passive absorption. In the plasma, folate is present as 5-methyltetrahydrofolate, it is bound loosely to albumin, from which it is readily taken up by the high-affinity folate receptors present on cells throughout the body. Folates undergo enterohepatic circulation and are thus reabsorbed from the gut; they also undergo urinary excretion (Johnson, 2002b; Stabler and Allen, 2004).

Studies reveal that folate deficiency may range from 2.5–34% among the elderly persons. Folate deficiency occurs within a few days of insufficient intake, however, clinical signs of deficiency develop after approximately 4 months of decreased intake. Folate deficiency can be determined on the basis of decreased serum folate levels; however, red cell folate levels may be better indicators if there has been a recent dietary change. Factors responsible for deficiency in the elderly include (*Vitamin Deficiency*, 2004; Larry, 1995; Johnson, 2002b; Stabler and Allen, 2004):

- inflammatory diseases of the GI tract;
- atrophic gastritis;
- part of generalized malnutrition;
- poor oral intake;
- excessive alcohol intake;
- smoking;
- medications such as cotrimazole, methotrexate, triamterene, phenobarbital, and phenytoin.

Folate deficiency can result in megaloblastic anemia, leukopenia, thrombocytopenia, anorexia, fatigue, delirium, diarrhea, glossitis, and hyperhomocysteinemia.

Current evidence suggests that high dietary intake of folate is associated with a decreased risk of developing colorectal cancer in both men and women. Data from the Nurses' Health Study reveal a protective effect of high dietary intake of folate on the development of breast cancer. There was a normalization in the risk of breast cancer associated with concurrent alcohol use (Zhang *et al.*, 1999b; Giovannucci *et al.*, 1998, 1993).

Folate deficiency is associated with hyperhomocysteinemia. Homocysteine is prothrombotic and atherogenic. It causes vascular injury characterized by thickened vascular intima, disruption of the elastic lamina, smooth muscle hypertrophy, platelet aggregation, and the formation of platelet-rich occlusive thrombi (Harker *et al.*, 1974; Tsai *et al.*, 1994). In a multicenter case-control study done by Robinson *et al.* (1998), lower levels of folate and vitamin B6 conferred an increased risk of atherosclerosis. The increased risk was explained partly by an elevated homocysteine level. In the Health Professional Follow-up Study, increased folate intake was associated with a decreased risk of ischemic stroke in men (He *et al.*, 2004). In another study, an inverse association between a high-folate diet and coronary heart disease was found to be strongest among women who consumed up to one alcoholic beverage per day (Rimm *et al.*, 1998).

Data also suggest that there may be a correlation of high homocysteine levels with osteoporotic fractures and dementia (Seshadri *et al.*, 2002; Kalmijn *et al.*, 1999; van Meurs *et al.*, 2004).

VITAMIN B12

Vitamin B12 is a group of cobalamin compounds that have a corrin ring with a cobalt atom at the center. The corrin ring is connected through an aminopropanol bridge to a ribonucleotide. Dietary sources of vitamin B12 include meat and dairy products. It is an important cofactor for the enzymes, methionine synthase, and methylmalonyl-coenzyme A (CoA) mutase. It is essential for the synthesis of succinyl coenzyme A (CoA) from methylmalonyl-CoA. Vitamin B12 serves as a cofactor in the conversion of 5-methylene THF (tetrahydrofolate) to THF (the active form of folate); during this reaction, the methyl group is donated to cobalamin, forming methylcobalamin. Methylcobalamin then donates its methyl group to homocysteine to form methionine. The synthesis of methionine is essential for purine and pyrimidine synthesis, methylation reactions, and the intracellular retention of folates. A deficiency of cobalamin leads to an increase in homocysteine and methylmalonic acid (Stabler and Allen, 2004; Snow, 1999).

Cobalamin is released from the food by the gastric enzymes and bound to R-binding proteins. Further, enzymatic degradation occurs in the small intestine and it then gets bound to the intrinsic factor (IF). The B12-IF complex is then absorbed in the ileum and stored in the liver. It is transported through the body attached to the protein transcobalamin II. Vitamin B12 undergoes enterohepatic circulation and most of it gets reabsorbed from the bile (Larry, 1995).

The prevalence of B12 deficiency ranges from 4 to 43%. The levels of vitamin B12 have been found to decline at the rate of $3.4\,\text{pmol}\,l^{-1}$ annually. Vitamin B12 deficiency may be seen in the elderly population as documented by elevated methylmalonic acid with or without elevated total homocysteine concentrations in combination with low or low-normal vitamin B12 concentrations. Owing to the long half-life and hepatic stores of vitamin B12, deficiency secondary to inadequate intakes takes 2–6 years to develop. Deficiency is seen in individuals with atrophic gastritis, total gastrectomy, pernicious anemia (may be seen in upto 5% of those aged 80 and above in some populations), terminal ileal resection, bacterial overgrowth of the bowel, drugs use such as prolonged use of H-2 antagonists, colchicines

and aminosalicylic acid, and practice of strict vegetarianism (*Vitamin Deficiency*, 2004; Larry, 1995; Johnson, 2002b).

Deficiency can result in (Johnson, 2002b; Stabler and Allen, 2004):

- increased homocysteine levels;
- increased methylmalonic acid levels;
- megaloblastic anemia;
- neurologic syndrome manifested as

1. peripheral neuropathy with paresthesias and decreased vibratory sensation, which may progress to ataxia, weakness, and an inability to walk. It affects both the dorsal and lateral spinal cord columns and is termed *subacute combined degeneration*;
2. impaired mentation, memory loss, and depression. This syndrome may occur without evidence of anemia and may not be associated with macrocytic erythrocytes.

Current evidence suggests an increased risk of cardiovascular disease associated with elevated homocysteine levels. Vitamins B12, folate, and vitamin B6 are needed for homocysteine metabolism and deficiency results in elevated levels of homocysteine. Although studies have shown a decreased risk of cardiovascular disease with high levels of folate and vitamin B6, this has not been shown with B12 supplementation (Thomas, 2004; Eikelbloom *et al.*, 1999).

In a study by Lindenbaum *et al.*, neuropsychiatric disorders due to cobalamin deficiency were seen in the absence of anemia or an elevated mean cell volume. They recommend measuring of serum methylmalonic acid and total homocysteine, both before and after treatment for diagnosis in these patients (Lindenbaum *et al.*, 1988).

Vitamin B12 supplementation should be considered in the elderly and at-risk individuals.

VITAMIN B6

Vitamin B6 comprises of the various derivatives of pyridine, which include pyridoxine, pyridoxal, and pyridoxamine. As a coenzyme, B6 is involved in many transamination reactions. It is required for the synthesis of niacin from tryptophan. Vitamin B6 is involved in the synthesis of several neurotransmitters (γ-aminobututyric acid (GABA), serotonin, and norepinephrine), and δ-aminolevulinic acid (and therefore in heme synthesis). Dietary sources include meats, whole grains, vegetables, and nuts (Johnson, 2002b; Mason, 2004; Jacobs and Wood, 2003e).

Pyridoxine-5′-β-D-glucoside is the major, naturally occurring form of vitamin B6. It undergoes hydrolysis in the intestine and is absorbed by diffusion from the lumen of the small intestine. Vitamin B6 is not stored, and cannot be synthesized. Dietary intake thus provides the metabolic requirements (Jacobs and Wood, 2003e).

Dietary deficiency is rare; however, there is evidence that the requirements are increased in the elderly. Deficiency may result from alcoholism, malabsorption, and high-energy states such as dialysis. Medications such as isoniazid, hydralazine, cycloserine, penicillamine, ethanol, and theophylline act as pyridoxine antagonists (Russell, 1992; Johnson, 2002b).

Vitamin B6 deficiency usually occurs in association with deficiencies of other water-soluble vitamins. Deficiency can be diagnosed by assessing plasma or erythrocyte pyridoxal-5-phosphate (PLP) levels. Manifestations of deficiency include (Johnson, 2002b; Mason, 2004; Jacobs and Wood, 2003e)

- stomatitis, angular cheilosis, glossitis;
- irritability, depression, and confusion, occurring in moderate to severe depletion;
- normochromic, normocytic anemia that has been reported in severe deficiency;
- abnormal electroencephalograms, convulsions, and peripheral neuropathy.

Long-term use with doses exceeding 200 mg/day (in adults) may cause peripheral neuropathies and photosensitivity (Mason, 2004).

Elevated homocysteine levels are associated with an increased risk of cardiovascular disease. Vitamin B6 deficiency is associated with elevated homocysteine levels; low levels of vitamin B6 may be independently associated with CHD (9; Eikelbloom *et al.*, 1999; Folsom *et al.*, 1998). In a case-control study, lower levels of folate and vitamin B6 were associated with an increased risk of atherosclerosis (Robinson *et al.*, 1998). The Nurses' Health Study found an inverse association between higher dietary intakes of folate and vitamin B6 and CHD (Rimm *et al.*, 1998) There is evidence of a lower risk of breast cancer in women with higher plasma levels of vitamin B6 (Zhang *et al.*, 2003). In another study, vitamin B6 supplementation in the elderly resulted in improvement of long-term memory by improving storage of information (Deijen *et al.*, 1992).

ZINC

Zinc is a bivalent trace metal that plays a critical role in protein synthesis. It also serves as a cofactor, catalyst or a part of several enzymes. It is involved in the synthesis of nucleic acids and gene regulation. Zinc is required for the maintenance of genetic stability and gene expression and for controlling differentiation, proliferation, maturation, and programed cell death. It is essential for the maintenance of plasma membrane integrity. It may have antioxidant and antiatherogenic properties (Jacobs and Wood, 2003a; Powell, 2000; Hennig *et al.*, 1996).

Dietary sources of zinc are red meat, seafood, fresh fruit, vegetables, and dairy products. During the process of digestion, zinc is released from these dietary sources. It is primarily absorbed in the jejunum. Its absorption is inhibited by phytates present in many staple foods. Metallothionein, present in the gut enterocyte is responsible for the homeostatic control of zinc absorption. Ninety percent of the total

body zinc stores are in bone and skeletal muscle. It undergoes enterohepatic circulation. Excretion is mainly fecal, with small amounts being excreted in the urine (McClain, 2002; Pazirandeh and Burns, 2005b; Jacobs and Wood, 2003a).

Data at present are insufficient to determine the frequency of zinc deficiency in the elderly. Deficiency may be seen with poor dietary intake, inflammatory processes, malabsorption, chronic diarrhea, sickle-cell anemia, diabetes, cirrhosis of the liver, thiazide diuretics, lung cancer, following thermal injury, in drug addiction, and renal injury (Hennig *et al.*, 1996; Sandstead *et al.*, 1982). Low zinc levels seen in inflammatory conditions result from redistribution of zinc; an action mediated by cytokines. Serum and plasma levels of zinc do not correlate with tissue levels and are not reliable indicators (McClain, 2002; Pazirandeh and Burns, 2005b; Jacobs and Wood, 2003a; Hennig *et al.*, 1996; Sandstead *et al.*, 1982). Manifestations of deficiency in the elderly may be subtle; these include the following:

- Impaired immune response. Aging is associated with an altered T-cell response. Zinc has been identified as a potent T-lymphocyte mitogen. Studies have revealed a beneficial effect of zinc supplementation of immune function (Bogden *et al.*, 1987; Fraker *et al.*, 2000; High, 2001; Williams and Loer, 1973; Duchateau *et al.*, 1981).
- Anorexia resulting from impaired taste and smell. Several mechanisms have been hypothesized to result in anorexia; however, the relationship of zinc status to anorexia still remains unclear (Shay and Mangian, 2000).
- Confusion, irritability, and restlessness. Acrodermatitis enteropathica (AE) is an autosomal recessive inherited disease. The manifestations of AE are thought to occur secondary to zinc deficiency. Confusion and apathy in these children responds to zinc supplementation. Also, zinc deficiency induced in humans may be associated with irritability or apathy, which is reversed with zinc supplementation. However, data on the role of zinc deficiency on mental status in the elderly are limited (McClain, 2002; McClain *et al.*, 1985).
- Impaired wound healing. Studies have shown impaired wound healing of pilonidal sinuses and venous leg ulcers in patients with low serum zinc levels (Pories *et al.*, 1967; Hallbook and Lanner, 1972). Current data on zinc supplementation for pressure ulcers is controversial.
- Diarrhea has been reported in patients who develop severe zinc deficiency during total parenteral nutrition therapy. There are no randomized studies on zinc supplementation in the elderly with diarrhea (McClain, 2002; Latimer *et al.*, 1980).
- Impaired vision. In a study by Keeling *et al.* (1982), adaptation to darkness was impaired in cirrhotics with low neutrophil zinc concentrations.
- Epidermal abnormalities characterized by skin lesions around body orifices and the extremities as seen in AE. In a study of institutionalized patients with skin lesions and low zinc levels, there was no improvement in skin lesions following supplementation with zinc (Weismann *et al.*, 1978).
- Impaired spermatogenesis and testosterone steroidogenesis resulting in impaired testicular function. In one study, individuals on a zinc-deficient diet developed decreased libido, depressed serum testosterone levels, and marked reduction in sperm counts. Hydrochlorthiazide induced sexual dysfunction associated with low zinc levels may respond to zinc supplementation in some individuals (McClain, 2002; Abbasi *et al.*, 1980; Prasad, 1979).
- Disruption of vascular endothelium with possible implications for atherosclerosis (Hennig *et al.*, 1996)

Zinc toxicity is relatively unusual; however, high dietary intake may cause nausea, vomiting, epigastric pain, lethargy, and fatigue. Immune response may be impaired. It can cause hypocupremia, macrocytosis, or neutropenia (Jacobs and Wood, 2003a).

COPPER

Copper plays a significant role in several enzymatic pathways. Some of these enzymes include monoamine oxidase, dopamine-beta-hydroxylase, cytochrome-C oxidase, ferroxidase II, superoxide dismutase, and lysyl oxidase. Copper plays an important role in iron absorption and mobilization to sites of erythropoesis. Copper is essential for inactivation of catecholamines, synthesis and cross-linking of collagen, and the conversion of dopamine to norepinephrine (McClain, 2002; Morley, 1995b; Jacobs and Wood, 2003f).

The various dietary sources for humans are legumes, nuts and meats (Pazirandeh and Burns, 2005b). A study by Ma *et al.* revealed less-than-recommended intakes of copper by the elderly (Ma and Betts, 2000). Individuals at risk of copper deficiency include patients with chronic diarrhea, those on chronic TPN and chronic peritoneal dialysis (Pazirandeh and Burns, 2005b). Deficiency can be seen in individuals on high-dose oral zinc supplementation. Serum copper levels are used to assess copper status. These levels however are affected by inflammation and hormonal status. Ceruloplasmin, the copper binding protein is an acute phase reactant. Serum copper levels therefore increase during stress and inflammation (McClain, 2002). Serum copper levels increase with aging; however, there is no change in the leukocyte copper levels. Advancing age is also associated with an increase in ceruloplasmin (Morley, 1995b).

Dietary copper is absorbed from the upper gastrointestinal tract (from the stomach to the distal small bowel). Bioavailability is affected by dietary fiber and protein content and the ingestion of other minerals such as zinc. Copper undergoes enterohepatic circulation and only small amounts are excreted in the urine. Portal flow delivers histidine-bound and albumin-bound copper to hepatocytes. Release into systemic circulation is primarily via the specific transporter known as *ceruloplasmin* (McClain, 2002; Jacobs and Wood, 2003f).

The classic manifestations of copper deficiency can be seen in the congenital disorder, Menkes Syndrome. It is characterized by eating difficulties, hypothermia, seizure activity, and

"steel wool" hair, cerebellar ataxia, profound arteriopathy and early death. Copper deficiency may present as follows (Tamura *et al.*, 1994; Masugi *et al.*, 1994; Christen, 2000; Saari, 2000):

- Anemia, leukopenia, and neutropenia. Anemia is unresponsive to iron supplementation;
- hypopigmentation;
- immune dysfunction;
- skeletal abnormalities;
- increased cholesterol with atherosclerosis;
- neurologic problems such as AD.

Copper metabolism seems to be conserved with aging. Although older individuals ingest lower amounts than younger individuals, they are able to maintain a metabolic balance (Jacobs and Wood, 2003f).

Severe copper toxicity can result in hepatic necrosis, coma, oliguria, renal failure, hypotension, and even death. Mild gastrointestinal symptoms such as nausea, vomiting, and abdominal pain can occur in less acute and less serious toxic conditions (Pazirandeh and Burns, 2005b).

CHROMIUM

Chromium, an essential trace element, was first identified as the glucose tolerance factor which corrected hyperglycemia in rats (Schwarz and Mertz, 1957). Glucose Tolerance Factor is a combination of chromium and nicotinamide. Chromium functions as a coenzyme and is also a component of metalloenzymes (Mertz, 1993). Low chromium levels may be seen in some diabetic patients and it may have a role in glucose homeostasis (Anderson, 2000; Anderson *et al.*, 1991). Data suggest that chromium may augment the production and binding of insulin to the receptors (Vincent, 2000). Data suggest that chromium may have a role in elevating high-density lipoprotein (HDL) and lowering overall cholesterol levels (Railes and Albrink, 1981).

Dietary sources of chromium include brewer's yeast, cereals, fruits, vegetables, grains, and processed meats (Pazirandeh and Burns, 2005b; Morley, 1995b). Chromium is absorbed in the small intestine and its absorption is determined by the total body chromium concentration. Its

Table 5 Micronutrient functions and the effects of aging on these micronutrients

Micronutrient	Function	Effect of aging
Vitamin A	Prevention of xeropthalmia, phototransduction, cellular differentiation, and integrity	Intake decreases with aging, retinol levels correlate poorly with vitamin A status. Hepatic levels appear unchanged
Vitamin D	Calcium and phosphorus homeostasis	Decreased levels of 1,25-dihydroxyvitamin D
Vitamin E	Antioxidant and free-radical scavenger, stabilization of cell membranes	Unknown
Vitamin K	Central role in blood coagulation	Unknown
Vitamin B1 (thiamine)	Oxidative decarboxylation of alpha ketoacids and trans ketolase degradation	Decreased thiamine levels
Vitamin B2 (riboflavin)	It acts with its coenzymes Flavin mononucleotide and flavin adenine dinucleotide in oxidation–reduction reactions	Erythrocyte glutathione reductase activity declines with aging
Vitamin B3 (niacin)	Dehydrogenase reactions as a coenzyme for nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate	Probably decrease with aging
Vitamin B6 (pyridoxine)	Cofactor for intermediary metabolism	Pyridoxal phosphate levels decline
Folate	Single carbon atom transfer in intermediary metabolism	Unknown
Vitamin B12 (cobalamin)	Metabolism of fatty acids and methyl transfer	Levels decrease with aging
Vitamin C (ascorbic acid)	Antioxidant and reduces harmful free radicals. Important for collagen and norepinephrine synthesis	Levels decrease with aging
Arsenic	Urea cycle, myocardial muscle function and triglyceride synthesis	Unknown
Boron	Bone structure, mineral metabolism	Unknown
Chromium	Glucose homeostasis, lipid metabolism	Decrease
Cobalt	Erythropoesis and triglyceride synthesis	No change
Copper	Cholesterol metabolism, erythropoesis, collagen cross-linking, conversion of dopamine to norepinephrine, electron transport chain, coagulation factor V	Increase in serum, decrease in saliva, hair, and heart
Fluoride	Bone structure and tooth enamel	Increase up to age 60, then decline in skeleton
Iodine	Thyroid hormones	Increase in serum after age 45
Lead	Uncertain	Unknown
Lithium	Endocrine secretory functions	Unknown
Manganese	Protein and energy metabolism, mucopolysaccharides	No change in serum, reduced in the kidney and heart
Molybdenum	Uric acid production, oxidation of sulfite to sulfate	Unknown
Nickel	RNA and DNA structure, membrane stabilization, iron absorption and metabolism, pituitary function	Increase in lungs
Selenium	Constituent of glutathione peroxidase, T and B cell function, muscle metabolism	Decrease
Silicon	Bone and connective tissue structure	Decrease in aorta and skin
Tin	Induces hemoxygenase and carbon monoxide production	Increased in Alzheimer's Disease
Vanadium	Cholesterol synthesis, catalysis of oxidation–reduction reactions	Unknown

absorption is enhanced in the presence of zinc and iron deficiency (Pazirandeh and Burns, 2005b; Offenbacher *et al.*, 1997). Vitamin C also enhances its absorption. Nonsteroidal anti-inflammatory medications and antacids decrease its absorption (Jeejeebhoy *et al.*, 1977; Kamath *et al.*, 1997).

Chromium deficiency is seen in individuals on total parenteral nutrition. Tissue chromium levels decline with age and urinary excretion increases (Pazirandeh and Burns, 2005b; Morley, 1995b). Chromium deficiency has been associated with (McClain, 2002)

- glucose intolerance with peripheral insulin resistance;
- altered lipid metabolism;
- neuropathy;
- encephalopathy.

Chromium toxicity has been described in a patient on chromium supplements who presented with renal insufficiency, elevated liver enzymes, anemia, and thrombocytopenia. Discontinuation of the supplement and supportive measures resulted in normalization of all laboratory values within a year. Attention to the use of over the counter (OTC) nutritional supplements is important, especially in the elderly (Cerulli *et al.*, 1998).

Table 5 summarizes the functions of various vitamins and trace metals and the effects of aging on these micronutrients.

CONCLUSION

It is important to maintain adequate intake of micronutrients to maintain health. Data suggest that vitamin and mineral deficiencies exist in the elderly; these are exacerbated during hospitalization, hypermetabolic states, alcohol use, liver disease, diuretic use, and laxative abuse. Observational data suggest a link between dietary micronutrient intake and health outcomes. However, randomized control trials have not supported the use of vitamin and mineral supplements among well-nourished individuals. Food still remains the best vehicle for nutrient consumption. The elderly are at great risk of toxicity with a greater potential for drug–nutrient interaction. Other concerns in the elderly include cost and convenience of administration. The use of vitamin and mineral supplements as antiaging treatments or as treatments for specific diseases in the elderly is not supported by the currently available scientific data. Education and counseling is important in this age-group in order to maintain adequate nutrient intake via methods that are both convenient and affordable (Tripp, 1997; Dangour, 2004).

KEY POINTS

- The elderly are at increased risk of undernutrition as a result of multiple factors such as physiologic anorexia of aging, physiological changes affecting digestion, absorption, and metabolism of nutrients, social isolation, chronic diseases, sensory impairment, cognitive impairment, depression, and polypharmacy.
- There is overall lack of evidence on the nutritional needs of the elderly, with particular lack of data from clinical trials.
- Vitamin disorders present atypically or are masked by coexisting diseases or a general failure to thrive.
- Vitamin preparations are consumed on a daily basis by 20–60% of the elderly and drug–nutrient interactions are common in this population because of the high incidence of polypharmacy.
- The use of vitamin and mineral supplements as antiaging treatments or as treatments for specific diseases in the elderly is not supported by the currently available scientific data.

Obesity in the Elderly

Richard Y.T. Chen *and* Gary A. Wittert

University of Adelaide, Royal Adelaide Hospital, Adelaide, South Australia, Australia

AGE-RELATED CHANGES IN BODY COMPOSITION

Body weight increases until approximately the age of 60–65 years, and decreases in over 60% of the population thereafter. Muscle mass peaks between the third and fourth decades, followed by a decline of about 1.2 kg/decade in men and 0.1 kg/decade in women. Muscle mass and strength decrease by approximately 15% and 30%, respectively, between the second and seventh decades (Hughes *et al.*, 2002). Factors which may be responsible for, or are at least associated, with these changes include decreased physical activity, inadequate nutrition, vascular disease, increased activity of the cytokines interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor alpha (TNF α), and decreased levels of the anabolic hormones testosterone, dehydroepiandrosterone (DHEA), growth hormone (GH), and insulin-like growth factor-1 (IGF-1) (Morley *et al.*, 2001).

The contribution of fat mass to the weight loss that occurs in the elderly is small, and occurs predominantly in women over the age of 70 years (Mott *et al.*, 1999; Perry *et al.*, 1997). Fat mass has also been reported to increase with increasing age in both genders (Hughes *et al.*, 2002). More importantly, adipose tissue tends to be redistributed toward the abdomen, particularly viscerally (Beaufrere *et al.*, 2000).

There are a number of longitudinal studies that have examined the changes in body composition that occur with increasing age. The SENECA study included elderly Europeans aged between 65–70 years at baseline and 80–85 years at follow-up. Stature decreased by 1.5–2.0 cm. Mean weight decreased by 2.6–4.2 kg in three towns. Overall, body weight increased by 5 kg in 13% of men and women, but decreased by 5 kg in 23% of men and 27% women. Waist circumference increased by 3.0–4.0 cm (de Groot *et al.*, 2002). Gallagher *et al.* (2000) studied a group of men and women, aged over 60 years, in 1986 and, again, in 1994. Although there was no significant change in the overall body weight of men, fat mass increased by approximately 1.2 kg and total appendicular skeletal muscle mass decreased by approximately 0.8 kg. In women, both body weight and fat mass were reduced by about 0.8 kg, while appendicular skeletal muscle mass decreased by about 0.4 kg (Gallagher *et al.* 2000). Malnutrition may also be a significant problem as it was present in 5% of both genders (Perissinotto *et al.*, 2002). There is also data suggesting that visceral redistribution in old age predominantly affects females (Perissinotto *et al.*, 2002).

ASSESSMENT OF OBESITY WITH INCREASING AGE

At different ages, the same levels of body mass index (BMI), calculated as $kg\,m^{-2}$, correspond to different amounts of fat and fat-free mass. BMI is a poor indicator of obesity after it has peaked at about the fifth decade, as some elderly individuals with low BMI have been shown to carry as much fat as those with high BMI (Seidell and Visscher, 2000). The prevalence of overweight and obesity, with its attendant risks for chronic disease, may be underestimated using BMI (Baumgartner *et al.*, 1995) in the elderly. Increased (abdominal) fatness is better reflected by increased waist circumference which, in turn, relates better to obesity-related disease risk (Seidell and Visscher, 2000; Baumgartner *et al.*, 1995). Low lean body mass is better reflected by low BMI. The accurate identification of sarcopenic obesity requires precise simultaneous methods of measuring fat and lean components, such as dual-energy X-ray absorptiometry (Baumgartner *et al.*, 1995). The value of bioelectrical impedance analysis (BIA) has been questioned because the prediction errors are larger as compared to young and middle-aged subjects (Visser *et al.*, 1995). However, BIA models with increased accuracy and precision for predicting extracellular water and total body water have now been derived in healthy elderly subjects (Vache *et al.*, 1998).

 ISBN 0-470-09055-3

PREVALENCE OF OBESITY IN THE ELDERLY

Studies of the prevalence of obesity in the elderly are all based on standard BMI criteria. The prevalence of obesity has been reported to be 28% and 16% in elderly Italian women and men, respectively (Perissinotto *et al.*, 2002). In a representative sample of elderly Mexicans from five southwestern states in the United States, 23% of men and 35% of women were obese (Ostir *et al.*, 2000). In elderly Taiwanese subjects, 27.3% of men and 34.9% of women were overweight, while obesity was present in 3.2% of men and 6.4% of women (Chiu *et al.*, 2000). A Dutch nutrition survey of 539 healthy, independently living elderly persons, aged 65–79 years, found an overall prevalence of obesity of 13% (Lowik *et al.*, 1990). In urban Mexican women with a mean age of 71.6 years, the proportion of overweight and obese women was 60.7%, 36.2%, and 76.5% in urban, rural, and marginal areas, respectively (Gutierrez *et al.*, 2001).

Among residents aged over 50 years in a defined area in Jerusalem, the prevalence of obesity, standardized by age and sex, was 21% in 1970 and 25% in 1986, although the increase was statistically significant only in men (Gofin *et al.*, 1996). In elderly Italians aged 65–95 years, the prevalence of obesity in 1985 was 28% in women and 13% in men; this increased to 16% in men in a little over a decade, while remaining unchanged in the women (Perissinotto *et al.*, 2002). Analysis of data from the Longitudinal Study of Aging and the Assets and Health Dynamics of the Oldest Old Survey showed that the prevalence of obesity, over time, increased among those aged 70 years and older (Himes, 2000). Data from male participants of the Normative Aging Study showed that new cases of obesity, defined on the basis of BMI, increased over time while the numbers of subjects classified as lean and intermediate decreased. Among the oldest subjects, both the lean and obese had slight but significant decreases in mean BMI. Amongst the lean subjects, only the young showed consistent increments (Grinker *et al.*, 1996).

MECHANISMS OF OBESITY OF THE ELDERLY (TABLE 1)

Table 1 Mechanisms of obesity in older persons

1. *Reduced energy expenditure*
   - Reduced physical activity
   - Reduced resting metabolic rate
   - Poorer health status
2. *Lesser degree of fall in energy intake compared to fall in energy expenditure*
3. *Dysfunctional hormonal regulation*
   - Leptin resistance
   - Lack of ghrelin suppression after food intake
4. *Others*
   - Increased fat accumulation
   - Reduced fat oxidation

Energy Expenditure

Energy expenditure decreases by around 165 kcal/decade in men, and 103 kcal/decade in women, primarily due to changes in voluntary physical activity and, to a lesser extent, a decrease in resting metabolic rate (RMR) (Elia, 2001). In a population-based cohort of 33 466 men aged 45–79 years in central Sweden, total daily physical activity was found to decrease by approximately 4% by age 50 as compared to age 15. Physical activity was 2.6% lower in obese men compared to those with normal weight. Men with self-rated poor health had 11.3% lower levels of physical activity than those reporting very good health (Norman *et al.*, 2002; Norman *et al.*, 2003). A progressive decline in RMR is seen with increasing age. This is explained by both a loss of fat-free mass and a decrease in physical activity. RMR is around 6% higher in physically active older men than in untrained older men, independent of differences in fat-free mass (Poehlman, 1992).

Energy Intake

Food intake is regulated by a complex system involving orexigenic (appetite-stimulating) and anorexigenic (appetite-inhibiting) hormones that link hypothalamic satiety centers with gastrointestinal function and energy stores (Figure 1). Ghrelin, which is produced in and secreted from the gastric mucosa, increased by fasting and low protein diets, and inhibited by somatostatin, growth hormone, and high fat diet, is responsible for the main orexigenic signal that stimulates neuropeptide Y (NPY) and agouti-related peptide (AgRP) in the hypothalamus (Inui *et al.*, 2004). NPY and AgRP, which are capable of orexigenic stimuli themselves while simultaneously antagonizing anorexigenic melanocortin pathways, increase appetite, gastric motility, and triglyceride stores in adipocytes, but reduces energy expenditure, resulting in net body weight gain (Inui *et al.*, 2004). Cerebrospinal fluid levels of NPY increase with age in women, but not men (Morley, 1997). Conversely, the actions of NPY and AgRP are inhibited by the anorexigenic stimulus of leptin, produced from adipose tissue, especially after a meal. Leptin levels are higher in women as compared to men and this does not appear to change with age (Mann *et al.*, 2003). Other gastrointestinal peptides, such as cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), pancreatic polypeptide (PP) and peptide YY (PYY) 3–36, act in synergy with leptin to reduce gastric emptying, resulting in increased gastric distension, which has been identified as a satiety signal to inhibit food intake (Inui *et al.*, 2004). Ghrelin and leptin are, thus, complementary, but antagonistic, in their actions on hypothalamic satiety and gastrointestinal functions.

Obesity in humans is characterized by low ghrelin and weight loss leads to an increase in ghrelin levels, indicating that ghrelin plays an important role in the long-term maintenance of body weight despite its low levels (Hansen *et al.*, 2002). The sustained suppression of ghrelin levels in patients who have lost weight through gastric bypass surgery further

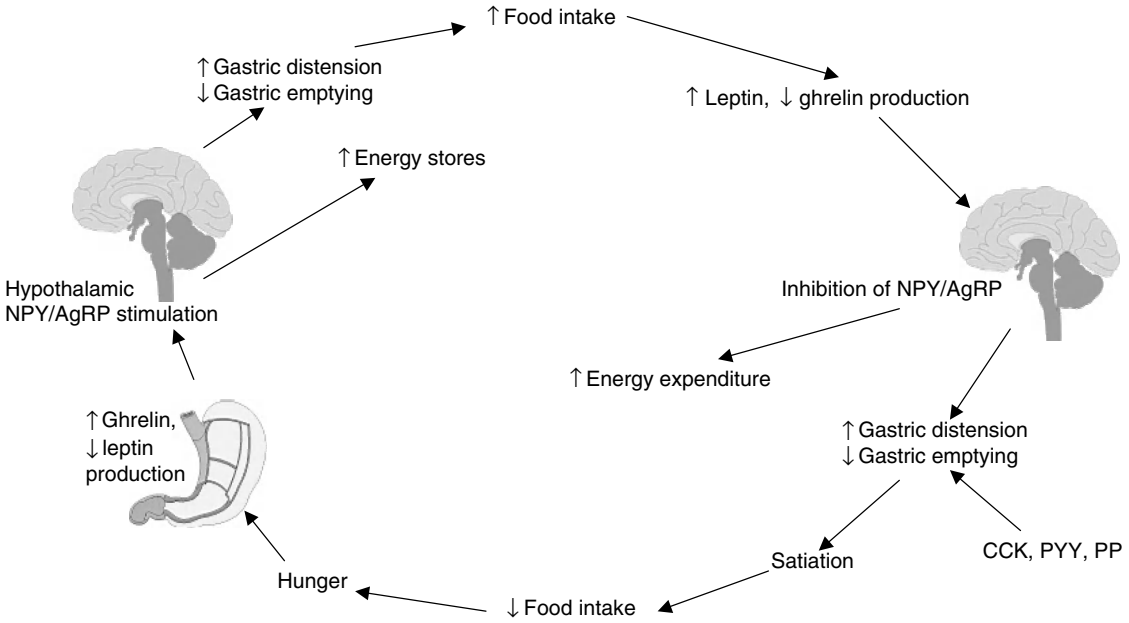

Figure 1 Hormonal regulation of energy homeostasis

supports this view (Hasler, 2003). The lack of ghrelin suppression after a meal in obese persons may also result in persistent food intake (English *et al.*, 2002). Ghrelin and CCK appear to be similarly regulated in older subjects as compared to younger ones (Sturm *et al.*, 2003). There is also no evidence that PYY regulation changes with aging.

The higher circulating levels of free (bioactive) leptin in obese persons suggest the presence of leptin resistance, as they do not result in reduced caloric intake (Mann *et al.*, 2003). In addition, leptin has been found to correlate strongly with body weight and fat mass, but not age or waist-hip ratio, in older subjects, suggesting that the accumulation of adipose tissue directly supports greater leptin production (Maugeri *et al.*, 2002).

While there is no data suggesting that significant changes in either the neural circuits or gut peptides regulating food intake changes with age, energy intake decreases with advancing age, but probably to a lesser extent than energy expenditure (Poehlman, 1992). In a cross-sectional study of 15 266 healthy men aged 55–79 years, total energy and energy from fat, but not from other nutrients, increased linearly with increasing BMI, which increased by 0.53 kg m^{-2} and 0.14 kg m^{-2} for every 500 kcal of fat and total energy consumed, respectively (Satia-Abouta *et al.*, 2002). Specific nutrient deficiency is also a problem in the elderly; up to 30% community dwelling older persons have diets deficient in at least one major nutrient (Morley, 1986).

Nutrient Utilization

Other changes that occur with aging that increase the propensity to the accumulation of fat include: a decrease in whole body fat oxidation (0.5 g year^{-1} from age 30–70 years) associated with the decrease in fat-free mass (Poehlman *et al.*, 1995), a diminished ability to use fat as a fuel during exercise (Blaak, 2000), reduced adipose tissue lipoprotein lipase activity (Berman *et al.*, 1999), catecholamine (Blaak, 2000) and leptin (Berman *et al.*, 1999) resistance.

THE CONSEQUENCES OF OBESITY IN THE ELDERLY (TABLE 2)

Overall Mortality

The relative contribution of increased fat mass to mortality is, on the whole, less pronounced in the elderly. Although there is some variability between studies, it is clear that higher BMI values are associated with a smaller relative mortality risk in elderly persons compared with young and middle-aged populations (Heiat *et al.*, 2001). For example, older men and women (BMI range of 25 kg m^{-2} to less than 32 kg m^{-2}) have been shown to have no excess mortality (Bender *et al.*, 1999). In another study, the BMI range of 25–27 kg m^{-2} was reported not to be a risk factor for all-cause and cardiovascular mortality among elderly persons, whereas a BMI $\geq$ 27 kg m^{-2} was a significant prognostic factor for all-cause

Table 2 Consequences of obesity in older persons

- ↑ In mortality those with sarcopenic obesity
- ↑ Physical disability
- ↑ Glucose intolerance
- ↑ Blood pressure
- ↑ Hepatic steatosis
- ↓ Lung capacity
- ↑ Relative hypogonadism (men)

and cardiovascular mortality among 65 to 74 year olds. The same study found a significant positive association between overweight and all-cause mortality among those aged 75 years or older (Heiat *et al.*, 2001). In 2032 subjects (999 men, 1033 women) with a mean age of 80 years, recruited by random sampling of the Old Age and Disability Allowance Schemes in Hong Kong, stratified by sex and 5-year-age groups from 70 years onwards, overall mortality was negatively associated with BMI and participation in physical activity, after adjusting for age and sex (Woo *et al.*, 1998). Overall, the evidence suggests that the standardized mortality rate increases with increasing BMI but, within each BMI group, the standardized mortality rate decreases with age.

The elderly at greatest risk are those who are simultaneously sarcopenic and obese (Morley *et al.*, 2001). Low BMI and weight loss in the elderly are both strong and independent predictors of subsequent mortality, and low BMI better predicts mortality than low waist circumference (Seidell and Visscher, 2000). Prior weight history has also been shown to be important in predicting risk. Older heavier people who had gained more than 10% of midlife body weight, or thinner older people who had lost 10% or more of body weight, are at higher risk compared with thinner people whose weight had remained stable (Harris *et al.*, 1997).

A high waist circumference (in nonsmoking men) may be a better predictor of all-cause mortality than high BMI (Seidell and Visscher, 2000). In a prospective cohort study of 31 702 healthy Iowa women aged 55–69 years, waist-hip ratio was the best anthropometric predictor of total mortality (Folsom *et al.*, 2001). In men and women aged 67–78 years, waist circumference and supine sagittal abdominal diameter were closely related to cardiovascular disease (CVD) risk factors (Turcato *et al.*, 2000).

DISEASE-SPECIFIC RISKS

Mobility Related Disability

Among 2714 women and 2095 men aged 65–100 years, there was a positive association between fat mass and disability at baseline. Moreover, fat mass was predictive of disability 3 years later independently of low fat–free mass, age, physical activity, or chronic disease (Visser *et al.*, 1998). Data from the First USA National Health and Nutrition Examination Survey (NHANES I, 1971 through 1987) showed that high BMI is a strong predictor of long-term risk for mobility disability in older women and that this risk persists even to very old age. On the other hand, weight loss is associated with an increased risk of disability in very elderly women (Launer *et al.*, 1994).

Impaired Glucose Tolerance and Type 2 Diabetes Mellitus

The prevalence of type 2 diabetes mellitus (T2DM) increases progressively with age, peaking at 16.5% in men and 12.8% in women at the age of 75–84 years. T2DM or glucose intolerance was present in 30–40% of Framingham Study subjects over 65 years of age (Wilson and Kannel, 2002). Age associated increase in total adiposity is a major contributor to impaired glucose tolerance in middle-aged and older men. A prospective relationship between abdominal adiposity and the risk of T2DM was found among 1972 male participants in the Department of Veterans Affairs Normative Aging Study cohort (Cassano *et al.*, 1992). Increased body fatness and increased abdominal obesity, rather than aging *per se*, are thought to be directly linked to the greatly increased incidence of T2DM among the elderly (Colman *et al.*, 1995). Nevertheless, there is evidence that insulin secretion decreases with age even after adjusting for differences in adiposity, fat distribution, and physical activity (Muller *et al.*, 1996).

Hypertension

Data from the Honolulu Heart Program showed that obesity and high blood pressure continued to be highly correlated even in old age (Masaki *et al.*, 1997). Furthermore, the Veterans Administration Normative Aging Study showed that abdominal accumulation of body fat, apart from overall level of adiposity, was associated with an increased risk of hypertension (Cassano *et al.*, 1990).

Fatty Liver

In the elderly, the prevalence of fatty liver has been reported to be 3.3% in male and 3.8% in female nonobese individuals, compared with 21.6% in male and 18.8% in female obese individuals, and was shown to be independently related to coronary risk factors (Akahoshi *et al.*, 2001).

Pulmonary Function

Among 1094 men and 540 women from the Baltimore Longitudinal Study of Aging, there was a strong inverse association of WHR with forced expiratory volume (FEV_1) and forced vital capacity (FVC) in men, but not women (Harik-Khan *et al.*, 2001). Weight loss has been shown to improve static lung volumes, but not dynamic pulmonary function, in moderately obese, sedentary men (Womack *et al.*, 2000).

Hypogonadism

Plasma total testosterone levels are significantly lower in men with visceral obesity compared to their lean counterparts, independently of age (Seidell *et al.*, 1990; Vermeulen *et al.*, 1999). While male hypogonadism had previously been thought to predispose toward the development of metabolic

syndrome and T2DM (Laaksonen *et al.*, 2003; Tibblin *et al.*, 1996; Stellato *et al.*, 2000), there is increasing evidence that it results from visceral adiposity (Niskanen *et al.*, 2004; Phillips *et al.*, 2003) and, thus, acts as a marker of poor metabolic status. Our analysis of data (unpublished) from the Australian Longitudinal Study of Aging, in men aged 70 years or greater, is consistent with the latter view. It remains unknown whether the hypogonadism is reversible with a reduction in fat mass, as seen in younger men (Niskanen *et al.*, 2004).

Plasma testosterone levels in men are also inversely associated with circulating leptin concentrations, even after adjusting for fast mass (Luukka *et al.*, 1998), and testosterone therapy reduces leptin levels (Hislop *et al.*, 1999). The long-term consequences of hypogonadism in elderly men have not been well established.

The Management of Obesity in the Elderly (Table 3)

Modifiable behavioral factors (physical activity, smoking, and obesity) and cardiovascular risk factors (T2DM, high density lipoprotein (HDL) cholesterol, and blood pressure) are associated with maintenance of good health in older adults (Burke *et al.*, 2001). Many obesity-related health conditions (e.g. hypertension, dyslipidemia, insulin resistance, glucose intolerance) can be ameliorated independently of weight loss (Gaesser, 1999). It is appropriate to advise a reduction in fat intake, to increase fiber and to ensure that the diet contains sufficient micronutrients.

Calorie Restriction

Thinness and weight loss (regardless of initial BMI) are associated with increased mortality rates in humans, independently of smoking or weight loss resulting from subclinical disease. For overweight individuals in good health, there is no good evidence to show that mortality rates are reduced with weight loss. Even among overweight persons with one or more obesity-related health conditions, specific weight loss recommendations may be unnecessary (Gaesser, 1999).

Table 3 Management of obesity in older persons

   - Resistive training
2. *Pharmacological*
   - Treat hypertension
   - Treat hypercholesterolemia
   - TZDs?
3. *Others*
   - Bariatric surgery?

Physical Activity

Regular exercise is the best predictor of successful weight maintenance. An increase in physical activity leads to improved insulin sensitivity and glucose tolerance, with a corresponding reduction in all-cause and cardiovascular mortality (Gaesser, 1999). Endurance training increases fatty acid oxidation, leads to a reduction in visceral fat, and increases, or attenuates, the decline in RMR that otherwise occurs with aging (Poehlman *et al.*, 1995). Beginning moderately vigorous sports activity, quitting cigarette smoking, maintaining normal blood pressure, and avoiding obesity were separately associated with lower rates of death from all causes and from coronary heart disease among middle-aged and older men (Paffenbarger *et al.*, 1993). Resistive training has particular benefits and improves quality and function of skeletal muscle, decreases total and intra-abdominal fat, improves insulin action, and lowers blood pressure (Ryan *et al.*, 2001; Hurley and Roth, 2000). Improvements in fitness have been shown to attenuate age-related increases in adiposity. People who exercise regularly have a lower risk of cardiovascular disease (Paffenbarger *et al.*, 1986), and appear to accumulate less adipose tissue in upper, central body regions as they get older, potentially reducing the risk for the metabolic disorders associated with upper body obesity (Kohrt *et al.*, 1992).

Drugs and Surgery

While most clinical trials exclude older patients, and little is known about benefits of diets or drugs inducing weight loss in these age groups, drug treatment of hypercholesterolemia and hypertension, in older people has proven to be beneficial in the primary and secondary prevention of cardiovascular morbidity and mortality (Aronow 2003; Grant and Meigs, 2004). Aggressive lowering of low density lipoprotein (LDL)-cholesterol to levels below 1.81 mmol L^{-1} may be necessary in the elderly at high risk of coronary events (Aronow, 2004). The use of metformin or thiazolidinediones to delay or prevent the onset of T2DM in elderly populations remains uncertain (Grant and Meigs, 2004). Administration of leptin in humans led to some degree of weight loss in obese individuals (Heymsfield *et al.*, 1999); however, there is no available data on such treatment in older subjects. Bariatric surgery can be safely performed in patients above age 70 with the same benefits as for younger subjects (St Peter *et al.*, 2005).

KEY POINTS

- Body mass index (kg m^{-2}) is not a useful measure of obesity in the elderly. Waist circumference should be utilised instead.

- Those elderly individuals with excessive visceral fat and loss of muscle mass (sarcopenia) are at greatest risk of excess morbidity and mortality.
- Increased physical activity, particularly with a resistance component is the management strategy associated with the greatest benefit.
- Diet-induced weight loss is of uncertain benefit, but saturated fat should be limited and nutrient density should always be optimized.
- There is no data to support the use of pharmacotherapy for the of obesity in the elderly.

Changes in Gastrointestinal Motor and Sensory Function Associated with Aging

Christopher K. Rayner *and* Michael Horowitz
University of Adelaide, Adelaide, South Australia, Australia

INTRODUCTION

The purpose of this chapter is to review changes in gastrointestinal contractile and sensory function associated with healthy aging, and their clinical significance. Furthermore, illnesses with clinical manifestations in the gut that are common, or present management problems in older patients, are considered. Mucosal functions of secretion and absorption are not discussed here (*see* **Chapter 25, Absorption of Nutrients**), and the focus is on the esophagus, stomach, and small intestine, since the oropharynx (*see* **Chapter 73, Communication Disorders and Dysphagia**), gallbladder (*see* **Chapter 33, Liver and Gall Bladder**), and colon and anorectum (*see* **Chapter 34, Sphincter Function**, **Chapter 35, Constipation**) are dealt with elsewhere.

CONTROL OF GASTROINTESTINAL MOTILITY AND SENSATION

Patterns of motor activity, involving the circular and longitudinal layers of smooth muscle that extend throughout the length of the gut, are coordinated by plexuses of nerves within the gut wall known collectively as the *enteric nervous system*. Located in the submucosa (submucous plexus) and between the muscle layers (myenteric plexus), this network contains an equivalent number of neurons (about 100 million) to that present in the spinal cord (Goyal and Hirano, 1996). The intrinsic sensory neurons, interneurons, and motor neurons that comprise the enteric nervous system control basic contractile activity such as reflex responses to distension. However, these intrinsic patterns of gut motility are modulated by both extrinsic neural and humoral signals. Central modulation of gut motility occurs via extrinsic sympathetic and parasympathetic nerves, while gut sensation is conveyed to higher centers by both the vagus and spinal afferent nerves, with noxious signals transmitted predominantly via the latter. Descending pathways to the spinal cord modulate the transmission of sensory signals.

PATHOPHYSIOLOGY OF THE AGING GUT

In rodent models of aging, there is a substantial reduction in the number of neurons in the enteric nervous system, which becomes increasingly prominent and more distally in the gut (40% loss in the small intestine and 60% in the colon, in the myenteric plexus of rats) (Wade, 2002). Similar neuronal loss is reported in the esophagus in older humans, while in the human colon, the decline in neuron numbers begins as early as the fourth year, but is most marked between young adulthood and old age. Although a selective, rather than global, loss of enteric neurons might be expected on the basis of age-related changes observed in the central nervous system, there is comparatively little information as to which neurons are most susceptible. Preliminary data in rodents indicate preferential loss of sensory neurons, which could impair stimulus-evoked motor responses. Cholinergic neurons appear vulnerable, but these subserve a wide variety of functions; conversely, nitrergic neurons, which typically mediate inhibitory motor responses, seem protected (Wade and Cowen, 2004). Regarding the extrinsic nerve supply to the gut, the number of vagal fibers innervating the upper gastrointestinal tract does not appear to decline in aging rats. Limitations to our understanding include the relative lack of studies relating to the upper gut and the sphincters, and the paucity of human data.

The relatively good preservation of gastrointestinal motility in the healthy elderly may imply that the large number of neurons in the enteric nervous system provides a considerable functional reserve, but even this may be limited; transit

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

of a radiolabeled meal through the upper gut occurs at a comparable rate in the healthy elderly and the young, but is slower through the colon in the elderly, where the loss of enteric neurons is greatest (Madsen and Graff, 2004). In the esophagus, selective loss of intrinsic sensory neurons could explain why contractile activity in response to distension (so-called "secondary peristalsis") occurs less frequently in the healthy elderly than the young.

In contrast to motor function, gut sensation is more consistently impaired with age, as reflected by decreased perception of balloon distension in the esophagus (Lasch *et al.*, 1997), stomach (Rayner *et al.*, 2000), and rectum (Lagier *et al.*, 1999) in comparison to young subjects. A selective loss of intrinsic sensory enteric neurons may be responsible. However, the amplitude of cortical evoked potentials recorded from scalp electrodes during repeated esophageal distension in older subjects is lower than in the young, raising the possibility that altered central processing of signals might also contribute to diminished sensation (Weusten *et al.*, 1994). In addition to mechanical stimuli, perception of chemical stimuli such as acid decreases with age, suggesting a generalized impairment of gut sensation.

ESOPHAGUS

Patients with disordered esophageal function can present with dysphagia or "heartburn", or less specific symptoms such as chest pain or chronic cough. Age-related changes in esophageal motility are extensively documented, but probably impact mainly on the very old. Classic esophageal motility disorders like achalasia, while uncommon, can present particular challenges in the elderly. Gastroesophageal reflux disease (GERD) is as prevalent as in the young, often presents atypically, and is more likely to be severe.

Changes in Esophageal Motor Function Related to Aging

The esophagus incorporates striated muscle in the upper portion and smooth muscle in the lower, with an upper esophageal sphincter (UES) and lower esophageal sphincter (LES) at either end. The term "primary peristalsis" refers to the coordinated sequence of contraction associated with swallowing, propagated from proximal to distal esophagus. The LES relaxes early in this sequence to allow the swallowed bolus to enter the stomach. "Secondary peristalsis" is triggered by reflux of gastric contents into the esophagus, or experimentally by balloon distension, and serves to clear the esophagus of acid and bile. "Tertiary contractions" represent spontaneous, uncoordinated esophageal motor activity. While both tonic contraction of the LES and its position within the diaphragmatic hiatus are important barriers against acid reflux, transient sphincter relaxations, particularly after a meal, are the most prevalent mechanism of acid reflux in most GERD patients. Defenses against reflux include neutralization of acid by saliva (which contains bicarbonate), together with acid clearance by primary and secondary peristalsis.

Esophageal motility may be evaluated by manometry. In this procedure, a catheter incorporating multiple lumens within a relatively small external diameter is passed through the nose or mouth, and perfused with water. Each lumen terminates in a sidehole at a different level of the esophagus, and when coupled to pressure transducers, and displayed as recordings of pressure over time, the assembly provides information about the amplitude, duration, and propagation of pressure waves (Figure 1). Incorporation of a sleeve sensor into the assembly, which records the maximum pressure at any point along the sleeve, is ideal for measurement of both the resting pressure and relaxation of the UES and LES. Solid-state transducers, mounted at intervals along a catheter, represent an alternative method of manometry to water perfused catheters. Multichannel intraluminal impedance, a technique that records electrical impedance between sequential pairs of electrodes, is emerging as a method of evaluating flow of liquid and air in the esophagus. While offering new insights into esophageal function, it has yet to be applied specifically to the elderly. Radiographic imaging of swallowed contrast can reveal abnormal esophageal wall movements (especially cineradiography), dilatation, or delayed esophageal transit. Transit can also be evaluated by the passage of a radiolabeled bolus, imaged by a gamma camera – a technique known as *scintigraphy*. While endoscopy is most useful in demonstrating mucosal lesions or strictures, it may also provide evidence of abnormal motor activity in disorders such as esophageal spasm or achalasia.

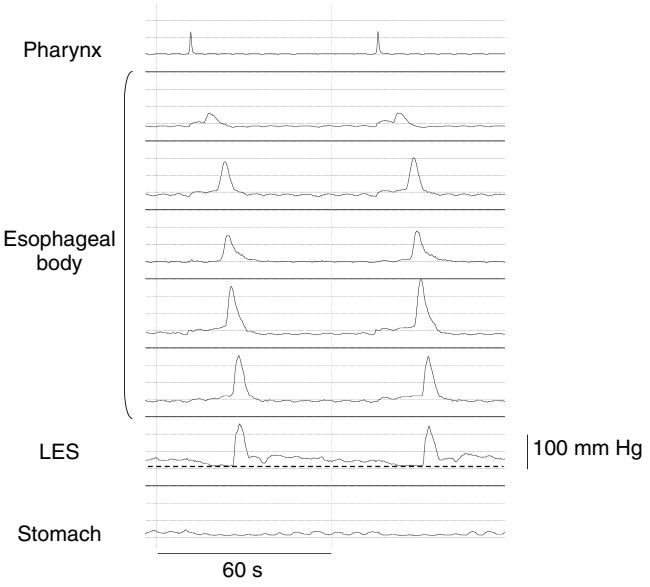

Figure 1 Normal esophageal manometry recording during water swallows, showing primary peristalsis. The pharyngeal pressure wave indicates the onset of swallowing, which is followed by an orderly sequence of waves from one channel to the next. Note the swallow-induced relaxations of the LES, whose pressure decreases to approximate intragastric pressure (dashed line)

The effects of aging have been studied more extensively in the esophagus than any other gastrointestinal region, reflecting both its accessibility and the importance of swallowing disorders in elderly. Soergel *et al.* coined the term "presbyesophagus" in 1964 when reporting radiological and manometric observations in a group of nonogenerians (Soergel *et al.*, 1964). Only two of 15 subjects had "normal" esophageal motility, and on barium examination there was a high prevalence of tertiary contractions, delayed clearance, and esophageal dilatation. Manometry showed nonperistaltic, multipeaked pressure waves. These subjects, however, could scarcely be described as healthy elderly, given the high prevalence of dementia and other chronic illnesses, including diabetes. Not surprisingly, more recent studies indicate that the prevalence and severity of esophageal motor dysfunction in healthy aging is less than suggested by early reports (Tack and Vantrappen, 1997). While there are other reports of esophageal dysmotility in the very old (Hollis and Castell, 1974), in subjects aged less than 80 years there appears to be little difference in primary peristalsis when compared to the young, though simultaneous contractions may occur more frequently. The impact of aging on the amplitude of esophageal pressure waves may vary by site; distal esophageal amplitudes increase with age, while a decrease is reported more proximally. Nevertheless, the magnitude of these changes is modest (Orr and Chen, 2002). Secondary peristalsis is elicited less consistently by distending stimuli in the healthy elderly when compared to the young (Ren *et al.*, 1995), and increasing esophageal stiffness, together with an increased threshold for perceiving distension, may contribute to this phenomenon (Rao *et al.*, 2003).

In the healthy elderly, while both the length of the UES high-pressure zone, and its resting pressure, are less than in young subjects, relaxation and opening of this sphincter are delayed (Shaw *et al.*, 1995). The result is a prolongation of the oropharyngeal phase of swallowing, and an increase in intrabolus pressure in the hypopharynx. While not clinically significant in the healthy elderly, these findings must be taken into account when evaluating swallowing studies in older patients with oropharyngeal dysphagia, where the use of reference ranges derived from the young would be inappropriate. Reflex responses of the UES to esophageal stimuli (increased pressure with esophageal balloon distension, and decreased pressure with air distension) appear to remain intact with healthy aging, but reflex UES contraction in response to laryngeal stimulation is impaired (Kawamura *et al.*, 2004); the latter could predispose to aspiration. Since only the frequency, and not the magnitude of the response, is diminished, the sensory side of the reflex arc appears to be impaired.

In contrast to the UES, both the length of the LES high-pressure zone, and its resting pressure, are comparable in older and younger subjects. However, in the elderly there is an increased prevalence of hiatus hernia (around 60% of those over 60 years) (Firth and Prather, 2002), and even in subjects without hiatus hernia apparent endoscopically, the respiratory inversion point (a marker of diaphragmatic position) tends to be located more distally in the high-pressure zone than is the case in young subjects. The implication is that, in general, the elderly have a less competent gastroesophageal junction than the young, predisposing them to GERD. Other predisposing factors include reduced flow of saliva, and impaired acid clearance. The frequency of transient LES relaxations, the major mechanism of acid reflux in most individuals, has not been specifically studied in the elderly; nor have mucosal repair mechanisms been compared with the young. The number of reflux episodes appears similar in both age-groups, but their duration appears to be more prolonged in the elderly (Smout *et al.*, 1989); this may relate to impaired clearance mechanisms. Nevertheless, reports relating to total acid exposure are inconsistent. The refluxate may be less acidic due to a higher prevalence of atrophic gastritis in the elderly, but it should be recognized that its bile content may be important in mucosal injury (e.g. Barrett's mucosa), and this has not been studied specifically in relation to age (Tack and Vantrappen, 1997).

Clinical Presentation of Disordered Esophageal Motility

Disordered esophageal motor function may present with symptoms of difficulty swallowing (dysphagia) or chest pain. In both nursing homes (50–60%) and general medical wards (10–30%), there is a high prevalence of dysphagia when patients are specifically questioned (Shaker and Staff, 2001), though less than half of elderly subjects who reported dysphagia in a population-based survey had consulted a physician about the problem. Potential consequences of dysphagia include aspiration, which contributes substantially to mortality, and inadequate intake of nutrition.

Swallowing disorders can be classified into those of oropharyngeal (difficulty initiating a swallow) or esophageal (impaired transport of swallowed material) origin, and these can usually be distinguished with a careful history and examination. The oropharyngeal component of swallowing comprises preparatory (chewing food, mixing with saliva, and bolus formation), oral (propulsion of the bolus by the tongue and palate to the pharynx), and pharyngeal (transport through the UES while protecting the airway) phases. A comprehensive discussion of dysphagia of oropharyngeal origin is included in the chapter on communication and swallowing disorders.

Potential causes of esophageal dysphagia are listed in Table 1. Key points in the history include whether dysphagia is for solids or liquids, is intermittent or progressive, and whether there are associated reflux symptoms like heartburn (Lock, 2001). Progressive difficulty in swallowing solids is suggestive of a structural lesion, while dysphagia for both liquids and solids is associated with motility disorders. Endoscopy provides a means to visualize and biopsy structural lesions, and may be therapeutic (e.g. dilatation of a peptic stricture). Endoscopy and biopsy are also likely to be helpful when odynophagia (painful swallowing) is the presenting complaint. Barium videofluoroscopy provides complimentary information regarding motor function as well

Table 1 Esophageal causes of dysphagia

Structural lesions
- Neoplasm
- Peptic stricture
- Rings and webs
- Vascular compression
- "Pill" esophagitis
- Reflux esophagitis
- Diverticula

Motility disorders
- Achalasia
- Diffuse spasm and "nutcracker" esophagus
- Nonspecific motility disorders
- Systemic disease (diabetes mellitus, progressive systemic sclerosis, Parkinson's disease)

as structural lesions, while manometry is of greatest use in confirming, or excluding, a diagnosis of achalasia.

Of the primary esophageal motility disorders, achalasia, diffuse spasm, and nutcracker esophagus are diagnosed over a wide age range. While the peak incidence of achalasia is in early to mid- adulthood, a second, smaller peak occurs in the elderly (Orr and Chen, 2002). Esophageal spasm is more commonly diagnosed over 50 years of age, while nonspecific motility disorders are particularly associated with an older population.

Achalasia

Achalasia is an esophageal motor disorder of unknown etiology, associated with incomplete or absent swallow-induced LES relaxation, and absence of peristalsis in the esophageal body. Occasionally, simultaneous esophageal pressure waves of high amplitude are observed (so-called "vigorous" achalasia). Inflammation of the myenteric plexus is an early histological finding, followed by ganglion loss and neural fibrosis. The condition typically presents with dysphagia for both liquids and solids, although weight loss, regurgitation, and aspiration may also be presenting symptoms, particularly in the elderly. Conversely, chest pain is reported less often than in young patients.

A barium swallow may show impaired peristalsis, delayed emptying, and dilatation of the esophageal body (the latter more characteristic in the elderly than the young), with "bird's beak" or "rat's tail" tapering at the LES (Figure 2). At manometry, the resting LES pressure may be high or within the normal range, but LES relaxation on swallowing is either absent or incomplete. In the esophageal body, pressure waves are simultaneous and of low amplitude, or absent altogether (Figure 3). Endoscopy (and sometimes endoluminal ultrasound, or computed tomography) must be performed to exclude "pseudo-achalasia", especially in the elderly; this entity presents with features of achalasia, but is due to carcinoma of the distal esophagus or cardia. A short history of symptoms and disproportionate weight loss are particularly suggestive of the diagnosis.

Pneumatic dilatation and surgical myotomy (now usually performed laparoscopically) represent the most efficacious

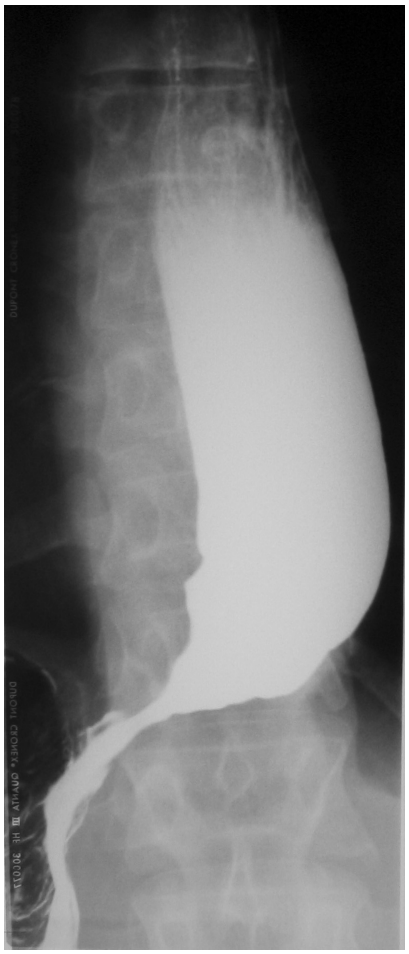

Figure 2 Barium swallow in a patient with achalasia, demonstrating a dilated esophagus with tapering at the distal end

treatments for achalasia. One large center has reported a symptomatic response of over 80% for each technique (Vela *et al.*, 2004), while the only randomized trial favored surgery (95% nearly completely relieved of symptoms, compared to 51% for dilatation (Spiess and Kahrilas, 1998). Esophageal emptying is improved in a smaller percentage, and neither therapy addresses aperistalsis of the esophageal body. Pneumatic dilatation produces controlled tearing of the LES, and is associated with a risk of esophageal perforation (about 3%) and induction of reflux symptoms (about 10%). Not infrequently, repeat dilatations are required. While myotomy may be associated with a greater risk of GERD, it can be combined with an antireflux procedure. The lower morbidity of dilatation may favor this procedure over surgery in older patients, with the caveat that a thoracotomy is required if perforation occurs. Pneumatic dilatation is more cost-effective than surgical myotomy.

Endoscopic injection of botulinum toxin into the LES represents an alternative and safe therapy, but adequate symptom relief may be achieved in fewer patients (around 60%) (Vela *et al.*, 2004), and the benefit lasts around 6 months, so that repeated treatments may be necessary.

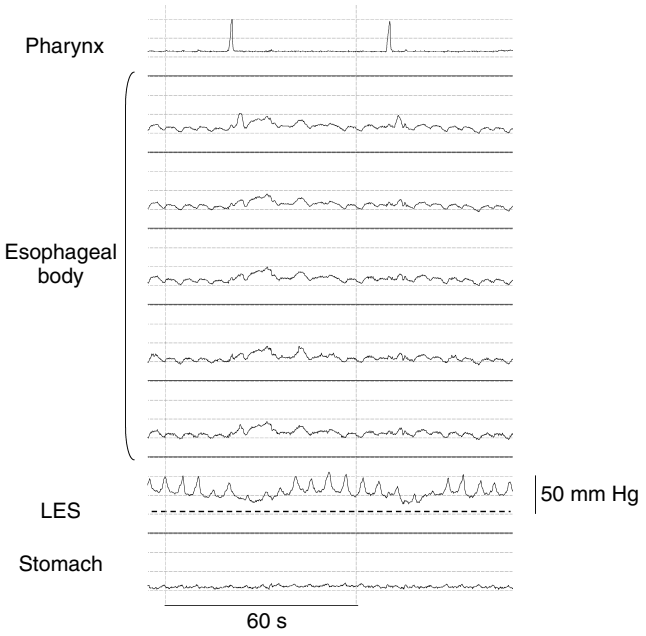

Figure 3 Esophageal manometry in achalasia. Note simultaneous, low amplitude pressure waves in the esophageal body, and minimal relaxation of the LES on swallowing

Therefore, this therapy is best reserved for patients in whom comorbidities represent contraindications to surgery or pneumatic dilatation; this group typically includes the frail elderly. This must be counterbalanced by evidence that the response to both pneumatic dilatation and botulinum toxin is better in older than younger patients. The cost of botulinum toxin injection is slightly greater than pneumatic dilatation, but substantially less than surgery.

Pharmacological therapy to reduce LES pressure (nitrates, calcium channel antagonists, or sildenafil) is of limited efficacy (possibly even less in the elderly than the young), requires frequent dosing, and is associated with side effects.

Patients with achalasia have an increased risk (estimated as 16-fold) of squamous cell carcinoma of the esophagus, but the absolute risk is small, and surveillance endoscopy has not been advocated (Spiess and Kahrilas, 1998). Occasional patients have persistent dysphagia despite therapy, together with a tortuous, dilated esophagus that empties poorly; in these circumstances, esophagectomy may be required.

Diffuse Esophageal Spasm and "Nutcracker Esophagus"

These disorders are diagnosed in a minority of patients with dysphagia or chest pain, and in many cases the relationship between symptoms and motor abnormalities is unclear. Criteria for the diagnosis of diffuse esophageal spasm are inconsistent; the presence of simultaneous esophageal pressure waves in more than 10%, but fewer than 100% of wet swallows, regardless of amplitude, is a reasonable definition (Dalton *et al.*, 1991) (Figure 4). The barium swallow may show segmentation of contrast by contractions, or a "corkscrew" appearance (Figure 5). Similar manometric abnormalities may occur in association with diabetes mellitus, alcohol abuse, amyloidosis, progressive systemic sclerosis, and GERD. "Nutcracker esophagus" is characterized by high amplitude esophageal pressure waves, but peristalsis is maintained. The management of both diffuse spasm and nutcracker esophagus is discussed below, in relation to noncardiac chest pain (NCCP).

Nonspecific Esophageal Motility Disorders

Many patients referred for investigation of symptoms such as dysphagia or chest pain have manometric features, which are outside the normal range, but do not meet formal criteria for the diagnosis of disorders such as achalasia and diffuse spasm. In cases where peristaltic waves are of abnormally low amplitude, absent, or fail to traverse the whole esophagus, often associated with a low LES pressure, a category of "ineffective esophageal motility" has been proposed (Spechler and Castell, 2001). Nonspecific abnormalities of esophageal motor function are evident in more than one-third of presentations with dysphagia in patients aged over 65, in contrast to the young, where a specific diagnosis can usually be made. It is important to recognize that a causal association cannot be assumed, since the presence of radiographic or manometric abnormalities of esophageal function correlates poorly with symptoms. Moreover, no specific therapy is available. Symptomatic management includes acid suppression when GERD is a feature, and optimizing nutrition.

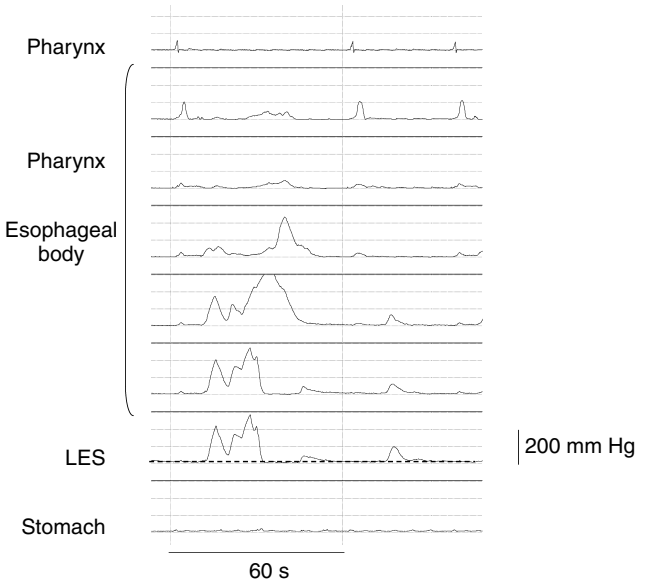

Figure 4 Manometry recording in diffuse esophageal spasm. Note simultaneous pressure waves after water swallows, including multipeaked and high amplitude waveforms

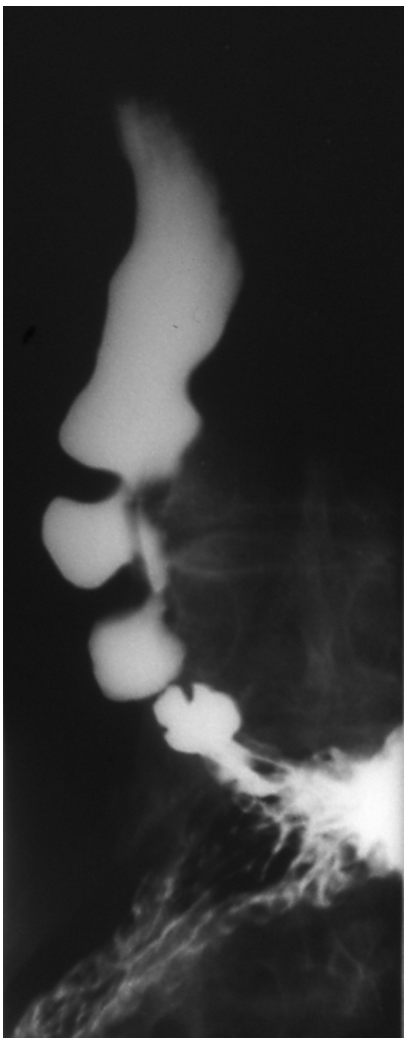

Figure 5 Barium swallow in a patient with diffuse esophageal spasm, demonstrating segmentation of the barium column by contractions, producing a "corkscrew" appearance

Pill Esophagitis

An important cause of dysphagia or odynophagia in older individuals is mucosal injury caused by impaction of medications in the esophagus, the incidence of which is likely to be increasing as the number of medications prescribed in this group escalates. Risk factors that are more prevalent in the elderly include less saliva, delayed esophageal transit, and immobility. Capsules may present a greater risk than tablets, owing to slower esophageal transit. The most frequent sites of hold-up are the upper and midesophagus, corresponding to extrinsic compression from left main bronchus, aortic arch, or enlarged left atrium, and also to a zone of low amplitude pressure waves between the proximal and distal esophagus. Numerous medications are associated with esophageal injury, including potassium chloride, tetracyclines, aspirin, nonsteroidal drugs, quinidine, theophylline, ferrous sulfate, and alendronate (Levine, 1999).

Symptoms usually resolve when the offending drug is withdrawn, but may sometimes be persistent, and related to stricture formation. Perforation and bleeding are other complications, associated particularly with potassium chloride, quinidine, and nonsteroidal drugs. The typical endoscopic or barium swallow appearance in pill esophagitis is of small superficial ulcers. There is anecdotal evidence that sucralfate is beneficial in severe or persistent disease. As a preventive measure, patients should be advised to take oral medications in the upright position, followed immediately by a full glass of water.

Noncardiac Chest Pain

Chest pain is a prevalent symptom in the community, and not infrequently presents a diagnostic difficulty, especially in older patients who are at greater risk of ischemic heart disease than the young. The esophagus is often implicated when cardiac causes have been excluded, but musculoskeletal, pulmonary, pericardial, gastric, and biliary pathology should also be considered, and an association with panic disorder has been reported (Eslick and Fass, 2003).

GERD may be responsible for NCCP, and a majority of NCCP patients (50–60%) have excessive esophageal acid exposure on pH studies. Many patients with excessive acid exposure do not have reflux esophagitis, which limits the value of endoscopic examination. Rather, a trial of double dose proton pump inhibitor (PPI) for between two and eight weeks (depending on symptom frequency) is a useful and cost-effective initial test in NCCP, with a sensitivity and specificity as high as 80% each for a diagnosis of GERD. If symptoms are relieved, the dose of medication can subsequently be titrated down to the minimum effective dose. If PPIs are ineffective, then esophageal manometry and ambulatory pH measurement (while remaining on the PPI) are indicated. Endoscopy should be performed whenever there are "alarm symptoms" such as dysphagia, anorexia, weight loss, hematemesis, or anemia. The threshold for endoscopy in older patients should be lower than in the young (age less than 40 years).

NCCP can be associated with esophageal motility disorders, including diffuse esophageal spasm, "nutcracker esophagus", hypertensive LES, and achalasia. A causal relationship between symptoms and abnormal motility can, however, be difficult to establish, even with 24-hour ambulatory manometry. A study from a large tertiary referral center indicates that esophageal dysmotility is evident in less than a third of patients with non-GERD-related NCCP (Katz *et al.*, 1987), a much lower prevalence than is assumed by many physicians. Sustained contraction of longitudinal, as opposed to circular, esophageal smooth muscle may account for some cases of esophageal chest pain, but detection of this phenomenon requires intraluminal ultrasound rather than manometry. Furthermore, medical therapy for esophageal motility disorders with smooth muscle relaxants such as nitrates, calcium channel antagonists, or sildenafil has limited efficacy, and assumes that excessive smooth muscle contraction is the

cause of pain. Surgical myotomy has had anecdotal success, but should only be considered in the presence of an intractable spastic motor disorder. Pain modifying agents such as tricyclic antidepressants or selective serotonin reuptake inhibitors, on the other hand, have been shown to be superior to placebo in non-GERD-related NCCP, regardless of whether a motility disorder is evident, but caution should be exercised in the elderly because of potential side effects, particularly when prescribing tricyclics.

Gastroesophageal Reflux Disease

GERD presents with more severe disease (erosive esophagitis, stricture, or Barrett's esophagus) than in the young (Fass *et al.*, 2000), perhaps related to the predisposing factors discussed earlier, or to a longer duration of disease (Firth and Prather, 2002). Conversely, symptoms are characteristically milder, or may be qualitatively different in the elderly, so that dysphagia, vomiting, respiratory difficulty, weight loss, or anemia are not uncommon presenting features, while "typical" reflux symptoms like heartburn occur less often than in the young – the latter perhaps as a result of diminished esophageal sensitivity. In the general population, symptoms of heartburn or regurgitation have a high sensitivity (about 70%) for a diagnosis of GERD, but a low specificity, when using 24-hour pH monitoring as the "gold standard"; corresponding data are not available for an aging population. The "alarm symptoms" mentioned for NCCP are indications for prompt endoscopic investigation.

Atypical or "extra-esophageal" manifestations of GERD include chronic cough and asthma, and may be mediated either directly by acid-pepsin reflux, or by esophageal acid exposure triggering vagal reflexes. The prevalence of excessive acid reflux in patients complaining of these symptoms is controversial, and as for NCCP, the most useful diagnostic test may be a therapeutic trial of intense acid suppression with double dose PPI, again for two to eight weeks, depending on symptom frequency.

There appear to be no significant differences in the capacity to heal esophagitis in older patients when compared to the young, and PPIs maintain their superiority over histamine receptor antagonists in this age-group. No dosage adjustment is needed in the elderly to compensate for age-related changes in renal or hepatic function, but downward titration of the dose according to symptoms may be less appropriate than in the young, especially when the original symptoms were mild, or in the setting of complicated GERD. Long-term acid suppression in individuals with *Helicobacter pylori* is associated with an increased prevalence of atrophic gastritis, which is thought to be a risk factor for gastric cancer. Therefore, *Helicobacter* eradication is generally recommended in patients on long-term PPI therapy, but this is unlikely to be of significance in the very old. Although impaired acid clearance may be an important contributor to GERD in the elderly, the role of prokinetic drugs in the treatment of reflux disease has not been specifically studied in this group, but is less of an issue since the withdrawal of cisapride in many countries. Maintenance therapy for GERD has not been specifically compared between elderly and young patients, but long-term medical therapy is likely to be more cost-effective than antireflux surgery in older patients, on the basis of the number of years of medical therapy likely to be needed. Nevertheless, the healthy elderly have outcomes from laparoscopic fundoplication that are comparable to the young (Firth and Prather, 2002). Endoscopic antireflux procedures have not been sufficiently evaluated to be widely recommended.

STOMACH AND DUODENUM

While only a modest delay in gastric emptying is observed with healthy aging, both the perception of gastric distension, and humoral responses to duodenal nutrient exposure, differ markedly from the young, and could contribute to the "anorexia of aging". Recent studies indicate that postprandial hypotension, a common cause of falls and syncope in the elderly, can be regarded as a gastrointestinal disorder, and can be related to both the rate of gastric emptying and the small intestinal response to ingested nutrient.

Changes in Gastric Motor Function Related to Aging

The stomach is responsible for the accommodation of ingested food and fluids, their mixing with digestive enzymes, and grinding of solids into small particles. Gastric emptying reflects the coordinated motor activity of the stomach and duodenum, which is controlled by feedback from neural and humoral signals generated by the interaction of nutrients with the small intestine. As a result of this, the rate of energy delivery to the small intestine is relatively constant, and independent of the ingested nutrient load. Small intestinal feedback may be modulated by previous patterns of nutrient intake, so that gastric emptying is retarded in starvation, while emptying of glucose is more rapid after dietary glucose supplementation. The proximal region of the stomach, comprising the fundus and much of the gastric body, relaxes after meal ingestion, and acts as a reservoir for the solid component of the meal, while liquids begin to empty. Tonic contraction of the proximal stomach also generates a pressure gradient to assist gastric emptying. The distal stomach, comprising the antrum and pylorus, is responsible for grinding solids, and for generating flow across the pylorus – the latter is predominantly pulsatile, rather than continuous. Contractions of the stomach are linked to an underlying electrical rhythm of about three cycles per minute, generated by a gastric pacemaker.

Scintigraphy remains the "gold standard" for measurement of gastric emptying, and the use of dual isotopes allows both the solid and liquid components of a meal to be studied (Figure 6). Regional meal distribution can also be evaluated by defining regions of interest within the stomach.

Figure 6 Scintigraphic gastric emptying study. Proximal and distal gastric "regions of interest" are outlined

Ultrasonography and ^{13}C isotope breath tests are alternative methods of measuring gastric emptying, though the former is restricted to liquid meals. Manometry is used predominantly for research purposes to record the frequency, amplitude, and organization of lumen-occlusive contractions in the antrum, pylorus, and duodenum. Proximal gastric relaxation in response to a meal can be evaluated in the laboratory using an electronic barostat; the volume of air required to maintain a fixed pressure in an intragastric bag is used as an index of proximal gastric tone. The electrical rhythm of the stomach may be recorded from cutaneous electrodes, although the clinical significance of abnormalities of this electrogastrogram (EGG) is unclear, since they are not specific for particular gastrointestinal disorders.

Healthy aging appears to be associated with modest slowing of gastric emptying of both solids and nutrient-containing liquids, but the rate of emptying generally remains within the normal range for young subjects (Moore *et al.*, 1983; Horowitz *et al.*, 1984). The relative slowing of gastric emptying may have implications for appetite regulation, potentially contributing to the "anorexia of aging"; prolongation of gastric distension and of exposure of the small intestine to nutrients might lengthen the period of postprandial satiation. Slow gastric emptying could also influence the absorption of orally administered medications, and a slight reduction in paracetamol absorption has been reported in the healthy elderly when compared to the young. However, absorption of benzodiazepines, tetracycline, or L-dopa is not significantly altered with age *per se*. A number of systemic disorders, which occur frequently in the elderly, are associated with markedly delayed gastric emptying or gastroparesis (Table 2) – acute gastroparesis may also result from the administration of a number of drugs (Table 3).

Table 2 Causes of delayed gastric emptying

Acute
- Drugs (opiates, anticholinergics, L-dopa)
- Postoperative ileus
- Viral gastroenteritis
- Metabolic (hyperglycemia, hypokalemia)
- Critical illness

Chronic
- Idiopathic/functional dyspepsia
- Postsurgical
- GERD
- Chronic liver disease
- HIV infection
- Endocrine and metabolic (diabetes mellitus, hypothyroidism, chronic renal failure, anorexia nervosa)
- Muscular and connective tissue diseases (myotonic dystrophy, muscular dystrophy, dermatomyositis, systemic sclerosis, amyloidosis, tumor-associated)
- Neurological (central nervous system disease, spinal cord injury, chronic idiopathic intestinal pseudo-obstruction, idiopathic autonomic degeneration)

Table 3 Medications with effects on gastrointestinal motility

Decreased motility or gut transit
- Opiates
- Anticholinergics
- L-dopa
- Tricyclic antidepressants
- Calcium channel antagonists
- Nitrates
- Phosphodiesterase type 5 inhibitors (e.g. sildenafil)
- Clonidine (an α-2 agonist)
- Sumatriptan (a 5HT-1P agonist)[a]

Increased motility or gut transit
- Metoclopramide
- Domperidone
- Cisapride, tegaserod, and other 5HT-4 agonists
- Erythromycin (a motilin analog)[b]
- β-blockers
- Selective serotonin reuptake inhibitors

[a]Relaxes the gastric fundus and delays gastric emptying, but increases esophageal motility. [b]Stimulates gastric emptying but slows small intestinal transit.

There is little information about the effects of aging on the mechanics of the stomach, but fasting and postprandial antral motility did not differ between patients aged 18–39 and those aged 40–69 years who were being investigated for unexplained gastrointestinal symptoms (Fich *et al.*, 1989). Proximal gastric compliance is unchanged in the fasting state in the healthy elderly compared to the young, but perception of gastric distension is diminished (Rayner *et al.*, 2000), akin to the reduction in visceral sensitivity evident in the esophagus and stomach. Moreover, proximal gastric accommodation to a meal is delayed when compared with young controls, which might contribute to early satiation. Conversely, the antrum is more distended after a nutrient drink in the healthy elderly, and antral width correlates

with both satiation and satiety, in both young and old subjects (Sturm *et al.*, 2004). EGG recordings are similar in healthy old and young subjects, with subtle differences in the response to nutrients.

There is some evidence for altered responses to the presence of nutrients in the small intestine in the elderly compared to the young. In particular, intraduodenal nutrients stimulate greater cholecystokinin release in the healthy elderly, even allowing for elevated fasting concentrations of cholecystokinin (CCK) in this group (Chapman *et al.*, 2002), while intraduodenal glucose is more satiating than in the young. This enhanced small intestinal feedback could contribute to both delayed gastric emptying, and impaired appetite.

Postprandial Hypotension

Blood pressure can decrease markedly after meals in the elderly, and this represents an important clinical problem, leading to syncope and falls (Jansen *et al.*, 1995). Older people with type 2 diabetes are at particular risk because of the associated autonomic neuropathy. Recent studies indicate that postprandial hypotension should, in the broadest sense, be regarded as a gastrointestinal disorder. The postprandial decline in blood pressure appears to be related to the regulation of splanchnic blood flow, and the release of gastrointestinal peptide hormones, and can be attenuated by administration of the somatostatin analog octreotide. Amongst the macronutrients, carbohydrate, rather than fat or protein, is primarily responsible for the fall in blood pressure. After oral or small intestinal administration of glucose, the magnitude of the fall in blood pressure is related to the rate at which glucose enters the small intestine (O'Donovan *et al.*, 2002). Dietary and pharmacologic approaches that slow gastric emptying and small intestinal carbohydrate absorption may prove to be effective in the treatment of postprandial hypotension.

SMALL INTESTINE

While small intestinal function is critical to good nutrition in the elderly, its motility does not appear to be substantially altered with healthy aging, but can be affected by a number of systemic illnesses.

Changes in Small Intestinal Motor Function Related to Aging

The small intestine is more difficult to study than the esophagus or stomach because of its length and relative inaccessibility. Like the stomach, the frequency of its contractions are linked to an underlying electrical rhythm – in this case between eight and twelve cycles per minute. During fasting, the small bowel undergoes cyclical activity about every 90 minutes known as the *migrating motor complex* (MMC), consisting of motor quiescence (phase I), irregular contractions of increasing frequency (phase II), and a brief (5–10 minutes) period of regular contractions that propagate distally and serve to sweep the lumen of debris (phase III). After a meal, the MMC is interrupted by irregular motor activity propagated over short distances that facilitates digestion and absorption.

Small intestinal manometry is carried out in specialized research laboratories, and has limited clinical application. Transport through the small intestine can be measured more readily, by either a breath test (which detects an increase in hydrogen resulting from breakdown of ingested nonabsorbable carbohydrate, such as lactulose, by colonic bacteria, and therefore reflects orocecal transit), or by scintigraphy.

MMC periodicity was not altered in healthy elderly volunteers aged 81 to 91 years when compared with the young, using ambulatory jejunal recording, though the propagation velocity of phase III was slower. The elderly had comparable amplitude and frequency of pressure waves to the young during phase III of the MMC and postprandially, but more propagated clustered contractions during fasting and postprandial recordings (Husebye and Engedal, 1992). The functional significance of the latter phenomenon is unclear, but similar patterns are seen in patients with the irritable bowel syndrome (IBS). Nevertheless, small intestinal transit in the healthy elderly seems to be comparable to the young, in contrast with the delayed transit characteristic of the colon (Madsen and Graff, 2004). This is consistent with the observation that small bowel bacterial overgrowth is uncommon in healthy older individuals (Mitsui *et al.*, 2003).

Aging is associated with an increased prevalence of conditions, such as diabetes mellitus, that potentially affect small intestinal motility, as well as small intestinal diverticula. Such conditions may induce stasis of small intestinal contents, and together with the reduction in gastric acid secretion often seen on the elderly, predispose to bacterial overgrowth, a potential cause of malnutrition and diarrhea (Firth and Prather, 2002). Small bowel bacterial overgrowth may be diagnosed by culture of duodenal aspirates, or by hydrogen breath tests (with glucose or xylose as a substrate), although the specificity of the latter may be poor in the elderly (about 30%). A subsequent negative test following a course of antibiotics increases the diagnostic certainty. Treatment is with antibiotics such as metronidazole, tetracycline, or quinolones, given for 1 to 4 weeks, and may need to be repeated on a cyclical basis in the event of recurrence.

SYSTEMIC DISORDERS ASSOCIATED WITH DISTURBANCE OF GASTROINTESTINAL MOTILITY

Although the effects of healthy aging *per se* on gastrointestinal motility are modest, the prevalence of comorbidities increases with advancing age, and these may impact on gut

function; Parkinson's disease and diabetes mellitus are typical examples. Progressive systemic sclerosis is less common, but has profound effects on gastrointestinal motility. Furthermore, numerous medications can affect gastrointestinal motility; some of these are listed in Table 3.

Parkinson's Disease

Gastrointestinal dysfunction represents a common manifestation of Parkinson's disease (Pfeiffer, 2003). Involvement of the dorsal motor nucleus of the vagus may influence parasympathetic innervation, while abnormalities of the enteric nervous system itself (such as Lewy bodies and loss of dopaminergic neurons) are also evident.

Dysphagia is common, with prominent disturbance of the oropharyngeal phase of swallowing, as well as impaired esophageal transit, associated with nonperistaltic or tertiary pressure waves. The effects of either L-dopa or anticholinergic therapy on swallowing disorders are inconsistent; both drugs may be associated with either improvement or deterioration in dysphagia. Limited data indicate benefit from apomorphine.

Gastric emptying may be delayed, even in the absence of L-dopa therapy, which in turn slows gastric emptying further. Delayed gastric emptying may contribute to a high prevalence of symptoms such as nausea and bloating, and result in impaired nutrition and absorption of oral medications. In particular, L-dopa may be metabolized to dopamine if retained in the stomach, and become unavailable for systemic absorption. In patients suffering from the "on–off" phenomenon of motor fluctuations, gastric emptying may normalize in the "on" phase, while conversely, variations in the rate of emptying may result in erratic L-dopa absorption, and in themselves contribute to the on–off phenomenon. Metoclopramide is contraindicated in parkinsonian patients because of its effects on striatal dopamine receptors, but other prokinetic agents such as domperidone (which does not cross the blood-brain barrier) can be used. Small intestinal, colonic, and anorectal dysmotility are also common in Parkinson's disease, and may be associated with bowel dilatation and constipation. Orocecal transit time is prolonged compared with age-matched controls.

Diabetes Mellitus

Diabetes mellitus, and particularly type 2 diabetes, is increasing dramatically in prevalence worldwide, and occurs frequently in older individuals. Disordered motor function involving all segments of the gastrointestinal tract is common in diabetes, and there is a high prevalence of gut symptoms (Horowitz *et al.*, 2002), though little information specific to elderly patients with diabetes. Although both disordered motility and gut sensation have been attributed to irreversible autonomic neuropathy, it is now recognized that acute changes in the blood glucose concentration have a major influence on gut function (Rayner *et al.*, 2001).

In the esophagus, manometric abnormalities observed in diabetes include reduction in amplitude of pressure waves, abnormal waves forms, and failure of peristalsis, which are associated with delayed esophageal transit. LES pressure may be diminished, and the prevalence of GERD is increased.

Up to 50% of patients with longstanding diabetes have delayed gastric emptying for solids, liquids, or both. Motor correlates of these abnormalities include diminished antral motility and impaired coordination of antroduodenal pressure wave sequences, together with reduced fundic tone. Both the delay in gastric emptying and the underlying motor mechanisms are more marked during acute hyperglycemia, when compared to euglycemia. Disordered gastric emptying potentially contributes to upper gut symptoms, impairs absorption of nutrients and orally administered medications, and may result in, as well as arise from, poor glycemic control. While a delay in gastric emptying may actually improve the postprandial blood glucose profile in noninsulin-requiring patients due to slower release of carbohydrate to the small intestine, it is likely to result in a mismatch between the absorption of glucose and the onset of insulin action in patients receiving exogenous insulin. Patients with upper gut symptoms referable to the stomach should be investigated with endoscopy to exclude mucosal lesions or obstruction, and consideration can then be given to evaluating the rate of gastric emptying, ideally with scintigraphy. Diabetic gastroparesis is usually treated with a prokinetic drug, such as cisapride (now withdrawn in many markets owing to a risk of cardiac arrhythmia), metoclopramide, domperidone, and erythromycin (an analog of motilin).

Small intestinal motility is also frequently abnormal in diabetes mellitus. During fasting, the duration of the phases of the MMC are reduced, while postprandially, bursts of nonpropagated pressure waves may occur, together with disordered flow patterns of chyme. Small bowel transit appears widely variable in patients with diabetes, and its relationship to gastrointestinal symptoms and glycemic control remains to be clarified. Both diarrhea and constipation appear common in diabetes; small bowel bacterial overgrowth, coeliac disease, and pancreatic exocrine insufficiency should be specifically excluded when patients with diabetes present with diarrhea. Loperamide and clonidine (an α-adrenergic agonist) may be of benefit when no specific cause for diarrhea is uncovered, although older patients may be particularly susceptible to adverse reactions (constipation, urinary retention, and glaucoma for loperamide; hypotension, bradycardia, sedation, and dry mouth for clonidine).

Progressive Systemic Sclerosis

The peak incidence of progressive systemic sclerosis is in the fifth and sixth decades, and gastrointestinal involvement is common (Rose *et al.*, 1998). Esophageal dysmotility has a prevalence of about 80%, with diminished amplitude of pressure waves, and sometimes a lack of peristalsis, leading to impaired acid clearance and severe reflux disease. LES resting pressure also tends to be extremely low. Furthermore,

the stomach, small and large intestines, and anorectum may be involved, with clinical manifestations of gastroparesis, pseudo-obstruction, bacterial overgrowth (sometimes associated with small intestinal diverticula), malnutrition, and constipation or fecal incontinence. Smooth muscle atrophy and fibrosis underlie some of these disturbances, but inhibition of cholinergic transmission in the enteric nervous system by antibodies to M3 muscarinic receptors may be important in the pathogenesis. Similar effects on gastrointestinal motility may be seen in other connective tissue disorders, and in amyloidosis. PPIs are effective in the treatment of GERD, while prokinetic drugs have a role when gastrointestinal transit is delayed.

FUNCTIONAL DISORDERS

Functional gastrointestinal diseases are characterized by recurrent or persistent symptoms referable to the gut, occurring in the absence of demonstrable organic disease. This group of disorders includes functional dyspepsia (upper abdominal pain, bloating, or nausea) and IBS (abdominal discomfort, which may be relieved by defecation, associated with abnormal bowel habit), as well as other syndromes related to the esophagus, anorectum, and biliary tract.

The prevalence of IBS appears to be less in the elderly than the middle aged in the United States and United Kingdom (Bennett and Talley, 2002), and at all ages the prevalence is greater in women than men. Somewhat surprisingly, the incidence, as opposed to prevalence, of IBS appears to increase with age, in at least one US population (Locke *et al.*, 2004). This may potentially reflect an increase in health care seeking behavior in the elderly, though no information regarding consulting behavior in IBS is available specifically for this age-group. In a study of 70-year olds in a Danish community, while 6 to 18% had gastrointestinal symptoms consistent with IBS according to various definitions, symptoms had resolved in at least half within the following five years (Kay, 1994), which is probably similar to the prognosis of IBS in the general community. Similar patterns were observed for upper gut symptoms consistent with functional dyspepsia, suggesting that abdominal symptoms are frequent in the elderly, but fluctuate considerably over time. In the general population, around 10% of functional gut disorders follow a bout of infectious gastroenteritis, but recent evidence suggests the elderly are less prone to developing chronic postinfective symptoms than the young. In contrast to IBS, there is little information regarding the prevalence of functional dyspepsia in older populations.

While, as discussed, visceral sensitivity seems to decline in healthy aging, patients with functional dyspepsia or IBS have, as a group, increased sensitivity to gastric and rectal distension. Nevertheless, chronic gastrointestinal symptoms consistent with IBS are common in the elderly, though not markedly greater than in the young, with the possible exception of constipation. Visceral sensitivity has not been studied in the elderly with gut symptoms; nor has tolerance to visceral pain (the lowest level of stimulation at which a subject withdraws or asks to stop). The latter may be relevant, since pain tolerance for somatic stimuli appears to decrease with aging. The prevalence of *Helicobacter pylori* is greater in the older individuals than the young (about 60% at 60 years), but in the absence of peptic ulceration, its contribution to dyspepsia is controversial (Firth and Prather, 2002).

It is important to exclude organic diseases such as cancer and mesenteric ischemia when gut symptoms arise in older patients, particularly as the prevalence of organic disease is greater than in the young (Bharucha and Camilleri, 2001). For example, when patients present with altered bowel habit, the threshold for colonoscopic investigation should be low. Comorbidities such as Parkinson's disease, medications, thyroid disease, diabetes, depression, and small bowel bacterial overgrowth must also be considered.

Chronic gastrointestinal symptoms impair quality of life, but many elderly do not present to their doctors, so their impact may go unrecognized in older populations. Depression associated with chronic pain does not appear to be greater in the elderly than the young, but it should be borne in mind that "gut" symptoms like anorexia or bowel habit disturbance can also be features of depression. The effects of anxiety on the perception of persistent, as opposed to acute, pain have not been studied closely (Bharucha and Camilleri, 2001).

All potential therapies for functional gut disorders must be evaluated against the high placebo response rate (between 20 and 70%) associated with these syndromes, but no clinical trials have focused specifically on the elderly (Bennett and Talley, 2002). When constipation is a feature of IBS, adequate hydration and fiber supplements should be tried, with the caveat that bloating may exacerbated by high fiber intake. Tegaserod (a 5HT-4 partial agonist) may have modest benefit for symptom improvement in constipation-predominant IBS; most patients in randomized controlled trails have been female, with a minority (about 10%) over 65 years old, for whom no subgroup analysis is available.

When diarrhea and fecal urgency predominate, loperamide can be beneficial; a liquid formulation, if available, makes dose titration easier. Alosetron (a 5HT-3 antagonist) may have a place in diarrhea-predominant IBS in women, but the association of this drug with ischemic colitis suggests the need to exercise caution, especially in the elderly. As with tegaserod, randomized controlled trials have only included a few patients over 65 years old. In theory, supplemental fiber should improve the water-holding capacity of stool, but its benefit in diarrhea has not been proven.

Antispasmodics (e.g. mebeverine, hyoscine) are helpful for abdominal pain in some patients, but have anticholinergic side effects such as postural hypotension, visual blurring, and urinary hesitancy, which may affect the elderly in particular. Antidepressants may also be useful when the predominant symptom is pain, as opposed to diarrhea or constipation, and response is as good in older patients as in the young. The dose of tricyclic antidepressant used in functional gut disorders is typically lower than standard

doses used to treat depression. Selective serotonin reuptake inhibitors may be better tolerated than tricyclics, but there are less data regarding their efficacy in IBS. Probiotics may be of benefit for bloating. Psychotherapy and hypnotherapy have recently shown promise in the management of functional bowel disorders, but no information is available about their applicability to the elderly.

Acknowledgments

The authors wish to thank Associate Professor Richard Holloway, Department of Gastroenterology, Hepatology, and General Medicine, Royal Adelaide Hospital, for providing material for the figures, and contributing suggestions for the manuscript, and Dr Karen Jones, Department of Medicine, University of Adelaide, for contributing the image for Figure 6.

KEY POINTS

- Healthy aging is associated with minimal change in gastrointestinal motor function, but visceral sensation declines with age.
- Gastrointestinal motility may be compromised by an increased prevalence of systemic illness and medication use in the elderly.
- Clinical sequelae of disturbed gut motility and sensation include swallowing disorders, impaired nutrition and absorption of medications, and altered bowel habit.
- Functional gastrointestinal disorders occur frequently in the elderly, but organic disease must be rigorously excluded.

Gastrointestinal Bleeding

Syed H. Tariq

Saint Louis University School of Medicine, St Louis, MO, USA

INTRODUCTION

Gastrointestinal bleeding (GI) is a common geriatric problem (Antler *et al.*, 1981; Allen and Dykes, 1976). In the United States, about 350 000 patients are hospitalized for upper GI bleeding each year (Papp, 1991) and 35–45% of these are 60 years or older (Reinus and Brandt, 1990). The incidence of upper GI bleeding ranges between 50 and 150 per 100 000 population per year (Gilbert, 1990). Women aged 60 years and older account for 60% of upper GI bleeding (Schiller *et al.*, 1970). The mortality of upper GI bleeding has remained approximately 6–10% for the last 60 years (Warren and Marshall, 1983; Peterson *et al.*, 1981; Browder *et al.*, 1986). No difference is present in morbidity and mortality between the young and old persons (Segal and Cello, 1997). In a British study, the mortality rate for upper GI bleeding was 14% for the entire population but only 0.6% for persons younger than age 60 without malignancy or organ failure at presentation. Most deaths were reported in elderly patients or those with severe concurrent illness (Silverstein *et al.*, 1981b).

The exact incidence of lower GI bleeding is not known (Vernava *et al.*, 1997) but incidence of hospitalization is about 20 to 27 episodes per 100 000 persons per year (Longstreth, 1997; Yovarski *et al.*, 1995) with a 200-fold increase with advancing age from the third to ninth decades (Longstreth, 1997). The mortality for lower GI bleeding is 4–10% or greater (Makela *et al.*, 1993; Velanovich, 1996). Presence of selected physical findings are related to increased mortality in patients with GI bleeding compared to the situation without these findings; respiratory failure (57%), jaundice (42%), mental confusion (31.2%), shock (30%), congestive heart failure (28%), and postural blood pressure change (14%) (Silverstein *et al.*, 1981b). Similarly, the presence of some underlying diseases process are responsible for increased mortality than if they were absent; renal 29.4%, liver 24.6%, neoplasm 24.3%, central nervous system 23.5%, and lung 22.6%.

Clinical Presentation

The most common presenting complaint in both younger and older people with acute upper GI bleeding is hematamesis as apposed to hematamesis and melena or melena alone. It might be difficult at times to determine accurate clinical presentation in older people because of poor vision or poor cognition, for example, providing vague description of hematamesis versus hemoptysis.

Table 1 shows the different sign and symptoms a patient with a GI bleeding presented to Saint Louis University Hospital. The most common presenting symptom was melena in both upper and lower GI bleeding. Some of the other presenting complaints were hematamesis, nausea, coffee ground emesis, abdominal pain, anemia, rectal bleeding (these patients had massive active bleeding requiring significant number of transfusions), and reflux symptoms. The common signs and symptoms for lower GI bleeding are melena, rectal bleeding, fecal occult bleeding, nausea, abdominal pain, and anemia. Fecal occult bleeding was seen in both upper and lower GI bleeding (Tariq *et al.*, 1999, 2000).

The manifestation of GI bleeding varies with underlying medical problems; for example, a patient with underlying ischemic heart disease may present with chest pain after brisk bleeding. Coexistent heart failure, hypertension, renal disease, diabetes, and pulmonary disease may be aggravated by severe GI bleeding, resulting in a shock. Some patients with chronic blood loss may present with signs of anemia (weakness, pallor, dizziness, fatigue) or cirrhosis and portal hypotension. GI bleeding can also cause hepatic encephalopathy in patients with existing liver disease or cause hepatorenal syndrome. Orthostatic changes may be seen with lesser or moderate degree of bleeding.

Clinical Course

The hospital course of GI bleeding is similar in both young and older persons with respect to endoscopic therapy for

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

Table 2 Factors predictive of ulcer rebleeding and mortality in older adults

Clinical factors	
Hemodynamic instability	
Bleeding manifested as hematamesis or hematochezia	
Failure of blood to clear with gastric lavage	
Age >60 years	
Coagulopathy	
Presence of underlying serious medical condition	
Hospitalization	
Endoscopic factors	*Risk of rebleeding*
Clean base	5%
Flat spot	10%
Adherent clot	22%
Nonbleeding vessel	43%
Arterial bleeding	55%

bleeding and rebleeding, need for admission to intensive care, blood transfusion requirements, need for surgery, and length of hospital stay (Antler *et al.*, 1981; Segal and Cello, 1997; Silverstein *et al.*, 1981b). The length of hospital stay has shortened since 1970–1980 into the 1990s (Silverstein *et al.*, 1981b). In 1992 and 1994, the mean hospital stay for upper GI bleeding in older adults (>60 years) was 6.0 days compared with 5.6 days in those less than 60 years of age. Table 2 describes factors predictive of ulcer rebleeding and mortality in older adults. The need for surgery is higher for adherent clot, nonbleeding vessel, and arterial bleeding compared to clean base and flat spot. Also, mortality rates are higher for arterial bleeding compared to clean base (Schiller *et al.*, 1970; Branicki *et al.*, 1990; Laine *et al.*, 1992).

Causes of GI Bleeding

In the elderly, esophagitis and gastritis in combination with peptic ulcer disease accounts for 70–91% of hospital admissions for upper GI bleeding. A greater percentage of patients with Mallory–Weiss tears, gastrointestinal varices, and gastropathy are seen in the younger population as a result of the greater degree of alcohol abuse in this age-group.

The causes of GI bleeding between the young-old and old-old are as shown in Table 3 at Saint Louis University Hospital. Gastritis was the most common endoscopic diagnosis of upper GI bleeding in the young-old and old-old group (34 vs 38%), followed by gastric ulcer (21 vs 19%), duodenitis (20 vs 16%), esophagitis (15 vs 14%), and duodenal ulcer (7 vs 12%) respectively. Esophageal varices and gastric angiodysplasia were more common in the young-old, while neither duodenal angiodysplasia nor Mallory–Weiss syndrome (2 vs 3%) was different. Table 4 shows the causes of lower GI bleeding at Saint Louis University; hemorrhoids ($p = 0.03$), diverticulosis ($p = 0.0006$), and polyps ($p = 0.06$) were more common in the old-old group as compared to the young-old group and there was no difference among the other lesions in the two groups.

The histological diagnosis of 183 patients was available with a total of 262 lesions, as shown in Table 5; gastritis was the most common lesion, which included both *Helicobacter pylori* gastritis and other gastritis. The diagnosis of gastritis included lesions such as acute gastric erosions, chronic active gastritis, and chronic active gastritis with metaplasia, chronic gastritis with inflammation, gastric atrophy with inflammation, and acute and chronic gastritis with or without inflammation. We used kappa statistics to see the agreement between the endoscopic and histological diagnosis of gastritis

HP, *Helicobacter pylori*; N, Total number of lesions; GI, Gastrointestinal.
[a]Includes patients with esophageal ulcer and carcinoma, gastric and duodenal Angiodysplasia and duodenal adenoma. [b]See text. [c]Includes patients with diverticulitis (4) and colonic ulcer (2) and angiodysplasia (2).

in 183 patients who were biopsied. The agreement was 57%, which means both the tests agreed on the diagnosis 57% of the times. Among the lesions with gastric carcinoma, three lesions were metastatic while the rest were primary gastric lesions. The other upper gastrointestinal lesions included three lesions each with esophageal ulcer, cancer, gastric angiodysplasia, and one lesion with duodenal angiodysplasia.

The total lesions in the LGI tract were 90; polyps (31), colon neoplasm (40), colitis (11), angiodysplasia (2), colon ulcer (2), and diverticulitis (4). Among these lesions, colon neoplasm was the most common. The neoplastic lesions were leiomyosarcoma (1), villous adenoma (2), rectal adenoma (2), tubular adenoma (26), and adeno-carcinoma (9). The polyps were split into adenomatous (5), hyperplastic (16), and adenomatous change (10). Colitis included cryptitis (2), ischemic colitis (4), pseudo-membranous colitis (1), radiation colitis (1), and nonspecific colitis (3).

Tables 6 and 7 summarize the site of different studies, number of patients, age, and physician by specialty involved for both upper and lower GI bleeding. Table 8 shows the prevalence of upper GI bleeding in different studies. The prevalence of upper GI causes are gastric ulcer (5–43%), duodenal ulcer (6–42%), gastritis (6–42%), esophagitis (2–15%), and esophageal varices (1–20%), Mallory–Weiss tear (1–16%), and others are reported (combination of lesions) between 2 and 17%. The common causes of lower GI bleeding are summarized in Table 9. The prevalence of diventricular bleeding 17–56%, angiodysplasia 3–30%, hemorrhoids 3–28%, polyp as a cause of bleeding 2–30%.

Evaluation and Management of Gastrointestinal Bleeding

In this section, the general evaluation and management of GI bleeding is discussed. For disease-specific treatment, refer to gastroenterology texts.

Initial Evaluation

The first step in the management of GI bleeding patient is stabilization with blood transfusion and other treatments deemed necessary before any diagnostic evaluation. If the patient's initial blood pressure and pulse rate are normal, consider performing orthostatic blood pressure and pulse (sitting/lying and standing positions). Orthostatic changes are usually suggestive of 10–20% loss in circulatory volume, although supine hypotension suggests greater than 20% loss. Hypotension with a systolic BP less than 100 mm Hg or baseline tachycardia suggests significant hemodynamic compromise that requires urgent volume resuscitation. All patients require a complete history and physical examination; blood studies (platelet count, prothrombin time, partial thromboplastin time); liver function tests, renal functions, and complete blood counts. Determination of blood group and typing and crossing 2–4 units of blood should be performed urgently.

Restoration of intravascular volume is established by inserting two large-bore intravenous peripheral lines with 18 gauge catheter or central venous line. Fluids used for resuscitation includes normal saline, lactated Ringer's solution or 5% hetastarch, and blood transfusion as soon as it is available to improve the oxygen carrying capacity. Those patients who are in shock may need volume administration using infusion devices or vasopressors if clinically indicated.

Correction of coagulopathy is absolutely necessary, if possible, using infusion of fresh frozen plasma to correct/prolong

coagulation parameters. Protamine infusion can be used for immediate reversal of anticoagulation from heparin drip. Parental vitamin K may be used for prolonging prothrombin time from warfarin therapy or liver disease. Platelets transfusion may be indicated when the count is less than 50 000/mm (Papp, 1991). Protection of the airway may be needed in circumstances where there is a decrease in mental status (shock, encephalopathy), massive hematamesis, or active variceal hemorrhage is present.

History

A detailed history could point toward a possible diagnosis. Pain in the epigastric region relieved by food or antacid suggests peptic ulcer disease. Weight loss and anorexia may suggest gastrointestinal malignancy, but in the geriatric population, the most common cause of weight loss is depression and should be ruled out before initiating malignancy workup. Dysphagia can be due to stricture or cancer of the esophagus. Mallory–Weiss tear can be caused by intractable vomiting. Hematamesis usually suggests upper GI bleeding, but precautions should be taken as older people may have poor vision and are unable to provide accurate description. Melena could be seen in both upper and lower GI bleeding, and usually requires about 100 cc of blood. The stool remains positive for blood for almost 2 weeks. Patient with inflammatory bowel disease or infectious colitis (Shigella, Salmonella, Campylobacter) usually present with

bloody diarrhea, fever, and abdominal pain. One needs to be very cautious initiating diagnostic workup in older patients for bleeding diathesis with skin tears and ecchymosis, since this is seen in older patients with minor trauma. Occult blood or hematochezia could be the first sign of colon cancer or polyps. Painless lower GI bleeding can also be seen in diverticulosis, angiodysplasia, or ulcerated cancerous lesion. Blood on the surface of stool or blood on toilet paper suggest internal hemorrhoids. It is equally important to determine the patient's cognitive ability by using Mini-mental status examination (Folstein *et al.*, 1975) or Saint Louis University Mental Status examination (Morley and Tumosa, 2002) to assess cognition. If a patient is demented, then it is advisable to obtain history from the caregiver accompanying the patient, or by obtaining history from the nursing home staff.

Drug history is very important, especially the use of aspirin, nonsteroidal anti-inflammatory, and anticoagulation drugs. Some over-the-counter cough medication are usually combined with aspirin and patients may not be aware of it.

Physical Examination

A detailed physical examination starting with inspection of the nose and throat is important to exclude bleeding in this

area. Look for signs of chronic liver failure (spider angiomas, hepatosplenomegaly, ascites, and jaundice). Look for arteriovenous malformation, especially of the mucous membranes, which may be associated with hereditary hemorrhagic telangiectasia (Rendu Osler–Weber syndrome), in which multiple angiomas of the gastrointestinal tract are associated with recurrent bleeding. Cutaneous nail bed and gastrointestinal telangiectasia may be associated with connective tissue disease or scleroderma. A digital rectal examination is very important to feel for masses, fissures, and obtain a sample of stool, to be tested chemically for blood. It is also mandatory to comment on the color of stools. Internal hemorrhoids, if thrombosed, could be felt by digital examination. If available, anoscopy or sigmoidoscopy should be used to confirm if internal hemorrhoids or ulcer or distal masses are the source of the problem.

If upper GI bleeding is suspected, a nasogastric lavage should be performed. Bloody nasogastric lavage is suggestive of upper GI bleeding but is negative in about 10% of cases. Coffee ground aspirates indicate bleeding that is slow or has stopped, but bright red blood indicates active bleed. Continuous nasogastric aspiration helps monitor the status of bleeding.

Esophagogastroduodenoscopy (EGD) can be performed at the bedside or in the GI suites, and is the preferred method of investigation and therapy of the upper GI tract bleeding. It has the highest diagnostic accuracy, therapeutic capacity, and low morbidity. It can be performed early in the clinical course, after the patient is hemodynamically stabilized. There is no role for barium X rays in acute upper GI bleeding. If EGD is not available or inconclusive and the patient is stable for more than 36 hours and upper GI bleed is suspected, then barium X rays should be considered.

Colonoscopy is performed if lower GI bleeding is suspected as a cause of bleeding; its yield is higher if performed in the first 24 hours. Colonoscopy is best performed in patients whose condition has clinically stabilized and who can tolerate adequate bowel purge. In order to get good results, patient should be able to drink adequate bowel prep. Many patients find polyethylene glycol (PEG)-based preparations difficult to take because of the large volume of fluid they are required to consume. Thomson *et al.* (1996) reported in a randomized prospective trial comparing sodium phosphate and PEG in a predominantly elderly population. One hundred and sixteen predominantly elderly patients were randomized to receive either sodium phosphate ($n = 61$) or PEG ($n = 55$) bowel preparations before colonoscopy. The patients found the sodium phosphate preparation slightly more tolerable than PEG. There were no significant side effects between the two groups. However, 91% of patients who had previously had PEG found sodium phosphate easier to take. The colonoscopists found no difference in the overall quality of the bowel preparation. Sodium phosphate was a safe and effective bowel preparation for colonoscopy in this carefully selected group of patients. It was preferred by patients who previously had PEG. In another study, Lashner *et al.* (1990) reported in a randomized clinical trial on 124 consecutive patients scheduled for colonoscopy who were 75 years of age or more. Sixty-three patients were randomized to receive Golytely; 17 were inpatients, 33 were outpatients, and colonoscopy was canceled in 13. Sixty-one patients were randomized to receive the enema preparation; 17 were inpatients, 30 were outpatients, and colonoscopy was canceled in 14. Both preparations were adequate but the enema preparation was superior in outpatients, while Golytely was superior in inpatients. Patients tolerated the enema preparation better, a finding present in both outpatients and inpatients. Contrary to previous reports of a significant advantage with Golytely, patients 75 years and older did not enjoy this advantage, but seemed to tolerate enemas better than Golytely with little difference in adequacy of the preparation.

When colonoscopy is negative and lower GI bleeding is suspected, a *tagged red blood cell* (*TRBC*) *scanning* should be considered. RBCs labeled with technetium 99 m remain in the circulation for 48 hours and extravasate into the lumen with active bleeding. This extravasation can be detected as a pooling of the radiotracer on scanning with a gamma camera. Bleeding rates as low as 0.1 ml/minute can be detected in research settings. When the test is positive, it is accurate in about 80% of the cases. About 20% of the localization is false positive, which precludes the use of this test alone for surgical resection of the bowel. The clinical utility of this test is for screening before arteriography.

Arteriography allows localization and potential therapy for GI bleeding when bleeding rate exceeds 0.5 ml/minute. It can provide the etiology, especially bleeding diverticula or angiodysplasia. Angiography can also be used in brisk upper GI bleeding when endocsopy is impossible. Embolization of the bleeding artery is infrequently performed because of the risk of bowel infarction. Small-bowel enteroscopes when radiological evaluation suggests jejunal bleeding source or in recurrent (obscure) GI bleeding in which conventional endoscopy is unrevealing.

Surgery is considered when the blood transfusion requirements exceeds 4–6 units over a 24-hour period or 10 units overall, as well as more than two to three recurrent bleeding episodes from the same course. It is prudent to perform EGD before undergoing emergent total colectomy. The extent of comorbid conditions and the degree of bleeding needs to be factored in when considering surgery. Therapies for specific lesions are mentioned here that require a different treatment modality than already mentioned.

Peptic Ulcer Disease

The use of high-dose proton pump inhibitors reduces the rate of recurrent bleeding, and is especially useful in patients awaiting endoscopic treatment or in those for whom endocsopy is contraindicated or postponed. The conventional PPI may suffice after endoscopic therapy has been administered. A gastric or duodenal biopsy or rapid urease assay (CLO test), histopathology, or culture is required to look for *Helicobacter pylori*. If *H. pylori* are identified, it is prudent to eradicate it by using antimicrobial therapy in addition to antisecretory medications.

Variceal Hemorrhage

Management of variceal bleeding usually requires intensive-care monitoring and endotracheal intubation for airway protection. Octreotide infusion should be initiated immediately (50–100 μg/hour bolus followed by an infusion 25–50 μg/hour). Octreotide is usually well tolerated and reduces portal pressure. Vasopressin is an alternative pharmacological agent but is used less frequently because of the side effects – myocardial ischemia and infarction, mesenteric ischemia and infarction, ventricular arrhythmias, cardiac arrest, and cutaneous ischemic necrosis. Concomitant infusion of nitroglycerin is used at times to reduce the undesirable side effects of vasopressin.

Variceal ligation or banding is the endoscopic therapy of choice. It is very effective and superior to sclerotherapy (Saeed, 1999; Saeed *et al.*, 1997; Saeed, 1996). Complications of banding include superficial ulcerations, dysphagia, transient chest discomfort, and rarely esophageal stricture.

Sclerotherapy is also effective but is used less frequently because of its complications (ulceration, stricture, perforation, pleural effusion, adult respiratory distress syndrome, and sepsis). Recurrent bleeding may be seen in up to 50% of the patients but will respond to repeated treatment. Fever may be seen in up to 40% of the patients but if it persists for more than 2 days, a bacteremia work may be necessary.

Transjugular intrahepatic portosystemic shunts (TIPS) have been used in the treatment of complications of portal hypertension. TIPS is used for the control of acute variceal bleeding, prevention of variceal rebleeding when pharmacologic therapy and endoscopic therapy have failed. TIPS is also helpful in patients with refractory ascites with adequate hepatic reserve and renal function who fail to respond to large volume paracentesis. Other indications for TIPS are Budd–Chiari syndrome uncontrolled by medical therapy, severe portal hypertensive gastropathy, refractory hepatic hydrothorax, and hepatorenal syndrome. The major limiting factors for TIPS' success are shunt dysfunction and hepatic encephalopathy. Because shunt stenosis is the most important cause of recurrent complications of portal hypertension, a surveillance program to monitor shunt patency is mandatory (Rosado and Kamath, 2003).

Shunt surgery (portacaval or distal splenorenal shunt) should be considered in patients with good hepatic reserve if the patient fails endoscopic or pharmacologic therapy, having difficulty to return for follow-up visits, increased risk of death due to recurrent bleeding, or lives away from medical care location. The morbidity and mortality is high with this procedure, as well as postoperative encephalopathy.

Balloon tamponade has a very big role in the therapy of variceal hemorrhage. It is used temporarily to stabilize patients in situations when more definite therapy is available. The commonly used balloon tamponade are the Sengstaken–Blakemore tube and the Minnesota tubes, both of which have a gastric and esophageal balloon. The following are general guidelines for the use of balloon tamponade. The details of how to use these balloon tamponades are discussed in gastrointestinal literature.

Angiodysplasia can occur anywhere in the GI tract and can be occult or overt GI bleeding. Actively bleeding angiodysplasia is best treated by endoscopic therapy (heater probe, laser, or organ plasma coagulation), intra-arterial vasopressin, or embolization during angiography or surgical resection. Endoscopic ablation is recommended even when nonbleeding angiodysplasia are found in the presence of iron deficiency anemia. The associated anemia should be treated with iron.

Stress ulcer is encountered in patients who are in the intensive-care unit and on ventilation for more than 48 hours with coagulopathy, sepsis, burns, and cerebrovascular events. Prophylactic therapy should be administered in patients who are at increased risk. Histamine-2 receptor antagonist, sucralfate, and proton pump inhibitors can be used.

Diverticulosis is usually seen on endocsopy but bleeding develops in about 5% of the patients with diverticula. Bleeding usually stops in these patients 80% of the time, but may reoccur. Persistent bleeding may require intra-arterial vasopressin at angiography or even surgical resection.

Aortoenteric fistula is an uncommon but lethal cause of GI bleeding. These patients usually have history of aortic graft surgery and present with bleeding after surgery. The fistula site is usually aortoduodenal but can be anywhere in the small and large intestine. The classic presentation is herald bleed hours to weeks before massive GI bleeding. Recognition of this condition is essential, as undiagnosed cases could be fatal. Endoscopy with examination of the fourth portion of the duodenum is essential and should be performed immediately. Angiography or CT scanning may show leak at the graft site. A negative study does not exclude an Aortoenteric fistula. If suspicion is high, a surgical consultation is absolutely necessary.

Radiation proctitis/colitis results years after exposure to radiation therapy. Intermittent hematochezia results from aberrant superficial mucosal vasculature in the distal colon. Treatment is usually supportive and laser photocoagulation of the mucosal telangiectasias may be needed.

Hemorrhoids are the most common cause of outpatient causes of hematochezia. Treatment is usually avoidance of constipation by using fiber-rich diet and supportive care. Surgical and endoscopic banding of the hemorrhoids is also available.

CONCLUSION

GI bleeding is a common geriatric problem. The incidence of GI bleeding is about 35–45% in people 60 years of age and older. The incidence of lower GI bleeding is unknown. The causes of GI bleeding vary in different studies. The diagnosis and management of GI bleeding is similar to that of young adults in many ways.

Liver and Gall Bladder

Margaret-Mary G. Wilson

Saint Louis University Health Sciences Center and Veterans' Affairs Medical Center, St Louis, MO, USA

The liver, that great maroon snail: No wave of emotion sweeps it. Neither music nor mathematics gives it pause in its appointed tasks. . . .

(Selzer, 1976)

AGE-RELATED HEPATOBILIARY CHANGES

Liver

Traditionally, hepatic biochemical parameters such as serum transaminases, hepatic alkaline phosphatase, γ-glutamyltranspeptidase, and serum bilirubin are considered indices of liver function. These parameters, which are indeed more reflective of disrupted hepatocyte integrity and liver dysfunction, are not altered with aging (James, 1997; MacMahon and James, 1994). However, there is an age-related compromise in more objective and sophisticated dynamic liver function indices. Available data shows that with aging hepatic volume and perfusion may decrease by approximately 30%. Other indices of hepatic metabolic function, such as nitrogen synthesis and aminopyrine clearance, also decrease with aging. Likewise, age-related reduction in hepatic microsomal cytochrome content may compromise efficient drug metabolism in the elderly (Wynne *et al.*, 1989; Fabbri *et al.*, 1994; James, 1997).

Histological studies have identified decreased smooth endoplasmic reticulum and fewer mitochondria in hepatocytes from older adults (Schmucker, 1990) Age-related reduction in hepatic regeneration is particularly concerning. Several studies suggest that the older liver is more vulnerable to stress, perhaps due to an age-related reduction in mitogen activated protein kinase activity (Liu *et al.*, 1996). These cellular changes contribute to the poorer outcomes observed in older adults following hepatic insult.

Few studies have specifically examined the effect of aging on the gallbladder and biliary tract. With aging, there is an increase in the diameter of the common bile duct, due to replacement of biliary ductal myocytes with connective tissue cells (Kialian and Aznaurian, 1995).

In addition, the lithogenicity of bile increases, resulting in an increased tendency to form cholesterol and calcium bilirubinate stones (Siegel and Kasmin, 1997). These preceding changes, set against a background of lifetime exposure to potentially hepatotoxic agents, set the stage for hepatobiliary disease as a major contender in geriatric medicine.

HEPATIC DISEASES OF THE ELDERLY

Viral Hepatitis

Classically, viral hepatitis is defined as hepatic inflammation induced by infection with specific hepatotrophic viruses. Histological features include diffuse or patchy necrosis of the liver acini. Severity of clinical presentation is variable. Some patients are asymptomatic, while others may complain of flu-like and fairly nonspecific symptoms such as myalgia, athralgia, anorexia, nausea, vomiting, and diarrhea. Physical examination may reveal fever, jaundice, hepatomegaly, and, in some cases, cutaneous manifestations such as purpura, urticaria, and other skin lesions.

Geographical distribution and prevalence of viral hepatitis vary with the infecting agent (Figure 1).

Hepatitis A Virus

Hepatitis A virus (HAV) is a 27-nm single-stranded, nonenveloped RNA picornavirus. Although infection typically occurs by fecal-oral transmission, a few cases of HAV have occurred through hematogenous transmission (Centers for Disease Control and Prevention, 1999). Onset of symptoms is usually 2–6 weeks after exposure. In younger adults, hepatitis A infection is usually subclinical with mild symptoms.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

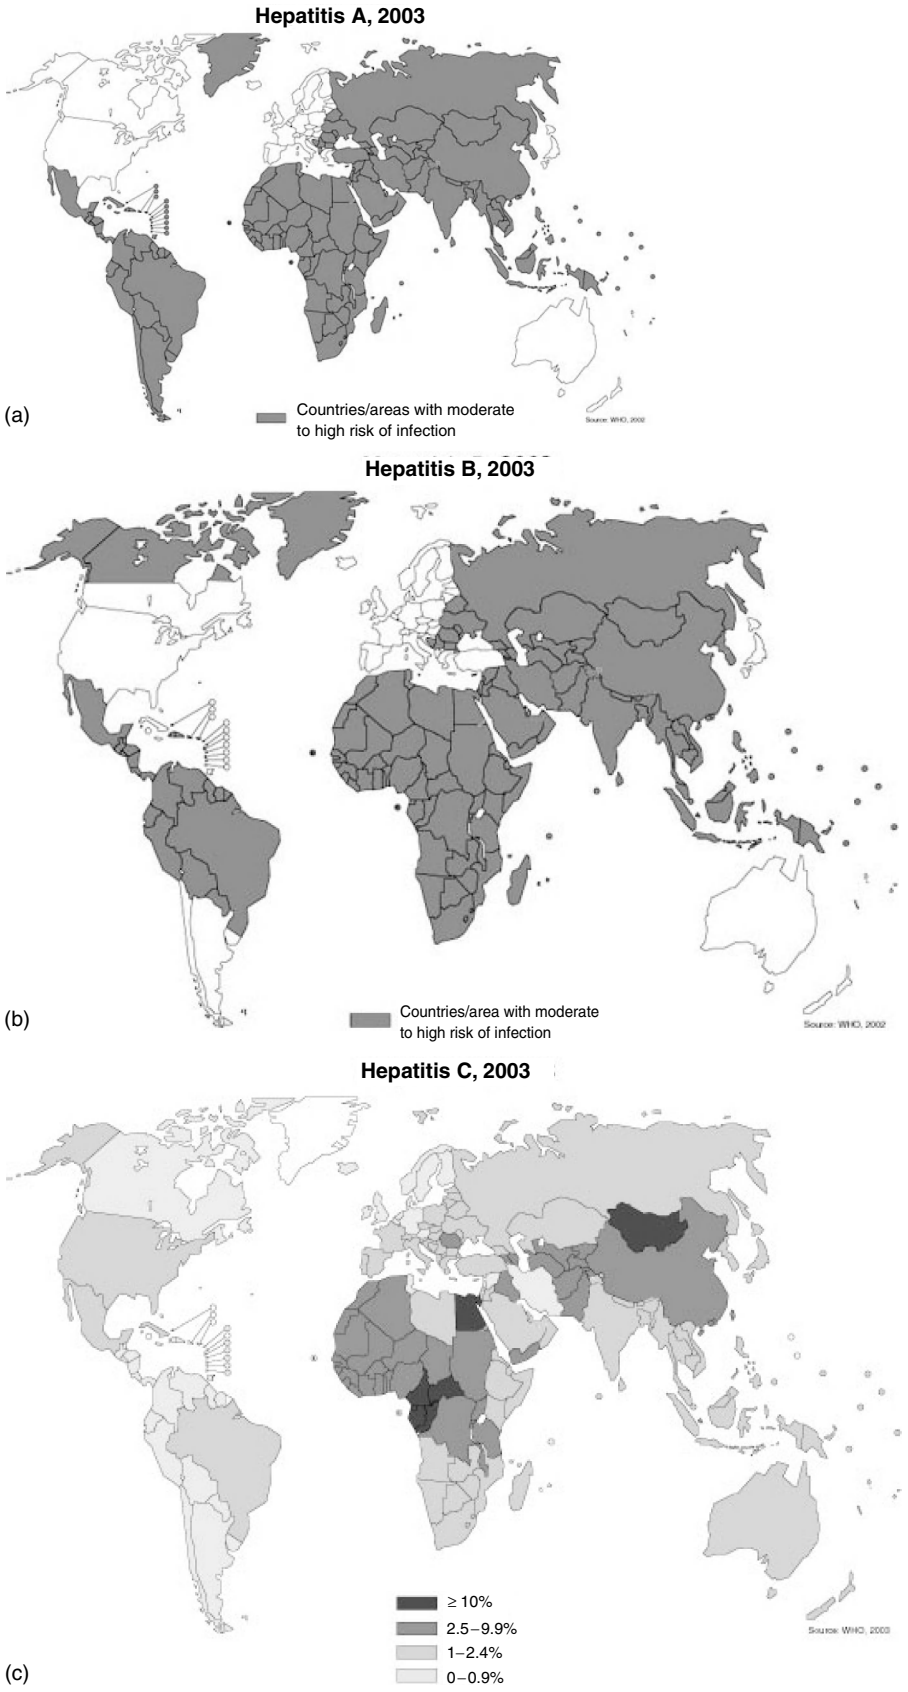

Figure 1 Geographical distribution of Hepatitis A, B, and C

Jaundice is present in less than 10% of cases. In contrast, although hepatitis A infections are less frequent in older adults, symptoms are likely to be more severe. In addition, the risk of developing and dying from complicating fulminant liver failure is far more common in infected elders. Reported case fatality rate among patients over the age of 65 years is 4% compared with 0.07% in patients aged 15–24 years (Forbes and Williams, 1988). Current recommendations state that older persons traveling to endemic areas should receive HAV vaccination. Additionally elderly food handlers and patients with chronic liver disease are also advised to receive HAV vaccination, although data regarding the efficacy and cost-effectiveness of the vaccine in older adults is lacking (James, 1997).

Hepatitis B Virus

Hepatitis B virus (HBV) is a 42-nm double-stranded, enveloped DNA hepadna virus. HBV is a highly infectious virus transmitted through sexual intercourse or contact with infected blood, blood products, and saliva. Vertical maternofetal transmission also occurs during childbirth. The incubation period of HBV is approximately 120 days (Lok and McMahon, 2001). Although most infections occur in young adulthood, serological evidence of HBV infection is threefold higher among older adults aged between 64 and 74 years. Rates of HBV infection are also higher among nursing home residents compared to those in community dwelling elders. Sporadic outbreaks of HBV infection in nursing home residents have been linked to inappropriate sharing of razors and bathing appliances. Data indicates that in older adults who contact HBV, the risk of progressing to chronic hepatitis is over 50% compared with 5% following acute infection in younger adults. Nevertheless, acute hepatitis B is rare among older adults, and older adults with acute HBV infection are usually only mildly symptomatic (Marcus and Tur-Kaspa, 1997; Reeder and Halket, 1987). Nevertheless, age remains a risk factor for the development of life-threatening fulminant hepatitis. Perhaps as a result of more prolonged exposure, older adults with HBV infection are more likely to develop hepatocellular carcinoma and liver cirrhosis (Beasley, 1988; MacMahon and James, 1994).

Hepatitis C Virus

Hepatitis C virus (HCV) is a 55-nm enveloped RNA flavivirus, with an incubation period ranging from 15–90 days. Of the six known genotypes, type 1 is the most common in the United States. Although transmission is primarily hematogenous, a few cases have been transmitted through saliva and human bites (Bukh *et al.*, 1995; Chu *et al.*, 2002). Data indicates that the prevalence of acute HCV infection among older adults equals, and, in some cases, surpasses that in the general population. Within the United States, reported seroprevalence rate among adults aged over 70 years is 1%, compared with 1.8% among the general population (Alter *et al.*, 1999). In an Italian cohort aged over 65 years, the HCV infection prevalence rate was over 4% compared with 3.2% among a comparable cohort of young subjects (Monica *et al.*, 1998). Although the incidence of new cases has declined over the past decade, projections indicate that over the next 20–30 years the prevalence of HCV among older adults will increase significantly.

As in younger adults, infection with HCV in elders is only mildly symptomatic during the acute phase. However, the clinical course in older patients is much more aggressive and lethal. Similarly, advanced age at diagnosis of the disease portends more rapid progression to fibrosis and cirrhosis (Seeff, 1997; Watson *et al.*, 1996). Other risk factors for the development of cirrhosis include alcohol use and obesity. Studies show that in patients who acquire HCV over the age of 60 years the risk of developing cirrhosis is reported to be as high as 46%, compared to approximately 7% among patients in the fourth decade of life. Reasons for the aggressive clinical course with aging are not clearly known, although age-related immunocompromise has been proffered as a likely theory (Simmonds *et al.*, 1996).

Hepatitis D Virus

Hepatitis D virus (HDV) is a single-stranded RNA viroid that is dependent on the HBV envelope protein for replication and pathogenicity. Transmission of HDV occurs hematogenously or through sexual contact and results in either coinfection or superinfection. Coinfection occurs when there is simultaneous transmission of both HDV and HBV, while superinfection refers to HDV infection of a previously HBV positive patient. Patients with coinfections have a better prognosis and progress to chronic disease in less than 5% of cases. In contrast, 70–90% of superinfected patients develop cirrhosis. Although HDV infection causes less than 5% of chronic hepatitis, it accounts for approximately 7500 new infections annually and has a mortality rate of 30% (Alter and Hadler, 1993). Data in older subjects is lacking.

Hepatitis E Virus

Hepatitis E virus (HEV) is a single-stranded RNA calicivirus that is transmitted feco-orally. This virus tends to infect younger adults and is rare in developed countries. Characteristically, pregnant women have a 20% mortality rate from this disease compared with 1% in the general population.

Older people traveling to endemic regions such as Asia, Mexico, and Africa may be at risk. Prophylaxis is ineffective and the avoidance of consumption of foods and water that may be contaminated is strongly recommended (Gilchrist, 1999).

Hepatitis F Virus

Viral particles identified in the stool of posttransfusion, non-A, non-B, non-C, non-E hepatitis cases and injected into

Indian rhesus monkeys caused acute hepatitis with elevated transaminases. Consequently, this viral enteric agent was named *hepatitis F virus* (HFV). However, to date there are no convincing corroborating scientific reports. Although sporadic cases in humans may have been identified in Europe, United States, and India, the validity of this virus remains questionable (Deka *et al.*, 1994).

GB Virus Type C (GBV-C)

This virus belongs to the *Flaviviridae* and was previously referred to as hepatitis G virus (HGV). Currently, the lack of proven association of this virus with either acute or chronic hepatitis has discouraged the use of the name HGV (Dickens and Lemon, 1997). The name GBV-C was derived from a surgeon, whose initials were GB, after marmosets inoculated with his serum developed hepatitis. On the basis of this single observation, the surgeon was erroneously thought to have posttransfusion hepatitis. Later evidence did not support this diagnosis (Almeida *et al.*, 1976). Indeed, GB virus type C (GBV–C) infection is common, but is yet to be associated with definite pathogenicity (Dickens and Lemon, 1997). Currently, the major clinical significance of this agent lies in the fact that HIV-positive patients infected with GBV-C may have prolonged survival (Xiang *et al.*, 2001). Little data exists regarding the pattern of GBV-C infection in aging adults.

Transfusion Transmitted Virus

Transfusion transmitted virus (TTV) is a single-stranded DNA virus. Despite the name, feco-oral transmission of the virus also occurs. Infection is usually acquired in childhood and may persist for years. Its role in causing hepatitis or other diseases has not been proven. Even though one of the genotypes of TTV is suspected to cause hepatitis, the pathogenicity of TTV in humans remains poorly defined (Takacs *et al.*, 2003). The prevalence of TTV is also unclear. Available data indicates that the virus has been identified in 1% of blood donors, 18% in posttransfusion subject, 15% of patients with liver cirrhosis, and 27% in patients with end-stage liver failure (Naoumov and Petrova, 1998). Notably, high TT virus load has been found to be independently associated with the occurrence of hepatocellular carcinoma among patients with HCV-related chronic liver disease (Nishizawa and Okomoto, 1997).

Autoimmune Hepatitis

Autoimmune hepatitis is characterized by severe chronic hepatitis in the presence of circulating autoantibodies. Characteristically, there is frequent progression to liver cirrhosis. Originally described as a disease of young women, autoimmune hepatitis is now known to affect all age groups and both genders. Approximately 20% of all patients diagnosed with autoimmune hepatitis are over the age of 65 years (Newton *et al.*, 1997). Diagnostic criteria for autoimmune hepatitis are unchanged with age, and the prognosis for affected older adults is no worse than for younger adults (Table 1). Nonetheless, older adults present with less acute symptoms, but are more likely to have severe histological inflammation and necrosis. Unfortunately, data indicates that older adults are less likely to be prescribed immunosuppressive therapy, even though this has been shown to prolong survival in patients with severe disease. There is no data to support the benefits of therapy in older adults with mild disease (Czaja and Freese, 2002).

Drug-induced Hepatitis

Several unique factors predispose the elderly to drug-induced hepatotoxicity. These include polypharmacy and, subsequently, an increased risk of drug-induced adverse

Table 1 Diagnostic criteria for autoimmune hepatitis (Alvarez *et al.*, 1999; Czaja and Freese, 2002)

Criteria	Definite	Probable
Genetic liver disease	Normal α1-antitrypsin, ceruloplasmin, iron, and ferritin levels	Partial α1-antitrypsin deficiency, nonspecific serum copper, ceruloplasmin, iron, and ferritin abnormalities
Viral infection	No markers of current infection with HAV, HBV, HCV	No markers of current infection with HAV, HBV, HCV
Toxic or alcohol injury	Daily alcohol $<25\,g\,day^{-1}$ and no recent use of hepatotoxic drugs	Daily alcohol $<50\,g\,day^{-1}$ and no recent use of hepatotoxic drugs
Laboratory features	Predominant serum aminotransferase abnormality, globulin, gamma globulin or immunoglobulin G level >1.5 times normal	Predominant serum aminotransferase abnormality; hypergammaglobulinemia of any degree
Autoantibodies	ANA, SMA, or anti-LKM1 >1 : 80; no AMA	ANA, SMA, or anti-LKM1 >1 : 40, or other autoantibodies[a]
Histologic findings	Interface hepatitis No biliary lesions, granulomas, or prominent changes suggestive of another disease	Interface hepatitis No biliary lesions, granulomas, or prominent changes suggestive of another disease

[a]Perinuclear antineutrophil cytoplasmic antibodies, antibodies to soluble liver antigen/liver pancreas, actin, liver cytosol type 1, and asialoglycoprotein receptor.
ANA, antinuclear antibody; SMA, smooth muscle antibody; LKM, liver kidney microsomal antibody; AMA, antimitochondrial antibody.

effects and drug–drug interactions. Age-related physiological changes, such as reduced liver mass, hepatic hypoperfusion, and reduced activity of phase 1 hepatic drug-metabolizing enzymes, further increase the likelihood of hepatic injury in response to toxic drugs. Age-related changes in body composition may compromise the volume of distribution, thereby increasing serum drug levels. Hypoalbuminemia resulting from excess cytokine elaboration, related to aging or disease, may reduce protein binding and further increase the likelihood of drugs attaining toxic levels. Finally, altered pharmacodynamics with aging affects the response to drugs at the tissue level (Regev and Schiff, 2001; Varanasi *et al.*, 1999).

Not surprisingly, drug-induced liver disease occurs more frequently, and is more severe, in older adults. In addition, older patients with coexisting renal or hepatic disease are more likely to be affected. Documented prevalence of drug-induced hepatitis ranges from 50–140 per 1 million person years in adults aged between 70 and 79 years (Almdal and Sorensen, 1990; Sgro *et al.*, 2003). Overall, the incidence of drug-induced liver disease may be higher in older adults simply because these drugs are used more frequently. Nonsteroidal agents (NSAIDs) are used extensively by older adults for a variety of arthritic and nonarthritic conditions. All NSAIDs are potentially hepatotoxic. Nevertheless, the reported rate of nonsteriodal anti-inflammatory drug NSAID-induced hepatotoxicity is less than 1%. Affected patients are usually asymptomatic, with elevated hepatic transaminases. Hepatic alkaline phosphatase may also be mildly elevated. Notably, patients with piroxicam-induced hepatitis may present with severe cholestatic features. NSAID hepatitis usually responds well to withdrawal of the offending agent. All older adults started on NSAIDs should have their liver function evaluated within two to three months of starting therapy (Hepps *et al.*, 1991; Solomon *et al.*, 2003).

Following a decline in the use of methyldopa, hepatic disease associated with the use of cardiac medications exhibited a decline. However, with the increased use of amiodarone, hepatocellular disease related to cardiac medications has begun to increase. Affected patients are usually asymptomatic. Approximately half of all patients on amiodarone exhibit a rise in serum transaminase levels. Amiodarone-induced hepatitis may occur with both oral and intravenous administration. These changes resolve if amiodarone is withdrawn early in the course of treatment. Other histological findings of amiodarone-induced hepatitis include steatohepatosis, cholestatic hepatitis, and micronodular cirrhosis (Tameda *et al.*, 1996; Traverse *et al.*, 1994; Gonzalez Galilea *et al.*, 2002)

With most medications, the increased prevalence of drug-induced hepatotoxicity in older adults is a consequence of increased exposure. However, certain drugs such as benoxaprofen, halothane, and several antituberculous agents – isoniazid (INH), rifampicin, and pyrazinamide – are inherently more likely to cause hepatotoxicity in older adults (Varanasi *et al.*, 1999; Nagayama *et al.*, 2003). Benoxaprofen is a nonsteroidal agent, which was withdrawn by the United States Food and Drug Administration (FDA) following several reports of fatal liver failure occurring specifically in adults over the age of 70 years. Similarly, animal studies indicate an age-related increase in sensitivity to the effects of halothane, resulting in an increased risk of hepatic failure and death among older adults exposed to this agent.

INH hepatitis is rare in young patients but occurs in more than 2% of patients aged over 50 years. Increased sensitivity to INH in older adults is related to changes in hepatic physiology and altered pharmacokinetics. INH metabolism produces toxic reactive metabolites presumably from acetylation. Traditionally, persons with the rapid INH acetylator phenotype were considered more prone to toxicity. Most recent studies have failed to confirm this relationship. Indeed, convincing data suggest that slow acetylators may divert larger amounts of INH to an alternate metabolic pathway (Cytochrome P450 2E1) that results in production of a toxic reactive metabolite (Huang *et al.*, 2003). The precise mechanism underlying INH toxicity is still unknown.

Presenting features of INH toxicity range from asymptomatic elevation of transaminases to fulminant hepatic failure requiring liver transplantation (Vasudeva and Woods, 1997). Thus, patients on INH should receive serial serum transaminase measurements to facilitate early detection of hepatotoxicity.

Diagnosis and Management of Hepatitis

Clinical presentation of hepatitis varies widely and affected patients may be entirely asymptomatic. Some patients present with flu-like symptoms, such as fever, chills, skin rash, nausea, vomiting, myalgia, athralgia, or malaise. System-specific symptoms such as jaundice, abdominal discomfort, dark urine, easy bruising, and hepatomegaly may also occur. Certain hepatitides, such as hepatitis C, are characteristically asymptomatic during the acute phase. Diagnosis in such cases is usually delayed until several years after infection. In autoimmune hepatitis, despite the chronic nature of the disease, 40% of patients present acutely with fever, jaundice, polyarthralgias, myalgias, thrombocytopenia, and biochemical evidence of severe hepatic dysfunction (Krawitt, 1996).

Serum testing in most cases of hepatitis will reveal elevated transaminases. In mild cases, elevation usually does not exceed three times normal, while in severe cases there may be a 20-fold increase. Clinical detectable jaundice is usually not present until serum bilirubin exceeds $3\,\mathrm{mg\,dl^{-1}}$. With severe disease, prothrombin time increases, and this is usually indicative of impending liver failure. Additional blood testing should be done in all cases to determine etiology of the hepatitis. Thus, viral antigen and antibody studies are conducted to screen for hepatitis A–E. GBV-C RNA may be identified using a reverse transcriptase polymerase chain reaction test. This test is not available for commercial use. There are also no serological assays routinely available for the diagnosis of GBV-C (HGV) or TTV (Stapleton, 2003).

An autoantibody profile for circulating autoantibodies should be conducted to screen for autoimmune hepatitis. Most patients will have elevated levels of circulating autoantibodies. However, only two-thirds will have one of the more specific autoantibodies. Patients are frequently screened for antinuclear and/or antismooth muscle antibodies (Lohse *et al.*, 1995; Czaja and Freese, 2002). Tests for other autoantibodies such as soluble liver antigen, liver cytosol antigen and the asialoglycoprotein receptor antibody are also helpful diagnostic tools with high specificity (Manns *et al.*, 1987; Martini *et al.*, 1988; Treichel *et al.*, 1994). Lab tests for autoimmune hepatitis should include serum protein electrophoresis. This may reveal hypergammaglobulinemia with a selective increase in IgG levels. Human leucocyte antigen (HLA) typing may be helpful as most patients are positive for HLA B8, DR3, or DR4 (Donaldson *et al.*, 1994).

The diagnosis of drug-induced hepatitis is usually one of exclusion based on the patient's medication history, which should include questions pertaining to the use of prescription, over-the-counter and herbal medications.

Imaging techniques, such as ultrasound, computed tomography (CT) scans, and MRI are helpful in further evaluation of patients with suspected hepatitis for etiology and severity of disease. Definitive diagnosis, assessment of severity, acuity, and activity of disease are based on histological findings and requires a liver biopsy.

On the basis of liver biopsy findings, hepatitis may be characterized as acute or chronic. Autoimmune hepatitis and all the viral hepatitides except HAV, HEV, and HFV exist in both the acute and chronic phases. Histologically, chronic hepatitis may be further characterized into four stages: (i) chronic persistent to mild chronic active hepatitis; (ii & iii) chronic active hepatitis with scarring; and (iv) cirrhosis (Bach *et al.*, 2000). Rapidity of clinical progression through these stages cannot be predicted.

The cornerstone of treatment of any hepatitides is primarily supportive care. Rest, adequate nutrition, and avoidance of additional injury from alcohol or other toxic insults should be stressed. Currently no specific medication is recommended for hepatitis A, D, E, or G. In 25–50% of patients with chronic HBV infection, treatment with interferon α-β results in disease remission within 6 months. Oral nucleoside analogs, such as lamivudine and famciclovir, have been shown to reduce HBV levels and the risk of fulminant hepatic failure in more than 50% of patients treated with these agents (Hoofnagle and DiBalart, 1997; Lai *et al.*, 1998). The decision to treat patients with HCV is usually made on an individual basis, using factors such as compliance, disease severity, and likelihood of favorable response. Standard therapy consists of pegylated interferon alpha and ribavarin. Following 24 weeks of therapy, undetectable levels of HCV RNA are achieved in over 50% of patients, indicating a sustained response. Patients infected with HCV genotype 1 are less likely to respond, with only 42–46% of patients achieving a sustained response with treatment. Forty-eight weeks of therapy is advised to maximize chances of favorable response. Patients infected with HCV genotype 2 or 3 have a sustained response exceeding 75% and generally require only 24 weeks of therapy. If HCV RNA remains detectable following the course of treatment, therapy should be discontinued, as less than 2% of patients will subsequently respond (Manns *et al.*, 2001; Fried *et al.*, 2002; Hadziyannis *et al.*, 2002).

Currently vaccinations are available only for HAV and HBV (Figure 2).

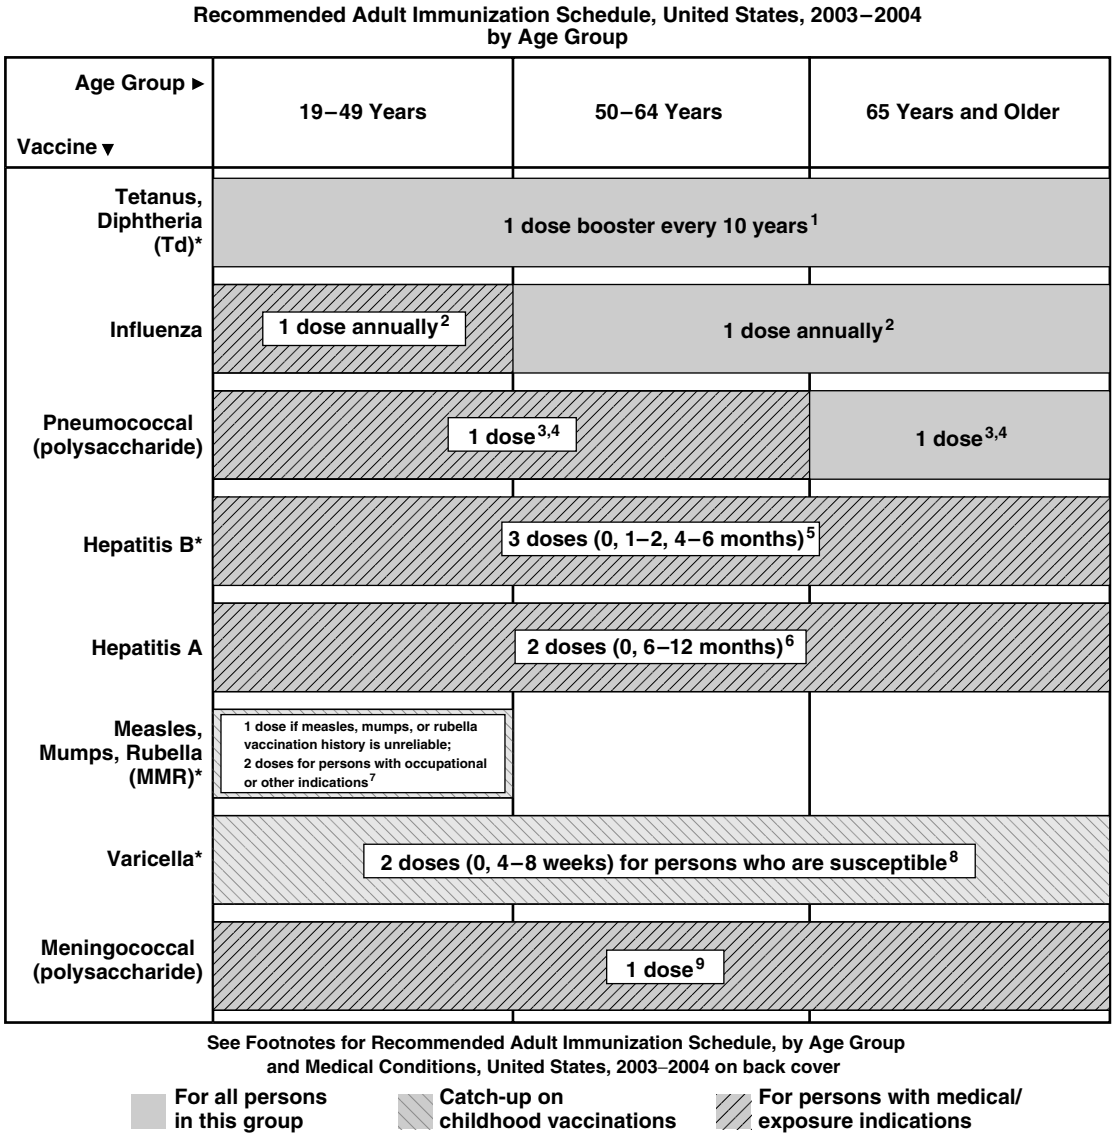
Patients with severe autoimmune hepatitis (aspartate transaminase (AST) > than 10-fold or AST > fivefold and serum gamma globulin > twofold) are definite candidates for treatment. Combination therapy using azathioprine and corticosteroids has been shown to prolong survival and improve outcomes in affected adults. Patients with mild autoimmune hepatitis do not benefit from treatment (Newton *et al.*, 1997).

Alcoholic Liver Disease

Excessive alcohol use is a major cause of liver disease. Approximately 10% of men and 2% of women over the age of 60 years suffer from an alcohol use disorder. Although age does not alter alcohol dehydrogenase activity, studies suggest a difference in the clinical course and outcomes of alcoholic disease in older adults compared with younger subjects. Older adults who present with alcoholic liver disease are more likely to have severe symptoms and present with complications such as portal hypertension or liver cirrhosis. Prognosis in older patients is directly related to age. Patients presenting with alcoholic liver disease over the age of 70 years have a mortality rate at one year of about 75% compared with 5% in patients aged less than 60 years (Varanasi *et al.*, 1999; Beresford and Lucey, 1995; Corrao *et al.*, 1997; James, 1997)

Laboratory testing reveals elevated serum aspartate aminotransferase, bilirubin, and alkaline phosphatase. Liver biopsy reveals a spectrum of histological changes ranging from steatosis, through acute hepatitis to cirrhosis. Animal models indicate that toxic oxidative stress and proinflammatory cytokine elaboration, arising from metabolism of ethanol to acetate, contributes significantly to the onset of alcohol-related steatosis and progressive forms of liver damage. Elevated serum concentration levels of tumor necrosis factor alpha (TNF α), interleukin (IL)-6, IL-8, IL-18, and transforming growth factors, occur in patients with alcoholic liver disease. Cytokine levels have been shown to correlate with liver dysfunction and clinical outcome. Cessation of alcohol intake results in resolution of steatosis and restoration of normal hepatic architecture within a few weeks. Acute alcoholic hepatitis, which comprises cellular inflammation and fibrosis, also responds to alcohol cessation. Persistent alcohol intake results in progressive fibrosis and subsequent cirrhosis within 5 years in 40% of affected patients (McClain *et al.*, 2004; McClain *et al.*, 1999).

Treatment of alcoholic liver disease does not vary with age. Abstinence is the cornerstone of effective management and is critical to the success of all other adjunctive therapy. Most patients with alcohol dependence are undernourished, which



*Covered by the Vaccine Injury Compensation Program. For information on how to file a claim call 800-338-2382. Please also visit www.hrsa.gov/osp/vicp To file a claim for vaccine injury contact: U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington D.C. 20005, 202-219-9657.

This schedule indicates the recommended age groups for routine administration of currently licensed vaccines for persons 19 years of age and older. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations.

Report all clinically significant post-vaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available by calling 800-822-7967 or from the VAERS website at www.vaers.org.

For additional information about the vaccines listed above and contraindications for immunization, visit the National Immunization Program Website at www.cdc.gov/nip/ or call the National Immunization Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Approved by the Advisory Committee on Immunization Practices (ACIP), and accepted by the American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Family Physicians (AAFP)

Figure 2 Summary of recommendations published by The Advisory Committee on Immunization Practices – Centers for Disease Control. Department of Health and Human Services

further increases their mortality risk. Severely undernourished veterans with acute alcoholic hepatitis had a 30-day mortality rate of 52% compared with a 2% mortality rate in their counterparts with only mild undernutrition. Protein energy undernutrition compromises the immune system and may therefore have a permissive effect on the toxicity of alcohol. In addition, hepatic regeneration may be compromised by impaired protein synthesis. Thus, aggressive nutritional support is recommended for patients with alcoholic liver disease.

Corticosteroids have been shown to ameliorate cytokine production, suppress acetaldehyde catabolism and thereby

blunt the hepatic inflammatory response. Nevertheless, data from several meta-analyses have failed to demonstrate consistent benefit from corticosteroid therapy in alcohol-related liver disease. Paucity of data in addition to potential side effects of steroid therapy in older adults renders steroid therapy an unwise choice in older adults. Several research studies are aggressively exploring the role of cytokine antagonism in the treatment of alcohol liver disease. Theoretically, TNFα antagonists could prove useful in suppressing alcohol-related hepatic inflammation. Recent studies suggest that anti-TNF therapy may improve histological features and enhance survival (Spahr *et al.*, 2002; Tilg *et al.*, 2003). However, well-controlled randomized trials are lacking. Pentoxifylline, a phosphodiesterase inhibitor, has proved useful in reducing the risk of hepatorenal syndrome (Akriviadis *et al.*, 2000).

Several studies have evaluated the effect of antioxidants, such as *S*-adenosyl methionine and silymarin (milk thistle), in the treatment of alcoholic liver disease. Available evidence fails to confirm benefit from any of these agents (Pares *et al.*, 1998; Mato *et al.*, 1999). Other potentially antioxidative agents such as propylthiouracil and phosphatidylcholine have also been studied. They had no effect on outcomes or survival (Rambaldi and Gluud, 2001; Lieber *et al.*, 2003). Colchicine, an inhibitor of collagen synthesis produced a paradoxical increase in the risk of adverse events (Rambaldi and Gluud, 2001).

Hepatocellular Carcinoma

In North America, hepatocellular carcinoma is predominantly a disease of older adults, with 50% of cases occurring in adults over the age of 60 years. In contrast, the peak incidence of hepatocellular carcinoma (HCC) in Sub-saharan Africa and China occurs in young to middle adulthood. Older adults are more likely to present with advanced disease and their survival rates are significantly lower than those of younger patients (10.5 weeks compared with 18.5 weeks in younger adults, Collier *et al.*, 1994; Regev and Schiff, 2001).

Hepatocellular carcinoma in older adults is more likely to be related to HCV than HBV (Hoshida *et al.*, 1999). Data from a Korean study identified a serological positivity ratio of 29.7 for hepatitis B surface antigen in patients younger than 50 years compared with 0.9 in patients older than 60 years (Lee *et al.*, 1993). Infection with HBV in the earlier years of life as opposed to in adulthood, as is the case with HCV, probably accounts for this difference. Additionally, the latent interval between acquisition of HCV and the development of hepatocellular is significantly longer than with HBV.

Available data indicate that treatment outcomes of hepatocellular carcinoma are unaffected by age. There is difference in morbidity, early mortality, or long-term survival between older and younger patients treated with either surgical resection or chemo-embolization (Bismuth, 1999; Hanazaki *et al.*, 2000). Thus, age should not be used as the sole determining criterion for deciding treatment options.

DISEASES OF THE GALLBLADDER AND BILIARY TRACT

Gallstone Disease

Age-related changes in biliary metabolism result in increased cholesterol saturation of bile and gallbladder dysmotility. In addition, there is increased activity of HMG-CoA reductase and reduced activity of 7-alpha hydroxylase. These changes enhance the lithogenicity of bile. Consequently, there is an increase in the prevalence and severity of gallstone disease, specifically cholesterol, and calcium bilirubinate stones, in older adults (Bowen *et al.*, 1992; Affronti, 1999).

In the United States, the incidence of gallstones in Caucasian women increases from 5% in the third decade of life to 25% in the seventh decade. Complications such as choledocholithiasis, emphysematous cholecystitis, ascending cholangitis, and pancreatitis are more apt to occur with aging. Although the precise reasons are yet to be defined, it has been proffered that atherosclerosis in older adults may cause gallbladder ischemia, thereby enhancing susceptibility to disease (Kahng and Roselyn, 1994).

Clinical Features

Although asymptomatic cholelithiasis is a common occurrence in older patients, most of them never experience complications. However, in older adults the frequent coexistence of multiple illnesses and the atypical presentation of diseases render complications more sinister and possibly life threatening when they do occur. Approximately one-fifth of older adults presenting with cholecystitis are likely to have coexisting choledocholithiasis and biliary colic, compared with about 5% of younger subjects. Ascending cholangitis is also more likely to occur in older patients. Following emergent cholecystectomy, approximately 50% of older subjects will develop choledocholithiasis (Siegel and Kasmin, 1997; Reiss and Deutsch, 1985; Rosenthal and Anderson, 1993).

Older adults are more likely to manifest with atypical features that may confound early diagnosis. Blunted febrile responses and minimal leucocytosis in the face of infection may delay diagnosis of cholecystitis. Abdominal pain in patients with impaired cognitive function may be poorly localized. Data indicates that in patients over the age of 65 years, 56% may be afebrile on presentation, 84% have poorly localized abdominal pain and 5% may be completely pain free. Delirium resulting from infection in cholecystitis may misdirect clinical focus toward the nervous system.

Physical diagnosis is less accurate in older patients. Murphy's sign in older adults is poorly sensitive (48%) compared with a sensitivity of 90% in younger patients. In older patients, Charcot's triad (right upper quadrant pain, jaundice, and fever) is more likely to present as Reynold's pentad with the additional features of delirium and hypotension (Hendrickson and Naparst, 2003; Parker, 1997; Adedeji, 1996). The onus rests with health professionals to

maintain a keen sense of awareness of the likelihood of this disorder in older patients.

Diagnosis and Management

Ultrasound is the imaging modality of choice in suspected cholelithiasis and cholecystitis. However, health professionals should be aware that older adults have a higher incidence of acalculous cholecystitis, which may not be identified on ultrasound. Utilization of hydroxy iminodiacetic acid (HIDA) scans as an adjunct in such cases may be helpful. Increasingly sophisticated endoscopic procedures have considerably enhanced diagnostic and therapeutic options in biliary tract disease (Hendrickson and Naparst, 2003). Ideally, an endoscopic retrograde cholangiopancreatography (ERCP) should always precede a cholecystectomy to facilitate accurate definition of the required surgical procedure. Endoscopic ultrasound is a newer technique that is just as sensitive as, but less risky than, ERCP. This may become the preferred procedure for older frail patients (Canto *et al.*, 1998).

ERCP is a safe and effective procedure in older adults. With experienced operators, the success rate is approximately 98%. Evidence suggests that older adults tolerate ERCP better than younger patients. In a cohort of 64 patients over the age of 90 years undergoing therapeutic ERCP, Kasmin *et al.* (1995) identified a complication rate of 3% with no incidents of pancreatitis and no procedure related deaths. Within the general population the expected overall complication rate ranges from 5 to 10% (Affronti, 1999).

Newer techniques such as endoscopic ultrasound, intraductal ultrasonography, magnetic resonance cholangiopancreatography and three-dimensional computed tomography continue to improve diagnostic accuracy (Domagk *et al.*, 2004).

Adoption of a "wait and see" approach is advocated as a reasonable therapeutic option in the management of cholelithiasis. However, data to support this was derived from studies of younger patients. The increased risk of complications and mortality following emergent surgery make this a less favorable solution for older adults. Reported mortality rates for elective procedures range from 4 to 10%, which is comparable to data obtained from younger adults. In emergent situations the mortality rate in older patients rises as high as 20% (Rosenthal and Anderson, 1993). Accordingly, the risks of expectant therapy in older adults with apparently asymptomatic disease must be carefully weighed against the benefits of elective intervention.

Laparoscopic cholecystectomy is the preferred therapeutic option in symptomatic cholelithiasis. Advantages of this procedure over open cholecystectomy include reduced length of stay and less patient discomfort. Anecdotal reports suggests that this minimally invasive procedure is well tolerated by older adults who are otherwise reasonable candidates for surgery. However, studies have yielded conflicting results with regards to morbidity and mortality data. The decision to perform laparoscopic cholecystectomy is still operator dependent. Nevertheless, increased proficiency at this procedure is rapidly relegating open cholecystectomy to the position of a salvage procedure following failure of a laparoscopic cholecystectomy (Kahng and Roselyn 1994; Ido *et al.*, 1995).

Pharmacological dissolution has rapidly fallen out of favor as a viable primary therapeutic option. Chenodeoxycholic acid was the first agent developed to reduce lithogenicity of bile and dissolve gallstones. Complete dissolution was rarely achieved and occurred in less than 15% of patients. Added disadvantages to the use of this agent were a high recurrence rate (50%), significant adverse effects and high cost. A newer and similar agent ursodeoxycholic acid is better tolerated and may be more effective. However, definitive evidence in older adults is lacking (Kahng and Roselyn 1994; Weinstein *et al.*, 1990).

Similarly, there is a striking lack of data concerning the safety and efficacy of contact dissolution in older adults. Methyl *tert*-butyl ether (MTBE), a potent cholesterol solvent, is instilled into the gallbladder during percutaneous transhepatic cholangiography to facilitate direct contact dissolution of gallstones. Catheter-related complications, MTBE toxicity, the high recurrence rate and the virtual absence of any data in older adults render this an inadvisable and obsolete option (Thistle and May, 1989).

Finally, biliary electroshock wave lithotripsy is a noninvasive procedure that appeared to be a potentially favorable option for older adults. However, efficacy of this technique depends on multiple factors, including size, calcium content and number of stones, and adequate gallbladder function and motility. Few patients qualify for this procedure (Magnuson *et al.*, 1989). There is no data in elders.

Gallbladder Perforation

Gallbladder perforations are more likely to occur in the fundus because, compared to the rest of the gallbladder, the fundal portion is relatively poorly vascularized. Type 1 gallbladder perforations are acute and associated with biliary peritonitis. Type II perforations are subacute and characterized by the presence of a pericholecystic abscess. Type III perforations generally result in a fistulous tract between the gallbladder and the duodenum.

Type III perforations occur most frequently and are more likely to be complicated by gallstone ileus. Though uncommon in the general population, gallstone ileus is the commonest cause of small bowel obstruction in older women, occurring in 25% of such cases. Definitive management is surgical enterotomy and stone extraction (Kahng and Roselyn, 1994)

Emphysematous Cholecystitis

This is a life-threatening condition characterized by gangrene of the gallbladder due to an infection with gas-forming organisms. Emphysematous cholecystitis is more likely in older patients with diabetes. Clostridial organisms are implicated in most patients. Cholelithiasis is present in only half of

affected patients. Ischemia has been implicated in this condition although the precise pathogenetic mechanisms remain unclear. Mortality is very high and emergent cholecystectomy is indicated (Affronti, 1999).

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is an autoimmune disease characterized by progressive destruction of intrahepatic biliary ducts and chronic cholestasis. Although predominantly a disease of middle-aged women, over one-third of patients are over the age of 65 years (Metcalf *et al.*, 1997). Several large case series indicate that the mean age at presentation is approximately 60 years with the peak incidence occurring between 70 and 79 years (Metcalf *et al.*, 1997; Howel *et al.*, 1997).

In patients who are symptomatic at presentation, advanced age is an independent adverse prognostic factors (Regev and Schiff, 2001). Treatment is generally reserved for selected older patients who are symptomatic. Outcomes for asymptomatic patients do not differ from that of the general population. Asymptomatic patients often come to attention following investigation of an unexplained elevation of serum alkaline phosphatase. Diagnosis of PBC is usually confirmed by the detection of antimitochondrial antibodies. Extrahepatic manifestations of PBC include hypothyroidism, sicca syndrome, hypothyroidism, and cutaneous xanthoma. Fat-soluble micronutrient deficiencies may occur resulting in an increased risk of osteoporosis and impaired coagulation (James, 1997).

Medical therapy is not very helpful in treating PBC. Colchicine may retard progression of liver fibrosis and improves laboratory values in patients with PBC but it has no effect on signs or symptoms of the disease. Corticosteroids and D-penicillamine are ineffective treatment options. Conflicting results have been obtained regarding other immunosuppressive agents such as Azathioprine (Imuran), methotrexate, and cyclosporin A. Ursodeoxycholic acid is a promising pharmacological agent. Data demonstrates not only improved symptoms and biochemical parameters but also retarded progression of PBC following ursodeoxycholic acid therapy. Recent evidence also suggests a role for selective estrogen receptor modulators in the treatment of PBC. Tamoxifen therapy has been associated with a decrease in serum alkaline phosphatase level in two women with coexistent PBC. Authors of these case reports suggest that Tamoxifen may act on cholangiocyte estrogen receptors to inhibit cholangiocyte proliferation. Further evidence is needed to support this hypothesis (Bergasa *et al.*, 2004; Reddy *et al.*, 2004). In contrast, orthotopic liver transplantation has very good outcomes in patients with end-stage liver disease resulting from PBC (Bergasa *et al.*, 2004).

Liver Transplantation

Liver cirrhosis, portal hypertension, and liver failure have a major impact on both hepatic and all-cause mortality in older adults. Indeed, the presence of liver cirrhosis in the setting of concomitant disease is an adverse prognostic factor. Subjects with chronic liver disease and complicating cirrhosis aged over 80 years had a cumulative survival rate of 59 and 19% at 5 and 9 years respectively, compared with 86 and 69% in their noncirrhotic counterparts with chronic liver disease (Hoshida *et al.*, 1999; del Olmo *et al.*, 2000; O'Mahony and Schmucker, 1994). Although management of liver cirrhosis in older adults is similar to younger adults, long-term survival rates are much worse in the elderly.

Previously, advanced age was considered a contraindication to liver transplantation and patients older than 55 were rarely accepted as transplant recipients. More recent evidence indicates a survival rate among older transplant recipients comparable to that of younger subjects. Age, as an isolated criterion, is therefore no longer considered a contraindication to liver transplantation (Tran *et al.*, 2004; Fattovich *et al.*, 1997).

Currently, approximately 20% of transplant recipients in the United States are over the age of 60 years compared with less than 10% in 1989 (Seaberg *et al.*, 1998). Additionally, quality of life, morbidity, and one year survival rates in older transplant recipients are comparable with those in their younger counterparts. Five year survival rates in older transplant recipients are worse due to excess cardiac, neurological, infective, and neoplastic deaths (Zetterman *et al.*, 1998; Varanasi *et al.*, 1999). Incidentally, the incidence of organ rejection following transplantation has consistently been shown to be lower in older adults possibly as a result of age-related immune dysfunction (James, 1997).

Although, the scarcity of donor organs has inappropriately fostered the use of age as a prioritizing factor, the absence of significant differences in outcomes does not justify this practice in older patients who would otherwise qualify for liver transplantation.

Similarly, available data indicates that livers harvested from elderly donors (50–70 years) may be transplanted with reasonable success rates. However, eligible older donors must be carefully screened to avoid the risk of early postoperative liver dysfunction and compromised graft survival (Hoofnagle *et al.*, 1996).

KEY POINTS

- Age-related pathophysiological changes include hepatic hypoperfusion, decreased hepatic mass, reduced activity of phase 1 hepatic drug-metabolizing enzymes, compromised hepatic regeneration, relative dilatation of the common bile duct, and increased lithogenicity of bile. These changes result in enhanced vulnerability of the aging hepatobiliary system to disease.
- Hepatobiliary diseases are a major cause of morbidity and mortality in older adults. The mortality rate from chronic liver disease in adults aged over 65 years

is 3–6 times higher than that in middle-aged adults. Biliary disease is the leading indication for acute abdominal surgery in older adults. Older adults with viral hepatitis are more likely to develop complications such as fulminant hepatic failure, liver cirrhosis, and hepatocellular carcinoma

- Twenty percent of all patients diagnosed with autoimmune hepatitis are over the age of 65 years. Drug-induced hepatitis is more common in older adults due to multiple factors including increased exposure to drugs, compromised hepatic metabolism and increased risk of hepatotoxicity with the use of certain drugs in older adults.
- Older adults are more likely to present with atypical features of biliary tract disease, and life-threatening complications such as gallbladder perforation and emphysematous cholecystitis. Emergency biliary surgery has worse outcomes in older adults. The risks of expectant therapy in older adults with asymptomatic biliary tract disease must be weighed against the benefits of elective intervention.
- Advanced age is not an absolute contraindication to liver transplantation. Quality of life, morbidity, and one year survival rates in older transplant recipients are comparable with those in their younger counterparts.

INTRODUCTION

Fecal incontinence is a common condition which affects up to 21% of community dwelling elderly individuals over the age of 65 (Campbell *et al.*, 1985; Kok *et al.*, 1992; Talley *et al.*, 1992). Prevalence in the institutionalized elderly (nursing homes) exceeds 50% (Chassagne *et al.*, 1999; Prather *et al.*, 2001). An attack of acute diarrhea can result in an incontinence episode even in healthy people, when the rectal reservoir is overwhelmed by the liquid/loose stools. Patients with fecal incontinence experience anxiety, fear of embarrassment, emotional and social devastation, silent suffering, isolation, and depression (Johanson and Lafferty, 1996). Patients underreport fecal incontinence unless prompted, placing the onus on the physician to ask about anorectal problems and to encourage patients toward the effective treatment options that are available. Fecal incontinence, along with urinary incontinence, is among the leading reasons for nursing home admission (Nelson *et al.*, 1998). In this chapter, we will discuss only the anal sphincter, its anatomy, physiological changes with aging, prevalence, importance, risk factors, causes of incontinence, evaluation, and treatment options of fecal incontinence.

ANATOMY AND PHYSIOLOGY OF THE ANAL CANAL AND RECTUM

In order to better understand the clinical presentation, evaluation, and treatment options for fecal incontinence, the anatomy and physiology of the anal canal and rectum are briefly reviewed along with changes that occur with aging.

The *rectum* is a tubular structure, 12–15 cm in length with the anal canal extending about 4 cm, from the anal verge to the anorectal ring. The anal canal is separated by a dentate line into an upper mucosal lining and lower cutaneous segment of the anal canal. The area above the dentate line is supplied by the sympathetic and parasympathetic systems, while below the dentate line the somatic nervous system provides innervation. Just above the dentate line there are 8–12 rectal columns (anal cushions) with their bases connected to each other. The high-pressure zone of the anal sphincter is formed by the combination of muscles (internal anal, external anal, and the puborectalis) and anal cushions (Lestar *et al.*, 1989; Schweiger, 1979).

The *internal anal sphincter* is a circular muscle layer that starts from the rectum. The internal anal sphincter is tonically contracted at rest, preventing the involuntary loss of stool and gas.

Tone of the anal sphincter:

The internal anal sphincter contributes 50–85% of the resting tone of the sphincter with the external anal sphincter contributing 25%–30%, the remaining 15% coming from the anal cushions (Lestar *et al.*, 1989; Schweiger, 1979; Taylor *et al.*, 1984; Gibbons *et al.*, 1986). In response to rectal distention, the internal anal sphincter tone increases initially, followed by decreased tone constituting the recto-anal inhibitory response (Lestar *et al.*, 1989).

Changes with Aging:

The thickness of internal anal sphincter increases with age and is confirmed by ultrasound and magnetic resonance imaging (Papachrysostomou *et al.*, 1994; Rociu *et al.*, 2000; Burnett and Bartram, 1991; Nielsen and Pedersen, 1996). The functional significance of this change is unclear. It could be a compensatory change for the maintenance of continence (Papachrysostomou *et al.*, 1994). This is unlikely as the age-related changes in anal sphincter pressures are quite modest in healthy individuals (Loening-Baucke and Anuras, 1985; Barrett *et al.*, 1989). The most likely explanation is increased connective tissue or "sclerosis" of the internal anal sphincter with aging (Klosterhalfen *et al.*, 1990).

The external anal sphincter is a striated muscle surrounding the inner smooth muscle and terminating distal to the internal anal sphincter. Both the puborectalis and the external anal sphincter provide the voluntary control of

continence in response to various stimuli such as increased intra-abdominal pressure that occurs with coughing, rectal distention, and anal dilatation (Schweiger, 1979; Sun *et al.*, 1990). Voluntary anal sphincter pressures decrease with age and pressures are lower in women than in men (Enck *et al.*, 1989).

The levator ani muscle is a major component of the pelvic floor and is composed predominantly of three striated muscles: iliococcygeus, pubococcygeous, and puborectalis. The puborectalis muscle plays the largest role in continence and is a U shaped loop of striated muscle slinging around the posterior aspect of the external anal sphincter, pulling the anal canal forward creating the anorectal angle (Figure 1). The puborectalis and resultant anorectal angle aid in the maintenance of continence, as this angle becomes more acute with voluntary sphincter contraction providing an anatomic obstruction to the distal movement of stool retained above the angle (Hajivassiliou *et al.*, 1996).

Physiology of Defecation:

Both the sensory and motor neurons of the anorectum interact to maintain continence and control the process of defecation. The desire to defecate is usually preceded by propagation of contractions in the proximal colon resulting in the movement of feces into the rectum with relaxation of the distal colon/rectum, relaxation of internal anal sphincter, and contraction of the external anal sphincter until the socially appropriate time for defecation is desired (Gowers, 1877; Gordon, 2001). The sensory receptors in the anal canal determine the nature of luminal contents, that is, whether the contents are solid, liquid, or gas (Miller *et al.*, 1988). When voluntary defecation is desired, intra-abdominal pressure rises from abdominal wall contraction. The muscles of the pelvic floor (external anal sphincter, puborectalis, and other muscles of the levator ani) relax. Relaxation of the puborectalis results in straightening of the anorectal angle providing a straightened conduit for stool movement (Figure 2). The anal canal relaxes with the increased rectal pressure resulting in the evacuation of stool.

Mechanism of Continence:

It is maintained through the combined action of several muscles:

(a) The external and internal anal sphincters and the puborectalis muscle.
(b) Determinants of continence include resting anal tone, resistance to opening at the anus, rectal compliance, normal anorectal sensation, and the consistency of stools (Tobin and Brocklehurst, 1986). In addition, mobility and intact cognition is required to have a bowel movement. Impairment in any of these mechanisms may result in fecal incontinence.

PREVALENCE AND IMPORTANCE

The prevalence of fecal incontinence in the general population is 2.2% (Nelson *et al.*, 1995). This study did not include individuals residing in nursing homes. When individuals above the age of 65 years were studied, the frequency of fecal incontinence increased from 3.7 to 27% (Table 1). The greatest prevalence of fecal incontinence is found in nursing homes with more than 50% of the long-term care residents affected by chronic fecal incontinence (Chassagne *et al.*, 1999). Higher prevalence of fecal incontinence is seen in geriatric hospital wards (20–32%) and geriatric psychiatry centers (up to 56%) (Thomas *et al.*, 1987; Issac and

Table 2 Risk factors and causes of fecal incontinence

Risk factors (Gordon, 2001; Nelson *et al.*, 1995)
Prior history of urinary incontinence
Presence of neurological disease
Presence of psychiatric disease
Poor mobility
Age greater than 70 years
Dementia

Causes of fecal incontinence (Madoff *et al.*, 1992)
A. Fecal impaction
B. Loss of normal continence mechanism
   1. Local neuronal damage (e.g. pudendal nerve)
   2. Impaired neurological control
   3. Anorectal trauma/sphincter disruption
C. Problems overwhelming normal continence mechanism
D. Psychological and behavioral problems
   1. Severe depression
   2. Dementia
   3. Cerebrovascular disease
E. Neoplasm (rare)

Walkley, 1964). Eighty percent of patients hospitalized with dementia also experienced fecal incontinence (Taylor *et al.*, 1984). Double incontinence (i.e. fecal incontinence and urinary incontinence) occurs twelve times more commonly than fecal incontinence alone with 50 to 70% of patients with urinary incontinence also suffering from fecal incontinence (Nelson *et al.*, 1995; Thomas *et al.*, 1987; Issac and Walkley, 1964; Ouslander *et al.*, 1982). This is not surprising, as the combination of urinary and fecal incontinence is the second most common cause of institutionalization in elderly persons (Nelson *et al.*, 1998; O'Donnell *et al.*, 1992).

Fecal incontinence is a marker for poorer overall health and is associated with increased mortality (Chassagne *et al.*, 1999; Nakanishi *et al.*, 1999). Incontinent nursing home residents experience more urinary tract infections and pressure ulcers (Borrie and Davidson, 1992). The total health-care costs attributable to fecal incontinence are difficult to determine as few studies examine health-care costs for fecal incontinence alone. Most health-care cost information comes from nursing homes caring for patients with fecal incontinence, urinary incontinence or both. The nursing home related costs for incontinence were $3.26 billion in 1987 and the yearly cost of adult diapers alone is $400 000 000 (Hu, 1990; Mandelstam, 1985). The additional health expenditures reach in excess of $9000 per patient year of incontinence (Borrie and Davidson, 1992).

RISK FACTORS AND CAUSES OF FECAL INCONTINENCE

The risks and causes of fecal incontinence are summarized in Table 2. Risk factors for fecal incontinence include a prior history of urinary incontinence, the presence of neurological or psychiatric disease, poor mobility, age greater than 70, and dementia (Nelson *et al.*, 1995; Madoff *et al.*, 1992; Tobin and Brocklehurst, 1986). Possibly the most common predisposing condition to fecal incontinence is fecal impaction, which is reported in up to 42% of elderly patients admitted to geriatric units (Read and Abouzekry, 1986). These patients are often chronically constipated and receive large doses of laxatives resulting in incontinence from leakage around the large fecal impaction (Read and Abouzekry, 1986). The problem is further complicated by the presence of decreased rectal sensation allowing the progressive accumulation of stool in the rectum (Read *et al.*, 1985). Fecal incontinence in diabetes mellitus occurs from autonomic neuropathy and is exacerbated in the presence of diabetic diarrhea (Schiller *et al.*, 1982). Pelvic neuropathy may result from prolonged straining and birth trauma. Fecal incontinence results in these patients because of sphincter damage and pudendal neuropathy (Sultan *et al.*, 1994). Trauma to the anal canal such as anal surgery including hemorrhoidectomy, anal fissure repair, and anal dilatation may disrupt the anal sphincter muscles resulting in impaired continence (Rieger *et al.*, 1997; Read *et al.*, 1982b). Patients with total internal sphincterotomy have a 40% risk of fecal incontinence, while partial sphincterotomy carries a risk of 8–15% (Bennet and Goligher, 1962; Walker *et al.*, 1985; Pernikoff *et al.*, 1994). Altered cognition is commonly associated with fecal incontinence (Chassagne *et al.*, 1999). The combination of altered cognition and fecal incontinence are important factors leading to institutionalization (Borrie and Davidson, 1992).

CLINICAL SUBGROUPS

There are three main types of fecal incontinence:

1. Overflow
2. Reservoir and
3. Rectosphincteric

Overflow incontinence is specially seen in cognitively impaired, bed ridden nursing home individuals and the risk factors are outlined in Table 3. Reservoir incontinence is seen

Table 3 Risk factors for overflow incontinence

Inadequate fiber
Inadequate water intake
Immobility
Inadequate toileting facilities
Mental status changes
Metabolic abnormalities
Hypothyroidism
Hypercalcemia
Hypokalemia
Medication
Narcotics
Antipsychotics
Antidepressants
Calcium channel blockers
Diuretics

in individuals with diminished colonic or rectal capacity. This condition is commonly seen with radiation proctopathy, chronic rectal ischemia, idiopathic inflammatory bowel disease, and proctocolectomy with ileoanal anastomosis. Rectosphincteric incontinence is seen in conditions associated with structural damage to one or both anal sphincters, pudendal neuropathy affecting the external anal sphincter and or puborectalis muscle and or rectal sensation, or to degenerative or myogenic disorders affecting internal anal sphincter or external anal sphincter.

EVALUATION OF FECAL INCONTINENCE

The goals in evaluating fecal incontinence include establishing the severity of incontinence, understanding the pathophysiology present and directing the patient to appropriate therapy for their condition. This is accomplished through the history, physical examination, and investigations targeted to determine the etiology of fecal incontinence.

HISTORY AND PHYSICAL EXAMINATION

The physician may find it difficult to recognize fecal incontinence since patients usually will not volunteer information about incontinence unless asked (Johanson and Lafferty, 1996). This information is best elicited through direct questioning regarding bowel habit and continence. It is helpful to identify when the symptoms first occurred, determine if the patient has any sensation such as the passage of stool or gas, fullness in the rectum, or warning symptoms such as abdominal cramps and urgency. Inquiry about the home environment may reveal barriers to bathroom facilities especially in nursing homes, particularly in patients with walkers. Table 4 summarizes important areas to address during history. Colitis of any cause may result in loose stools that overwhelm the continence mechanisms. Patients with perianal Crohn's disease may also develop fecal incontinence from fistula formation. In the evaluation of fecal incontinence, several components of the neurological history deserve attention. A cerebrovascular accident may limit the patient's physical ability to use the toilet facility. The new onset of fecal incontinence may also herald the presence of cord compression, especially when associated with other neurologic symptoms.

Table 4 Evaluation of fecal incontinence

1. History
Chronic medical condition
Diabetes and chronic diarrhea or constipation
Cerebrovascular accidents or cord compression
Dementia and depression
Immobility
Trauma during child birth
Surgeries history
Hemorrhoidectomy
Sphincterotomy
Fistulectomy
Colon resection and dilatation
Radiation to the prostate or cervix for carcinoma
Review of medications such as antipsychotic, sorbitol base medications (theophyline)
2. Physical examination
Saint Louis University Mental Status examination or Mini-Mental State Exam
Geriatric depression scale
Neurological examination
Rectal examination

A thorough review of prescription, over-the-counter medicine, and supplements may reveal an underlying cause for the altered bowel habit. Medicines causing diarrhea include magnesium containing antacids and poorly absorbed sugars such as sorbitol and mannitol (used in dietetic products). Sorbitol is also frequently used as a base in elixirs, for example, theophyline elixir. The intentional or inadvertent use of cathartics may contribute to diarrhea and incontinence. Similarly, a medication responsible for constipation may cause a worsening of incontinence through overflow.

The physical examination helps to identify the pathophysiology of fecal incontinence and can guide the ordering of appropriate tests for further evaluation (Rosen, 1990). The usual physical examination may be supplemented by a Mini-Mental Status Examination, or Saint Louis University Mental Status Examination, which help identify patients with cognition problems (Crum *et al.*, 1993; Morley and Tumosa, 2002). The neurological examination includes assessment of general patient mobility, motor strength, and sensory testing. The "anal wink" is elicited by stroking the skin lateral to the anal canal and observing the contraction. Absence of this reflex suggests significant neural damage. Anal gaping can be seen when the buttocks are parted in patients with paraplegia (Read and Sun, 1991). The perineum is inspected for dermatitis, hemorrhoids, fistula, surgical scars, skin tags, rectal prolapse, soiling and ballooning of the perineum (suggesting weakness of the pelvic floor). Following inspection, the next step is digital rectal examination to note the baseline sphincter tone, squeeze pressure, any asymmetry of the sphincter on squeeze (especially anteriorly), and the amount and character of the stool (hard and ball like or soft). The positive predictive value of digital exam is 67% for detecting

decreased anal tone when compared to anal manometry (Hill *et al.*, 1994). Patients with high or normal sphincter tone can also be incontinent especially in the setting of large rectal volumes or altered rectal sensation. In patients with lesions of the spinal cord or cauda equina the sphincter tone may be normal, but when pressure is applied to any part of the anorectal ring the phenomena of gaping can be seen. Findings in the normal elderly patient typically reveal lower anal canal pressures (Bannister *et al.*, 1987).

DIAGNOSTIC TESTS

A number of tests are available to provide data on colonic and anorectal function (Barnett *et al.*, 1999). Table 5 outlines most of the tests necessary for the investigation of fecal incontinence. In the elderly population the most important thing is to exclude fecal impaction. Even in the absence of stool in the rectal vault, a higher impaction may be present. If the patient is at risk, a plain abdominal radiograph is required to exclude high impaction. A flexible sigmoidoscopy or colonoscopy examines the colorectal mucosa for evidence of colitis, neoplasia, inflammatory bowel disease, colonic and rectal ischemia, laxative abuse, and other structural abnormalities. Anorectal manometry provides comprehensive information regarding anorectal function as it quantifies anal sphincter tone and assesses anorectal sensory responses, the recto-anal inhibitory reflex, and rectal compliance (Rao and Patel, 1997). Anorectal manometry gives either new information or confirms the suspected diagnosis in patients with fecal incontinence (Wexner and Jorge, 1994). A finding of decreased rectal compliance may point to fecal incontinence from increased stress on the continence mechanism as the stool is received in the rectum (i.e. a stiff rectum does not accommodate the stool bolus resulting in overflow) (Rasmussen *et al.*, 1990). Electromyography measures the neuromuscular integrity between the distal portion of pudendal nerve and the anal sphincter muscle (Rao, 1997). Electromyography correlates well with anorectal manometry but its use in the routine assessment of fecal incontinence is controversial (Barnett *et al.*, 1999; Wexner *et al.*, 1991). Anal ultrasound defines the internal and external anal sphincters (Law *et al.*, 1991). Anal ultrasound can be used to identify isolated sphincter defects present in about two-thirds of incontinent patients (Chen *et al.*, 1999; Liberman *et al.*, 2001). Ultrasonographic findings correlate with both surgical and electromyographic findings (Deen *et al.*, 1993; Meyenberger *et al.*, 1996). Magnetic resonance imaging (MRI) has also been used to evaluate the sphincter defects with definition superior to anal ultrasound as it provides higher spatial resolution and better contrast for lesion characterization (Beets-Tan *et al.*, 2001). Given the added expense and need for special coils, the clinical relevance of the improved resolution in debatable. Not all patients require all tests. An algorithm outlining one possible management strategy is shown in Figure 3.

Table 5 Diagnostic test for fecal incontinence

Diagnostic tests
Plain abdominal X ray
Sigmoidoscopy/colonoscopy
Anorectal manometry
Electromyography
Anal ultrasound or magnetic resonance imaging (MRI)

TREATMENT

The treatment of fecal incontinence depends on the underlying etiology and severity of the incontinence. Table 6 summarizes the main treatment options for fecal incontinence. Minor degrees of fecal incontinence can be treated conservatively, whereas patients with severe fecal incontinence require more aggressive treatment (Tariq, 2004; Tariq *et al.*, 2003).

Conservative Therapy

Patients with mental impairment such as in dementia may simply need to be directed to the toilet or reminded of such use. Physical limitations and environmental obstacles need to be addressed if these are contributing to incontinence as they can often be overcome by simple measures. *Habit training* involves a regular schedule of defecation, usually after breakfast, often incorporating the use of supplemental fiber and regularly scheduled enemas when defecation is delayed more than 2 days. Habit training is particularly effective for patients with overflow incontinence (Ouslander *et al.*, 1996). It has been shown that *prompted voiding* increases the number of continent bowel movements and reduces the number of incontinent movements; this study was designed primarily for urine incontinence (Ouslander *et al.*, 1996). *Sphincter training exercises* ("Kegel" exercises) alone do not increase the number of continent episodes (Whitehead *et al.*, 1985). Nocturnal diarrhea is primarily seen in diabetic patients. In cases where gut dysmotility is suspected, clonidine may be used. Topical application is

Table 6 Summary of treatment options

Conservative
Redirection in persons with cognitive impairment
Habit training
Adding Fiber into the diet
Prompt voiding
Kegel exercise
Anti diarrheal agents (once infection is excluded)
Biofeedback
Surgical (little or no data in older persons)
Sphincter repair
Neosphincter operation
Alternative therapy
Artificial anal sphincter implantation
Injection of glutaraldehyde
Sacral nerve stimulation
Colostomy

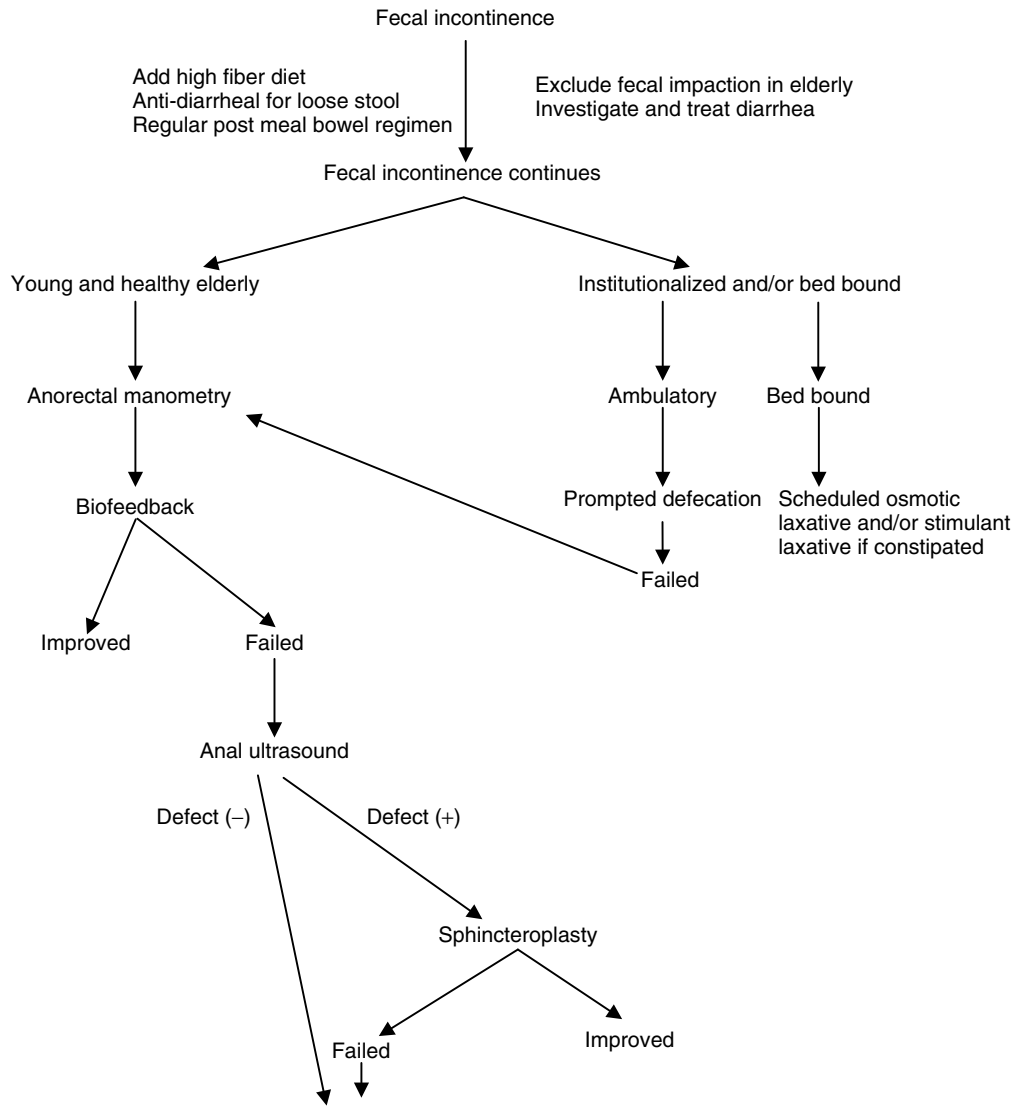

Figure 3 Algorithm for the management of fecal incontinence (Reprinted from *American Journal of Medicine*, V115, Tariq SH *et al.*, Fecal incontinence in the elderly patient, pp 217–226, Copyright 2003, with permission from Excerpta Medica Inc.)

preferred over the oral preparation. A trial of cholestyramine may be helpful if bile acid malabsorption is suspected. Antidiarrheals such as loperamide are helpful when the stool is loose (Read *et al.*, 1982a). A double-blind crossover study of 30 patients receiving loperamide, codeine, or diphenoxylate with atropine for 4 weeks found that all reduced the stool frequency but loperamide and codeine were more effective in reducing fecal incontinence compared to diphenoxylate (Palmer *et al.*, 1980). Diphenoxylate and codeine have more central nervous system side effects than loperamide and are generally best avoided in the elderly in this setting.

Biofeedback is classically described as a learning theory with operant conditioning as its theoretical basis and was first described by Engel *et al.* (1974). Biofeedback is a nonsurgical, noninvasive, relatively inexpensive outpatient method of treating fecal incontinence (Wald, 1981). Biofeedback for fecal incontinence involves improving the strength of the external sphincter and improving anorectal sensation (Whitehead *et al.*, 1985). Biofeedback provides immediate and long-term improvement of fecal incontinence (Enck *et al.*, 1994). Biofeedback training teaches the patient to recognize small volumes of rectal distension and to contract the external anal sphincter while simultaneously keeping intra-abdominal pressure low. This is accomplished by measuring anal canal pressure, showing this on a visual display to the patient, and providing verbal feedback. Table 7 shows the success rate, age range, and number of sessions involved in different studies. Better results are achieved when treating motivated, mentally capable patients. Patients should also have some degree of rectal sensation and be able to contract the external anal sphincter (Latimer *et al.*, 1984). Miner *et al.* (1990) compared active sensory biofeedback with sham retraining. In the active group, biofeedback training reduced incontinent

Table 7 Technical details and results of biofeedback therapy

[a]Unchanged from controls.

episodes by 80% per week in this study, whereas the control group showed no change from the baseline. This improvement lasted over 2 years in 73% of the patients available for follow-up. Whitehead *et al.* (1985) reported a study in the geriatric population, who were treated initially for fecal impaction but in whom 13 patients continued to be incontinent. These patients were then treated with biofeedback, which improved sphincter strength and reduced incontinence episodes by more than 75%. Enck *et al.* in his review of biofeedback showed improved continence in 13 of 14 studies (Enck, 1993). In a recent review of 46 studies involving the use of biofeedback for fecal incontinence in 1 364 patients (76% female), less than 20% of these studies included randomization and most involved a relatively small number of subjects. Improvement in continence occurred in at least one-half of the patients. No specific details regarding age-related differences were noted (Norton and Kamm, 2001).

Surgical Therapy

Surgical intervention is generally considered when more conservative measures have failed in patients with severe incontinence and identifiable anatomic defects. Although surgery is more commonly recommended in younger patients, the appropriately selected elderly patient fairs well with surgical intervention (Simmang *et al.*, 1994).

Sphincter Repair

In the setting of an isolated sphincter defect, especially anterior sphincteroplasty, surgery is very successful (Mavrantonis and Wexner, 1998; Karoui *et al.*, 2000). Three basic approaches are described: direct apposition, overlapping anterior sphincteroplasty, and plication procedures (anterior, posterior, and total pelvic floor repair). It is reported that an improvement is seen in anal function demonstrated by anal manometry before and after anterior sphincter repair (Fleshman *et al.*, 1991). There was 96% improvement in anal function as compared to preoperative symptoms (all women aged 22–75 years, mean age 37.8 years). The outcome of surgical repair is variable as some patients may continue to have incontinence and others develop new bowel problems postoperatively (Karoui *et al.*, 2000; Yoshioka and Keighley, 1989).

Neosphincter Operations

Muscle transposition may be considered for severe fecal incontinence where standard therapy has failed. Techniques include graciloplasty, dynamic graciloplasty, and gluteus maximus transposition. The result of graciloplasty varies significantly (Leguit *et al.*, 1985; Corman, 1985; Corman, 1980). The result of graciloplasty is improved by electrical stimulation after the implantation of electrical electrodes and a pulse generator (Baeten *et al.*, 1995). Electrical stimulation provides the gracilis muscle with the properties to function as a sphincter (George *et al.*, 1993). In a prospective multicenter trial, 66% of patients with graciloplasty achieved continence in a follow-up at 2 years (Madoff *et al.*, 1999). The performance of graciloplasty in the elderly has not been reported.

Alternative Therapies

Newer techniques have been developed for the treatment of fecal incontinence, but these procedures are described predominantly in younger age-groups. Wong *et al.* published a multicenter prospective trial in 12 patients who failed in conventional management for severe fecal incontinence and had an artificial anal sphincter implanted (Wong *et al.*, 1996). A successful outcome was achieved in 75% of the patients with a mean age of 33 years. The result of this surgical technique has not been specifically addressed in the elderly.

Injections of glutaraldehyde cross-linked collagen are simple and well-tolerated for patients who do not respond to conservative therapy and have a surgically incorrectable problem (internal sphincter dysfunction). Seventeen patients (mean age = 53 years) participated in a study. Sixty-five percent of the patients had symptomatic improvement, 12% had minimal improvement, while 18% had no improvement (Kumar *et al.*, 1998).

Sacral nerve stimulation for fecal incontinence has been shown to improve fecal continence along with improved quality of life in selected patients (Vaizey *et al.*, 2000). In a nonrandomized study, the application of radiofrequency energy to the sphincter may improve continence and quality of life (Takahashi *et al.*, 2002; Takahashi *et al.*, 2003). Finally, for severe fecal incontinence, when all the other procedures have failed, a diverting colostomy is usually the surgical procedure of choice.

CONCLUSION

Fecal incontinence is a common problem in the elderly population, particularly affecting individuals in the community and nursing homes. In addition to the inconvenience of the incontinence for the patient and caregiver, it is a marker of poor health and associated increased mortality. Patients and their caregivers must be questioned specifically about the presence of fecal incontinence and its severity and the patients must be treated accordingly. All patients with fecal incontinence warrant an initial medical evaluation including the exclusion of fecal impaction by rectal exam and X-ray film of the abdomen. Cognitively impaired patients benefit most from habit training. Several surgical procedures are available and may be helpful in selected older persons in selected centers. Future studies are needed to identify which patients will obtain the most benefit from these interventions and to determine the most cost-effective evaluation and treatment regimens in the aging population.

KEY POINTS

- Fecal incontinence is a common problem that is often not reported to the physician.
- In persons with fecal incontinence, fecal impaction should always be excluded.
- In healthy elderly with fecal incontinence, anal manometry and biofeedback should be utilized.
- Anal ultrasound can also be used to identify a defect suitable for treatment with sphincteroplasty.
- Common causes of fecal incontinence include cognitive impairment and fecal impaction.

Constipation

Charlene M. Prather

Saint Louis University, St Louis, MO, USA

DEFINING CONSTIPATION

Constipation most classically refers to reduced defecation frequency. Physicians usually define constipation as less than three bowel movements per week. Patients more frequently describe constipation as defecatory difficulty with predominant complaints of straining or hard stools. Understanding the patient's view of "constipation" assists in the evaluation and treatment process.

The normal defecatory process requires normal colon transit and normal pelvic floor function. Normal colon transit ranges from 24 to 72 hours. Increased colonic contractions occur in response to meals, particularly those with higher concentrations of calories and fat. Once stool is delivered to the rectum, defecation may be voluntarily initiated through a set of coordinated actions, including relaxation of the puborectalis muscle, opening of the anorectal angle, and relaxation of the anal sphincters, accompanied by a simultaneous rise in intra-abdominal pressure (i.e. Valsalva maneuver). An abnormality affecting any of these areas results in the development of an altered bowel pattern.

Primary constipation refers to constipation without an obvious cause. Secondary constipation implies that the altered bowel function results from external etiologies such as metabolic abnormalities, medications, insufficient diet, or mechanical factors obstructing the movement of stool. Chronic constipation indicates that symptoms have been present for more than three months. Patients with chronic constipation, not responding to usual treatments, require further investigation to evaluate for evidence of slow transit constipation or dyssynergic defecation (also called *pelvic outlet dysfunction*). Although constipation commonly occurs in the setting of the irritable bowel syndrome (IBS), new onset IBS occurs less frequently in elders than in younger patients. Specific criteria have been defined for identifying constipation by different investigators. The most commonly used are the Rome criteria, a consensus definition by experts for the primary purpose of use in clinical trials (Thompson *et al.*, 1999).

EPIDEMIOLOGY, PATHOPHYSIOLOGY, AND IMPACT

Constipation has long been misunderstood as a common problem associated with aging. The prevalence of self-reported constipation, physician visits, and laxative use increases with aging (Harari *et al.*, 1996; Everhart *et al.*, 1989; Sonnenberg and Koch, 1989). In contrast, reported stool frequency does not change with age (Harari *et al.*, 1996; Everhart *et al.*, 1989). Challenges in defining the prevalence of constipation in elders relates to the variety of criteria used in different studies. Self-reported constipation affects 27% of individuals aged 65 years and older, whereas only 17% of elders meet more stringent (e.g. Rome criteria) diagnostic criteria for constipation (Pare *et al.*, 2001). Data from the National Health Interview Survey reveal a "U" shaped distribution to constipation with individuals aged 60–69 reporting the least constipation (Harari *et al.*, 1996). When adjusting for race and laxative use, odds ratios for less than three bowel movements per week in individuals aged 70–79 and $\geq$80 years were 0.61 (95% CI: 0.51–0.72) and 0.85 (95% CI: 0.68–1.03), respectively, compared to individuals less than 40 years (Harari *et al.*, 1996). Thus, age alone is not an independent risk factor for reduced stool frequency. Likewise, there exists little evidence to support low fiber diets, lack of fluid or reduced exercise as contributing to constipation in the otherwise healthy older patient (Annells and Koch, 2003; Muller-Lissner *et al.*, 2005). Women report fewer bowel movements per week than do men. Nonwhites and individuals of lower socioeconomic status report fewer stools (Higgins and Johanson, 2004).

In frail elders, up to 45% report constipation as a health concern (Wolfsen *et al.*, 1993). The prevalence of constipation is higher in nursing home residents, a finding partially explained by use of constipating medications (van Dijk *et al.*, 1998). Nursing home residents frequently (58%) use laxatives, usually on an as-needed basis (Lamy and Krug, 1978). Comorbidities and medication use explain much of the higher prevalence of constipation in older persons. However, the

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

traditional perceptions of constipation and aging no longer hold; the healthy older person is not predestined to develop constipation.

Elders' perceptions of what constitutes constipation differ from that of their physicians. Rather than reduced frequency, the presence of straining and hard bowel movements correlate most closely with self-reports of constipation in elders (Harari *et al.*, 1997). Bowel frequency clearly provides an inadequate measure of constipation in elders. Elders report a high prevalence of straining and defecatory difficulty (Harari *et al.*, 1996; Whitehead *et al.*, 1989). Population-based prevalence of constipation has been reported at 40% of community-dwelling adults over the age of 64 (Talley *et al.*, 1996). The risk factor most commonly reported for constipation is medication use, including nonsteroidal anti-inflammatory drugs (Talley *et al.*, 1996).

Despite the lack of difference in risk factor–adjusted constipation rates between elders and younger individuals, elders more frequently use laxatives. Up to 50% of elder women reporting use laxatives, typically due to difficulties with straining, rather than to infrequent defecation. Overall, 20–30% of community-dwelling elders use laxatives on at least a weekly basis. In nursing homes, 58% of residents receive laxatives on at least an intermittent basis (Lamy and Krug, 1978). Few economic studies in the United States outline the costs of laxative use by elders. One study in the United Kingdom estimated the annual cost to the National Health Service for prescription laxatives at 43 million pounds (Petticrew *et al.*, 1997). Most elders self-treat with over-the-counter products; thus, the economic impact of laxative use is likely considerably higher than this estimate.

The findings of similar stool frequency but increased defecatory difficulty parallel the reported physiologic changes occurring with the digestive tract with aging. Colon transit overall is generally well preserved with aging in humans (Melkersson *et al.*, 1983). Changes in pelvic floor function may contribute to defecatory difficulty, with older women demonstrating reduced opening of the anorectal angle and a greater degree of perineal descent compared to younger women (Bannister *et al.*, 1987). Pudendal neuropathy also occurs more commonly with aging and may negatively affect pelvic floor function (Pfeifer *et al.*, 1997). Other factors correlated with constipation in aging include reduced caloric intake, use of multiple medications, hemorrhoids, and pain in the abdomen (Towers *et al.*, 1994; Stewart *et al.*, 1992). Many diseases occurring more commonly in elders also contribute to the development of constipation, such as diabetes mellitus, Parkinson's disease, and stroke (Bytzer *et al.*, 2001; Doshi *et al.*, 2003; Quigley, 1996). Prior surgery may also affect bowel function in elders. In women over 50 years, hysterectomy results in prolonged colon transit time and greater complaints of constipation and straining than in controls (Heaton *et al.*, 1993). Since aging alone has little influence on the development of constipation, when complaints of constipation occur in elders, it commonly relates to medical comorbidities and increased defecatory difficulty.

The consequences of constipation in elders make it a significant health problem. The presence of chronic constipation impacts functioning in daily living, and elders with these complaints rate their health lower than people without gastrointestinal symptoms (O'Keefe *et al.*, 1995). These findings were not confounded by the presence of other chronic illnesses or medication use. Health-related quality of life is reduced in patients with chronic constipation (Glia and Lindberg, 1997). The presence of constipation has also been hypothesized to increase urinary tract symptoms, with treatment of constipation resulting in reduced urinary frequency, urgency, and dysuria (Charach *et al.*, 2001). Constipation is also associated with bowel incontinence and treatment of constipation reduces incontinence episodes (Lynch *et al.*, 2001; Chassagne *et al.*, 2000). Immobile or cognitively impaired individuals with constipation face an increased risk of fecal impaction and stercoral ulceration (Lynch *et al.*, 2001; Maull *et al.*, 1982). Constipation reduces quality of life and diminishes self-perceived health in community-dwelling elders (O'Keefe *et al.*, 1995). Effective strategies are needed for reducing the burden of illness and costs associated with constipation.

ETIOLOGY OF CONSTIPATION

Of the multiple causes of constipation in older persons, most relate to medication use or coexistent medical illness (Tables 1 and 2). The most commonly implicated medications are opiates, nonsteroidal anti-inflammatory drugs, and medications with anticholinergic effects. Although immobility, reduced fluid, and fiber intake are often implicated in the development of constipation, there exists little evidence to support this folklore. Increased physical activity does not reliably improve constipation (Meshkinpour *et al.*, 1998). Reduced caloric intake correlates more closely with constipation in elders than do differences in fiber intake (Towers *et al.*, 1994). Likewise, reduced liquid intake does not appear to cause constipation in most elders (Whitehead *et al.*, 1989). Increased psychological distress correlates with reports of constipation by elders, although the mechanism for this association remains unknown (Whitehead *et al.*, 1989; Towers *et al.*, 1994).

Table 1 Medications commonly associated with constipation

Antidepressants (SSRIs and TCAs)
Antihistamines
Antipsychotics
Bromocriptine
Calcium channel blockers
Calcium supplements
Diuretics
Ferrous gluconate and ferrous sulfate
Levo-dopa
Nonsteroidal anti-inflammatory drugs
Opiates

SSRI, Selective Serotonin Reuptake Inhibitors; TCA, Tricyclic Antidepressants.

Table 2 Medical conditions commonly associated with constipation

Mechanical obstruction
Colonic neoplasia
Colonic stricture (intrinsic or extrinsic)
Anal stenosis
Metabolic
Amyloidosis
Chronic renal failure
Diabetes mellitus
Electrolyte disturbance (hypercalcemia, hypomagnesemia)
Hyperparathyroidism
Hypothyroidism
Scleroderma
Neurologic
Autonomic neuropathy
Cerebrovascular accident
Dementia
Parkinson's disease
Psychiatric
Depression

CLINICAL APPROACH

History

The evaluation of constipation begins first with understanding the patients' perspective on their altered bowel function and the time course of constipation development. The acute or subacute onset of constipation requires a more aggressive diagnostic approach to exclude structural lesions, including colon neoplasia, stricture, and volvulus. Likewise, the presence of weight loss, rectal bleeding, history of inflammatory bowel disease, family history of colorectal neoplasia, or presence of iron deficiency anemia requires a structural examination to exclude cancer or other etiology. Additional helpful details in the patient history include onset of constipation, frequency of bowel movements, sensation of incomplete evacuation, straining to defecate, consistency of the stool, associated abdominal pain, the need for digitation, perineal splinting, or unusual postures for defecation to occur, episodes of bowel incontinence, prior abdominal or pelvic surgery, prior abdominal or pelvic radiation therapy, and prior pregnancies. It is also necessary to review current medications and supplements, current and previously used laxatives with their degree of effectiveness, use of enemas, and use of complementary therapies to treat constipation (e.g. high colonics, herbs, teas, etc.). Dietary history includes a general survey of calories ingested, fiber intake, and restricted foods. Given the consistent association of constipation with depression and anxiety, a brief psychological assessment is also warranted. In general, the ideal, evidence-based approach to the diagnostic evaluation of constipation remains to be identified.

Physical Examination

The physical examination is directed to identifying underlying medical causes for constipation, excluding fecal impaction and providing a preliminary assessment of anorectal function. A fecal mass may be palpable on abdominal palpation. Rectal examination includes inspection of the perineum at rest and with strain. Normal perineal descent during strain is 1–4 cm. No perineal descent suggests failure of the pelvic floor to relax and allow the passage of stool. Excessive perineal descent, sometimes characterized as a ballooning of the perineum, indicates excess laxity to the pelvic floor musculature and dyssynergic defecation. This finding is most common in multiparous women. The strength of the anal sphincter muscle at rest and with squeeze is assessed. Puborectalis and anal sphincter relaxation during strain provide a measure of the appropriateness of pelvic floor function. Failure of relaxation or very high anal sphincter resting pressure suggests dyssynergic defecation. The presence of weak anal sphincter pressures may place the patient at risk for incontinence during treatment of the constipation. Rectal prolapse can be associated with difficult evacuation due to blockage of the anal canal with rectum. These patients usually also described episodes of bowel incontinence. A more severe rectal prolapse can be identified during strain in the left lateral decubitus position. A better way to assess for rectal prolapse is to have the patient strain over a commode. The examiner places a gloved hand below anus and can feel the rectal prolapse descend and touch the glove. The degree of rectal prolapse can be assessed by visual inspection. The physical examination, including rectal exam, is a necessary part of the evaluation of any constipated patient.

Diagnostic Tests

Laboratory tests often recommended in the evaluation of constipation include a complete blood count, metabolic panel that includes electrolytes, creatinine, magnesium and calcium, and sensitive thyroid-stimulating hormone (sTSH). Stool examination for occult blood should be assessed. The need for a colonic structural examination is dictated by the need for routine colorectal screening, presence of worrisome signs such as bleeding or anemia or recent change in bowel habit. The yield of colonoscopy in identifying neoplasia is no different in the individual with constipation compared to what would be identified in an asymptomatic population undergoing screening. Many patients with long-standing constipation and no warning symptoms can undergo a therapeutic trial with fiber or an osmotic laxative, preserving further evaluation for those who fail to respond to simple interventions.

Patients with more severe or medication-unresponsive constipation may benefit from further evaluation, including physiologic testing. It is difficult to predict the underlying pathophysiology of chronic constipation by symptoms alone (Glia *et al.*, 1999). The presence of slow transit constipation or dyssynergic defecation may be suspected by a poor response to a trial of supplemental fiber (Voderholzer *et al.*, 1997). Additional tests include colon transit measurement, colonic manometry, anorectal manometry, balloon expulsion testing, and defecography. Colonic transit measurements may

be performed scintigraphically or using radio-opaque markers and plain abdominal radiographs. Practically, few centers have scintigraphy readily available. A variety of techniques have been described for measuring colonic transit using radio-opaque markers, some providing data on regional colon transit. Since treatments have not yet been identified to treat regional colonic abnormalities, total colon transit measurements suffice. The 5-day colon transit measurement involves ingestion of a commercially available capsule containing 24 radio-opaque markers (Sitzmark®) and performing a plain abdominal radiograph 5 days later (Hinton *et al.*, 1969). Transit is considered prolonged when five or more markers remain (Figure 1). Although markers remaining predominantly in the rectum suggest dyssynergic defecation or outlet dysfunction, the distribution pattern of the markers throughout the colon does not reliably differentiate between primary slow transit versus colon transit delayed as a result of outlet dysfunction (i.e. dyssynergic defecation).

Dyssynergic defecation refers to physiologic difficulty with the rectal evacuation process. Synonyms include pelvic outlet dysfunction, pelvic floor dysfunction, anismus, and paradoxical puborectalis contraction. Uncommonly, difficult rectal evacuation may be due to an anal stricture, obstructing rectocele, or internal intussusception. The latter two findings are most often the result of abnormal straining, rather than a primary problem themselves. The presence of dyssynergic defecation can be evaluated by anorectal manometry, electromyography of the anal sphincter, balloon defecation, and defecography. Anorectal manometry involves measuring the pressures of the anal sphincter with a manometric probe in response to different maneuvers, including straining. During strain, a rise should occur in intrarectal pressure and the anal sphincter should relax. The presence of a paradoxical increase in sphincter pressure suggests the possibility of dyssynergic defecation. False positives occur at least 10% of the time with all tests of pelvic floor function. Thus, two tests that independently confirm the same findings are required to make a secure diagnosis of dyssynergic defecation. Balloon expulsion testing is performed by placing a small balloon in the rectum and filling the balloon with 50–60 cc of warm water. The patient is asked to sit on a commode and expel the balloon. Normal expulsion occurs in 60 seconds or less. A prolonged time or failure to expel the balloon suggests dyssynergic defecation (Beck, 1992). Anorectal manometry and balloon expulsion testing are the most commonly performed tests to identify dyssynergic defecation. Electromyography will also assess for proper anal sphincter muscle relaxation and contraction. The need to place needles in the anal sphincter has made this technique less attractive for most patients. Defecography involves placing a paste in the rectum. The patient sits on a commode and radiographs are obtained during defecation. Defecography assesses the opening of the anorectal angle, provides an assessment of sphincter opening, perineal descent, and rectal emptying. Defecography typically is reserved for cases where an underlying structural abnormality is suspected or when other tests for dyssynergic defecation are equivocal. Additional physiologic tests of colon transit and pelvic floor function are required in only the subset of patients refractory to medical management. Even in this highly selected group of patients, an abnormality is identified only 50% of the time (Surrenti *et al.*, 1995). Patients with refractory symptoms and normal physiologic studies are defined as having "normal transit constipation". Many of these patients meet criteria for IBS, particularly if their symptoms have been long standing.

Figure 1 An abdominal radiograph obtained 5 days after ingestion of a capsule containing 24 radiopaque (small circles) markers. The presence of 16/24 markers on day 5 indicates the presence of slow colonic transit. The majority of the markers reside in the rectum with a few markers scattered in the sigmoid and descending colon

TREATMENT

The initial treatment strategy for constipation nearly always includes the ingestion of more dietary or supplemental fiber. Increased fiber intake improves stool consistency and accelerates colon transit in many individuals (Badiali *et al.*, 1995). However, constipated elders actually consume more fiber at baseline than nonconstipated controls (Johnson *et al.*, 1988). Nonetheless, fiber generally provides a safe, inexpensive first-line approach. Increased fluid intake is also frequently recommended. While this may have value in the dehydrated patient, increasing fluid intake in chronic constipation rarely improves constipation symptoms (Muller-Lissner *et al.*, 2005). Likewise, increased physical activity is also recommended without clear evidence of efficacy (Muller-Lissner *et al.*, 2005; Meshkinpour *et al.*, 1998). General nonpharmacologic advice given first line includes information

Table 3 Agents used in the treatment of constipation

Agent	Usual dosages
Fiber	
Oat bran	1–6 tbsp in divided dosages mixed with food
Psyllium	1–2 tbsp PO 1 to 4 times /day
Methylcellulose	1 heaping tbsp (2 g) PO 1–3 times /day
Osmotic laxatives	
Lactulose	15–60 ml PO in divided doses
Sorbitol 70% solution	15–150 PO in divided doses
Magnesium citrate	120 to 300 ml PO in divided doses daily
Magnesium hydroxide	15–60 ml PO at bedtime
Polyethylene glycol	17 g PO daily
Stimulant laxatives	
Senna	8.6 g–17.2 g PO daily
Castor oil	15–60 ml PO times one
Bisacodyl	10–30 ml PO daily
Enemas	
Tap water	500–1000 ml up to twice weekly
Sodium biphosphate	1 or 2 enemas weekly
Oil retention	4.5 oz as needed up to 1 to 2 times weekly

about a normal bowel habit, ingestion of a healthy, fiber rich diet, and taking advantage of the meal-related increase in colonic motor activity. Given the strong association of constipation in older persons with medication use, elimination or adjustments should be made in medications, substituting less constipating alternatives where possible. Agents used in the treatment of constipation are listed in Table 3.

Pharmacologic Management

Bulking Agents

Bulking agents commonly used include wheat or oat bran, psyllium, calcium polycarbophil, carboxymethylcellulose, and partially hydrolyzed guar gum. There are few high-quality randomized controlled studies assessing the efficacy of these agents. Studies with psyllium generally show improved stool form and frequency (Ashraf *et al.*, 1995; Cheskin *et al.*, 1995). Studies assessing the efficacy of wheat bran, oat bran, calcium polycarbophil, carboxymethylcellulose, and partially hydrolyzed guar gum are inadequate for assessing the efficacy of these agents.

Stool Softeners

Stool softeners such as dioctyl sodium sulphosuccinate (Colace®) or dioctyl calcium sulphosuccinate (Surfak®) are reported to soften the stool, easing defecation. Despite the widespread use of these agents, there are no randomized controlled trials showing efficacy. One study comparing dioctyl sodium sulphosuccinate to placebo showed no improvement in stool frequency or consistency (Castle *et al.*, 1991). Another study comparing dioctyl sodium sulphosuccinate to psyllium found psyllium to be superior (McRorie *et al.*, 1998). The therapeutic use of stool softeners appears limited for the treatment of chronic constipation.

Osmotic Laxatives

Osmotic laxatives improve stool form and bowel movement frequency by increasing the amount of water retained in the lumen of the gut. Polyethylene glycol (PEG) and lactulose have therapeutic value in the treatment of constipation. Other osmotic laxatives include sorbitol, magnesium salts, and saline salts. Polyethylene glycol, lactulose, and sorbitol have the greatest safety margins. Use of saline or magnesium salts comes with a risk for significant electrolyte disturbance, especially in older persons. Elders with normal renal function may become hypermagnesemic with chronic use, especially at higher doses (Golzarian *et al.*, 1994). Magnesium salts should not be used in renal disease and saline salts should be avoided in chronic renal failure, end stage liver disease, and heart failure. Polyethylene glycol appears to be the best tolerated overall in elders. Lactulose and sorbitol undergo bacterial metabolism in the gut, leading to increased symptoms of bloating, abdominal cramping, and flatulence in some patients.
