Long-term anticoagulation may be necessary for patients with recurrent thrombotic episodes. In patients with bone marrow failure, treatment options include immunosuppression with antilymphocyte globulin, ciclosporin, or bone marrow transplantation. Bone marrow transplantation has been successfully carried out using either HLA-matched sibling donors in patients under the age of 50 or matched unrelated donors in patients under the age of 25.

The course of PNH is variable. PNH may transform into aplastic anaemia or acute leukaemia, but it may remain stable for many years and the PNH clone may even disappear, which must be taken into account if considering potentially dangerous treatments such as bone marrow transplantation. The median survival is 10-15 years.

Gene therapy will perhaps be possible in the future.

^ .....

Red cells may be injured by physical trauma in the circulation. Direct injury may cause immediate cell lysis or be followed by resealing of the cell membrane with the formation of distorted red cells or 'fragments'. These cells may circulate for a short period before being destroyed prematurely in the reticuloendothelial system.

The causes of mechanical haemolytic anaemia include:

- damaged artificial heart valves
- march haemoglobinuria, where there is damage to red cells in the feet associated with prolonged marching or running
- microangiopathic haemolytic anaemia (MAHA), where fragmentation of red cells occurs in an abnormal microcirculation caused by malignant hypertension, eclampsia, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, vasculitis or disseminated intravascular coagulation.

MYELOPROLIFERATIVE DISORDERS

In these disorders there is uncontrolled clonal proliferation of one or more of the cell lines in the bone marrow, namely erythroid, myeloid and megakaryocyte lines. Myeloproliferative disorders include polycythaemia vera (PV), essential thrombocythaemia (ET), myelofibrosis and chronic myeloid leukaemia (CML). These disorders are grouped together as there can be transition from one disease to another; for example PV can lead to myelofibrosis. They may also transform to acute myeloblastic leukaemia. The non-leukaemic myeloproliferative disorders (PV, ET and myelofibrosis) will be discussed in this section. Chronic myeloid leukaemia is described on page 505.

POLYCYTHAEMIA

Polycythaemia (or crythrocytosis) is defined as an increase in haemoglobin, PCV and red cell count. PCV is a more reliable indicator of polycythaemia than is Hb, which may be disproportionately low in iron deficiency. Polycythaemia can be divided into absolute erythrocytosis where there is a true increase in red cell volume, or relative erythrocytosis where the red cell volume is normal but there is a decrease in the plasma volume (see Fig. 8.6).

Absolute erythrocytosis is due to primary polycythaemia (PV) or secondary polycythaemia. Secondary polycythaemia is due to either an appropriate increase in red cells in response to anoxia, or an inappropriate increase associated with tumours, such as a renal carcinoma. The causes of polycythaemia are given in Table 8.16.

Primary polycythaemia: polycythaemia vera (PV)

PV is a clonal stem cell disorder in which there is an alteration in the pluripotent progenitor cell leading to excessive proliferation of erythroid, myeloid and megakaryocytic progenitor cells. This is partly due to a failure of apoptosis as a result of deregulation of the *Bcl-x* gene (opposes programmed cell death, p. 162), in addition a mutation in the JAK2 protein has been found; this stimulates low grade erythropoeisis.

Clinical features

The onset is insidious. It usually presents in patients aged over 60 years with tiredness, depression, vertigo, tinnitus and visual disturbance. It should be noted that these symptoms are also common in the normal population

over the age of 60 and consequently PV is easily missed. These features, together with hypertension, angina, intermittent claudication and a tendency to bleed, are suggestive of PV.

Severe itching after a hot bath or when the patient is warm is common. Gout due to increased cell turnover may be a feature, and peptic ulceration occurs in a minority of patients. Thrombosis and haemorrhage are the major complications of PV.

The patient is usually plethoric and has a deep dusky cyanosis. Injection of the conjunctivae is commonly seen. The spleen is palpable in 70% and is useful in distinguishing PV from secondary polycythaemia. The liver is enlarged in 50% of patients.

Investigations

- **Hb and PCV** are increased. The WBC is raised in about 70% of cases of PV and the platelet count is elevated in about 50%.
- **Bone marrow** shows erythroid hyperplasia and increased numbers of megakaryocytes.
- **Red cell volume** measured using ^{51}Cr-labelled red cells is increased (> 36 mL/kg in males and 32 mL/kg in females).
- **Plasma volume** shows normal or increased values (normal range is 45 ± 5 mL/kg).
- **Serum uric acid** levels may be raised.
- **Leucocyte alkaline phosphatase** (LAP) score is usually high.
- **Serum vitamin B_{12} and vitamin B_{12}-binding protein** transcobalamin I (TC I) levels may be high, although these are not routinely measured.

Differential diagnosis

An increase in the red cell volume should be established. Raised WBC and platelet counts with splenomegaly makes a diagnosis of PV very likely. The principal secondary causes can often be excluded by the history and examination, but a renal ultrasound, an arterial Po_2 and carboxyhaemoglobin levels are of additional help.

The serum erythropoietin level is not diagnostic but may be helpful in distinguishing PV from secondary polycythaemia. In PV the level is low or normal, whereas in secondary polycythaemia the level may be raised, as expected, but also can be normal.

Course and management

Treatment is designed to maintain a normal blood count and to prevent the complications of the disease, particularly thromboses and haemorrhage. *Treatment* is aimed at keeping the PCV below 0.45 L/L and the platelet count below 400 x 10^9/L. There are three types of specific treatment:

- **Venesection.** This will successfully relieve many of the symptoms of PV. Iron deficiency limits erythropoiesis. Venesection is often used as the sole treatment and other therapy is reserved to control the thrombocytosis.
- **Chemotherapy.** Continuous or intermittent treatment with hydroxycarbmide (hydroxyurea) is used frequently because of the ease of controlling thrombocytosis and general safety in comparison to the alkylating agents such as busulfan, which carry an increased risk of acute leukaemia. Low-dose intermittent busulfan may be more convenient for elderly people, and this must be weighed against the potential risk of long-term complications.
- **Radioactive ^{32}P.** One dose may give control for up to 18 months, but the administration of ^{32}P carries an increased risk of transformation to acute leukaemia. ^{32}P is confined to the over-70 years age group.

General treatment

Allopurinol is given to block uric acid production. Low-dose aspirin (100 mg daily) can safely prevent thrombotic complications in treated patients. The pruritus is lessened by avoiding very hot baths. Hj-receptor antagonists have largely proved unsuccessful in relieving distressing pruritus, but H_2-receptor antagonists such as cimetidine are occasionally effective.

Patients with uncontrolled PV have a high operative risk; 75% of patients have severe haemorrhage following surgery and 30% of these patients die. Polycythaemia should be controlled before surgery. In an emergency, reduction of the haematocrit by venesection and appropriate fluid replacement must be carried out.

Prognosis

PV develops into myelofibrosis in 30% of cases and into acute myeloblastic leukaemia in 5% as part of the natural history of the disease.

Secondary polycythaemias

Many high-oxygen affinity haemoglobin mutants (HOAHM) have been described which lead to increased oxygen affinity but decreased oxygen delivery to the tissues, resulting in compensatory polycythaemia. A congenital (autosomal recessive disorder - Chuvasch polycythaemia) is due to a defect in the oxygen-sensing erythropoietin production pathway caused by a mutation of the von Hippel—Lindau (VHL) gene, resulting in an increased production of erythropoietin.

The causes of secondary polycythaemias are shown in Table 8.16.

The treatment is that of the precipitating factor; for example, renal or posterior fossa tumours need to be resected. Heavy smoking can produce as much as 10% carboxyhaemoglobin and this can produce polycythaemia because of a reduction in the oxygen-carrying capacity of the blood. Complications of secondary polycythaemia are similar to those seen in PV, including thrombosis, haemorrhage and cardiac failure, but the complications due to myeloproliferative disease such as progression to myelofibrosis or acute leukaemia do not develop. Venesection may be symptomatically helpful in the hypoxic patient, particularly if the PCV is above 0.55 L/L.

'Relative' or 'apparent' polycythaemia (Gaisbock's syndrome)

This condition was originally thought to be stress-induced. The red cell volume is normal, but as the result of a decreased plasma volume, there is a relative polycythaemia. 'Relative' polycythaemia is more common than PV and occurs in middle-aged men, particularly in smokers who are obese and hypertensive. The condition may present with cardiovascular problems such **as** myocardial or cerebral ischaemia. For this reason, it may be justifiable to venesect the patient. Smoking should be stopped.

Essential thrombocythaemia (ET)

ET is closely related to PV. The platelet count is usually > 1000 x 10^9/L. It presents with bruising, bleeding and cerebrovascular symptoms. Initially splenic hypertrophy may be seen but, as the condition progresses, recurrent thromboses owing to the increased number of platelets reduce the size of the spleen and it may atrophy.

ET should be distinguished from secondary thrombocytosis that is seen in haemorrhage, connective tissue disorders, malignancy, after splenectomy and in other myeloproliferative disorders.

Treatment is with hydroxycarbamide (hydroxyurea), anagrelide or busulfan to control the platelet count to less than 400 x 10^9/L.

a-Interferon is also effective but it is expensive and is administered by subcutaneous injection. ET may eventually transform into PV, myelofibrosis or acute leukaemia, but the disease may not progress for many years.

MYELOFIBROSIS (MYELOSCLEROSIS)

The terms myelosclerosis and myelofibrosis are interchangeable. There is clonal proliferation of stem cells and myeloid metaplasia in the liver, spleen and other organs. Increased fibrosis in the bone marrow is caused by hyperplasia of abnormal megakaryocytes which release fibroblast-stimulating factors such as platelet-derived growth factor. In about 25% of cases there is a preceding history of PV.

Clinical features

The disease presents insidiously with lethargy, weakness and weight loss. Patients often complain of a 'fullness' in the upper abdomen due to splenomegaly. Severe pain related to respiration may indicate perisplenitis secondary to splenic infarction, and bone pain and attacks of gout can complicate the illness. Bruising and bleeding occur because of thrombocytopenia or abnormal platelet function. Other physical signs include anaemia, fever and massive splenomegaly (for other causes, see p. 457).

Investigations

- **Anaemia** with leucoerythroblastic features is present (p. 464). Poikilocytes and red cells with characteristic tear-drop forms are seen. The WBC count may be over 100 x lO'/L, and the differential WBC count may be very similar to that seen in chronic myeloid leukaemia (CML); later leucopenia may develop.
- **The platelet count** may be very high, but in later stages, thrombocytopenia occurs.
- **Bone marrow aspiration** is often unsuccessful and this gives a clue to the presence of the condition. A bone marrow trephine is necessary to show the markedly increased fibrosis. Increased numbers of megakary ocytes may be seen.
- **The Philadelphia chromosome** is absent; this helps to distinguish myelofibrosis from most cases of CML.
- **The leucocyte alkaline phosphatase (LAP) score** is normal or high.
- **A high serum urate** is present.
- **Low serum folate** levels may occur owing to the increased haemopoietic activity.

Differential diagnosis

The major diagnostic difficulty is the differentiation of myelofibrosis from CML as in both conditions there may be marked splenomegaly and a raised WBC count with many granulocyte precursors seen in the peripheral blood. The main distinguishing features are the appearance of the bone marrow and the absence of the Philadelphia chromosome in myelofibrosis.

Fibrosis of the marrow, often with a leucoerythroblastic anaemia, can also occur secondarily to leukaemia or lymphoma, tuberculosis or malignant infiltration with metastatic carcinoma, or to irradiation.

Treatment

This consists of general supportive measures such as blood transfusion, folic acid, analgesics and allopurinol. Drugs such as hydroxycarbamide (hydroxyurea) and busulfan are used to reduce metabolic activity and high WBC count and platelet levels; hydroxycarbamide is the most common drug used. Chemotherapy and radiotherapy are used to reduce splenic size. If the spleen becomes very large and painful, and transfusion requirements are high, it may be advisable to perform splenectomy. Splenectomy may also result in relief of severe thrombocytopenia.

Prognosis

Patients may survive for 10 years or more; median survival is 3 years. Death may occur in 10-20% of cases from transformation to acute myeloblastic leukaemia. The most common causes of death are cardiovascular disease, infection and gastrointestinal bleeding.

MYELODYSPLASIA (MDS)

Myelodysplasia (MDS) describes a group of acquired bone marrow disorders that are due to a defect in stem cells. They are characterized by increasing bone marrow failure with quantitative and qualitative abnormalities of all three myeloid cell lines (red cells, granulocyte/monocytes and platelets). The natural history of MDS is variable, but there is a high morbidity and mortality owing to bone marrow failure, and transformation into

Table 8.17 **Classification of myelodysplasia (based on WHO and FAB)**

	Category	Peripheral blasts (%)	Bone marrow (%)	Median prognosis (months)
1a	Refractory anaemia (RA)	<1	Blasts < 5	50
2a	RA and ring sideroblasts (RARS)	<1	RS<15 Blasts < 5 RS> 15	= 50
3a	RA with excess blasts (RAEB) I	1-4	Blasts 5-10	10
3b	(RAEB-t) II	5-19	Blasts 11-19	5

In all categories, monocytes in the peripheral blood < 1.0 x 10^9/L
RS, ring sideroblasts; RAEB-t (in transformation) also includes the 5q syndrome (deletion of 5q~) - usually elderly females but with good prognosis

acute myeloblastic leukaemia occurs in about 30% of cases. A classification of the myelodsyplastic syndrome is shown in Table 8.17.

Clinical and laboratory features

MDS occurs mainly in the elderly, and presents with symptoms of anaemia, infection or bleeding due to pancytopenia. Serial blood counts show evidence of increasing bone marrow failure with anaemia, neutropenia, monocytosis and thrombocytopenia, either alone or in combination. In contrast, in chronic myelomonocytic leukaemias (CMML), monocytes are > 1 x 10^9/L and the WBC count may be > 100 x 10^9/L-

The bone marrow usually shows increased cellularity despite the pancytopenia. Dyserythropoiesis is present, and granulocyte precursors and megakaryocytes also have abnormal morphology. Ring sideroblasts are present in all types. In RAEB and RAEB-t, the number of blasts in the bone marrow is increased, and the prognosis is worse than in those types with a low number of blast cells (<5%).

Management

Patients with < 5% blasts in the bone marrow are usually managed conservatively with red cell and platelet transfusions and antibiotics for infections, as they are needed. Haemopoietic growth factors (e.g. erythropoietin, G-CSF) may be useful in some patients.

Patients with > 5% blasts have a less favourable prognosis, and a number of treatment options are available:

- **Supportive care** only is suitable for elderly patients with other medical problems.
- **'Gentle' chemotherapy** (low-dose or single-agent, e.g. azacytidine) may be useful in patients with high WBC counts.
- **Intensive chemotherapy** schedules used for acute myeloblastic leukaemia (see p. 504) may be tried in patients under the age of 60, but the remission rate is less, and prolonged pancytopenia may occur owing to poor haemopoietic regeneration because of the defect in stem cells.
- **Bone marrow transplantation** offers the hope of cure in the small proportion of MDS patients who are under the age of 50 and who have an HLA-identical sibling or an unrelated HLA-matched donor.

THE SPLEEN

The spleen is the largest lymphoid organ in the body and is situated in the left hypochondrium. There are two anatomical components:

- the red pulp, consisting of sinuses lined by endothelial macrophages and cords (spaces)
- the white pulp, which has a structure similar to lymphoid follicles.

Blood enters via the splenic artery and is delivered to the red and white pulp. During the flow the blood is 'skimmed', with leucocytes and plasma preferentially passing to white pulp. Some red cells pass rapidly through into the venous system while others are held up in the red pulp.

Functions

*Sequestration **and phagocytosis.*** Normal red cells, which are flexible, pass through the red pulp into the venous system without difficulty. Old or abnormal cells are damaged by the hypoxia, low glucose and low pH found in the sinuses of the red pulp and are therefore removed by phagocytosis along with other circulating foreign matter. Howell-Jolly and Heinz bodies and sideroblastic granules have their particles removed by 'pitting' and are then returned to the circulation. IgG-coated red cells are removed through their Fc receptors by macrophages.

Extramedullary haemopoiesis. Pluripotential stem cells are present in the spleen and proliferate during severe haematological stress, such as in haemolytic anaemia or thalassaemia major.

Immunological function. About 25% of the body's T lymphocytes and 15% of B lymphocytes are present in the spleen. The spleen shares the function of production of antibodies with other lymphoid tissues.

Blood pooling. Up to one-third of the platelets are sequestrated in the spleen and can be rapidly mobilized. Enlarged spleens pool a significant percentage (up to 40%) of the red cell mass.

SPLENOMEGALY

Causes

A clinically palpable spleen can have many causes.

- Infection:
  (a) acute - e.g. septic shock, infective endocarditis, typhoid, infectious mononucleosis
  (b) chronic - e.g. tuberculosis and brucellosis
  (c) parasitic - e.g. malaria, kala-azar and schistosomiasis.
- Inflammation: rheumatoid arthritis, sarcoidosis, SLE.
- Haematological: haemolytic anaemia, haemoglobinopathies and the leukaemias, lymphomas and myeloproliferative disorders.
- Portal hypertension: liver disease.
- Miscellaneous: storage diseases, amyloid, primary and secondary neoplasias, tropical splenomegaly.

Massive splenomegaly is seen in myelofibrosis, chronic myeloid leukaemia, chronic malaria, kala-azar or, rarely, Gaucher's disease.

Hypersplenism

This can result from splenomegaly due to any cause. It is commonly seen with splenomegaly due to haematological disorders, portal hypertension, rheumatoid arthritis (Felty's syndrome) and lymphoma. Hypersplenism produces:

- pancytopenia
- haemolysis due to sequestration and destruction of red cells in the spleen
- increased plasma volume.

Treatment is often dependent on the underlying cause, but splenectomy is sometimes required for severe anaemia or thrombocytopenia.

Splenectomy

Splenectomy is performed mainly for:

- trauma
- idiopathic thrombocytopenic purpura (p. 470)
- haemolytic anaemias (p. 441)
- hypersplenism.

Problems after splenectomy

An immediate problem is an increased platelet count (usually 600-1000 x 10^9/L) for 2-3 weeks. Thromboembolic phenomena may occur. In the longer term there is an increased risk of overwhelming infections, particularly pneumococcal infections.

***Box 8.1* Prophylaxis against infection after splenectomy or splenic dysfunction**

Vaccinate 2-3 weeks before elective splenectomy.

A 23-valent unconjugated pneumococcal polysaccharide vaccine repeated every 5 years Meningococcal group C conjugate vaccine Annual influenza vaccine *Haemophilus influenzae* type b (Hib) vaccine e Long-term penicillin V 500 mg 12-hourly (if sensitive, use erythromycin)

Meningococcal polysaccharide vaccine (ACWY) for travellers to Africa/Saudi Arabia, e.g. during Hajj and Umrah pilgrimages.

Prophylaxis against infection after splenectomy or splenic dysfunction (Box 8.1) All patients should be educated about the risk of infection and the importance of its early recognition and treatment. They should be given an information leaflet and should carry a card or bracelet to alert health professionals to their risk of overwhelming infection.

Postsplenectomy haematological features

- *Thrombocytosis* persists in about 30% of cases.
- *The WBC count* is usually normal but there may be a mild lymphocytosis and monocytosis.
- *Abnormalities in red cell morphology* are the most prominent changes and include Howell-Jolly bodies, Pappenheimer bodies (contain sideroblastic granules), target cells and irregular contracted red cells (see Fig. 8.28). Pitted red cells can be counted.

Splenic atrophy

This is seen in sickle cell disease due to infarction. It is also seen in coeliac disease, in dermatitis herpetiformis, and occasionally in ulcerative colitis and essential thrombocythaemia. Postsplenectomy haematological features are seen.

***Fig. 8.28* Postsplenectomy film with Howell-Jolly bodies (arrowed), target cells and irregularly contracted cells.**

BLOOD TRANSFUSION

The cells and proteins in the blood express antigens which are controlled by polymorphic genes; that is, a specific antigen may be present in some individuals but not in others. A blood transfusion may immunize the recipient against donor antigens that the recipient lacks (alloimmunization), and repeated transfusions increase the risk of the occurrence of alloimmunization. Similarly, the transplacental passage of fetal blood cells during pregnancy may alloimmunize the mother against fetal antigens inherited from the father. Antibodies stimulated by blood transfusion or pregnancy, such as Rhesus antibodies, are termed *immune* antibodies and are usually IgG, in contrast to *naturally occurring* antibodies, such as ABO antibodies, which are made in response to environmental antigens present in food and bacteria and which are usually IgM.

BLOOD GROUPS

The blood groups are determined by antigens on the surface of red cells; more than 400 blood groups have been found. The ABO and Rh systems are the two major blood groups, but incompatibilities involving many other blood groups (e.g. Kell, Duffy, Kidd) may cause haemolytic transfusion reactions and/or haemolytic disease of the newborn (HDN).

ABO system

This blood group system involves naturally occurring IgM anti-A and anti-B antibodies which are capable of producing rapid and severe intravascular haemolysis of incompatible red cells.

The ABO system is under the control of a pair of allelic genes, *H* and *h,* and also three allelic genes, *A, B* and O, producing the genotypes and phenotypes shown in Table 8.18. The A, B and H antigens are very similar in structure; differences in the terminal sugars determine their specificity. The *H* gene codes for enzyme *H,* which attaches fucose to the basic glycoprotein backbone to form H substance, which is the precursor for A and B antigens (Fig. 8.29).

Table 8.18 **The ABO system: antigens and antibodies**

Phenotype	Genotype	Antigens	Antibodies	Frequency UK (%)
0	00	None	Anti-A and anti-B	44
A	AAor AO	A	Anti-B	45
B	BB or BO	B	Anti-A	8
AB	AB	A and B	None	3

The *A* and *B* genes control specific enzymes responsible for the addition to H substance of N-acetylgalactosamine for Group A and D-galactose for Group B. The *O* gene is amorphic and does not transform H substance and therefore O is not antigenic. The A, B and H antigens are present on most body cells. These antigens are also found in soluble form in tissue fluids such as saliva and gastric juice in the 80% of the population who possess secretor genes.

Rh system

There is a high frequency of development of IgG RhD antibodies in RhD-negative individuals after exposure to RhD-positive red cells. The antibodies formed are of major importance in causing HDN and haemolytic transfusion reactions.

This system is coded by allelic genes, C and *c, E* and *e,* D and no D, which is signified as *d;* they are inherited as triplets on each chromosome, one from each pair of genes (i.e. *CDE/cde).* The presence of the d antigen has not been demonstrated and the presence or absence of the D antigen determines whether an individual is characterized as RhD positive or negative.

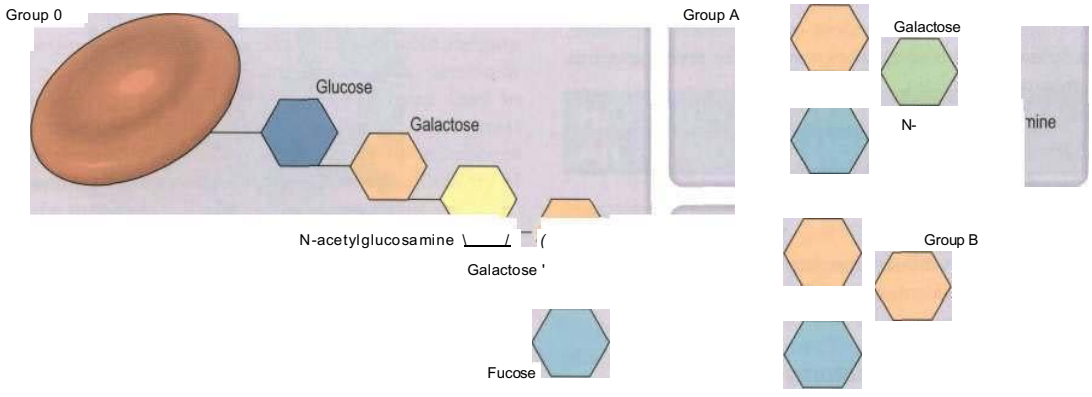

Fig. 8.29 **Sugar chains in the ABO blood group system.** Reproduced from Fricker J (1996) Conversion of red blood cells to group 0. *Lancet* 347: 680, © The Lancet Ltd. 1996.

PROCEDURE FOR BLOOD TRANSFUSION

The safety of blood transfusion depends on meticulous attention to detail at each stage leading to and during the transfusion. Avoidance of simple errors involving patient and blood sample identification at the time of collection of the sample for crossmatching and at the time of transfusion would avoid most serious haemolytic transfusion reactions, almost all of which involve the ABO system.

Pretransfusion compatibility testing

This involves a number of steps, outlined below.

Blood grouping

The ABO and RhD groups of the patient are determined.

Antibody screening

The patient's serum or plasma is screened for atypical antibodies that may cause a significant reduction in the survival of the transfused red cells. The patient's serum or plasma is tested against red cells from at least two group O donors, expressing a wide range of red cell antigens, for detection of IgM red cell alloantibodies (using a direct agglutination test of cells suspended in saline) and IgG antibodies (using an indirect antiglobulin test, see p. 449). About 10% of patients have a positive antibody screening result; in which case, further testing is carried out using a comprehensive panel of typed red cells to determine the blood group specificity of the antibody (clinically significant red cell antibodies are detected in about 20% of patients with positive antibody screens).

Selection of donor blood and crossmatching

Donor blood of the same ABO and RhD group as the patient is selected. Matching for additional blood groups is carried out for patients with clinically significant red cell antibodies (see below), for patients who are likely to be multitransfused and at high risk of developing antibodies, e.g. sickle cell disease, and many centres routinely provide c-negative and Kell-negative blood for women of child-bearing age to minimize the risk of alloimmunization and subsequent HDN.

Crossmatching procedures

Patients without atypical red cell antibodies. The full crossmatch involves testing the patient's serum or plasma against the donor red cells suspended in saline in a direct agglutination test, and also using an indirect antiglobulin test. In some hospitals the *serologicd crossmatch* has been omitted as the negative antibody screen makes it highly unlikely that there will be any incompatibility with the donor units. A greater risk is that of a transfusion error involving the collection of the patient sample or a mix-up of samples in the laboratory. Laboratories can use the blood bank computer to check its records of the patient and the donor units and authorize the release of the donor units if a number of criteria are met *(computer* or *electronic crossmatching),* including:

- The system is automated for ABO and RhD grouping and antibody screening including positive sample identification and electronic transfer of results.
- The antibody screening procedure conforms to national recommendations.
- The patient's serum or plasma does not contain clinically significant red cell antibodies.
- The release of ABO incompatible blood must be prevented by conformation of laboratory computer software to the following requirements:
  (a) the issue of blood is not allowed if the patient has only been grouped once
  (b) the issue of blood is not allowed if the current group does not match the historical record
  (c) the system must not allow the reservation and release of units which are ABO incompatible with the patient.
- The laboratory must assure the validity of the ABO and RhD group of the donor blood either by written verification from the National Blood Service or confirmatory testing in the laboratory; the UK National Blood Service guarantees that the blood group information is correct.

Alternatively, the crossmatch can be shortened to an immediate spin crossmatch where the patient's serum or plasma is briefly incubated with the donor red cells, followed by centrifugation and examination for agglutination; this rapid crossmatch is an acceptable method of excluding ABO incompatibility in patients known to have a negative antibody screen.

Patients with atypical red cell antibodies. Donor blood should be selected that lacks the relevant red cell antigen(s), as well as being the same ABO and RhD group as the patient. A full crossmatch should always be carried out.

Several other systems for blood grouping, antibody screening and crossmatching are available to hospital transfusion laboratories. They do not depend on agglutination of red cells in suspension, but rather on the differential passage of agglutinated and unagglutinated red cells through a column of dextran gel matrix (e.g. DiaMed, and Ortho Biovue systems), or on the capture of antibodies by red cells immobilized on the surface of a microplate well (e.g. Capture-R solid phase system).

Blood ordering

Elective surgery

Many hospitals have guidelines for the ordering of blood for elective surgery (maximum surgical blood ordering schedules). These are aimed at reducing unnecessary crossmatching and the amount of blood that eventually becomes outdated. Many operations in which blood is required only occasionally for unexpectedly high blood loss can be classified as 'group and save'; this means that, where the antibody screen is negative, blood is not reserved in advance but can be made available quickly if necessary, using serum or plasma saved in the laboratory.

If a patient has atypical antibodies, compatible blood should always be reserved in advance.

Emergencies

There may be insufficient time for full pretransfusion testing. The options include:

- Blood required immediately - use of 2 units of O RhD negative blood *('emergency stock')*, to allow additional time for the laboratory to group the patient.
- Blood required in 10-15 minutes - use of blood of the same ABO and RhD groups as the patient.
- Blood required in 45 minutes - most laboratories will be able to provide fully crossmatched blood within this time.

COMPLICATIONS OF BLOOD TRANSFUSION

(see Table 8.19)

In the United States, it has been mandatory to report transfusion-associated deaths to the Food and Drug Administration since 1975; such reports have provided useful data which have contributed to efforts to improve the safety of blood transfusion. Similar reporting schemes under the term *'haemovigilance'* have been set up in other countries, including the Serious Hazards of Transfusion (SHOT) scheme which produced its first report in the UK in 1997. Figure 8.30 shows the reports to SHOT in 2002/03, indicating that *'incorrect blood component transfused'* was the most frequent type of serious incident. Errors in collection and administration of blood were the commonest source of error followed by laboratory errors and mistakes in the prescription of blood or the collection of blood samples for compatibility testing. Death or serious morbidity can also be attributed to other complications of blood transfusion including transfusion-associated lung injury (TRALI), transfusion-associated graft-versus-host disease (TA-GvHD), and bacterial infection of blood components.

***Table 8.19* Complications of blood transfusion**

Immunological	Non-immunological
Alloimmunization and incompatibility	***Transmission of infection***
Red cells	Viruses:
Immediate haemolytic transfusion reactions	HAV, HBV, HCV
Delayed haemolytic transfusion reactions	HIV
Leucocytes and platelets	CMV, EBV, HTLV-1, West Nile virus
Non-haemolytic (febrile) transfusion reactions	Parasites:
Post-transfusion purpura	malaria, trypanosomiasis
Poor survival of transfused platelets and granulocytes	toxoplasmosis Bacteria

Immunological complications

Alloimmunization and incompatibility

Blood transfusion carries a risk of alloimmunization to the many 'foreign' antigens present on red cells, leucocytes, platelets and plasma proteins. Alloimmunization may also occur during pregnancy - to fetal antigens inherited from the father and not shared by the mother (p. 451).

Alloimmunization does not usually cause clinical problems with the first transfusion but these may occur with subsequent transfusions. There may also be delayed consequences of alloimmunization, such as HDN and rejection of tissue transplants.

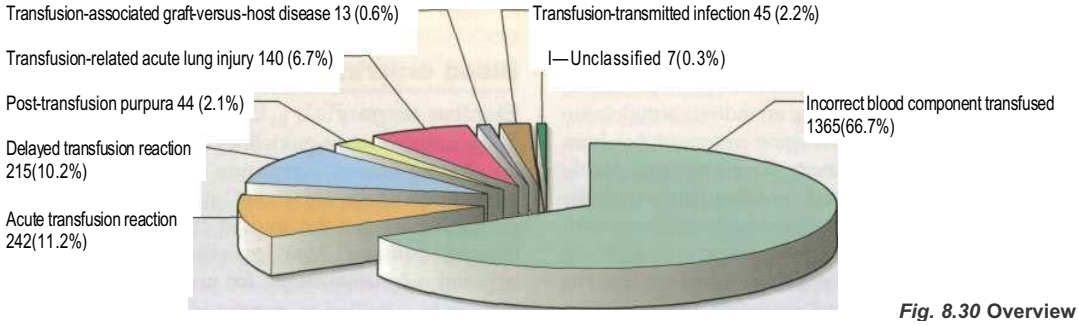

***Fig. 8.30* Overview of 2191 cases reported to the Serious Hazards of Transfusion (SHOT) scheme between 1996 and 2003.**

Incompatibility

This may result in poor survival of transfused cells, such as red cells and platelets, and also in the harmful effects of antigen-antibody reaction.

Red cells

Haemolytic transfusion reactions

Immediate reaction. This is the most serious complication of blood transfusion and is usually due to ABO incompatibility. There is complement activation by the antigen-antibody reaction, usually caused by IgM antibodies, leading to rigors, lumbar pain, dyspnoea, hypotension, haemoglobinuria and renal failure. The initial symptoms may occur a few minutes after starting the transfusion. Activation of coagulation may also occur and bleeding due to disseminated intravascular coagulation (DIC) is a bad prognostic sign. Emergency treatment may be needed to maintain the blood pressure and renal function.

Diagnosis

This is confirmed by finding evidence of haemolysis (e.g. haemoglobinuria), and incompatibility between donor and recipient. All documentation should be checked to detect errors such as:

- failure to check the identity of the patient when taking the sample for compatibility testing (i.e. sample from the wrong patient)
- mislabelling the blood sample with the wrong patient's name
- simple labelling or handling errors in the laboratory
- errors in the collection of blood, leading to delivery of the wrong blood to the ward/theatre
- failure to perform proper identity checks before the blood is transfused (i.e. blood transfused to the wrong patient).

The serious consequences of such failures emphasize the need for meticulous checks at all stages in the procedure of blood transfusion.

Investigations

To confirm where the error occurred, blood grouping should be carried out on:

- the patient's original sample (used for the compatibility testing)
- a new sample taken from the patient after the reaction
- the donor units.

At the first suspicion of any serious transfusion reaction, the transfusion should always be stopped and the donor units returned to the blood transfusion laboratory with a new blood sample from the patient to exclude a haemolytic transfusion reaction.

Delayed reaction. This may occur in patients alloimmunized by previous transfusions or pregnancies. The antibody level is too low to be detected by pretransfusion compatibility testing, but a secondary immune response occurs after transfusion, resulting in destruction of the transfused cells, usually by IgG antibodies.

Haemolysis is usually extravascular as the antibodies are IgG, and the patient may develop anaemia and jaundice about a week after the transfusion, although most of these episodes are clinically silent. The blood film shows spherocytosis and reticulocytosis. The direct antiglobulin test is positive and detection of the antibody is usually straightforward.

Leucocytes and platelets

Non-haemolytic (febrile) transfusion reactions

Febrile reactions are a common complication of blood transfusion in patients who have previously been transfused or pregnant. The usual causes are the presence of leucocyte antibodies in an alloimmunized recipient acting against donor leucocytes in red cell concentrates leading to release of pyrogens, or the release of cytokines from donor leucocytes in platelet concentrates. Typical signs are flushing and tachycardia, fever (> 38°C), chills and rigors. Aspirin may be used to reduce the fever, although it should not be used in patients with thrombocytopenia. The introduction of leucocyte-depleted blood in the UK, to minimize the risk of transmission of variant Creutzfeldt-Jakob disease (vCJD) by blood transfusion (see below), has reduced the incidence of febrile reactions.

Potent leucocyte antibodies in the plasma of donors, who are usually multiparous women, may cause severe pulmonary reactions (called transfusion-related acute lung injury or TRALI) characterized by dyspnoea, fever, cough, and shadowing in the perihilar and lower lung fields on the chest X-ray.

Plasma proteins

Urticaria and anaphylaxis

Urticarial reactions are often attributed to plasma protein incompatibility, but in most cases, they are unexplained. They are common but rarely severe; stopping or slowing the transfusion and administration of chlorphenamine (chorpheniramine) 10 mg i.v. are usually sufficient treatment.

Anaphylactic reactions (see p. 997) occasionally occur; severe reactions are seen in patients lacking IgA who produce anti-IgA that reacts with IgA in the transfused blood. The transfusion should be stopped and epinephrine (adrenaline) 0.5 mg i.m. and chlorphenamine lOmgi.v. should be given immediately; endotracheal intubation may be required. Patients who have had severe urticarial or anaphylactic reactions should receive either washed red cells, autologous blood, or blood from IgA-deficient donors for patients with IgA deficiency.

Non-immunological complications

Transmission of infection

Viral contamination: donor blood in the UK is currently tested for HBV, HCV, HIV-1 and HTLV-1. CMV-seronegative tested blood is given to immunosuppressed patients who are susceptible to acquiring CMV. Blood Services continue a vigilant search for new infectious

agents. Donor questionnaires now record recent travel to exclude possible risks of West Nile virus (WNV) and severe acute respiratory syndrome (SARS). Recently, WNV has been the causal agent of meningoencephalitis transmitted by transfusion or transplantation in the USA.

The incidence of transmission of HBV is about 1 in 900 000 units transfused, and it is less than 1 in 30 million units transfused for HCV since the introduction of testing minipools of donor plasma (48 donations per pool) for viral DNA.

In the UK the incidence of transmission of HIV by blood transfusion is extremely low - under 1 in 8 million units transfused. Prevention is based on self-exclusion of donors in 'high-risk' groups and testing each donation for anti-HIV.

There is still a potential risk of viral transmission from coagulation factor concentrates prepared from large pools of plasma. Measures for inactivating viruses such as treatment with solvents and detergents are undertaken. Viral transmission via blood transfusion is still a major issue in the developing world.

Bacterial contamination of blood components is rare but it is one of the most frequent causes of death associated with transfusion. Some organisms such as *Yersinia enterocolitica* can proliferate in red cell concentrates stored at 4°C, but platelet concentrates stored at 22°C are a more frequent cause of this problem. Systems to avoid bacterial contamination include automated culture systems and bacterial antigen detection systems, but none are currently in routine use in the UK.

Transfusion-transmitted syphilis is very rare in the UK. Spirochaetes do not survive for more than 72 hours in blood stored at 4° C, and each donation is tested using the *Treponema pallidum haemagglutination assay* (TPHA).

There continues to be concern about the risk of transmitting the prion protein causing vCJD (p. 60) by transfusion: a possible transmission occurred following a transfusion in 2003. A number of measures have been taken in the UK, including universal leucocyte depletion of blood components (in 1999) because the prion protein is thought to be primarily associated with lymphocytes. UK donor plasma is not used for the manufacture of blood products; imported plasma from the US is used instead. For children born after January 1 1996, fresh frozen plasma (FFP) is sourced from plasma (from unremunerated donors) imported from the USA, on the basis that exposure to bovine spongiform encephalitis (BSE) from food was eliminated by 1 January 1996. FFP for this group is treated with methylthioninium chloride (methylene blue) to inactivate viruses. Blood donors must not have had a blood transfusion since 1980.

While stringent measures are being taken to minimize the risk of transfusion-transmitted infection in the UK, it may never be possible to guarantee that donor blood is absolutely 'safe'. The current approach to the safety of blood components and plasma in the UK is extremely cautious, but it is not an absolute guarantee of safety. Clinicians should always carefully consider the patient's requirement for transfusion, and only transfuse if clinically appropriate.

Immunosuppression

Ever since observations were made of the favourable effect of transfusion on survival of subsequent renal allografts, the basis of transfusion-induced immunomodulation has been the subject of debate. It is assumed that allogeneic leucocytes are required to cause transfusion-induced immunosuppression, but the underlying mechanisms remain uncertain. There has been considerable interest in other clinical effects caused by transfusion-induced immunosuppression, such as postoperative infection and tumour recurrence.

Strategies for avoiding or reducing the use of blood transfusion should be used. These include stopping drug therapy that may cause bleeding and treatment of anaemia prior to surgery.

Strict criteria for the use of blood components and blood products must be in place.

Artificial haemoglobin solutions and other blood substitutes are in clinical trial. They have a short intravascular half-life, and are likely to find their initial clinical application in trauma and surgery.

Autologous transfusion

An alternative to using blood from volunteer donors is to use the patient's own blood. There are three types of autologous transfusion:

- *Predeposit.* The patient donates 2-5 units of blood at approximately weekly intervals before elective surgery.
- *Preoperative haemodilution.* One or two units of blood are removed from the patient immediately before surgery and retransfused to replace operative losses.
- *Blood salvage.* Blood lost during or after surgery may be collected and retransfused. Several techniques of varying levels of sophistication are available. The operative site must be free of bacteria, bowel contents and tumour cells.

There is little demand for pre-deposit autologous transfusion in the UK as blood is generally perceived as being 'safe'. Blood salvage is increasingly being used as a way of avoiding the use of donor blood. In developing countries, autologous blood and blood from relatives are commonly used.

BLOOD, BLOOD COMPONENTS AND BLOOD PRODUCTS

Most blood collected from donors is processed as follows:

- **Blood components,** such as red cell and platelet concentrates, fresh frozen plasma (FFP) and cryoprecipitate, are prepared from a single donation of blood by simple separation methods such as centrifugation and are transfused without further processing.
- **Blood products,** such as coagulation factor concentrates, albumin and immunoglobulin solutions, are prepared by complex processes using the plasma from many donors as the starting material (UK donor plasma is not used, see above).

In most circumstances it is preferable to transfuse only the blood component or product required by the patient (component therapy) rather than use whole blood. This is the most effective way of using donor blood, which is a scarce resource, and reduces the risk of complications from transfusion of unnecessary components of the blood.

Whole blood

The average volume of blood withdrawn is 470 mL taken into 63 mL of anticoagulant. Blood stored at 4°C has a 'shelf-life' of 5 weeks when at least 70% of the transfused red cells should survive normally. Whole blood is rarely used; packed cells or red cell concentrates plus crystalloid or colloid solutions are acceptable alternatives even for the management of acute blood loss.

Red *cell concentrates*

Virtually all the plasma is removed and is replaced by about 100 mL of an optimal additive solution, such as SAG-M, which contains sodium chloride, adenine, glucose and mannitol. The mean volume is about 330 mL. The PCV is about 0.57 L/L, but the viscosity is low as there are no plasma proteins in the additive solution, and this allows fast administration if necessary. All blood components (red cell and platelet concentrates, and plasma) are leucocyte-depleted in the UK by filtration within 48 hours of collection of the donor blood.

Washed red cell concentrates

These are preparations of red cells suspended in saline, produced by cell separators to remove all but traces of plasma proteins. They are used in patients who have had severe recurrent urticarial or anaphylactic reactions.

Platelet concentrates

These are prepared either from whole blood by centrifugation or by plateletpheresis of single donors using cell separators. They may be stored for up to 5 days at 22°C. They are used to treat bleeding in patients with severe thrombocytopenia, and prophylactically to prevent bleeding in patients with bone marrow failure.

Granulocyte concentrates

These are prepared from single donors using cell separators and are used for patients with severe neutropenia with definite evidence of bacterial infection. The numbers of granulocytes are increased by treating donors with G-CSF and steroids.

Fresh frozen plasma

FFP is prepared by freezing the plasma from 1 unit of blood at -30°C within 6 hours of donation. The volume is approximately 200 mL. FFP contains all the coagulation factors present in fresh plasma and is used mostly for replacement of coagulation factors in acquired coagulation factor deficiencies. For children, see p. 462.

Cryoprecipitate

This is obtained by allowing the frozen plasma from a single donation to thaw at 4-8°C and removing the supernatant. The volume is about 20 mL and it is stored at -30°C. It contains factor VIII:C, von Willebrand factor (vWF) and fibrinogen, and may be useful in DIC and other conditions where the fibrinogen level is very low. It is no longer used for the treatment of haemophilia A and von Willebrand's disease because of the greater risk of virus transmission compared with virus-inactivated coagulation factor concentrates.

Factor VIII and IX concentrates

These are freeze-dried preparations of specific coagulation factors prepared from large pools of plasma. They are used for treating patients with haemophilia and von Willebrand's disease, where recombinant coagulation factor concentrates are unavailable. Recombinant coagulation factor concentrates, where they are available, are the treatment of choice for patients with inherited coagulation factor deficiencies (see p. 472).

Albumin

There are two preparations:

- *Human albumin solution 4.5%,* previously called plasma protein fraction (PPF), contains 45 g/L albumin and 160 mmol/L sodium. It is available in 50,100, 250 and 500 mL bottles.
- *Human albumin solution 20%,* previously called 'salt-poor' albumin, contains approximately 200 g/L albumin and 130 mmol/L sodium and is available in 50 and 100 mL bottles.

Human albumin solutions are generally considered to be inappropriate fluids for acute volume replacement or for the treatment of shock because they are no more effective in these situations than synthetic colloid solutions such as polygelatins (Gelofusine) or hydroxyethyl starch (Haemaccel). However, albumin solutions are indicated for treatment of acute severe hypoalbuminaemia and as the replacement fluid for plasma exchange. The 20% albumin solution is particularly useful for patients with nephrotic syndrome or liver disease who are fluid overloaded and resistant to diuretics. Albumin solutions should not be used to treat patients with malnutrition or chronic renal or liver disease with low serum albumin.

Normal immunoglobulin

This is prepared from normal plasma. It is used in patients with hypogammaglobulinaemia, to prevent infections, and in patients with, e.g. idiopathic thrombocytopenia (p. 470).

Specific immunoglobulins

These are obtained from donors with high titres of antibodies. Many preparations are available, such as anti-D, anti-hepatitis B, and anti-varicella zoster.

THE WHITE CELL lso Ch. 41

The five types of leucocytes found in peripheral blood are neutrophils, eosinophils and basophils (which are all called *granulocytes)* and lymphocytes and monocytes. The development of these cells is shown in Figure 8.1.

NEUTROPHILS

The earliest morphologically **identifiable** precursors of neutrophils in the bone marrow are myeloblasts, which are large cells constituting up to 3.5% of the nucleated cells in the marrow. The nucleus is large and contains 2-5 nucleoli. The cytoplasm is scanty and contains no granules. Promyelocytes are similar to myeloblasts but have some primary cytoplasmic granules, containing enzymes such as myeloperoxidase. Myelocytes are smaller cells without nucleoli but with more abundant cytoplasm and both primary and secondary granules. Indentation of the nucleus marks the change from myelocyte to metamyelocyte. The mature neutrophil is a smaller cell with a nucleus with 2-5 lobes, with predominantly secondary granules in the cytoplasm which contain lysozyme, collagenase and lactoferrin.

Peripheral blood neutrophils are equally distributed into a circulating pool and a marginating pool lying along the endothelium of blood vessels. In contrast to the prolonged maturation time of about 10 days for neutrophils in the bone marrow, their half-life in the peripheral blood is extremely short, only 6-8 hours. In response to stimuli (e.g. infection, corticosteroid therapy) neutrophils are released into the circulating pool from both the marginating pool and the marrow. Immature white cells are released from the marrow when a rapid response (within hours) occurs in acute infection (described as a 'shift to the left' on a blood film).

Function

The prime function of neutrophils is to ingest and kill bacteria, fungi and damaged cells. Neutrophils are attracted to sites of infection or inflammation by chemotaxins. Recognition of foreign or dead material is aided by coating of particles with immunoglobulin and complement (opsonization) as neutrophils have Fc and C3b receptors (see p. 201). The material is ingested into vacuoles where it is subjected to enzymic destruction, which is either oxygen-dependent with the generation of hydrogen peroxide (myeloperoxidase) or oxygen-independent (lysosomal enzymes and lactoferrin). Leucocyte alkaline phosphatase (LAP) is an enzyme found in leucocytes. It is raised when there is a neutrophilia due to an acute illness. It is also raised in the polycythaemia and myelofibrosis and reduced inCML.

Neutrophil leucocytosis

A rise in the number of circulating neutrophils to > 10 x 10^9/L occurs in bacterial infections or as a result of tissue damage. This may also be seen in pregnancy, during exercise and after corticosteroid administration (Table 8.20). With any tissue necrosis there is a release of various soluble factors, causing a leucocytosis. Interleukin-1 is also released in tissue necrosis and causes a pyrexia. The pyrexia and leucocytosis accompanying a myocardial infarction are a good example of this and may be wrongly attributed to infection.

A leukaemoid reaction (an overproduction of white cells, with many immature cells) may occur in severe infections, tuberculosis, malignant infiltration of the bone marrow and occasionally after haemorrhage or haemolysis.

In leucoerythroblastic anaemia, nucleated red cells and white cell precursors are found in the peripheral blood. Causes include marrow infiltration with metastatic carcinoma, myelofibrosis, osteopetrosis, myeloma, lymphoma, and occasionally severe haemolytic or megaloblastic anaemia.

Neutropenia and agranulocytosis

Neutropenia is defined as a circulatory neutrophil count below 1.5 x 10^9/L. A virtual absence of neutrophils is called agranulocytosis. The causes are given in Table 8.21. It should be noted that black patients may have somewhat lower neutrophil counts. Neutropenia caused by viruses is probably the most common type. Chemotherapy

Inflammation, e.g. gout, rheumatoid arthritis
Drugs, e.g. corticosteroids, lithium
Haematological:
myeloproliferative disease
leukaemoid reaction
leucoerythroblastic anaemia Physiological, e.g. pregnancy, exercise Malignant disease, e.g. bronchial, breast, gastric
Metabolic, e.g. renal failure, acidosis Congenital, e.g. leucocyte adhesion deficiency, hereditary
neutrophilia

Table 8.21 Causes of neutropenia

Acquired
Viral infection
Severe bacterial infection, e.g. typhoid
Felty's syndrome
Immune neutropenia - autoimmune, autoimmune neonatal neutropenia Pancytopenia from any cause, including drug-induced marrow aplasia (see p. 435)
Pure white cell aplasia

Inherited
Ethnic (neutropenia is common in black races) Kostmann's syndrome (severe infantile agranulocytosis) Cyclical (genetic defect with neutropenia every 2-3 weeks) Others, e.g. Schwachman-Diamond syndrome, dyskeratosis congenita, Chediak-Higashi syndrome

and radiotherapy predictably produce neutropenia; many other drugs have been known to produce an idiosyncratic cytopenia and a drug cause should always be considered.

Clinical features

Infections may be frequent, often serious, and are more likely as the neutrophil count falls. An absolute neutrophil count of less than 0.5 x 10^9/L is regarded as 'severe' neutropenia and may be associated with life-threatening infections such as pneumonia and septicaemia. A characteristic glazed mucositis occurs in the mouth, and ulceration is common.

Investigations

The blood film shows marked neutropenia. The appearance of the bone marrow will indicate whether the neutropenia is due to depressed production or increased destruction of neutrophils. Neutrophil antibody studies are performed if an immune mechanism is suspected.

Treatment

Antibiotics should be given as necessary to patients with acute severe neutropenia (see p. 495).

If the neutropenia seems likely to have been caused by a drug, all current drug therapy should be stopped. Recovery of the neutrophil count usually occurs after about 10 days. G-CSF (see p. 421) is used to decrease the period of neutropenia after chemotherapy and haemopoietic transplantation. It is also used successfully in the treatment of chronic neutropenia.

Steroids and high-dose intravenous immunoglobulin are used to treat patients with severe autoimmune neutropenia and recurrent infections, and G-CSF has produced responses in some cases.

EOSINOPHILS

Eosinophils are slightly larger than neutrophils and are characterized by a nucleus with usually two lobes and large cytoplasmic granules that stain deeply red. The eosinophil plays a part in allergic responses (p. 200) and in the defence against infections with helminths and protozoa.

Table 8.22 Causes of eosinophilia

Parasitic infestations, such as:
Ascaris
Hookworm
Strongyloides

Allergic disorders, such as:
Hayfever (allergic rhinitis)
Other hypersensitivity reactions, including drug reactions

Skin disorders, such as:
Urticaria
Pemphigus
Eczema

Pulmonary disorders, such as:
Bronchial asthma
Tropical pulmonary eosinophilia Allergic bronchopulmonary aspergillosis Churg-Strauss syndrome

Malignant disorders, such as:
Hodgkin's lymphoma
Carcinoma Eosinophilic leukaemia

Miscellaneous, such as:
Hypereosinophilic syndrome
Sarcoidosis Hypoadrenalism
Eosinophilic gastroenteritis

Eosinophilia is > 0.4 x 10^9/L eosinophils in the peripheral blood. The causes of eosinophilia are listed in Table 8.22.

BASOPHILS

The nucleus of basophils is similar to that of neutrophils but the cytoplasm is filled with large black granules. The granules contain histamine, heparin and enzymes such as myeloperoxidase. The physiological role of the basophil is not known. Binding of IgE causes the cells to degranulate and release histamine and other contents involved in acute hypersensitivity reactions (p. 220).

Basophils are usually few in number (< 1 x 10^9/L) but are significantly increased in myeloproliferative disorders.

MONOCYTES

Monocytes are slightly larger than neutrophils. The nucleus has a variable shape and may be round, indented or lobulated. The cytoplasm contains fewer granules than neutrophils. Monocytes are precursors of tissue macrophages and spend only a few hours in the blood but can continue to proliferate in the tissues for many years.

A monocytosis (> 0.8 x 10^9/L) may be seen in chronic bacterial infections such as tuberculosis or infective endocarditis, chronic neutropenia and patients with myelodysplasia, particularly chronic myelomonocytic leukaemia.

LYMPHOCYTES

Lymphocytes form nearly half the circulating white cells. They descend from pluripotential stem cells (see Fig. 8.1).

Circulating lymphocytes are small cells, a little larger than red cells, with a dark-staining central nucleus. There are two main types: T and B lymphocytes (see p. 205).

Lymphocytosis (lymphocyte count > 5 x 10^9/L) occurs in response to viral infections, particularly EBV, CMV and HIV, and chronic infections such as tuberculosis and toxoplasmosis. It also occurs in chronic lymphocytic leukaemia and in some lymphomas.

HAEMOSTASIS AND THROMBOSIS

The integrity of the circulation is maintained by blood flowing through intact vessels lined by endothelial cells. Injury to the vessel wall exposes collagen and together with tissue injury sets in motion a series of events leading to haemostasis.

HAEMOSTASIS

Haemostasis is a complex process depending on interactions between the vessel wall, platelets and coagulation and fibrinolytic mechanisms. The formation of the haemostatic plug is shown in Figure 8.31.

Vessel wall

The vessel wall is lined by endothelium which, in normal conditions, prevents platelet adhesion and thrombus formation. This property is partly due to its negative charge but also to:

- thrombomodulin and heparan sulphate expression
- synthesis of prostacyclin (PGI_2) and nitric oxide (NO), which cause vasodilatation and inhibit platelet aggregation
- production of plasminogen activator.

Injury to vessels causes reflex vasoconstriction, while endothelial damage results in loss of antithrombotic properties, activation of platelets and coagulation and inhibition of fibrinolysis (Fig. 8.31).

Platelets

Platelet adhesion (Fig. 8.31a) to collagen is dependent on platelet membrane receptors: glycoprotein la (GPIa), which binds directly to collagen; and glycoprotein Ib (GPIb), which binds to von Willebrand factor (vWF) in the plasma, and vWF in turn adheres to collagen. Following adhesion, platelets undergo a shape change from a disc to a sphere, spread along the subendothelium and release the contents of their cytoplasmic granules, i.e. the dense bodies (containing ADP and serotonin) and the a-granules (containing platelet-derived growth factor, heparin antagonist (platelet factor 4), f5-thromboglobulin, fibrinogen, vWF, fibronectin, thrombospondin and other factors).

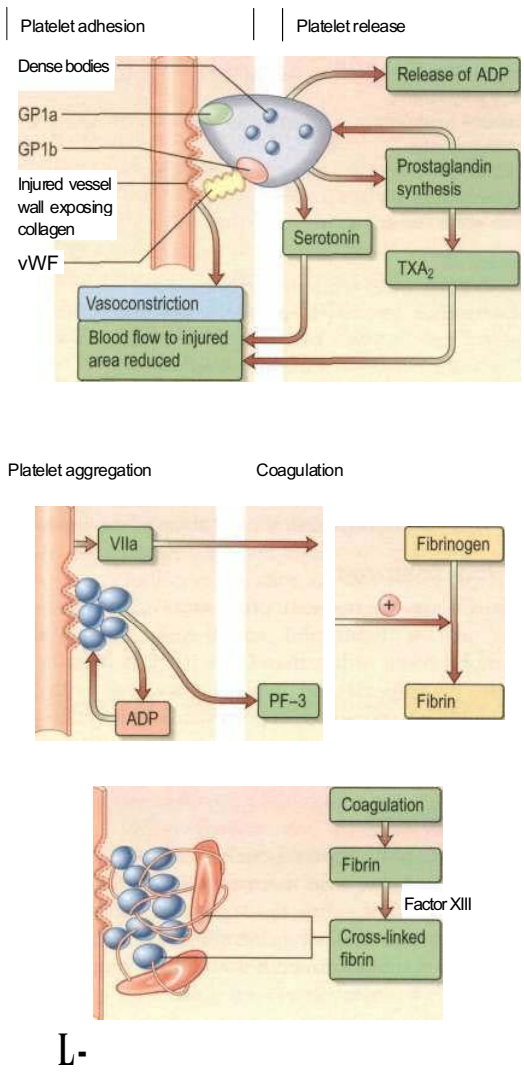

Fig. 8.31 **Formation of the haemostatic plug: sequential interactions between the vessel wall, platelets and coagulation factors.**
(a) Contact of platelets with collagen, either via the platelet receptor GPIb and factor vWF in plasma, or directly via GPIa, activates platelet prostaglandin synthesis which stimulates release of ADP from the dense bodies. Vasoconstriction of the vessel occurs as a reflex and by release of serotonin and thromboxane A_2 (TXA_2) from platelets.
(b) Release of ADP from platelets induces platelet aggregation and formation of the platelet plug. The coagulation pathway is stimulated leading to formation of fibrin.
(c) Fibrin strands are cross-linked by factor XIII and stabilize the haemostatic plug by binding platelets and red cells. PF-3, platelet factor-3 (platelet phospholipid).

Platelet release: the release of ADP leads to a conformational change in the fibrinogen receptor, the glycoprotein IIb-IIIa complex (GPIIb-IIIa), on the surfaces of adherent platelets allowing it to bind to fibrinogen (see also Fig. 8.39).

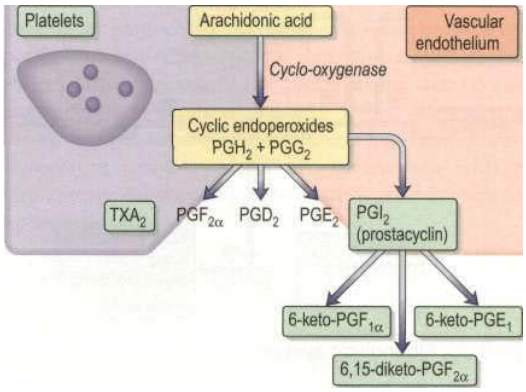

Fig. 8.32 **Prostaglandin synthesis.**

Platelet aggregation (Fig. 8.31b): fibrinogen then binds platelets into activated aggregates (platelet aggregation) and further platelet release occurs. A self-perpetuating cycle of events is set up leading to formation of a platelet plug at the site of the injury.

Coagulation: further platelet membrane receptors, e.g. P_2Y_{12} are exposed during aggregation, providing a surface for the interaction of coagulation factors; this platelet phospholipid activity is referred to as platelet factor 3 (PF-3). The presence of thrombin encourages fusion of platelets, and fibrin formation reinforces the stability of the platelet plug.

Central to normal platelet function is platelet *prostaglandin synthesis,* which is induced by platelet activation and leads to the formation of TXA_2 in platelets (Fig. 8.32). Thromboxane (TXA_2) is a powerful vasoconstrictor and also lowers cyclic AMP levels and initiates the platelet release reaction.

Prostacyclin (PGI_2) is synthesized in vascular endothelial cells and opposes the actions of TXA_2. It produces vasodilatation and increases the level of cyclic AMP, preventing platelet aggregation on the normal vessel wall as well as limiting the extent of the initial platelet plug after injury.

Coagulation and fibrinolysis

Coagulation involves a series of enzymatic reactions leading to the conversion of soluble plasma fibrinogen to fibrin clot (Fig. 8.33). Roman numerals are used for most of the factors, but I and II are referred to as fibrinogen and prothrombin respectively; III, IV and VI are redundant. The active forms are denoted by 'a'.

The coagulation factors are primarily synthesized in the liver and are either enzyme precursors (factors XII, XI, X, IX and thrombin) or cofactors (V and VIII), except for fibrinogen, which is degraded to form fibrin.

Coagulation pathway

This enzymatic amplification system is traditionally divided into 'extrinsic' and 'intrinsic' pathways. This concept remains very useful for the interpretation of clinical laboratory tests (see p. 469) but is an over-

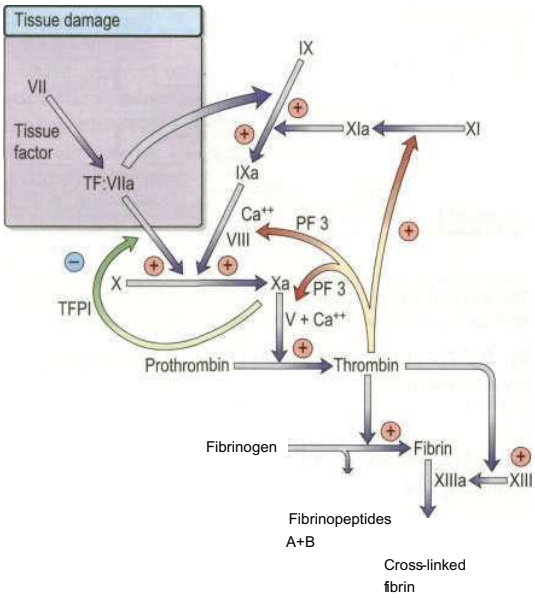

Fig. 8.33 **Coagulation mechanism.** The in vivo pathway begins with the activation of factor IX by factor Vila. Factor XI is activated by thrombin. TFPI, tissue factor pathway inhibitor.

simplification. Coagulation is initiated by binding of activated factor VII (Vila) in plasma to tissue factor (TF), a glycoprotein which is expressed on the surface of cells which are exposed after injury. The complex of Vila and tissue factor (TF:VIIa) activates factor X but this reaction is opposed by tissue factor pathway inhibitor (TFPI), and the main role of TF:VIIa in vivo is to activate factor IX (Fig. 8.33). Activated factor IX then works with factor VIII to initiate the crucial activation of factor X. (It is this reaction which amplifies the generation of thrombin and which fails in haemophilia A and B. Factor XI is activated in vivo by thrombin and makes a limited contribution to haemostasis so that factor XI deficiency results in a rather mild bleeding disorder.)

Activated factor X induces the conversion of prothrombin to thrombin. Thrombin hydrolyses the peptide bonds of fibrinogen, releasing fibrinopeptides A and B, and allowing polymerization between fibrinogen molecules to form fibrin. At the same time, thrombin, in the presence of calcium ions, activates factor XIII, which stabilizes the fibrin clot by cross-linking adjacent fibrin molecules. The presence of thrombin helps in the activation of factors XI, V, VIII and XIII (and protein C; see limitation of coagulation below and Fig. 8.34).

Factor VIII consists of a molecule with coagulant activity (VIII:C) associated with von Willebrand factor. VWF's function here is to stabilize factor VIII:C and to promote platelet-endothelial interaction. VIII:C is a single-chain protein with a molecular weight of about 350 000.

Von Willebrand Factor (vWF) is a glycoprotein with a molecular weight of about 200 000 which readily forms multimers in the circulation with molecular weights of up to 20 x 10^6. It is synthesized by endothelial cells and megakaryocytes and stored in platelet and granules as well as the endothelial cells. The high-molecular-weight

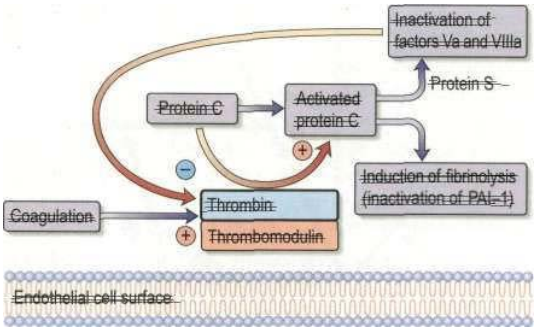

Fig. 8.34 **Activation of protein C.** PAI-1, plasminogen activator inhibitor 1.

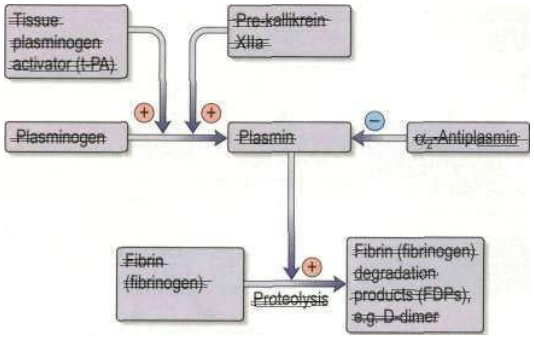

Fig. 8.35 Fibrinolytic system.

multimeric forms of vWF are the most effective in promoting platelet function (see p. 467 and Fig. 8.37).

Limitation of coagulation

Antithrombin. Antithrombin (AT), a member of the serine protease inhibitor (serpin) superfamily, is a potent inhibitor of coagulation. It inactivates the serine proteases by forming stable complexes with them, and its action is greatly potentiated by heparin.

Activated protein C. This is generated from its vitamin K-dependent precursor by the action of thrombin; thrombin activation of protein C is enhanced when thrombin is bound to thrombomodulin, which is an endothelial cell receptor (Fig. 8.34). Activated protein C destroys factor V and factor VIII, reducing **further thrombin generation.**

Protein S. This is a cofactor for protein C which acts by enhancing binding of activated protein C to **the** phospholipid surface. It circulates bound to C4b binding protein but some 30-40% remains unbound and active (free protein S).

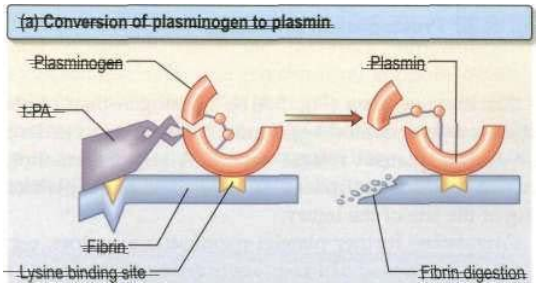
Other inhibitors. Other natural inhibitors of coagulation include a_2-macroglobulin, o^-antitrypsin and cx_2-antiplasmin.

Fibrinolysis

Fibrinolysis, which helps to restore vessel patency, also occurs in response to vascular damage. In this system (Fig. 8.35), an inactive plasma protein - plasminogen - is converted to plasmin by plasminogen activators derived from the plasma or blood cells (intrinsic activation) or the tissues (extrinsic activation).

Plasmin is a serine protease which breaks down fibrinogen and fibrin into fragments X, Y, D and E, collectively known as fibrin (and fibrinogen) degradation products (FDPs). D-dimer is produced when cross-linked fibrin is degraded. Its presence in the plasma indicates that the coagulation mechanism has been activated (see p. 467). Plasmin is also capable of breaking down coagulation factors such as factors V and VIII.

The fibrinolytic system is activated by the presence of fibrin. Plasminogen is specifically adsorbed to fibrin and



(M Plncmin i

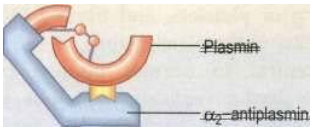


Fig. 8.36 Fibrinolysis.
(a) The conversion of plasminogen to plasmin by plasminogen activator (t-PA) occurs most efficiently on the surface of fibrin, which has binding sites for both plasminogen and t-PA.
(b) Free plasmin in the blood is rapidly inactivated by a_2-antiplasmin. Plasmin generated on the fibrin surface is partially protected from inactivation. The lysine-binding sites on plasminogen are necessary for the interaction between plasmin(ogen) and fibrin and between plasmin and a_2-antiplasmin.

fibrinogen by lysine-binding sites. However, little plasminogen activation occurs in the absence of fibrin, as fibrin also has a specific binding site for plasminogen activators, whereas fibrinogen does not (Fig. 8.36).

The major plasminogen activator is tissue-type plasminogen activator (t-PA); vascular endothelium is the major source of t-PA in plasma. Its release is stimulated by a number of mediators, including thrombin. Another plasminogen activator is urokinase, synthesized in the kidney and released into the urogenital tract. Intrinsic plasminogen activators such as factor XII and pre-kallikrein are of minor physiological importance.

t-PA is inactivated by plasminogen activator inhibitor-1 (PAI-1). Activated protein C inactivates PAI-1 and therefore induces fibrinolysis (Fig. 8.34). Inactivators of plasmin such as a_2-antiplasmin (Fig. 8.36) and thrombin -

activatable fibrinolysis inhibitor (TAFI) also contribute to the regulation of fibrinolysis.

investigation of bleeding disorders

Although the precise diagnosis of a bleeding disorder may depend on laboratory tests, much information may be obtained from the history and physical examination:

- **Is there a generalized haemostatic defect?** Supportive evidence for this includes bleeding from multiple sites, spontaneous bleeding, and excessive bleeding after injury.
- **Is the defect inherited or acquired?** A family history of a bleeding disorder should be sought. Severe inherited defects usually become apparent in infancy, while mild inherited defects may only come to attention later in life, for example with excessive bleeding after surgery, childbirth, dental extractions or trauma. Some defects are revealed by routine coagulation screens which are performed before surgical procedures.
- **Is the bleeding suggestive of a vascular/platelet defect or a coagulation defect?**

Vascular/platelet bleeding is characterized by easy bruising and spontaneous bleeding from small vessels. There is often bleeding into the skin. The term purpura includes both petechiae, which are small skin haemorrhages varying from pinpoint size to a few millimetres in diameter and which do not blanch on pressure, and ecchymoses, which are larger areas of bleeding into the skin. Bleeding also occurs from mucous membranes especially the nose and mouth.

Coagulation disorders are typically associated with haemarthroses and muscle haematomas, and bleeding after injury or surgery. There is often a short delay between the precipitating event and overt haemorrhage or haematoma formation.

Laboratory investigations

- **Blood count and film** show the number and morphology of platelets and any blood disorder such as leukaemia or lymphoma. The normal range for the platelet count is 150-100 x 10^9/L.
- **Bleeding time** measures platelet plug formation in vivo. It is determined by applying a sphygmomanometer cuff to the arm and inflating it to 40 mmHg. Two 1 mm deep, 1 cm long incisions are made in the forearm with a template. Each wound is blotted every 30 s and the time taken for bleeding to stop is recorded, normally between 3 and 10 minutes. Prolonged bleeding times are found in patients with platelet function defects, and there is a progressive prolongation with platelet counts less than 80 x 10^9/L. The bleeding time should not be performed at low platelet counts.
- **Coagulation tests** are performed using blood collected into citrate, which neutralizes calcium ions and prevents clotting.

The *prothrombin time* (PT) (also see p. 480) is measured by adding tissue thromboplastin in the form of animal brain extract, or a recombinant equivalent, and calcium to the patient's plasma ('extrinsic' system). The normal PT is 16-18 s, and it is prolonged with abnormalities of factors **VII,** X, V, II or I, liver disease, or if the patient is on warfarin.

The *activated partial thromboplastin time* (APTT) is also sometimes known as the PTT with kaolin (PTTK). It is performed by adding a surface activator (such as kaolin), phospholipid (as platelet substitute) and calcium to the patient's plasma ('intrinsic' system). The normal APTT is 30-50 s depending on the exact methodology, and it is prolonged with deficiencies or inhibitors of one or more of the following factors: XII, XI, IX, VIII, X, V, II or I (but not factor **VII)** (see Fig. 8.33).

The *thrombin time* (TT) is performed by adding thrombin to the patient's plasma. The normal TT is about 12 s, and it is prolonged with fibrinogen deficiency, dysfibrinogenaemia (normal level of fibrinogen but abnormal function) or inhibitors such as heparin or FDPs.

Correction tests can be used to differentiate prolonged times in the PT, APTT and TT due to various coagulation factor deficiencies and inhibitors of coagulation. Prolonged PT, APTT or TT because of coagulation factor deficiencies are corrected by addition of normal plasma to the patient's plasma; no correction of an abnormal result after the addition of normal plasma is suggestive of the presence of an inhibitor of coagulation.

Factor assays are used to confirm coagulation defects, especially where a single inherited disorder is suspected.

Special tests of coagulation will often be required to confirm the precise haemostatic defect. Such tests include estimation of fibrinogen and FDPs, platelet function tests such as platelet aggregation and tests of the fibrinolytic pathway which include the euglobulin clot lysis time (ELT) and assays of plasminogen, t-PA and PAI-1. The ELT involves precipitation by acidification of the euglobulin fraction of plasma, which contains fibrinogen, plasminogen and plasminogen activators but excluding a_2-antiplasmin. The euglobulin fraction is clotted with thrombin and the time taken for lysis of the fibrin clot is a measure of fibrinolytic activity; the normal range is 60-270 minutes. Factor XIII can be estimated by a clot stability screening test or by direct assay.

VASCULAR DISORDERS

The vascular disorders (Table 8.23) are characterized by easy bruising and bleeding into the skin. Bleeding from mucous membranes sometimes occurs but the bleeding is rarely severe. Laboratory investigations including the bleeding time are normal. The vascular disorders include the following.

Hereditary haemorrhagic telangiectasia is a rare disorder with autosomal dominant inheritance. Dilatation of capillaries and small arterioles produces characteristic small red spots that blanch on pressure in the skin and mucous membranes, particularly the nose and gastrointestinal tract. Recurrent epistaxis and chronic gastrointestinal bleeding are the major problems and may cause chronic iron deficiency anaemia.

Table 8.23 Vascular disorders

Others
Senile purpura
Easy bruising syndrome
Scurvy
Factitious purpura

Easy bruising syndrome is a common benign disorder occurring in otherwise healthy women. It is characterized by bruises on the arms, legs and trunk with minor trauma, possibly because of skin vessel fragility. It may give rise to the suspicion of a serious bleeding disorder.

Senile purpura and purpura due to steroids are both due to atrophy of the vascular supporting tissue.

Purpura due to infections is mainly caused by damage to the vascular endothelium. The rash of meningococcal septicaemia is particularly characteristic (p. 75).

Henoch-Schonlein purpura (p. 629) occurs mainly in children. It is a type III hypersensitivity reaction that is often preceded by an acute upper respiratory tract infection. Purpura is mainly seen on the legs and buttocks. Abdominal pain, arthritis, haematuria and glomerulonephritis also occur. Recovery is usually spontaneous, but some patients develop renal failure.

Episodes of inexplicable bleeding or bruising may represent abuse, either self-inflicted or caused by others. These various forms of artificial or factitious purpura are expressions of severe emotional or psychiatric disturbances.

Table 8.24 Clinical effects caused by different levels of platelet count

PLATELET DISORDERS

Bleeding due to thrombocytopenia or abnormal platelet function is characterized by purpura and bleeding from mucous membranes. Bleeding is uncommon with platelet counts above 50 x 10^9/L, and severe spontaneous bleeding is unusual with platelet counts above 20 x 10^9/L (Table 8.24).

Thrombocytopenia

This is caused by reduced platelet production in the bone marrow or excessive peripheral destruction of platelets (Table 8.25). The underlying cause may be revealed by history and examination but a bone marrow examination will show whether the numbers of megakaryocytes are reduced, normal or increased, and will provide essential information on morphology. Specific laboratory tests may be useful to confirm the presence of such conditions as paroxysmal nocturnal haemoglobinuria (PNH) or systemic lupus erythematosus (SLE).

In patients with thrombocytopenia due to failure of production, no specific treatment may be necessary but the underlying condition should be treated if possible. Where the platelet count is very low or the risk of bleeding is very high, then platelet concentrate administration is indicated.

Idiopathic thrombocytopenic purpura (ITP)

Thrombocytopenia is due to immune destruction of platelets. The antibody-coated platelets are removed following binding to Fc receptors on macrophages.

ITP in children

The condition is usually acute but self-limiting and may follow a viral infection or immunization. Bone marrow examination is not usually performed unless treatment becomes necessary on clinical grounds.

ITP in adults

The presentation is usually less acute than in children. Adult ITP is characteristically seen in women and may be associated with other autoimmune disorders such as SLE, thyroid disease and autoimmune haemolytic anaemia (Evans' syndrome), in patients with chronic lymphocytic

leukaemia and solid tumours, and after infections with viruses such as HIV. Platelet autoantibodies are detected in about 60-70% of patients, and are presumed to be present, although not detectable, in the remaining patients; the antibodies often have specificity for platelet membrane glycoproteins lib/Ilia and/ or Ib.

Clinical features

Major haemorrhage is rare and is seen only in patients with severe thrombocytopenia. Easy bruising, purpura, epistaxis and menorrhagia are common. Physical examination is normal except for evidence of bleeding. Splenomegaly is rare.

Investigation

The only blood count abnormality is thrombocytopenia. Normal or increased numbers of megakaryocytes are found in the bone marrow (if examination is performed), which is otherwise normal. The detection of platelet autoantibodies is not essential for confirmation of the diagnosis, which often depends on exclusion of other causes of excessive destruction of platelets.

Treatment

Children

Children do not usually require treatment. Where this is necessary on clinical grounds, high-dose prednisolone is effective, given for a very short course. Intravenous immunoglobulin (i.v. IgG) should be reserved for very serious bleeding or urgent surgery. Chronic ITP is rare and requires specialist management, avoiding cytotoxic agents.

Adults

Patients with platelet counts greater than 30 x 10^9/L require no treatment unless they are about to undergo a surgical procedure.

First-line therapy consists of oral corticosteroids 1 mg/kg body weight but i.v. IgG is useful where a rapid rise in platelet count is desired, especially before surgery. There are also advocates for high-dose corticosteroids as initial therapy.

Second-line therapy involves splenectomy, to which the majority of patients respond, but a wide range of treatments is available in chronic ITP. These include high-dose corticosteroids, high-dose i.v. IgG, intravenous anti-D, vinca alkaloids, danazol, immunosuppressive agents such as azathioprine, ciclosporine and dapsone. There is also interest in the use of specific monoclonal antibodies such as rituximab, as well as recombinant thrombopoietin.

Platelet transfusions are reserved for intracranial or other extreme haemorrhage, where emergency splenectomy may be justified.

Other immune thrombocytopenias

Drugs cause immune thrombocytopenia by the same mechanisms as described for drug-induced immune haemolytic anaemia (p. 450). The same drugs can be responsible for immune haemolytic anaemia, thrombocytopenia or neutropenia in different patients.

Heparin-induced thrombocytopenia. See page 480.

Neonatal alloimmune thrombocytopenia is due to feto-maternal incompatibility for platelet-specific antigens, usually for HPA-la (human platelet alloantigen) and is the platelet equivalent of haemolytic disease of the newborn (HDN). The mother is HPA-la-negative and produces antibodies which destroy the HPA-la-positive fetal platelets.

Thrombocytopenia is self-limiting after delivery, but platelet transfusions may be required initially to prevent or treat bleeding associated with severe thrombocytopenia; platelets are prepared from HPA-la-negative volunteers or the mother herself. Severe bleeding such as intracranial haemorrhage may also occur in utero. Antenatal treatment of the mother - with platelet transfusions given directly to the fetus by ultrasound-guided needling of the umbilical vessels - has been effective in preventing haemorrhage in severely affected cases.

Post-transfusion purpura (PTP) is rare, occurring 2-12 days after a blood transfusion. PTP is associated with a platelet-specific alloantibody, usually anti-HPA-la in an HPA-la-negative individual. PTP almost invariably occurs in females who have been previously immunized by pregnancy or blood transfusion. The cause of the destruction of the patient's own platelets is not well understood, but they may be destroyed as 'bystanders' during the acute immune response to HPA-la. PTP is self-limiting, but high-dose intravenous immunoglobulin may limit the period of thrombocytopenia.

Thrombotic thrombocytopenic purpura (TTP) (p. 636)

TTP is a rare, but very serious condition, in which platelet destruction leads to profound thrombocytopenia. There is a characteristic symptom complex of florid purpura, fever, fluctuating cerebral dysfunction and haemolytic anaemia with red cell fragmentation, often accompanied by renal failure. The coagulation screen is usually normal but lactic dehydrogenase (LDH) levels are markedly raised as a result of haemolysis.

The underlying cause is not fully understood but TTP seems to be due to endothelial damage associated with the presence in the circulation of very-high-molecular-weight multimers of von Willebrand factor (vWF) which accumulate owing to the absence of a protease which is normally responsible for vWF degradation. This absence is due to mutations in the *ADAMTS 13* gene. In some cases there is a true deficiency of the protease, while in others an immune response appears to reduce protease activity temporarily. TTP is associated with pregnancy, oral contraceptives, systemic lupus erythematosus, infection and drug treatment, including the use of ticlopidine and clopidogrel, but many cases have no obvious cause.

Treatment consists of plasma exchange, using cryoprecipitate-depleted FFP (cryo-poor supernatant) or solvent detergent-treated FFP, both of which contain reduced amounts of high-molecular-weight vWF multimers. It is also thought that FFP supplies the missing I

protease. Most patients are also treated with prednisone 1 mg/kg daily and low-dose aspirin 75 mg daily is often given as the platelet count rises above 50 x 10^9/L. Disease activity is monitored by measuring the platelet count and serum LDH. Platelet concentrates are contraindicated.

The untreated condition has a mortality of up to 90% but modern management has reduced this figure to about 10%. Recurrent and relapsing TTP occurs, often associated with a persistent lack of vWF protease.

Platelet function disorders

These are usually associated with excessive bruising and bleeding and, in some of the acquired forms, with thrombosis. The platelet count is normal or increased and the bleeding time is prolonged. The rare inherited defects of platelet function require more detailed investigations such as platelet aggregation studies and factor VIII:C and vWF assays, if von Willebrand's disease is suspected.

Inherited types of platelet dysfunction

- *Glanzmann's thrombasthenia* - lack of the platelet membrane glycoprotein lib/Ilia complex resulting in defective fibrinogen binding and failure of platelet aggregation.
- *Bernard-Soulier syndrome* - lack of platelet membrane glycoprotein Ib, the binding site for factor vWF. This causes a failure of platelet adhesion and moderate thrombocytopenia.
- *Storage pool disease* - lack of the storage pool of platelet dense bodies, causing poor platelet function.

Acquired types of platelet dysfunction

- Myeloproliferative disorders
- Renal and liver disease
- Paraproteinaemias
- Drug-induced, such as by aspirin or other platelet inhibitory drugs.

If there is serious bleeding or if the patient is about to undergo surgery, drugs with antiplatelet activity should be withdrawn and any underlying condition should be corrected if possible. In patients with renal failure, the haematocrit should be increased to greater than 0.30 and the use of desmopressin may be helpful. Platelet transfusions may be required if these measures are unsuccessful or if the risk of bleeding is high.

Thrombocytosis

The platelet count may rise above 400 x 10^9/L as a result of:

- splenectomy
- Hodgkin's lymphoma and other malignancies
- inflammatory disorders such as rheumatoid arthritis, ulcerative colitis and Crohn's disease
- major surgery.

Thus thrombocytosis is part of the acute-phase reaction, although following splenectomy platelet numbers are also elevated because of the loss of a major site of platelet destruction.

Essential thrombocyihaemia, a myeloproliferative disorder which is described on page 455, and other myeloproliferative conditions such as polycythaemia vera (PV) and chronic myeloid leukaemia (CML) may also be associated with a high platelet count.

A persistently elevated platelet count can lead to arterial or venous thrombosis. It is usual to treat the underlying cause of the thrombocytosis but a small dose of aspirin (75 mg) is also sometimes given. In myeloproliferative disease there is also a paradoxical risk of abnormal bleeding and specific action to reduce the platelet count, usually with hydroxycarbamide (hydroxyurea) is often taken.

INHERITED COAGULATION DISORDERS

Coagulation disorders may be inherited or acquired. The inherited disorders are uncommon and usually involve deficiency of one factor only. The acquired disorders occur more frequently and almost always involve several coagulation factors; they are considered in the next subsection.

In inherited coagulation disorders, deficiencies of all factors have been described. Those leading to abnormal bleeding are rare, apart from haemophilia A (factor VIII deficiency), haemophilia B (factor IX deficiency) and von Willebrand's disease.

Haemophilia A

In haemophilia A, the level of factor VIII:C is reduced but the level of factor vWF is normal (see Fig. 8.37). The prevalence of haemophilia A is about 1 in 5000 of the male population. It is inherited as an X-linked disorder. If a female carrier has a son, he has a 50% chance of having haemophilia, and a daughter has a 50% chance of being a carrier. All daughters of men with haemophilia are carriers and the sons are normal.

The human factor VIII gene is enormous, constituting about 0.1% of the X chromosome, encompassing 186 kilobases of DNA. Various genetic defects have been found, including deletions, duplications, frameshift mutations and insertions. In approximately 50% of families with severe disease, the defect is an inversion. There is a high mutation rate, with one-third of cases being apparently sporadic with no family history of haemophilia.

Clinical and laboratory features

The clinical features depend on the level of factor VIII:C.

- *Levels of less than 1%* are associated with frequent spontaneous bleeding from early life. Haemarthroses are common and may lead to joint deformity and crippling if adequate treatment is not given. Bleeding into muscles is also common, and intramuscular injections should be avoided.

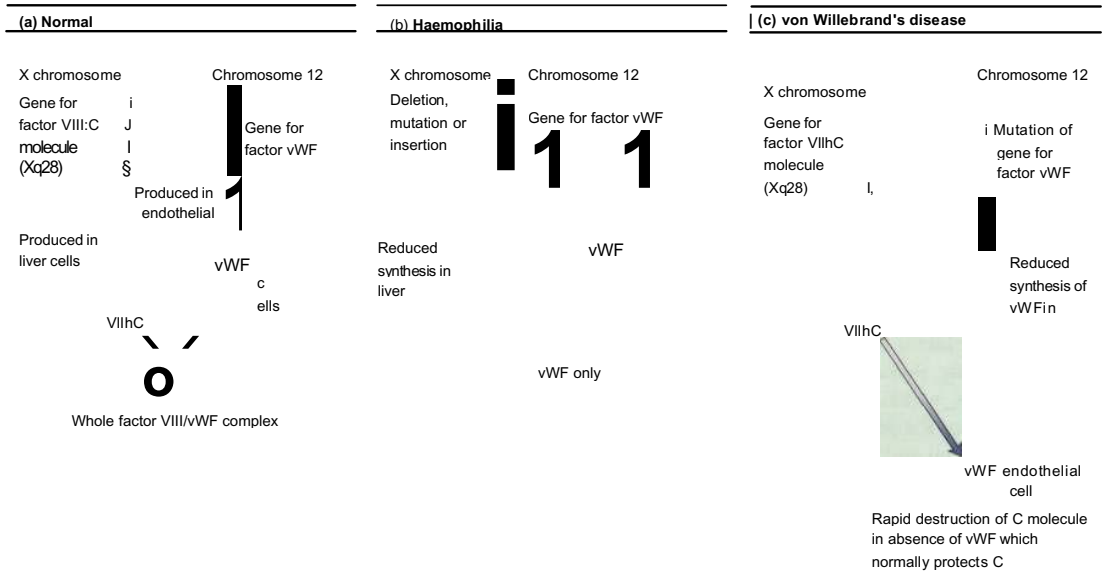

Fig. 8.37 (a) Normal factor VIII synthesis, (b) Haemophilia A showing defective synthesis of factor VIIIc. (c) von Willebrand's disease showing reduced synthesis of vWF.

- *Levels of 1-5%* are associated with severe bleeding following injury and occasional apparently spontaneous episodes.
- *Levels above 5%* produce mild disease, usually with bleeding only after injury or surgery. It should be noted that patients with mild haemophilia can still bleed badly once haemostasis has failed. Diagnosis in this group is often delayed until quite late in life.

The most common causes of death in people with haemophilia are cancer and heart disease, as for the general population. Cerebral haemorrhage is much more frequent however, and in recent years, HIV infection and liver disease (due to hepatitis C) have become a more common cause of death.

The main laboratory features of haemophilia A are shown in Table 8.26. The abnormal findings are a prolonged APTT and a reduced level of factor VIILC. The PT, bleeding time and vWF level are normal.

Treatment

Bleeding is treated by administration of factor VIII concentrate by intravenous infusion.

- *Minor bleeding:* the factor VIII:C level should be raised to 20-30%.

Table 8.26 Blood changes in haemophilia A, von Willebrand's disease and vitamin K deficiency

	Haemophilia A	von Willebrand's disease	Vitamin K deficiency
Bleeding time	Normal	t	Normal
PT	Normal	Normal	t
APTT	T+	t±	T
VIIhC	4++	*i*	Normal
vWF	Normal	*i*	Normal

- *Severe bleeding:* the factor VIII:C should be raised to at least 50%.
- *Major surgery:* the factor VIII:C should be raised to 100% preoperatively and maintained above 50% until healing has occurred.

Factor VIII has a half-life of 12 hours and therefore must be administered at least twice daily to maintain the required therapeutic level. Continuous infusion is sometimes used to cover surgery. Factor VIII concentrate is freeze-dried and may be stored in domestic refrigerators at 4°C. This allows it to be administered by the patient immediately after bleeding has started, reducing the likelihood of chronic damage to joints and the need for inpatient care.

Recombinant factor VIII concentrate is well established as the treatment of choice for people with haemophilia, but economic constraints and limited production capacity for recombinant factors have resulted in many previously treated patients still being offered treatment with plasma-derived concentrates, particularly in developing countries.

The majority of severely affected patients are given prophylaxis three times per week from early childhood in an attempt to prevent permanent joint damage.

Synthetic vasopressin (Desmopressin - an anologue of vasopressinj - intravenous, subcutaneous or intranasal -produces a rise in factor VIII:C proportional to the initial level of factor VIII. It avoids the complications associated with blood products and is useful for treating bleeding episodes in mild haemophilia and as prophylaxis before minor surgery. It is ineffective in severe haemophilia.

People with haemophilia should be registered at comprehensive care centres (CCC), which take responsibility for their full medical care, including social and psychological support. Each person with haemophilia carries a special medical card giving details of the disorder and its treatment.

Complications

Up to 30% of people with severe haemophilia will develop antibodies to factor VIII:C during their lifetime, usually after the first few treatment doses of factor VIII. The prevalence of antibodies in the UK haemophilia population is 5-10% because they uncommonly develop in more mildly affected patients and often disappear spontaneously or with continued treatment.

Management of such patients may be very difficult, and even extremely high doses of factor VIII may not produce a rise in the plasma level of factor VIII:C. Purified porcine factor VIII may not cross-react with the patient's antibody. Some factor IX concentrates contain activated factors, which may 'bypass' the inhibitor and stop the bleeding. Recombinant factor VIIa also has this bypassing potential and shows great promise as an agent for treating patients with inhibitors. There is a growing interest in immune tolerance induction, especially in the management of recently developed inhibitors in young people. Similar strategies, including immunosuppression and immunoabsorption, have been described.

The risk of viral transmission has been virtually eliminated in developed countries by excluding high-risk blood donors, testing all donations for HBsAg, HCV and HIV antibodies, and by including steps to inactivate viruses during the preparation of plasma-derived concentrate.

Hepatitis A and B vaccination is offered routinely to all patients with haemophilia and von Willebrand's disease. The clinical consequences of haemophilia patients infected with HIV are similar to other HIV-infected patients (see p. 132), except that Kaposi's sarcoma does not occur. A number of patients with hepatitis C will progress to develop chronic liver disease and cirrhosis (see p. 372).

The use of recombinant factor VIII eliminates any residual risk of transfusion-transmitted infection, and it is safe and effective; but there is a similar incidence of inhibitor development as with plasma-derived factor VIII.

Carrier detection and antenatal diagnosis

Determination of carrier status in females begins with a family history and coagulation factor assays. Female carriers usually have a factor VIII level of about 50% of normal, but the exact value is very variable, partly because of lyonization. Owing to this process early in embryonic life (that is, random inactivation of one chromosome; see p. 172), some carriers have very low levels of factor VIII while others will have normal levels. Carriers could be diagnosed with reasonable confidence if the level of factor VIII:C was 50% or less of that expected from the level of factor vWF measured at the same time, but often no clear-cut answer was provided by this method. Carrier detection can be carried out using molecular genetic testing, either by direct detection of mutations within the factor VIII gene or by tracking of the abnormal gene using DNA polymorphisms as markers.

Antenatal diagnosis may be carried out by molecular analysis of fetal tissue obtained by chorionic villus biopsy at 11-12 weeks' gestation.

Haemophilia B (Christmas disease)

Haemophilia B is caused by a deficiency of factor IX. The inheritance and clinical features are identical to haemophilia A, but the incidence is only about 1 in 30 000 males. The gene is smaller at 34 kilobases and the half-life of the factor is longer at 18 hours. Haemophilia B is treated with factor IX concentrates, recombinant factor IX now being available, and prophylactic doses are given twice a week. Desmopressin is ineffective.

Von Willebrand's disease (vWD)

In vWD, there is defective platelet function as well as factor VIII:C deficiency, and both are due to a deficiency or abnormality of vWF (see Fig. 8.37). vWF plays a role in platelet adhesion to damaged subendothelium as well as stabilizing factor VIII:C in plasma (see p. 467).

The vWF gene is located on chromosome 12 and numerous mutations of the gene have been identified. vWD has been classified into three types:

- *Type 1* is characterized by a mild reduction in vWF and is usually inherited as an autosomal dominant.
- *Type 2* is due to a decrease in the proportion of high-molecular-weight multimers, and it too is usually inherited as an autosomal dominant.
- *Type 3* is recessively inherited and patients have barely detectable levels of factor vWF (and therefore also of factor VIII:C). Their parents are often phenotypically normal.

Many subtypes have also been described, such as type 2B where increased vWF avidity for platelets causes mild thrombocytopenia, and type 2N where there is an abnormal vWF binding site for VIII:C.

Clinical features. These are variable. Type 1 and type 2 patients usually have mild clinical features. Bleeding follows minor trauma or surgery, and epistaxis and menorrhagia often occur. Haemarthroses are rare. Type 3 patients have more severe bleeding but rarely experience the joint and muscle bleeds seen in haemophilia A.

Characteristic laboratory findings are shown in Table 8.26. These also include defective platelet aggregation with ristocetin.

Treatment depends on the severity of the condition and may be similar to that of mild haemophilia, including the use of Desmopressin where possible. Intermediate purity factor VIII or von Willebrand factor concentrates should be used to treat bleeding or to cover surgery in patients who require replacement therapy, especially in type 3

(severe disease. Cryoprecipitate should be avoided transmitted infection, since cryoprecipitate is not a
) because of the greater risk of transfusion- virally inactivated product.

ACQUIRED COAGULATION DISORDERS

Vitamin K deficiency (see also p. 242)

Vitamin K is necessary for the y-carboxylation of glutamic acid residues on coagulation factors II, VII, IX and X and on proteins C and S. Without it, these factors cannot bind calcium.

Deficiency of vitamin K may be due to:

- *inadequate stores,* as in haemorrhagic disease of the newborn and severe malnutrition (especially when combined with antibiotic treatment) (see p. 352)
- *malabsorption of vitamin K,* a fat-soluble vitamin, which occurs in cholestatic jaundice owing to the lack of intraluminal bile salts
- *oral anticoagulant drugs,* which are vitamin K antagonists.

The PT and APTT are prolonged (see Table 8.26) and there may be bruising, haematuria and gastrointestinal or cerebral bleeding. Minor bleeding is treated with phytomenadione (vitamin Kj) 10 mg intravenously. Some correction of the PT is usual within 6 hours but it may not return to normal for 2 days.

Newborn babies have low levels of vitamin K, and this may cause minor bleeding in the first week of life {*classical haemorrhagic disease of the newborn).* Vitamin K deficiency may also cause *late haemorrhagic disease of the newborn,* which occurs 2-26 weeks after birth and may result in severe bleeding such as intracranial haemorrhage. Most infants with these syndromes have been exclusively breast-fed, and both conditions may be prevented by administering 1 mg i.m. vitamin K to all neonates (p. 242). Concerns about the safety of this are unfounded.

Liver disease

Liver disease may result in a number of defects in haemostasis:

- *Vitamin K deficiency.* This occurs owing to intrahepatic or extrahepatic cholestasis.
- *Reduced synthesis.* Reduced synthesis of coagulation factors may be the result of severe hepatocellular damage. The use of vitamin K does not improve the results of abnormal coagulation tests, but it is generally given to ensure that a treatable cause of failure of haemostasis has not been missed.
- *Thrombocytopenia.* This results from hypersplenism due to splenomegaly associated with portal hyper tension or from folic acid deficiency.
- *Functional abnormalities.* Functional abnormalities of platelets and fibrinogen are found in many patients with liver failure.
- *Disseminated intravascular coagulation.* DIC (see below) may occur in acute liver failure.

Disseminated intravascular coagulation (DIC)

There is widespread generation of **fibrin within** blood vessels, owing to activation of coagulation by release of

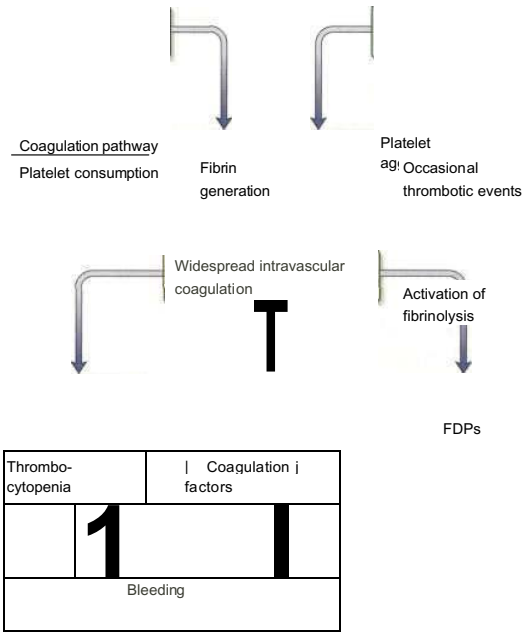

Fig. 8.38 **Disseminated intravascular coagulation.** FDR fibrin degradation products.

procoagulant material, and by diffuse endothelial damage or generalized platelet aggregation. Activation of leucocytes, particularly monocytes causing expression of tissue factor and the release of cytokines, may play a role in the development of DIC.

There is consumption of platelets and coagulation factors and secondary activation of fibrinolysis leading to production of fibrin degradation products (FDPs), which may contribute to the coagulation defect by inhibiting fibrin polymerization (Fig. 8.38). The consequences of these changes are a mixture of initial thrombosis followed by a bleeding tendency due to consumption of coagulation factors and fibrinolytic activation.

Causes of DIC

These include:

- malignant disease
- septicaemia (e.g. Gram-negative and meningococcal)
- haemolytic transfusion reactions
- obstetric causes (e.g. abruptio placentae, amniotic fluid embolism)
- trauma, burns, surgery
- other infections (e.g. falciparum malaria)
- liver disease
- snake bite.

Clinical features

The underlying disorder is usually obvious. The patient is often acutely ill and shocked. The clinical presentation of DIC varies from no bleeding at all to profound haemostatic failure with widespread haemorrhage. Bleeding may occur from the mouth, nose and venepuncture sites and there may be widespread ecchymoses.

Thrombotic events may occur as a result of vessel occlusion by fibrin and platelets. Any organ may be

involved, but the skin, brain and kidneys are most often affected.

Investigations

The diagnosis is often suggested by the underlying condition of the patient.

Severe cases with haemorrhage

- The PT, APTT and TT are usually very prolonged and
  the fibrinogen level markedly reduced.
- High levels of FDPs, including D-dimer are found
  owing to the intense fibrinolytic activity stimulated by
  the presence of fibrin in the circulation.
- There is severe thrombocytopenia.
- The blood film may show fragmented red blood cells.

Mild cases without bleeding

- Increased synthesis of coagulation factors and platelets
- Normal PT, APTT, TT and platelet counts
- FDPs are raised.

Treatment

The underlying condition is treated and this may be all that is necessary in patients who are not bleeding. Maintenance of blood volume and tissue perfusion is essential. Transfusions of platelet concentrates, FFP, cryoprecipitate and red cell concentrates is indicated in patients who are bleeding. The use of heparin to prevent intravascular coagulation is rarely indicated. Inhibitors of fibrinolysis such as tranexamic acid should not be used in DIC as dangerous fibrin deposition may result. Antithrombin and/or activated protein C concentrates have been used in selected cases.

Excessive fibrinolysis

Excessive fibrinolysis may occur during surgery involving tumours of the prostate, breast, pancreas and uterus owing to release of tissue plasminogen activators.

Primary hyperfibrinolysis is very rare but activation of fibrinolysis occurs in DIC as a secondary event in response to intravascular deposition of fibrin.

The clinical picture is similar to DIC with widespread bleeding. Laboratory investigations are also similar with a prolonged PT, APTT and TT, a low fibrinogen level, and increased FDPs, although fragmented red cells and thrombocytopenia are not seen, since disseminated coagulation is not present.

If the diagnosis is certain, fibrinolytic inhibitors such as e-aminocaproic acid (EACA) or tranexamic acid should be considered. If DIC cannot be excluded, it is safer to treat as for DIC.

Massive transfusion

Few platelets and reduced levels of factors V and VIII are found in stored blood, although there are adequate amounts of the other coagulation factors. During massive transfusion (defined as transfusion of a volume of blood equal to the patient's own blood volume within 24 hours,

e.g. approximately 10 units in an adult), the platelet count and PT and APTT should be checked at intervals. Transfusion of platelet concentrates and FFP should be given if thrombocytopenia or defective coagulation are thought to be contributing to continued blood loss. Other problems of massive transfusion are described on page 974.

Inhibitors of coagulation

In addition to the factor VIII:C alloantibodies that are found in 5-10% of people with severe haemophilia A, factor VIILC autoantibodies arise occasionally in patients with autoimmune disorders such as SLE, in elderly patients, and sometimes after childbirth. There can be severe bleeding. The antibodies sometimes disappear spontaneously, but treatment with plasma exchange, high-dose intravenous immunoglobulin and immuno-suppressive drugs may be required in addition to any replacement therapy with factor concentrates (see above). Lupus anticoagulant antibodies (p. 534) are autoantibodies directed against phospholipids (anti-phospholipid antibodies). They are found in about 10% of patients with SLE and also occur in otherwise healthy individuals. They lead to prolongation of phospholipid-dependent coagulation tests, particularly the APTT, but do not inhibit coagulation factor activity. Bleeding does not occur unless there is coexistent severe immune thrombocytopenia. The main clinical problems are thrombosis and recurrent miscarriages (p. 577).

THROMBOSIS

A thrombus is defined as a solid mass formed in the circulation from the constituents of the blood during life. Fragments of thrombi (emboli) may break off and block vessels downstream. Thromboembolic disease is much more common than abnormal bleeding; nearly half of adult deaths in England and Wales are due to coronary artery thrombosis, cerebral artery thrombosis or pulmonary embolism.

A thrombus results from a complex series of events involving coagulation factors, platelets, red blood cells and the vessel wall.

Arterial thrombosis

This usually occurs in association with atheroma, which tends to form at areas of turbulent blood flow such as the

bifurcation of arteries. Platelets adhere to the damaged vascular endothelium and aggregate in response to ADP and TXA_2 to form a 'white thrombus'. The growth of the platelet thrombus is limited at its margins by PGI_2 and NO. Plaque rupture leads to the exposure of blood containing factor Vila to tissue factor within the plaque which may trigger blood coagulation and lead to thrombus formation. This results in complete occlusion of the vessel or embolization that produces distal obstruction. The risk factors for arterial thrombosis are related to the development of atherosclerosis (see p. 799).

Arterial thrombi may also form in the heart, as mural thrombi in the left ventricle after myocardial infarction, in the left atrium in mitral valve disease, or on the surfaces of prosthetic valves.

Venous thrombosis

Unlike arterial thrombosis, venous thrombosis often occurs in normal vessels. Major causes are stasis and hypercoagulability. The majority of venous thrombi occur in the deep veins of the leg, originating around the valves as 'red thrombi' consisting mainly of red cells and fibrin. The propagating thrombus is formed of fibrin and platelets and is particularly liable to embolize. Chronic venous obstruction following thrombosis in the deep veins of the leg frequently results in a permanently swollen limb and may lead to ulceration (post-phlebitic syndrome).

Risk factors for venous thrombosis are shown in Table 8.27. Venous thrombosis may occur with changes in blood cells such as polycythaemia and thrombocythaemia, and with coagulation abnormalities (thrombophilia; see below).

Table 8.27 **Risk factors of venous thromboembolism**

Patient factors	Disease or surgical procedure
Age	Trauma or surgery, especially of pelvis, hip or lower limb
Obesity	Malignancy
Varicose veins	Cardiac failure
Long air travel	Recent myocardial infarction
Immobility (bed rest > 4 days)	Infection
Pregnancy and puerperium	Inflammatory bowel disease
Previous deep vein thrombosis or pulmonary embolism	Nephrotic syndrome
Thrombophilia	Polycythaemia
Antithrombin deficiency	Thrombocythaemia
Protein C or S deficiency	Paroxysmal nocturnal haemoglobinuria
Resistance to activated protein C (caused by factor V Leiden variant)	Sickle cell anaemia
Prothrombin gene variant	
Homocysteinaemia	
Antiphospholipid antibody/lupus anticoagulant	
Oestrogen therapy including HRT	

The clinical features and diagnosis of venous thrombosis are discussed on page 870.

Thrombophilia

Thrombophilia is a term describing inherited or acquired defects of haemostasis leading to a predisposition to venous or arterial thrombosis. It should be considered in patients with:

- recurrent venous thrombosis
- venous thrombosis for the first time under age 40 years
- an unusual venous thrombosis such as mesenteric or cerebral vein thrombosis
- unexplained neonatal thrombosis
- recurrent miscarriages
- arterial thrombosis in the absence of arterial disease.

Coagulation abnormalities

Factor V Leiden

Factor V Leiden is formed by a single nucleotide substitution (Arg506Gln) in the factor V gene (factor V Leiden mutation). This makes factor V less likely to be cleaved by activated protein C. Factor V is a cofactor for thrombin generation (see Fig. 8.33) and the failure of activated protein C to inactivate factor V (see Fig. 8.34) results in a tendency to thrombosis. Factor V Leiden is found in 3-5% of healthy individuals in the western world and in about 20% of patients with venous thrombosis.

The risk of venous thrombosis is increased in women with factor V Leiden who are pregnant or taking oral contraceptives. Screening for the defect before prescribing oral contraceptives or during pregnancy would be costly and might deny oral contraception to a substantial number of women who would then be at an increased risk of pregnancy, and therefore thrombosis. In addition, the use of oral anticoagulants in pregnancy carries a risk of fatal maternal bleeding, which may equal the risk of death due to postpartum thrombosis, and the fetus is also at risk of complications from the use of oral anticoagulants (see p. 481).

Prothrombin variant

A mutation in the 3' untranslated region of the prothrombin gene has been described (G20210A). This variant is associated with elevated levels of prothrombin and a two- to threefold increase in the risk of venous thrombosis. There is an interaction with factor V Leiden and contraceptive pill use or pregnancy. The prevalence is 2% in Caucasian populations, 6% in unselected patients with thrombosis and about 18% in families with unexplained thrombophilia.

Antithrombin (AT) deficiency

This deficiency can be inherited as an autosomal dominant. Many variations have been described that lead to a conformational change in

the protein. It can also be acquired following trauma, with major surgery and with the contraceptive pill. Low levels are also seen in severe proteinuria (e.g. the nephrotic syndrome). Recurrent

thrombotic episodes occur starting at a young age in the inherited variety. Patients are relatively resistant to heparin as antithrombin is required for its action. Anti-thrombin III concentrates are available.

Protein C and S deficiency
These autosomal dominant conditions result in an increased risk of venous thrombosis, often before the age of 40 years. Homozygous protein C or S deficiency causes neonatal purpura fulminans, which is fatal without immediate replacement therapy. Protein C concentrate and a recombinant activated protein C are available.

Antiphospholipid antibody
See pages 534 and 577.

Investigations

Haemostatic screening tests
- **Full blood count** including platelet count
- **Coagulation screen** including a fibrinogen level.

These tests will detect erythrocytosis, thrombocytosis, and dysfibrinogenaemia and the possible presence of a lupus anticoagulant.

Testing for specific causes of thrombophilia
- **Assays** for naturally occurring anticoagulants such as AT, protein C and protein S
- **Assay** for activated protein C resistance and molecular testing for factor V Leiden and the prothrombin variant
- **Screen for a coagulation factor** inhibitor including a lupus anticoagulant (and anticardiolipin antibodies) (see p. 534)
- **Fibrinolytic pathway tests** (see p. 469).

Prevention and treatment of arterial thrombosis

Attempts to prevent or reduce arterial thrombosis are directed mainly at minimizing factors predisposing to atherosclerosis. Treatment of established arterial thrombosis includes the use of antiplatelet drugs and thrombolytic therapy.

Antiplatelet drugs

Platelet activation at the site of vascular damage is crucial to the development of arterial thrombosis, and this can be altered by the following drugs (Table 8.28):

- *Aspirin* irreversibly inhibits the enzyme cyclo-oxygenase (COX), resulting in reduced platelet production of TXA_2 (see Fig. 8.32). At the low doses used in cardiovascular disease prevention or treatment, there is selective inhibition of the isoform COX-1 found within platelets. This inhibition cannot be repaired and is effective for the life of the circulating platelet, which is about 1 week.
- *Dipyridamole* - which inhibits platelet phosphodiesterase, causing an increase in cyclic AMP with potentiation of the action of PGI_2 - has been used widely as an anti-thrombotic agent, but there is little evidence that it is effective.

Table 8.28 **Drugs used in the treatment of thrombotic disorders**

Antiplatelet
Aspirin
Dipyridamole
Clopidogrel
Gp, IIb/IIIa inhibitors, e.g. abciximab, eptifibatide, tirofiban Epoprostenol

Thrombolytic
Streptokinase Tissue-type plasminogen activator (t-PA or alteplase)
Reteplase (r-PA) Tenecteplase (TNK-tPA)

Anticoagulant
Heparin:
unfractionated (or standard)
low molecular weight
Hirudins, e.g. lepirudin
Fondaparinux
Warfarin
Ximelagatran

- *Clopidogrel* - affects the ADP-dependent activation of the glycoprotein lib/Ilia complex. It is similar to ticlopidine but has fewer side-effects. Trials support its use in acute coronary syndromes (p. 808), particularly if aspirin is contraindicated.
- *Glycoprotein IIb/IIIa receptor antagonists* block a receptor on the platelet for fibrinogen and von Willebrand factor (Fig. 8.39). Three classes have been described:
  (a) murine—human chimeric antibodies (e.g. abciximab)
  (b) synthetic peptides (e.g. eptifibatide)
  (c) synthetic non-peptides (e.g. tirofiban).
  They have been used as an adjunct in invasive coronary intervention and as primary medical therapy in coronary heart disease. Excessive bleeding has been a problem.
- *Epoprostenol* is a prostacyclin which is used to inhibit platelet aggregation during renal dialysis (with or without heparin) and is also used in primary pulmonary hypertension.

The indications for and results of antiplatelet therapy are discussed in the appropriate sections (pp. 806 and 1215).

Thrombolytic therapy

Streptokinase

Streptokinase is a purified fraction of the filtrate obtained from cultures of haemolytic streptococci. It forms a complex with plasminogen, resulting in a conformational change which activates other plasminogen molecules to form plasmin.

Streptokinase is antigenic and the development of streptococcal antibodies precludes repeated use. Activation of plasminogen is indiscriminate so that both fibrin in clots and free fibrinogen are lysed, leading to low fibrinogen levels and the risk of haemorrhage.

Plasminogen activators (PA)

Tissue-type plasminogen activators (alteplase (t-PA), tenecteplase (TNK-PA)) are produced by recombinant technology. Reteplase (r-PA) is also a recombinant plasminogen activator. They are not antigenic and do not give allergic reactions. They have a slightly higher risk of intracerebral haemorrhage (see also p. 813).

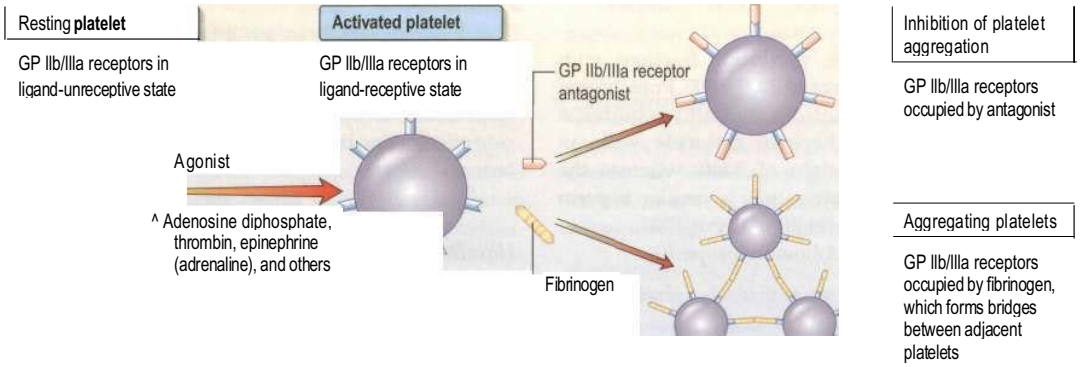

Fig. 8.39 **The role of glycoprotein IIb/IIIa in platelet aggregation and the inhibition of platelet aggregation by inhibitors of glycoprotein IIb/IIIa receptors.** Modified from Lefkovits J, Plow EF, Topol EJ (1995) *New England Journal of Medicine* **332:** 1554, with permission.

Indications

The use of thrombolytic therapy in myocardial infarction is discussed on page 813. The combination of aspirin with thrombolytic therapy produces better results than thrombolytic therapy alone. The extent of the benefit depends on how quickly treatment is given. They are also used in cerebral infarction (p. 1214) and occasionally in massive pulmonary embolism.

The main risk of thrombolytic therapy is bleeding. Treatment should not be given to patients who have had recent bleeding, uncontrolled hypertension or a haemorrhagic stroke, or surgery or other invasive procedures within the previous 10 days.

Prevention and treatment of venous thromboembolism

Venous thromboembolism is a common problem after surgery, particularly in high-risk patients such as the elderly, those with malignant disease and those with a history of previous thrombosis (Table 8.29). The incidence is also high in patients confined to bed following trauma, myocardial infarction or other illnesses. The prevention and treatment of venous thrombosis includes the use of anticoagulants.

Anticoagulants

Heparin (standard or unfractionated)

Heparin is not a single substance but a mixture of poly-saccharides. Commercially available unfractionated heparin consists of components with molecular weights varying from 5000 to 35 000 with an average of about 13 000. It was initially extracted from liver (hence its name) but it is now prepared from porcine gastric mucosa.

Heparin has an immediate effect on coagulation by potentiation of the formation of irreversible complexes between antithrombin and activated serine protease coagulation factors (thrombin, XIIa, XIa, Xa, IXa and VIIa).

Table 8.29 **Classification of risk of deep vein thrombosis and pulmonary embolism for hospital patients**

Low risk (proximal vein thrombosis 0.4%; fatal pulmonary embolism < 0.2%) Patients < 40 years undergoing major surgery (> 30 minutes) with no other risk factors Patients undergoing minor surgery (< 30 minutes) with no other risk factors Patients with minor trauma or illness with no thrombophilia but history of deep vein thrombosis or previous pulmonary embolism

Medium risk (proximal vein thrombosis 2-4%; fatal pulmonary embolism 0.2-0.5%) Major general, urological, gynaecological, cardiothoracic, vascular or neurological surgery in patients > 40 years or with one or more other risk factor(s) Major acute medical illness such as myocardial infarction, heart failure, chest infection, cancer or inflammatory bowel disease Major trauma Minor surgery, trauma or illness in patients with previous deep vein thrombosis, pulmonary embolism or thrombophilia Plastercast immobilization of the leg in patients with minor injury

High risk (proximal vein thrombosis 10-20%; fatal pulmonary embolism 1-5%) Fracture or major orthopaedic surgery of pelvis, hip or leg Major pelvic or abdominal surgery for cancer Major surgery, trauma or illness in patients with previous deep vein thrombosis, pulmonary embolism or thrombophilia Leg paralysis Critical leg ischaemia or major leg amputation

Verstraete M (1997) Fortnightly review: prophylaxis of venous embolism. *BMJ* 314:124, with permission of the BMJ.

Low-molecular-weight heparins (LMW heparins)
These are produced by enzymatic or chemical degradation of standard heparin, producing fractions with molecular weights in the range of 2000-8000. Potentiation of thrombin inhibition (anti-IIa activity) requires a minimum length of the heparin molecule with an approximate molecular weight of 5400, whereas the inhibition of factor Xa requires only a smaller heparin molecule with a molecular weight of about 1700. LMW heparins have the following properties:

- Bioavailability is better than that of unfractionated heparin.
- They have greater activity against factor Xa than against factor Ha, suggesting that they may produce an equivalent anticoagulant effect to standard heparin but have a lower risk of bleeding, although this has not generally been confirmed. In addition, LMW heparins cause less inhibition of platelet function.
- They have a longer half-life than standard heparin and so can be given as a once-daily subcutaneous injection instead of every 8-12 hours.
- They produce little effect on tests of overall coagulation, such as the APTT at doses recommended for prophylaxis. They are not fully neutralized by protamine.

LMW heparins are widely used for antithrombotic prophylaxis, e.g. high-risk surgical patients and for the treatment of established thrombosis (see p. 870).

The main complication of all heparin treatment is bleeding. This is managed by stopping heparin. Very occasionally it is necessary to neutralize unfractionated heparin with protamine. Other complications include osteoporosis with prolonged therapy and thrombo-cytopenia.

Heparin-induced thrombocytopenia (HIT). HIT is an uncommon complication of heparin therapy and usually occurs 5-14 days after first heparin exposure. It is due to an immune response directed against heparin/platelet factor 4 complexes. All forms of heparin have been implicated but the problem occurs less often with LMW heparins. A separate and unimportant immediate thrombocytopenia has also been described.

HIT is paradoxically associated with severe thrombosis and when diagnosed all forms of heparin must be discontinued, including heparin flush. Unfortunately the diagnosis can be difficult to make because patients on heparin are often very sick and may be thrombocytopenic for many other reasons. Laboratory tests based on bioassay or immunoassay are available but are neither sensitive nor specific and management decisions often have to be made before results are available.

It is usually necessary to continue some form of anti-coagulation in patients with HIT and the choice lies between the heparinoid danaparoid and the antithrombin hirudin. The introduction of warfarin should be covered by one of these agents, as warfarin alone may be ineffective or even exacerbate thrombosis as protein C levels fall.

Fondaparinux
This is a new synthetic pentasaccharide which inhibits activated factor X, similar to the LMW heparins. It will now be necessary to establish comparative efficacy (prevention or treatment of thrombosis) against risk of side-effects (bleeding) before the position of fondaparinux becomes clear.

Hirudin
A recombinant form of hirudin, lepirudin, is available. Lepirudin is used for anticoagulation in patients with HIT. Hirudins act directly on thrombin and can be monitored by the use of the APTT. They are excreted by the kidney and must be used with caution in renal failure.

Oral anticoagulants
These act by interfering with vitamin K metabolism. There are two types of oral anticoagulants, the coumarins and indanediones. The coumarin warfarin is most commonly used because it has a low incidence of side-effects other than bleeding.

The dosage is controlled by PT tests. Thromboplastin reagents for PT testing are derived from a variety of sources and give different PT results for the same plasma. It is standard practice to compare each thromboplastin with an international reference preparation so that it can be assigned an international sensitivity index (ISI). The international normalized ratio (INR) is the ratio of the patient's PT to a normal control when using the international reference preparation. Therapeutic ranges using the INR for oral anticoagulation in various conditions are shown in Box 8.2.

Each laboratory can use a chart adapted to the ISI of their thromboplastin to convert the patient's PT to the INR. Suitably selected control plasmas can also be used to achieve the same objective. The use of this system means that PT tests on a given plasma sample using different thromboplastins result in the same INR and that anticoagulant control is comparable in different hospitals across the world.

Box 8.2 **Indications for oral anticoagulation and target INR (British Society for Haematology 1998)**

Target INR	
2.5	Pulmonary embolism, proximal and calf deep vein thrombosis, recurrence of venous thromboembolism when no longer on warfarin therapy, symptomatic inherited thrombophilia, atrial fibrillation, cardioversion, mural thrombus, cardiomyopathy.
3.5	Recurrence of venous thromboembolism while on warfarin therapy, antiphospholipid syndrome, mechanical prosthetic heart valve, coronary artery graft thrombosis

Contraindications to the use of oral anticoagulants are seldom absolute and include:

- severe uncontrolled hypertension
- non-thromboembolic strokes
- peptic ulceration (unless cured by *Helicobacter pylori* eradication)
- severe liver and renal disease
- pre-existing haemostatic defects
- non-compliance.

Oral anticoagulants should be avoided in pregnancy because they are teratogenic in the first trimester and may be associated with fetal haemorrhage later in pregnancy. When anticoagulation is considered essential in pregnancy, specialist advice should be sought. Self-administered subcutaneous heparin should be used as an alternative, although this may not be as effective for women with prosthetic cardiac valves.

Many drugs interact with warfarin (see Ch. 16). More frequent PT testing should accompany changes in medication, which should occur with the full knowledge of the anticoagulant clinic.

An increased anticoagulant effect due to warfarin (Emergency box 8.1) is usually produced by one of the following mechanisms:

- drugs causing a reduction in the metabolism of warfarin, including tricyclic antidepressants, cimetidine, sulphonamides, phenothiazines and amiodarone
- drugs such as clofibrate and quinidine which increase the sensitivity of hepatic receptors to warfarin

***Emergency Box** 8.1*
Management of bleeding and excessive oral anticoagulation (modified from British Society for Haematology 1998)

INR > 3.0 < 6.0 (target INR 2.5)	(1) reduce warfarin dose or stop
INR > 4.0 < 6.0 (target INR 3.5)	(2) restart warfarin when INR < 5.0
INR > 6.0 < 8.0 no bleeding or minor bleeding	(1) stop warfarin (2) restart when INR < 5.0
INR > 8.0, no bleeding or minor bleeding	(1) stop warfarin (2) restart warfarin when INR <5.0 (3) if other risk factors for bleeding give 0.5-2.5 mg of vitamin K (oral)
Major bleeding	(1) stop warfarin (2) give prothrombin complex concentrate 50 units/kg or FFP 15 mL/kg (3) give 5 mg of vitamin K (oral or i.v.)

If unexpected bleeding occurs investigate the possibility of a local anatomical cause.

- drugs interfering with vitamin K absorption (such as broad-spectrum antibiotics and colestyramine) which also potentiate the action of warfarin
- displacement of warfarin from its binding site on serum albumin by drugs such as sulphonamides (this is not usually responsible for clinically important interactions)
- drugs that inhibit platelet function (such as aspirin) which increase the risk of bleeding
- alcohol excess, cardiac failure, liver or renal disease, hyperthyroidism and febrile illnesses which result in potentiation of the effect of warfarin.

A decreased anticoagulant effect due to warfarin. This is usually produced by drugs that increase the clearance of warfarin by induction of hepatic enzymes that metabolize warfarin, such as rifampicin and barbiturates.

Ximelagatran

This oral direct thrombin inhibitor is a potential alternative to warfarin and has already been evaluated in patients with venous thromboembolism, atrial fibrillation and myocardial infarction. It has a rapid onset of action and can be administered in a fixed dose without the need for monitoring. Drug interactions are also less than for warfarin but elimination is primarily renal and abnormalities of liver function have been described during its use.

Prophylaxis to prevent venous thromboembolism

Prophylactic measures to prevent venous thrombosis during surgery are aimed at procedures for preventing stasis, such as early mobilization, elevation of the legs, compression stockings, and possibly calf-muscle stimulation and passive calf-muscle exercises during surgery, and methods for preventing hypercoagulability, usually using heparin.

Low-risk patients (Table 8.29) require no specific measures other than early mobilization.

Moderate-risk patients should receive a standard dose of LMW heparin e.g. enoxaparin 20 mg (2000 i.u.) subcutaneously daily until the patient is ambulatory.

In *high-risk patients,* such as patients undergoing total hip replacement, LMW heparin once daily, such as enoxaparin 40 mg (4000 i.u.), has been shown to be more effective than standard low-dose heparin in preventing thrombosis. There is evidence to suggest that it is most effective when administered for a total of 1 month post-operatively rather than merely during the admission for surgery.

LMW heparin has replaced standard low-dose heparin for all surgical prophylaxis and is increasingly used for medical prophylaxis.

Treatment of established venous thromboembolism

The aim of anticoagulant treatment is to prevent further thrombosis and pulmonary embolization while resolution

of venous thrombi occurs by natural fibrinolytic activity. Anticoagulation is started with heparin as it produces an immediate anticoagulant effect. There is no evidence that it is necessary to use heparin for any longer than it takes for simultaneously administered warfarin to produce an anticoagulant effect (INR 2.5) usually about 3^ days.

LMW heparin (e.g. tinzaparin 175 units/kg daily) is equally effective and as safe as unfractionated heparin in the immediate treatment of deep vein thrombosis and pulmonary embolism. This creates the opportunity for treatment of venous thromboembolism without admission to hospital, in compliant patients without coexisting risk factors for haemorrhage.

Anticoagulation (with warfarin approximately 3-9 mg daily for 6 weeks) is sufficient for patients after their first thrombosis provided there are no persisting risk factors. There is much interest in the use of longer-term anticoagulation in patients with previous thrombosis. It has been suggested that a lower INR might be safer and equally effective but the current view is that the target INR should be 2.0 to 3.0 where oral anticoagulation is used. Secondary prophylaxis should be offered to patients with unprovoked venous thromboembolism, for a period of 6-12 months. Very long-term treatment should be reserved for those with repeated episodes or continuing risk factors. Outpatient anticoagulation is best supervised in anticoagulant clinics. Patients are issued with national booklets for recording INR results and anticoagulant doses.

The role of thrombolytic therapy in the treatment of venous thrombosis is not established. It is sometimes used in patients with massive pulmonary embolism and in patients with extensive deep venous thrombi.

Thrombolytic therapy should be followed by anti-coagulation with heparin for a few days and then by oral anticoagulants for a few months to prevent rethrombosis.

Malignant disease 9

The term 'malignant disease' encompasses a wide range of illnesses, including common ones such as lung, breast and colorectal cancer (Table 9.1), as well as rare ones, like the acute leukaemias. Malignant disease is widely prevalent and, in the West, almost a third of the population will develop cancer at some time during their life. It is second only to cardiovascular disease as the cause of death. Although the mortality of cancer is high, many advances have been made, both in terms of treatment, and in understanding the biology of the disease at the molecular level.

Treatment is given with curative or palliative intent, depending upon the evidence from continuing clinical trials. For many people, the word 'cancer' implies certain death, although this is clearly not always the case. Physicians have an obligation to be honest with their patients, combining realism about the prognosis with compassion and understanding so that patients can take an informed part in treatment decisions.

AETIOLOGY AND EPIDEMIOLOGY

In most patients the cause of their cancer remains unknown and is probably multifactorial. Several environmental factors have, however, been identified as being associated with the development of malignancy (Table 9.2).

Table 9.1 **Epidemiology of cancer by site of origin in England and Wales**

Type	% of all cancers (1998)	% of cancer deaths	M : F
Oral cavity/pharynx	1	1.2	2.3 : 1
Oesophagus	2.3	4.4	2 : 1
Stomach	3.7	4.7	2.4 : 1
Colorectal	11.1	11.0	1.4 : 1
Pancreas	2.3	4.3	1.5 : 1
Lung	13.6	22.2	1.6 : 1
Melanoma	1.8	1.0	0.6 : 1
Other skin	14.1	0.3	1.5 : 1
Breast	12.2	8.6	0.01 : 1
Cervix	1.2	1.1	
Uterus	1.5	0.7	
Ovary	2.0	2.9	
Prostate	7.4	6.3	
Bladder	4.5	3.5	3.6 : 1
Kidney	1.8	2.0	2.1 : 1
Brain	1.3	2.1	1.4 : 1
Non-Hodgkin's lymphoma	2.8	2.9	1.5 : 1
Myeloma	1.1	1.6	1.5 : 1
Leukaemias	2.1	2.6	1.5 : 1

Derived from Doll R, Peto R (2003) In: *Oxford Textbook of Medicine.* 4th edn. Oxford: Oxford University Press

Tobacco

The incidence of lung cancer in both men and women has increased dramatically in the last 25 years. The association of smoking with lung cancer is indisputable and causative mechanisms have been identified: cigarette tobacco is responsible for one-third of all deaths from cancer in the UK. Smoking not only causes lung cancer, it is also associated with cancer of the mouth, larynx, oesophagus and bladder. Smoking is discussed on page 893.

Alcohol

Alcohol is associated with cancers of the upper respiratory and gastrointestinal tracts (Table 9.2), and it also interacts

Table 9.2 Some causative factors associated with the development of cancer at various sites

Smoking	Mouth, pharynx, oesophagus, larynx, lung, bladder, lip
Alcohol	Mouth, pharynx, larynx, oesophagus, colorectal
Iatrogenic:	
Alkylating agents	Bladder, bone marrow
Oestrogens	Endometrium, vagina, breast
Androgens	Prostate
Radiotherapy	e.g. mantle radiotherapy – carcinoma of breast and bronchus
Diet:	
High-fat diet	Colorectal cancer
Environmental/ occupation:	
Vinyl chloride	Liver (angiosarcoma)
Polycyclic hydrocarbons	Skin, lung, bladder, myeloid leukaemia
Aromatic amines	Bladder
Asbestos	Lung, mesothelium
Ultraviolet light	Skin, lip
Radiation	e.g. leukaemia, thyroid cancer
Aflatoxin	Liver
Biological agents:	
Hepatitis B virus	Liver (hepatocellular carcinoma)
Hepatitis C virus	Liver (hepatocellular carcinoma)
Human T cell leukaemia virus	Leukaemia/lymphoma
Epstein–Barr virus	Burkitt's lymphoma Hodgkin's lymphoma
Schistosoma japonicum	Bladder
Helicobacter pylori	Stomach

with tobacco in the aetiology of these tumours. It may be associated with an increased risk of breast cancer.

Diet

Dietary factors have been attributed to account for a third of cancer deaths, although it is often difficult to differentiate these from other epidemiological factors. For example, the incidence of stomach cancer is particularly high in the Far East, while breast and colon cancers are more common in the western, economically more developed countries. Many associations have been observed without a causative mechanism being identified between the incidence of cancer and the consumption of dietary fibre, red meat, saturated fats, salted fish, vitamin E, vitamin A and many others. Food and its role in the causation of gastrointestinal cancer is discussed in Chapter 5.

Environmental/occupational

Ultraviolet light is known to increase the risk of skin cancer (basal cell, squamous cell and melanoma). The incidence of melanoma is therefore particularly high in the white Anglo-Celtic population of Australia, New Zealand and South Africa, where exposure to UV light is combined with a genetically predisposed population.

Occupational factors. In 1775, Percival Pott described the association between carcinogenic hydrocarbons in soot and the development of scrotal epitheliomas in chimney sweeps.

The principal causes now are asbestos (lung and mesothelial cancer) and combustion of fossil fuels releasing polycyclic hydrocarbons (skin, lung, bladder cancers). Organic chemicals such as benzene may cause molecular abnormalities associated with the development of myeloid leukaemia.

Infectious agents

The geographical distribution of a rare malignancy may suggest that it might be caused by, or associated with, an infective agent. For example, a specific type of T-cell leukaemia, seen almost exclusively in residents of the southern island of Japan and in the West Indies, is caused by infection with the retrovirus, HTLV-1 (human T-cell leukaemia virus) which is endemic in these areas.

Hepatocellular carcinoma occurs in patients with hepatitis B and C virus infections, and Burkitt's lymphoma and nasopharyngeal carcinoma are associated with the Epstein–Barr virus. EBV is also linked with Hodgkin's lymphoma (p. 508). Patients with HIV infection or immunosuppression from organ transplantation have an increased incidence of EBV-related lymphoma and herpesvirus-8-associated Kaposi's sarcoma. The incidence of cervical cancer is increasing amongst younger women in association with human papillomavirus infection. Early sexual activity and multiple sexual partners have both been found to be associated with increased risk.

Bacterial infection with *Helicobacter pylori* predisposes to the development of gastric cancer and gastric lymphoma, while *Schistosoma japonicum* infection predisposes to the development of squamous carcinomas in the bladder.

Iatrogenic

Drugs. Oestrogens have been implicated in the development of vaginal, endometrial and breast carcinoma. Alkylating agents and radiotherapy given, for example, for Hodgkin's lymphoma (see later) are themselves associated with an increased incidence of secondary acute myelogenous leukaemia (AML), bladder and lung cancer. The epipodophyllotoxin drug, etoposide, has also been shown to be associated with the development of secondary AML.

Radiation. The nuclear disasters of Hiroshima, Nagasaki and Chernobyl led to an increased incidence of leukaemia after 5–10 years in the exposed population. Increased incidences of thyroid and breast cancer have also been reported. Radiotherapy used, for example, in ankylosing spondylitis and Hodgkin's lymphoma, has led to increased incidences of cancer.

Geographical distribution

The incidence of specific tumours varies with geographical location but the cause varies; for example England, Scotland and Wales have the highest death rate from malignant disease in the world, mainly because of the very

high incidence of lung cancer due to smoking. India also has the highest incidence of cancers of the gall bladder, mouth and lower pharynx. Breast, colon and prostatic cancer have a relatively low incidence in Asian countries. Liver cancer occurs world-wide but is rare in Europe and North America where the HBV carrier rate is low. Stomach cancer is particularly prevalent in Japan and is thought to be due to dietary factors.

Environmental factors have been clearly implicated. For example, subsequent generations of people moving from countries with a low incidence to those with a high incidence of breast or colon cancer acquire the cancer incidence of the country to which they have moved. This suggests that for these specific cancers, environmental factors are more significant than genetic ones.

THE BIOLOGY OF CANCER

Most human neoplasms are monoclonal in origin, i.e. they arise from genetic mutations within a single affected cell. However, over subsequent cell divisions heterogeneity develops with the accumulation of further abnormalities. The genes most commonly affected can be characterized as those controlling cell cycle check points, DNA repair and DNA damage recognition, apoptosis, differentiation, and growth signalling. Proliferation may continue at the expense of differentiation, which together with the failure of apoptosis leads to tumour formation with the accumulation of abnormal cells varying in size, shape and nuclear morphology as viewed down the light microscope.

The *kinetics* of cancer cell growth are exponential; however, the doubling times of human tumours are enormously variable. Mutations are common in the genes controlling a series of intracellular proteins, such as the cyclins and cyclin-dependent kinases (p. 157), and oncogene products such as c-*myc*, and the *ras* proteins (see Cancer genetics, p. 188) that regulate proliferation. Proliferation may also be abnormal due to defects in the nuclear enzyme telomerase, contact with other cells, nutrient supply or cytokine signalling. Telomerase is an enzyme that prevents the normal shortening of DNA with each cell division that leads to senescence. Persistent telomerase activity helps to maintain the neoplastic state in cancer cells.

Epithelial growth factor (EGF) and its receptors are overexpressed in many human epithelial tumours, constitutively switching on unrestrained growth of these tumours. Transforming growth factor-β (TGF-β), a cytokine which has effects on extracellular matrix proteins, angiogenesis (see below) and immune effector cells, is also often overexpressed in tumour cells, and defects in TGF-β signalling are often found in cancer cells. This signalling pathway is activated by cytoplasmic proteins, e.g. MADH4. Defects in tumour suppressor genes such as *MADH4* (*SMAD4* or *DPC4*) and *p53* (see p. 189) have a major part to play and occur, for example, in most pancreatic cancers.

Apoptosis and growth

Tumour cell death may also be dysregulated. Normal cells usually die by an active and tightly regulated process known as apoptosis, or 'programmed cell death' (p. 162). Apoptosis can occur in response to a number of physiological or pathological stimuli (tumour necrosis factor, Fas ligand, and DNA-damaging cytotoxic drugs) and is mediated within the cell by a family of proteins known as caspases. Caspase activity is, in turn, regulated by intracellular inhibitors such as the Bcl-2 family of proteins and the inhibitor of apoptosis proteins (IAPs). Disturbances in the normal balance of these various proteins have been identified which favour survival of tumour cells over their normal counterparts. An example is the upregulation of the bcl-2 protein in follicular non-Hodgkin's lymphoma.

Tumour immunology

Tumour cells are usually not recognized and killed by the immune system. There are two main causes. The first is failure to express molecules such as HLA and costimulatory B7 molecules which are required for activation of cytotoxic, or 'killer', T lymphocytes, since expression of these 'costimulatory' molecules following gene transfection may augment an immune response. Secondly, tumours may also actively secrete immunosuppressive cytokines and cause a generalized immunosuppression, leading for example to the reactivation of latent herpes zoster in shingles associated with malignancy.

Angiogenesis

For many tumours, there is a progressive slowing of the rate of growth as the tumours become larger. This occurs for many reasons, but outgrowing the blood supply is paramount. Tumours need to establish a new blood supply. This new vessel formation (angiogenesis) is stimulated by a variety of peptides produced both by tumour cells and by host inflammatory cells, such as basic fibroblast growth factor (bFGF), angiopoietin 2 and vascular endothelial growth factors (VEGFs), which are stimulated by hypoxia. Inhibition of angiogenesis is a potentially novel method of cancer therapy, as new vessel formation within and around tumours not only provides the cancer with nutrients and oxygen, but permits haematogenous spread, or metastasis.

Invasion and metastasis

Cancers spread by both local invasion and by metastasis in vessels of the blood or lymphatic systems. Infiltration into surrounding tissues is associated with loss of cell–cell cohesion. Cohesion is mediated by active homotypic cell adhesion molecules (CAMs). The cadherin molecules are transmembrane glycoproteins able to mediate cellular attachment. Epithelial cadherin (E-cadherin) is expressed by many carcinomas, e.g. gastric carcinoma (p. 289), and

loss of E-cadherin expression is associated with an increase in invasion of the tumour.

Invasion is partly determined by the balance of activators to inhibitors of proteolysis. Secretion of proteolytic enzymes, including the matrix metalloproteinases (particularly the collagenases), occurs from adjacent fibroblasts owing to failure of production of tissue inhibitors. The balance between the expression and activity of the matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) is involved in tumour growth, invasion, metastasis and angiogenesis. Some TIMPs may regulate cell proliferation and survival of cancer cells independently of MMP activity.

Dissemination of tumour cells occurs when they enter the vascular and lymphatic vessels. Here they must survive host-defence mechanisms so as to spread throughout the body. The disseminated cancer cells lodge in distant sites, partly by chance, but also because of specific interactions between receptors/ligands found on endothelial cells and on tumour cells. This may account for the specific pattern of metastases with certain tumours; for example, breast tumours frequently metastasize to long bones (see below).

The attachment of tumour cells to the endothelial cells is partly through adhesion molecules. Integrins are transmembrane heterodimeric glycoproteins formed by non-covalent association of α and β chains. These molecules are normally responsible for cell-substrate adhesion. Patterns of integrin expression in tumours are complex but, nevertheless, certain tumours demonstrate up-regulation of specific integrins, such as the alpha v family, during tumour progression, and this may allow migration of tumour cells through the extracellular matrix substrate and invasion through the basement membrane and formation of a metastatic deposit. Integrins also act as receptors for signals regulating gene expression and apoptosis.

Bone metastases. These occur in 75% of patients with advanced breast and prostate cancer and in 25% of patients with other solid tumours, e.g. lung, GI tract, thyroid, bladder or kidney.

Metastases are either osteolytic or osteoblastic with some patients having both.

Prostate cancer is predominantly osteoblastic while most patients with breast cancer have osteolytic lesions. In multiple myeloma (p. 517) the lesions are purely osteolytic.

Bone is a frequent site of metastases due to:

- high blood flow
- tumour cell production of adhesins which bind them to marrow stromal cells
- growth factors in bone, including TGFβ, insulin-like growth factor (ILG)-1 and 2, platelet-derived growth factor and fibroblastic growth factors.

Osteolytic metastases (Fig. 9.1). The destruction of bone is mediated by osteoclasts and not the tumour cells. Tumour cells produce parathyroid hormone-related peptide, IL-6, prostaglandin E_2, TNF and macrophage colony-stimulating factor (M-CSF) which increase the expression of receptor activity of nuclear factor κB ligand (RANKL) which directly induces formation of osteoclasts and bone resorption. Bone destruction increases calcium levels, which promotes both tumour growth and the production of PTH-related peptide, which is a major factor in osteolytic bone destruction in many tumours. In multiple myeloma there is, additionally, inhibition of osteoblast activity (p. 517).

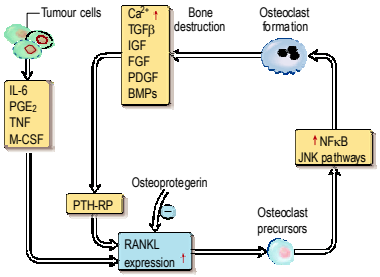

Fig. 9.1 **Mechanisms of osteolytic metastases**. Tumour cells secrete hormones as shown. These increase various factors, e.g. RANKL, and lead to increased osteoclastic activity. Bone destruction (resorption) in turn produces factors which increase tumour growth. Osteoprotegerin (see p. 592) has an inhibitory effect on RANKL. BMPs, bone morphogenic proteins; FGF, fibroblast growth factor; IGF, insulin-like growth factor; IL-6, interleukin 6; JNK, jun N-terminal kinase; M-CSF, macrophage colony-stimulating factor; NFκB, nuclear factor kappa B; PDGF, platelet-derived growth factor; PGE2, prostaglandin E2; PTH-RP, parathyroid hormone-related peptide; RANKL, receptor activator of NFκB ligand; TGF, transforming growth factor; TNF, tumour necrosis factor.

Osteoblastic metastases. The mechanism for this is less clear. It has been suggested that osteoclastic activity precedes osteoblastic activity and bone formation. It is also possible that the vicious circle (as in osteoclastic activity) may be in action, whereby the tumour induces osteoblastic activity and the release of growth factors for osteoblasts, which then increases the growth of tumours. Endothelin 1 has been shown to stimulate bone formation and its levels are increased in, for example, prostate and breast cancers.

Cancer genetics

The development of cancer is associated with a fundamental genetic change within the cell. Evidence for the genetic origin of cancer is based on the following:

- Some cancers show a familial predisposition.
- Most known carcinogens act through induced mutations.

- Susceptibility to some carcinogens depends on the ability of cellular enzymes to convert them to a mutagenic form.
- Genetically determined traits associated with a deficiency in the enzymes required for DNA repair are associated with an increased risk of cancer.
- Some cancers are associated with chromosome 'instability' because of deficiencies in mismatch repair genes.
- Many malignant tumours represent clonal proliferations of neoplastic cells.
- Many tumours contain well-described cytogenetic abnormalities, which involve mutated or abnormally regulated oncogenes and tumour suppressor genes with transforming activity in cell lines.

Mutations may occur in the germline and therefore be present in every cell in the body, or they may occur by somatic mutation in response, for example, to carcinogens, and therefore be present only in the cells of the tumour.

Expression of the mutation and hence carcinogenesis will depend upon the penetrance (due to level of expression and presence of other genetic events) of the gene and whether the mutated allele has a dominant or recessive effect. There are a small group of autosomal dominant inherited mutations such as *RB* (in retinoblastoma) and a small group of recessive mutations (Table 9.3). Carriers of the recessive mutations are at risk of developing cancer if the second allele becomes mutated, leading to 'loss of heterozygosity' within the tumour, although this is seldom sufficient as carcinogenesis is a multistep process.

Malignant transformation may result from a gain in function as cellular proto-oncogenes become mutated, (e.g. *ras*), amplified (e.g. *HER2*), or translocated (e.g. *BCR-ABL*). However, these mutations are insufficient to cause malignant transformation by themselves. Alternatively, there may be a loss of function of tumour suppressor genes that normally suppress growth and differentiation. A third mechanism involves alterations in the genes controlling the transcription of the oncogenes or tumour suppressor genes (e.g. p. 189) (Tables 9.3 and 9.4).

DNA repair

Autosomal recessive

Some relatively rare autosomal *recessive* diseases associated with abnormalities of DNA repair predispose to the development of cancer (Table 9.3).

- *Xeroderma pigmentosum*. There is an inability to repair DNA damage caused by ultraviolet light and by some chemicals, leading to a high incidence of skin cancer.
- *Ataxia telangiectasia*. Mutation results in an increased sensitivity to ionizing radiation and an increased incidence of lymphoid tumours.
- *Bloom's syndrome and Fanconi's anaemia*. An increased susceptibility to lymphoid malignancy is seen.

It is not known why these chromosome-break syndromes predispose to tumours of lymphatic tissue.

Autosomal dominant

The following are examples of cancer syndromes that exhibit *dominant* inheritance (Table 9.3):

- *Retinoblastoma*, an eye tumour found in young children. It occurs in both hereditary (40%) and non-hereditary (60%) forms. The 40% of patients with the hereditary form have a germline mutation on the long arm of chromosome 13 that predisposes to retinoblastoma. In addition to the latter, children inheriting this mutation

Table 9.3 Familial cancer syndromes

	Gene	Neoplasms
Autosomal dominant		
Retinoblastoma	*RB1*	Eye
Wilms' tumour	*WT1*	Kidney
Li–Fraumeni	*p53*	Sarcoma/ brain/ leukaemia
Neurofibromatosis type 1	*NF1*	Neurofibromas
Familial adenomatous polyposis (FAP)	*APC*	Colon
Hereditary non-polyposis colon cancer (HNPCC)	*MLH1* and *MSH2*	Colon, endometrium
Breast ovary families	*BRCA1* and *BRCA2*	Breast/ovary
Melanoma	*p16*	Skin
Von Hippel–Lindau	*VHL*	Renal cell carcinoma and haemangioblastoma
Multiple endocrine neoplasia Type 1	*MEN1*	Pituitary, pancreas, parathyroid
Multiple endocrine neoplasia Type 2	*RET*	Thyroid, adrenal medulla
Autosomal recessive		
Xeroderma pigmentosa	*XP*	Skin
Ataxia telangiectasia	*AT*	Leukaemia, lymphoma
Fanconi's anaemia	*FA*	Leukaemia, lymphoma
Bloom's syndrome	*BS*	Leukaemia, lymphoma

Table 9.4 Examples of acquired/somatic mutations and proto-oncogenes

Point mutation	
K-*ras*	Pancreatic cancer
DNA amplification	
myc	Neuroblastoma
HER2-neu	Breast cancer
Chromosome translocation	
BCR-ABL	CML, ALL
PML-RAR	APML
Bcl-2/IgH	Follicular lymphoma
c-myc and Ig	Burkitt's lymphoma

CML, chronic myeloid leukaemia; ALL, acute lymphoblastic leukaemia; APML, acute promyelocytic leukaemia

at the so-called *RB1* locus are at risk for developing other tumours, particularly osteosarcoma.

- *Breast and ovarian cancer.* Two genes have been identified – *BRCA1* and *BRCA2*. A strong family history along with germline mutation of these genes accounts for most cases of familial breast cancer and over half of ovarian cancers. BRCA1 and 2 proteins bind to the DNA repair enzyme Rad51 to make it functional in repairing DNA breaks. Mutations in the *BRCA* genes will lead to accumulation of unrepaired mutations in tumour-suppressor genes and crucial oncogenes.
- *Neurofibromatosis.* Inactivation of the *NF1* gene will lead to constitutive activation of *ras* proteins.
- *Multiple-endocrine-adenomatosis syndromes* (p. 1099). Multiple endocrine neoplasia type 1 is associated with the *MEN1* gene and type 2 (MEN2) is associated with mutations in the *RET* proto-oncogene on chromosome 10 and as such are the exception to all the other syndromes which involve tumour suppressor genes.

THE DIAGNOSIS OF MALIGNANCY

Most common cancers (but not the haematological cancers) start as focal microscopic clones of transformed cells, and diagnosis only becomes likely once sufficient tumour bulk has accumulated to cause symptoms or signs. In order to try to make an earlier diagnosis and increase the curative possibilities, an increasing number of screening programmes are being investigated which target the asymptomatic or preinvasive stages of the cancer.

Screening

Genetic screening is used to target screening to those people at most risk of developing cancer. The aim is to improve individual and/or population survival. This strategy is dependent upon finding tests that are sufficiently sensitive and specific, using detection methods that identify cancer before it has spread, and having curative treatments that are practical and consistent with maintenance of a normal lifestyle and quality of life.

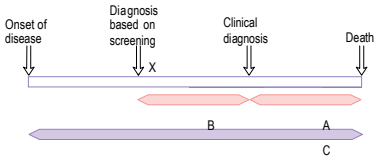

Fig. 9.2 **Lead time bias.** Earlier diagnosis, at X, made by screening tests before the clinical diagnosis, at Y, suggests an increased survival time of A + B. The actual survival time (C) remains unchanged.

The ability to detect cancer at its very early stages when the patient is asymptomatic is the goal of every healthcare system.

Screening is provided to populations, e.g. for breast and cervical cancer in the UK, and also to individuals via annual check-ups, or opportunistic when patients see their doctor for other reasons.

Unfortunately, earlier diagnosis does not necessarily mean longer survival. The patient is merely treated at an earlier date and hence the survival appears longer, death still occurs at the same time from the point of genesis of the cancer. This is called lead time bias (Fig. 9.2). With length time bias, a greater number of slowly growing tumours are detected when screening asymptomatic individuals.

An effective screening procedure should:

- be affordable to the healthcare system
- be acceptable to all social groups so that they attend the screening session
- have a good discriminatory index between benign and malignant lesions
- show a reduction in mortality from the cancer.

Cervical cancer

This test is cheap and safe but cervical smears require a well-trained cytologist to identify the early changes (dyskaryosis and cervical intraepithelial neoplasia (CIN)). This test reduces the incidence and mortality from cervical cancer.

Breast cancer

The UK NHS Breast Screening Programme (i.e. mammography) for women aged 50–64 years has been shown to reduce mortality from breast cancer, and randomized control studies from other countries have also shown reductions in mortality. The test is acceptable to most women with 75% of women attending for screening.

The cost is estimated to be between £250 000 and £1.3 million per life saved, money which according to critics of screening, could be used more appropriately in better treatment.

Other population-based screening programmes that are being used or are in trials are:

Prostate cancer

There is an easy, cheap, effective test – serum prostate-specific antigen (PSA) for the detection of this cancer, which is on the increase. The problems are that no easy acceptable treatment is available (p. 686) and the natural history of the disease is unclear (many men over 70 have evidence of prostate cancer at post-mortem with no symptoms of the disease) and no survival advantage has yet been shown.

Colorectal cancer (CRC)

Faecal occult blood is an acceptable and cheap test for the detection of CRC. The false-positive rates are high, meaning many unnecessary colonoscopies (p. 330). Screening with flexible sigmoidoscopy is discussed on p. 331. No clear benefit on survival has yet been shown.

Symptoms of cancer

Patients present with tumour site-specific symptoms, e.g. pain, and physical signs, e.g. a mass, which readily identify the primary site of the cancer. On the other hand, many seek medical attention when more systemic and non-specific symptoms occur such as weight loss, fatigue, and anorexia. These usually indicate a more advanced stage of the disease except in some paraneoplastic and ectopic endocrine syndromes (see below). Other patients are only diagnosed upon the discovery of established metastases such as the back pain of metastatic prostatic cancer or the liver enlargement of metastatic gastrointestinal cancer.

Other indirect effects of the cancer manifest as paraneoplastic syndromes (Box 9.1) that are often associated with specific types of cancer and are reversible with treatment of the cancer. The effects and mechanisms can be very variable. For example in the Lambert–Eaton syndrome (p. 1269) there is cross-reactivity between tumour antigens and the normal tissues, e.g. the acetylcholine release at neuromuscular junctions.

The *coagulopathy of cancer* may present with thrombophlebitis, deep venous thrombosis and pulmonary emboli, particularly in association with cancers of pancreas, stomach and breast.

Other symptoms are related to peptide or hormone release, e.g. carcinoid or Cushing's syndrome.

Cachexia of advanced cancer is due to release of chemokines such as tumour necrosis factor (TNF), as well as the fact that patients have a loss of appetite.

Cancer-associated immunosuppression can lead to reactivation of latent infections such as herpes zoster.

Physical examination

A general examination should be performed to include:

- main symptomatic areas, e.g. site, size of mass and associated lymphadenopathy
- precursor lesions, e.g. solar keratosis, dysplastic naevi
- general signs, e.g. jaundice, clubbing
- functional capacity (see Table 9.6).

***Box 9.1* Paraneoplastic syndromes**

Syndrome	Tumour
Neurological	
Lambert–Eaton syndrome	Lung (small cell)
Peripheral sensory neuropathy	Lung (small cell), breast and ovary
Cerebellar degeneration	Lung (particularly small cell)
Endocrine/metabolic	
SIADH	Lung (small cell)
Ectopic ACTH secretion	Lung (small cell)
Hypercalcaemia	Renal, breast
Musculoskeletal	
Hypertrophic pulmonary osteoarthropathy	Lung (non-small cell)
Clubbing	Lung
Skin	
Dermatomyositis/polymyositis	Lung and upper GI
Acanthosis nigricans	Mainly gastric
Hyperpigmentation	Lung (small cell)
Pemphigus	
Haematological	
Erythrocytosis	Renal cell carcinoma, hepatocellular carcinoma, cerebellar haemangioblastoma
Migratory thrombophlebitis	Pancreatic adenocarcinoma
DIC	Adenocarcinoma

SIADH, syndrome of inappropriate antidiuretic hormone secretion; ACTH, adrenocorticotrophic hormone; DIC, disseminated intravascular coagulation

Histology

The diagnosis of cancer may be suspected by both patient and doctor but advice about treatment can usually only be given on the basis of a tissue diagnosis. This may be obtained by surgical biopsy or on the basis of cytology (e.g. lung cancer diagnosed by sputum cytology or cervix cancer diagnosed on the basis of a cervical smear). Malignant lesions can be distinguished morphologically from benign by the pleomorphic nature of the cells, increased numbers of mitoses, nuclear abnormalities in size, chromatin pattern and nucleolar organization, and evidence of invasion into surrounding tissues.

The degree of differentiation (or conversely of anaplasia) of the tumour has prognostic significance: generally speaking, more differentiated tumours have a better prognosis than poorly differentiated ones. Immunocytochemistry, using monoclonal antibodies against tumour antigens, is very helpful in differentiating between lymphoid and epithelial tumours and between some subsets of these, for example T and B cell lymphomas, germ cell tumours, prostatic tumours, neuroendocrine tumours, melanomas, and sarcomas. However, many adenocarcinomas and squamous carcinomas do not bear any distinctive immunohistochemical markers that are diagnostic of their primary site of origin.

There are several tests for genetic markers in tissue sections. For example, fluorescent in situ hybridization (FISH, p. 177) can be used to look for characteristic chromosomal translocations, deletions or duplications (see genetic basis of cancer, p. 486). Tissue microarrays can identify genomic imbalances, e.g. in breast cell cancer lines and lymphoma (see p. 170).

Staging

Before a decision about treatment can be made, not only the type of tumour but also its extent and distribution need to be established. Various 'staging investigations' are therefore performed before a treatment decision is made. To be useful clinically the staging system must subdivide the patients into groups of different prognosis which can guide treatment selection.

The staging systems vary according to the type of tumour and may be site specific (see Hodgkin's lymphoma, p. 510), or the TNM (tumour, node, metastases) classification shown in Table 9.5 which can be applied to most common cancers.

Performance status

In addition to anatomical staging, the person's age and general state of health need to be taken into account when planning treatment. The latter has been called 'performance status' and is of great prognostic significance for all tumour types (Table 9.6). Performance status reflects the effects of the cancer on the patient's functional capacity. An alternative performance rating scale is by Karnowsky.

Tumour markers (Table 9.7)

Tumour markers are intracellular proteins or cell surface glycoproteins released into the circulation and detected by immunoassays. Alpha-fetoprotein, β-human chorionic gonadotrophin and prostate-specific antigen are useful in the diagnosis of cancer but the remainder in Table 9.7 should be used with great care in diagnosis because of low specificity. They can be useful in the serial monitoring of response to treatment, as they can be quite sensitive to changes in the tumour burden.

CANCER TREATMENT

Aims of treatment

Cancer treatment requires the cooperation of a multidisciplinary team to coordinate the delivery of the appropriate treatment (surgery, chemotherapy, radiotherapy and biological/endocrine therapy), supportive and symptomatic care, and psychosocial support. While all members will have the patient's care as their central concern, someone, often the oncologist, has to take responsibility for the coordination of the many professionals involved. Central to this endeavour is the

Table 9.5 **TNM classification as used for lung cancer**

T = extent of primary tumour; N = extent of regional lymph node involvement; M = presence of distant metastases

Tx	Positive cytology only
T1	< 3 cm diameter
T2	> 3 cm/extends to hilar region/invades visceral pleura/partial atelectasis
T3	Involvement of chest wall, diaphragm, pericardium, mediastinum, pleura, total atelectasis
T4	Involvement of heart, great vessels, trachea, oesophagus, malignant effusion
N1	Peribronchial, ipsilateral hilar lymph node involvement
N2	Ipsilateral mediastinal
N3	Contralateral mediastinal, scalene or supraclavicular
M0	No distant metastases
M1	Metastases present

Table 9.6 **Eastern Cooperative Oncology Group (ECOG) performance status scale**

Status	Description
0	Asymptomatic, fully active and able to carry out all predisease performance without restrictions
1	Symptomatic, fully ambulatory but restricted in physically strenuous activity and able to carry out performance of a light or sedentary nature, e.g. light housework, office work
2	Symptomatic, ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours: in bed less than 50% of day
3	Symptomatic, capable of only limited self-care, confined to bed or chair more than 50% of waking hours, but not bedridden
4	Completely disabled. Cannot carry out any self-care. Totally bedridden

Table 9.7 Serum tumour markers

α-Fetoprotein	Hepatocellular carcinoma, and non-seminomatous germ cell tumours of the gonads
β-Human chorionic gonadotrophin (β-HCG)	Choriocarcinomas, germ cell tumours and lung cancers
Prostate-specific antigen (PSA)	Carcinoma of prostate
Carcinoma embryonic antigen (CEA)	Gastrointestinal cancers
CA-125	Ovarian cancer
CA-19-9	Gastrointestinal cancers particularly pancreatic cancer
CA-15-3	Breast cancer

involvement of the patient, through education as to the nature of their disease and the treatment options available. An informed choice can then be made, even if in the end it is simply to abide by the decisions made by the professionals. Good communication embodies a humane approach which preserves hope at an appropriate level through empathy and understanding of the patient's position.

Curing cancer

For most solid tumours local control is possible but not sufficient for cure because of the presence of systemic (microscopic) disease, while haematological cancers are usually disseminated from the outset. Improvement in the rate of cure of most cancers is thus dependent upon earlier detection and effective systemic treatment. The likelihood of cure of the systemic disease depends upon the type of cancer, its chemo-/hormonal sensitivity, and tumour bulk (microscopic or clinically detectable). A few rare cancers are so chemosensitive that even bulky metastases can be cured, e.g. leukaemia, lymphoma, gonadal germ cell tumours, and choriocarcinoma. For most common solid tumours such as breast and colorectal cancer, there is no current cure of bulky (clinically detectable) metastases, but micrometastatic disease treated by adjuvant chemotherapy (see below) after surgery can be cured in 10–20% of patients.

Palliation

When cure is no longer possible, palliation, i.e. relief of tumour symptoms and prolongation of life, is possible in many cancers in proportion to their chemo- and radiosensitivity. There is on average a 2–18 months prolongation in median life expectancy with treatments for solid tumours and up to 5–8 years for some leukaemias and lymphomas, with those with the most responsive tumours experiencing the greatest benefit. The development of more effective chemotherapeutic drugs and better supportive care such as antiemetics has done much to reduce the side-effects of chemotherapy and to improve the cost/benefit ratio for the patient receiving palliative treatment. In addition, through early assessment during treatment, it is possible to stop if there is no evidence of benefit within 6–8 weeks of starting, so as to minimize exposure to toxic and unsuccessful treatment.

Measuring response to treatment

A measurable response to treatment can serve as a useful early surrogate marker when assessing whether to continue a given treatment for an individual patient.

Response to treatment can be subjective or objective. A *subjective response* is one perceived by the patient in terms of, for example, relief of pain and dyspnoea, or improvement in appetite, weight gain or energy. Such subjective response is a major aim of most palliative treatments. Quantitative measurements of these subjective symptoms form a part of the assessment of response to chemotherapy, especially in those situations where cure is not possible and where the aim of treatment is to provide prolongation of good-quality life. In these circumstances, measures of quality of life enable an estimate of the balance of benefit and side-effects to be made.

Objective response to treatment is measured either as a complete response, which is a complete disappearance of all detectable disease clinically and radiologically or partial response, which is conventionally defined as more than a 50% reduction in the size of the tumour. The terms used to evaluate the responses of tumours are given in Box 9.2. The term 'remission' is often used synonymously with 'response' which if complete means an absence of detectable disease without necessarily implying a cure of the cancer.

Oncological emergencies

- *Superior vena caval obstruction* can arise from any upper mediastinal mass but is most commonly associated with lung cancer and lymphoma. The patient presents with difficulty breathing and/or swallowing, with stridor, swollen, oedematous facies and venous congestion. *Treatment* is with immediate steroids, vascular stents, anticoagulation and mediastinal radiotherapy or chemotherapy. Some tumours, e.g. lymphomas and germ cell tumours, are so sensitive to chemotherapy that this is preferred to radiotherapy, as the masses are likely to be both large and associated with more disseminated disease elsewhere. An early decision is necessary on the patient's likely prognosis, as ventilatory support may be required until treatment has had time to relieve the obstruction.

Box 9.2 Definitions of response

Complete response	Complete disappearance of all detectable disease
Partial response	More than 50% reduction in the product of the bidimensional diameters of the tumour
Stable disease	No change, or < 50% reduction and < 25% increase
Progressive disease	Increase in size of tumour by at least 25% at any site

- *Spinal cord compression* (p. 1250) needs to be rapidly diagnosed and urgent treatment arranged to salvage as much functional capacity as possible. Early neurological clinical features may be incomplete, more subjective than objective and gradual in onset. MR scanning is the investigation of choice. *Treatment* should begin with high-dose steroids followed by surgical decompression and radiotherapy to the affected vertebrae to achieve the best disease control and palliation.
- *Neutropenic sepsis* (p. 495).
- *Acute lysis syndrome.* This occurs if treatment produces a massive breakdown of tumour cells, leading to increased serum levels of urate, potassium and phosphate. Urate deposition in the renal tubules can cause renal failure (hyperuricaemic nephropathy) requiring dialysis. The xanthene oxidase inhibitor (allopurinol) is given before treatment is started. Intravenous rasburicase, a recombinant urate oxidase, is occasionally used for prophylaxis and treatment but is very expensive.
- *Acute hypercalcaemia* presents with vomiting, confusion, constipation and oliguria Treatment is by resuscitation with intravenous fluids until a saline diuresis is established, followed by i.v. pamidronate (Emergency box 18.2).
- *Raised intracranial pressure* due to intracerebral metastases presents classically with headache, nausea and vomiting. However, for many there is a slower onset with non-specific symptoms such as drowsiness or mental deterioration. *Treatment* is by high-dose steroids and investigation by MRI as to whether surgery is appropriate or chemotherapy and radiotherapy are required.
- *Hypervisosity* affects those with a very high haematocrit (> 50), white cell count (> 100×10^9/L) or platelet cell count (> 1000×10^9/L) from untreated acute leukaemia, or polycythaemia. *Treatment* is by leucopheresis and plasmapheresis followed by chemotherapy treatment for the underlying malignancy.

Adjuvant therapy for solid tumours

This is defined as treatment given in the absence of macroscopic evidence of metastases, to patients at risk of recurrence from micrometastases, after treatment of the primary lesion has been given. 'Neoadjuvant' therapy is given before primary therapy, which may shrink the tumour size and treat any micrometastases as soon as possible.

Micrometastatic spread by lymphatic or haematological dissemination often occurs early in the development of the primary tumour, and can be demonstrated by molecular biological methods capable of detecting the small numbers (1 in 10^6) of circulating cells. Studies correlating prognosis with histological features of the primary cancer, e.g. differentiation or presence of early metastatic invasion of blood vessels or regional lymph nodes, have led to an increasing ability to predict which patients are at high risk of local or distant recurrence from micrometastatic disease.

Trials of treatment with local radiotherapy or endocrine, biological or chemotherapy treatments have shown a significant improvement in survival in common adult cancers such as breast, bowel, prostate, head and neck, cervical cancer, choriocarcinoma and gonadal germ cell cancers. Central to these studies has been the careful selection of patients according to defined risk criteria, and the reduction of treatment toxicity to reach a balanced risk/benefit ratio. Absolute improvements in survival of 5–10% and relative risk reductions in the order of 12–25% (dependent upon the pre-existing risk) have been achieved in common epithelial cancers such as bowel, breast and prostate, with greater absolute improvements of 25% in the more sensitive germ cell tumours.

While these improvements currently translate into many lives saved from common diseases at a public health level, the majority who receive such treatment do not benefit because they were already cured, or because the cancer is resistant to the treatment. Better tests in the future will identify those with the micrometastases who really need treatment. On an individual patient basis the decision on whether adjuvant treatment will be worthwhile must include consideration of other factors such as the patient's life expectancy, concurrent medical conditions, and lifestyle priorities.

Treatment of malignancy in sanctuary sites

A 'sanctuary site' is the term used to indicate that metastatic disease has involved a site that is not accessible to conventional drug therapy. An example of this is leukaemic infiltration of the meninges in children with acute lymphoblastic leukaemia. Because of the blood–brain barrier, agents such as vincristine and prednisolone do not enter the subarachnoid space in sufficient quantity to eliminate all the leukaemic cells, and are therefore ineffective in preventing the development of meningeal infiltration. In order to treat these cells, intrathecal chemotherapy and/or cranial irradiation are required for patients at risk (p. 505).

PRINCIPLES OF CHEMOTHERAPY

Chemotherapy employs systemically administered drugs that directly damage cellular DNA (and RNA). It kills cells by promoting apoptosis and sometimes frank necrosis. There is a narrow therapeutic window between effective treatment of the cancer and normal tissue toxicity, because the drugs are not cancer specific (unlike some of the biological agents), and the increased proliferation in cancers is not much greater than in normal tissues (see tumour growth and failure of apoptosis, p. 162). The dose and schedule of the chemotherapy is limited by the normal tissue tolerance, especially in those more proliferative tissues of the bone marrow and gastrointestinal tract mucosa. All tissues can be affected, however, depending

upon the pharmacokinetics of the drug and affinity for particular tissues (e.g. heavy metal compounds for kidneys and nerves).

The therapeutic effect on the cancer is achieved by a variety of mechanisms which seek to exploit differences between normal and transformed cells. While most of the drugs have been derived in the past by empirical testing of many different compounds, e.g. alkylating agents, the new molecular biology is leading to targeting of particular genetic defects in the cancer (see tyrosine kinase inhibitors for CML, p. 506).

Toxicity to normal tissue can be limited in some instances by supplying growth factors such as granulocyte colony-stimulating factor (G-CSF) or by the infusion of stem cell preparations to diminish myelotoxicity. The use of more specific biological agents with relatively weak pro-apoptotic effects in combination with the general cytotoxics will also improve the therapeutic ratio (see trastuzumab and breast cancer, p. 521).

Most tumours rapidly develop resistance to single agents given on their own. For this reason the principle of intermittent combination chemotherapy was developed. Several drugs are combined together, chosen on the basis of differing mechanisms of action and non-overlapping toxicities. These drugs are given over a period of a few days followed by a rest of a few weeks, during which time the normal tissues have the opportunity for regrowth. If the normal tissues are more proficient at DNA repair than the cancer cells, it may be possible to deplete the tumour while allowing the restoration of normal tissues between chemotherapy cycles (Fig. 9.3).

In many experimental tumours it has been shown that there is a log–linear relationship between drug dose and number of cancer cells killed and that the maximum effective dose is very close to the maximum tolerated dose at which dose-limiting toxicity is reached. With a chemosensitive tumour, relatively small increases in dose may have a large effect on tumour cell kill. It is therefore apparent that where cure is a realistic option the dose administered is critical and may need to be maintained despite toxicity. In situations where cure is not a realistic possibility and palliation is the aim, a sufficient dose to exceed the therapeutic threshold, but not cause undue toxicity, is required as the short-term quality of life becomes a major consideration.

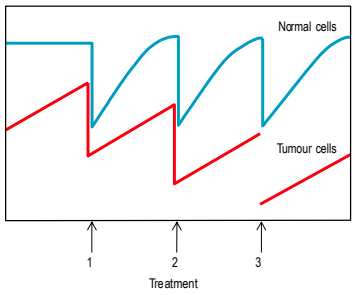

Fig. 9.3 **Effects of multiple courses of cytotoxic chemotherapy.**

Classification of cytotoxic drugs (Table 9.8)

DNA damaging

Alkylating agents

Alkylating agents act by covalently binding alkyl groups, and their major effect is to cross-link DNA strands, interfering with DNA synthesis and causing strand breaks. Despite being among the earliest cytotoxic drugs developed, they maintain a central position in the treatment of cancer. Melphalan is one of the original nitrogen mustards and is used in multiple myeloma. Chlorambucil is used in Hodgkin's lymphoma and chronic lymphocytic leukaemia. Other common alkylating agents include cyclophosphamide and ifosfamide, as well as the nitrosoureas, carmustine (BCNU) lomustine (CCNU) and busulfan used in chronic myeloid leukaemia. Tetrazines also alkylate DNA; dacarbazine is used in malignant melanoma and temozolomide in malignant gliomas.

Platinum compounds

Cisplatin, carboplatin and oxaliplatin cause interstrand cross-links of DNA and are often regarded as non-classical alkylating agents. They have transformed the treatment of testicular cancer and have a major role against many other tumours, including lung, ovarian and head and neck cancer. Toxicity, as for other heavy metals, includes renal and peripheral nerve damage.

Antimetabolites

Antimetabolites are usually structural analogues of naturally occurring metabolites that interfere with normal synthesis of nucleic acids by falsely substituting purines and pyrimidines in metabolic pathways. Antimetabolites can be divided into:

Table 9.8 **Chemotherapy: some cytotoxic drugs**

DNA damaging
Free radicals – alkylators, e.g. cyclophosphamide
DNA cross-linking – platinum, e.g. cisplatin, carboplatin, oxaliplatin
Antimetabolites
Thymidine synthesis, e.g. 5-fluorouracil, methotrexate, cytarabine and mercaptopurine
DNA repair inhibitors
Topoisomerase inhibitors – epipodophyllotoxins, e.g. etoposide; campothecins, e.g. irinotecan
DNA intercalation – anthracyclines, e.g. doxorubicin
Antitubulin
Tubulin binding – alkaloids, e.g. vincristine, vinorelbine
Taxanes – e.g. paclitaxel, docetaxel

- *Folic acid antagonist*, e.g. methotrexate. This is structurally very similar to folic acid and binds preferentially to dihydrofolate reductase, the enzyme responsible for the conversion of folic acid to folinic acid. It is used widely in the treatment of solid tumours and haematological malignancies. Folinic acid is often given to 'rescue' normal tissues from the effects of methotrexate.
- *Pyrimidine antagonists*. 5-Fluorouracil (5-FU) consists of a uracil molecule with a substituted fluorine atom. It acts by blocking the enzyme thymidylate synthase, which is essential for pyrimidine synthesis. 5-Fluorouracil has a major role in the treatment of solid tumours, particularly gastrointestinal cancers. Capecitabine is metabolized to 5-FU, and is useful in colorectal cancer. Tegafur with uracil is used with calcium folinate in metastatic colorectal cancer.
- *Arabinosides* inhibit DNA synthesis by inhibiting DNA polymerase. Cytosine arabinoside (cytarabine) is used almost exclusively in the treatment of acute myeloid leukaemia where it remains the backbone of therapy, while its analogue gemcitabine is proving useful in a number of solid cancers such as lung and ovary. Fludarabine is used in the treatment of B cell chronic lymphocytic leukaemia; it is also used in reduced intensity stem cell transplantation (p. 496) because of its immunosuppressive effect.
- *Purine antagonists*, e.g. 6-mercaptopurine and 6-tioguanine, which are both used almost exclusively in the treatment of acute leukaemia.

DNA repair inhibitors

Epipodophyllotoxins

These are semisynthetic derivatives of podophyllotoxin, which is an extract from the mandrake plant. Etoposide is a drug used in a wide range of cancers and works by maintaining DNA strand breaks by acting on the enzyme topoisomerase II. Topoisomerase I inhibitors such as irinotecan and topotecan have also proved active against a variety of solid tumours. Both these enzymes allow unwinding and uncoiling of supercoiled DNA.

Cytotoxic antibiotics

These drugs such as doxorubicin and bleomycin act by intercalating adjoining nucleotide pairs on the same strand of DNA and by inhibiting DNA repair. They have a wide spectrum of activity in haematological and solid tumours. Doxorubicin is one of the most widely used of all cytotoxic drugs but has cumulative toxicity to the myocardium, while bleomycin has particular toxicity for the lungs. Pegylated liposomal doxorubicin is used as second-line treatment for advanced ovarian cancer with reduction of cardiotoxicity, but infusion reactions occur.

Antitubulin agents

Vinca alkaloids

Drugs such as vincristine, vinblastine and vinorelbine act by binding to tubulin and inhibiting microtubule formation (see p. 158). They are used in the treatment of haematological and non-haematological cancers. They are associated with neurotoxicity due to their antimicrotubule effect and must never be given intrathecally.

Taxanes

Paclitaxel is isolated from the bark of the western yew. Docetaxel is a semisynthetic taxane. They bind to tubulin dimers and prevent their assembly into microtubules. They are active drugs against many cancers such as ovarian, breast and lung cancer. Taxanes can cause neurotoxicity and hypersensitivity reactions and patients should be premedicated with steroids, H_1 and H_2 histamine antagonists prior to treatment.

Side-effects of chemotherapy

Chemotherapy carries many potentially serious side-effects and should be used only by trained practitioners. The four most common side-effects are vomiting, hair loss, tiredness and myelosuppression (Table 9.9). Side-effects are much more directly dose related than anticancer effects and it has been the practice to give drugs at doses close to their maximum tolerated dose, although this is not always necessary to achieve their maximum anticancer effect. Common combination chemotherapeutic regimens are shown in Table 9.10.

Nausea and vomiting

The severity of this common side-effect varies with the cytotoxic and it can be eliminated in 75% of patients by using modern antiemetics. Nausea and vomiting are particular problems with platinum analogues and with doxorubicin. A stepped policy with antiemetics such as metoclopramide and domperidone or 5-HT_3 serotonin antagonists (e.g. ondansetron, granisetron) combined with dexamethasone should be used to match the emetogenic potential of the chemotherapy. Aprepitant, a neurokinin receptor antagonist is helpful in preventing acute and delayed nausea and vomiting associated with cisplatin-based chemotherapy. It is used with dexamethasone and a 5-HT_3 antagonist.

Table 9.9 Side-effects of chemotherapy

Common
Nausea and vomiting
Hair loss
Myelosuppression
Mucositis
Fatigue
Drug-specific
Cardiotoxicity, e.g. anthracyclines
Pulmonary toxicity, e.g. bleomycin
Neurotoxicity, e.g. cisplatinum, vinca alkaloids, taxanes
Nephrotoxicity, e.g. cisplatinum
Skin plantar–palmar dermatitis, e.g. 5-fluorouracil
Sterility, e.g. alkylating agents
Secondary malignancy, e.g. alkylating agents, epipodophyllotoxins

Table 9.10 Some chemotherapy regimens

Hodgkin's lymphoma	ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine
	BEACOPP	Bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisolone
Non-Hodgkin's lymphoma	CHOP	Cyclophosphamide, hydroxy-doxorubicin, vincristine, prednisolone
Breast	CMF	Cyclophosphamide, methotrexate, 5-fluorouracil
	AC	Doxorubicin, cyclophosphamide
	MM	Mitoxantrone, methotrexate
Stomach	ECF	Epirubicin, cisplatin, 5-fluorouracil

Box 9.3 Febrile neutropenia treatment

Resuscitation with intravenous fluids to restore circulatory function, e.g. urine output, followed by cultures of blood, urine, sputum and stool and empirical antibiotics:

- Commonly used antibiotics should include activity against pseudomonas, e.g. ceftazidime or ticarcillin with gentamicin
- May require antibiotics against *Staph. aureus* especially with indwelling venous access lines, e.g. flucloxacillin or vancomycin.

If the patient deteriorates clinically and/or temperature still elevated after 48 hours, change antibiotics according to culture results or empirically increase Gram-negative and Gram-positive cover.

- Consider adding treatment for opportunistic infections if fever not responding to broad-spectrum antibiotics, e.g. amphotericin B
  liposomal amphotericin B or voriconazole (latter two are very expensive) or caspofungin – fungus
  high-dose co-trimoxazole – pneumocystis
  clarithromycin – mycoplasma.

Hair loss

Many but not all cytotoxic drugs are capable of causing hair loss. Scalp cooling can sometimes be used to reduce hair loss but in general this side-effect can only be avoided by selection of drugs where this is possible. Hair always regrows on completion of chemotherapy.

Bone marrow suppression and immunosuppression

Suppression of the production of red blood cells, white blood cells and platelets occurs with most cytotoxic drugs and is a dose-related phenomenon. Severely myelosuppressive chemotherapy may be required if treatment is to be given with curative intent despite the potential for rare but fatal infection or bleeding. Anaemia and thrombocytopenia are managed by erythropoetin or red cell or platelet transfusions.

Neutropenic patients are at high risk of bacterial and fungal infection, often from enteric bowel flora. Those with a fever > 37°C and less than 0.5×10^9 neutrophils/L are managed by the immediate introduction of broad-spectrum antibiotics intravenously for the treatment of infection (Box 9.3). Initial empirical therapy should be reviewed following microbiological results. Haemopoietic growth factors and peripheral blood stem cells can reduce the duration of neutropenia significantly, benefiting patients at high risk of infectious complications.

Mucositis

This common side-effect of chemotherapy reflects the sensitivity of the mucosa to antimitotic agents. It causes severe pain and problems with swallowing. Treatment is with antiseptic and anticandidal mouthwash and, if severe, fluid and antibiotic support, as the mouth is a portal for entry of enteric organisms. A recent study has shown a keratinocyte growth factor to be helpful (palifermin).

Cardiotoxicity

This is a rare side-effect of chemotherapy, usually associated with anthracyclines such as doxorubicin. It is dose-related and can largely be prevented by restricting the cumulative total dose of anthracyclines within the safe range (equivalent to 450 mg/m^2 body surface area cumulative doxorubicin dose).

Neurotoxicity

This occurs predominantly with the plant alkaloids, vinca, taxanes and platinum analogues (but not carboplatin). It is dose-related and cumulative. Chemotherapy is usually stopped before the development of a significant polyneuropathy, which once established is only partially reversible. Vincristine must *never* be given intrathecally as the neurological damage is progressive and fatal.

Nephrotoxicity

Cisplatin (but not oxaliplatin or carboplatin), methotrexate and ifosfamide can potentially cause renal damage. This can usually be prevented by maintaining an adequate diuresis during treatment.

Sterility

Some anticancer drugs, particularly alkylating agents, may cause sterility, which may be irreversible. In males the storage of sperm prior to chemotherapy should be offered to the patient when chemotherapy is given with curative intent. In females it may be possible to collect oocytes to be fertilized in vitro and cryopreserved as embryos. Cryopreservation of ovarian tissue and retrieval

of viable oocytes for subsequent fertilization is still experimental.

Secondary malignancies

Anticancer drugs have mutagenic potential and the development of secondary malignancies, predominantly acute leukaemia, is an uncommon but particularly unwelcome long-term side-effect in patients otherwise cured of their primary malignancies. The alkylating agents and epipodophyllotoxins are particularly implicated in this complication.

Drug resistance

Drug resistance is one of the major obstacles to curing cancer with chemotherapy. Some tumours have an inherently low level of resistance to currently available treatment and are often cured. These include gonadal germ cell tumours, Hodgkin's lymphoma and childhood acute leukaemia. Solid tumours such as small-cell lung cancer initially appear to be chemosensitive, with the majority of patients responding, but most patients eventually relapse with resistant disease. In other tumours such as melanoma the disease is largely chemoresistant from the start.

Most resistance occurs as a result of genetic mutation and becomes more likely as the number of tumour cells increases. It has also been shown that anticancer drugs can themselves increase the rate of mutation to resistance. Resistance to cytotoxic drugs is often multiple and is then known as multidrug resistance (MDR), e.g. resistance to doxorubicin is often associated with resistance to vinca alkaloids and epipodophyllotoxins, and is mediated through increased expression of P-glycoprotein (a 170 kDa membrane phosphoglycoprotein), which mediates the efflux of cytotoxic drugs out of the cells. Many other mechanisms may also be involved in resistance to chemotherapy, such as the upregulation of anti-apoptotic proteins Bcl-2 and Bax.

High-dose therapy

Most anticancer drugs have a sigmoid dose-response relationship which suggests that, up to a point, a higher dose of a cytotoxic drug will induce a greater response. However, increasing cytotoxic drug doses is often not possible, owing to toxicity. For many chemotherapeutic agents the toxicity which limits the dose is bone marrow failure, and infusion of stem cells is necessary to restore the lymphohaemopoietic system.

Haemopoietic stem cell transplantation

Bone marrow and transplanted cells may be:

- autologous – from self or identical twin
- syngeneic – from identical twin
- allogeneic – from non-identical donor (matched or sometimes mismatched)
- from umbilical cord blood. This is increasingly being used for adult and childhood leukaemia.

It usually takes 2–3 weeks for engraftment to take and during this time patients need supportive care with nursing in isolated cubicles with air filtration.

Principles of autologous stem cell transplantation

Autologous stem cells are used as rescue from myeloablative chemotherapy. Haemopoietic stem cells are collected from the patients' bone marrow, or more commonly by leucopheresis from peripheral blood following administration of the growth factor granulocyte colony-stimulating factor (G-CSF) prior to chemotherapy. They are stored by cryopreservation. These cells are then re-infused intravenously after an intensive, myeloablative chemotherapy regimen. This approach has been particularly effective in relapsed leukaemias, lymphomas and in myeloma. There is no risk of graft rejection or graft-versus-host disease (GVHD) but the graft-versus-tumour effect is lost (see below).

Principles of allogeneic stem cell transplantation

Historically, the transplantation of donor haemopoietic cells has been combined with myeloablative chemotherapy ± radiotherapy. This has the dual effects of treating the malignancy as well as immunosuppression that allows the graft 'to take'. Anti-T cell antibodies are often given to reduce graft-versus-host disease and immune-related infection. It is thought that the engraftment of the donor immune system, with antitumour activity (graft versus tumour), is primarily responsible for the increased effectiveness of this approach. In general, ideal donors are fully matched at the major HLA antigens. Thus siblings are more likely to be found to be potential donors than unrelated volunteers. Some degree of HLA antigen mismatch may be tolerated in children, but is problematic in adults. Allogeneic transplantation has been successfully used in acute and chronic leukaemias, and myeloma.

Complications include 'graft-versus-host disease', an immune reaction of the donor cells against normal host organs, which can affect 30–50% of transplant recipients and is potentially fatal in some cases. Immunosuppression, both from conditioning therapy and from the immunosuppressive drugs (ciclosporin or tacrolimus) given to prevent graft-versus-host disease, results in a high incidence of opportunistic infections. All patients receive prophylactic antibacterial, antifungal and antiviral drugs but infections still occur. Mortality therefore from conventional allogeneic stem cell transplantation is a major problem, with 20–40% at risk of dying from the procedure, depending on the age and status of the recipient, and the degree of HLA compatibility of the donor (see also Immunotherapy, p. 498).

Non-myeloablative allogenoic stem cell transplantation

In this procedure, also known as 'reduced intensity' transplantation, conditioning therapy is non-myeloablative

without radiation therapy but it is immunosuppressant. The principle is that the anticancer effect of the stem cell transplantation will still be present without the complications of conventional allogeneic stem cell transplantation. Mortality (mainly GVHD) is lower, and the technique is being used more widely, particularly in the elderly.

PRINCIPLES OF ENDOCRINE THERAPY

Oestrogens are capable of stimulating the growth of breast and endometrial cancers, and androgens the growth of prostate cancer. Removal of these growth factors by manipulation of the hormonal environment may result in apoptosis and regression of the cancer. Endocrine therapy can be curative in a proportion of patients treated for micrometastatic disease in the adjuvant setting for breast and prostate cancer and provides a minimally toxic non-curative (palliative) treatment in advanced/metastatic disease. The presence of detectable cellular receptors for the hormone markedly increases the likelihood that the therapy will be effective. Figure 9.4 shows the binding of the hormone to the receptor.

Oestrogens and progestogens

Breast cancer (see Table 9.21)

About one-third of patients have receptors for oestrogens and progesterones. Hormonal manipulation includes the use of tamoxifen, which blocks oestrogen receptors, and the reduction of endogenous oestrogen by oophorectomy or 'medical oophorectomy' via pituitary downregulation using a gonadotrophin-releasing hormone (GnRH) analogue such as goserelin.

Tamoxifen is used as an adjuvant therapy to surgery and in advanced metastatic breast disease (see p. 519).

Progestogens have a direct effect on breast tumour cells through progesterone receptors, as well as effects on the pituitary/ovarian (premenopausal) and adrenal/pituitary axis (postmenopausal) and can be as effective as tamoxifen.

In postmenopausal women, androgens are synthesized by the adrenal glands and converted in subcutaneous fat to estrone by the enzyme aromatase. Aromatase inhibitors, for example anastrozole, letrozole and exemestane, reduce circulating oestrogen levels and oestrogen synthesis in tumour cells and have shown greater efficacy than tamoxifen in the treatment of metastatic breast cancer and equivalence in the adjuvant setting in the postmenopausal woman.

Endometrial cancers

Endometrial cancers have receptors for both oestrogens and progestogens. Approximately 20% of receptor-positive metastases will regress for a median 20 months with synthetic progestogens such as medroxyprogesterone acetate but paradoxically tamoxifen has little effect. Trials to date with adjuvant progestogens have not been successful in increasing survival.

Androgens

In advanced prostate cancer, androgen deprivation induces regression in 70% of cases for a median duration of 24 months. GnRH agonists, e.g. goserelin, and orchidectomy, are equally effective; however, androgen receptor blockers such as flutamide are less so. Combinations of goserelin and flutamide may be used in the initial phase of treatment to avoid a disease flare from the initial agonist action of GnRH analogues, but prolonged combination therapy has been no more effective than goserelin alone. In the adjuvant setting, the addition of androgen deprivation to prostatic radiotherapy or surgery has improved survival.

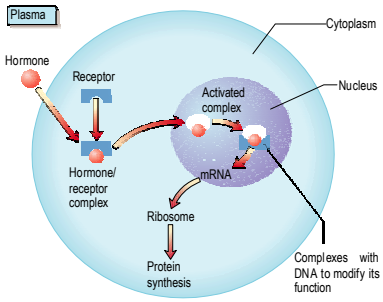

Fig. 9.4 **Mechanism of the interaction between a steroid hormone and its receptor**. This interaction modifies DNA activity and hence cell growth and replication.

PRINCIPLES OF BIOLOGICAL THERAPY

The group includes a range of protein molecules, from small peptide chemokines, larger cytokines, to complex antibody molecules, made available by genetic engineering.

Interferons

Interferons (p. 202) are naturally occurring cytokines that mediate the cellular immune response. They have many actions in treatment of malignant disease with both antiproliferative activity and stimulation of humoral and cell-mediated immune responses to the tumour that can result in an antitumour effect if the host effector mechanisms are present and fully competent.

Alpha-interferon (IFN-α) has been used against several malignancies to treat established disease such as melanoma, renal cell carcinoma and chronic myeloid leukaemia. In the latter, it results in a reduction in the number of Philadelphia (Ph) chromosome-positive cells in at least 50% of patients, with total elimination in 10%.

It has been replaced by imatinib first-line treatment (p. 506). Interferon has also been used to maintain remission after cytotoxic treatment by suppressing microscopic residual disease, e.g. myeloma. In renal cell carcinoma alpha-interferon has a low (10–15%) but significant anticancer effect and prolongation of survival.

Treatment with IFN has side-effects (p. 371), most commonly flu [illegible] with time, and be treatment cutaneous injection, but conjugation with polyethylene glycol (PEG interferon) has led to a reduction in frequency of injection and severity of side-effects.

Colorectal cancer	Anti-EGF receptor	Cetuximab
Colorectal cancer	Anti-VEGF	Bevacizumab
Lymphoma	Anti-CD20 on B cells	Rituximab

Interleukins

Originally described for their activity in modulating leucocyte activation, these cytokines have widespread activity in coordinating cellular activity in many organs. Interleukin-2, a recombinant protein, is used to activate T cell responses, often in conjunction with interferon-stimulated B cell activation. Antitumour activity has been observed in renal cell carcinoma and melanoma with responses in 10–20% of patients, occasionally for prolonged periods. Toxicity is common; acutely this includes the capillary leak syndrome with hypotension, whilst pulmonary oedema, autoimmune thyroiditis and vitiligo occur later.

Haemopoietic growth factors

Erythropoietin for anaemia and granulocyte (G-CSF) or granulocyte–macrophage colony-stimulating factor (GM-CSF) are used:

- to reduce the duration of neutropenia following chemotherapy
- with or without chemotherapy, to stimulate the proliferation of haemopoietic progenitor cells in the marrow so that they enter the circulation and can be collected from the peripheral blood to support high-dose chemotherapy treatment, particularly in myeloma (p. 518).

Monoclonal antibodies (Table 9.11)

Monoclonal antibodies directed against tumour cell surface antigens are 'humanized' by being genetically engineered as a chimera comprising a human constant region with the murine heavy and light chains of the antigen-combining site, to reduce formation of blocking human anti-mouse antibodies when used in patients. Uses include:

- *In vitro,* in conjunction with complement, they are used to deplete autologous bone marrow of tumour cells in patients with leukaemia and lymphoma receiving high-dose treatment with autologous haemopoietic progenitor cell support.
- *In vitro* in immunoadsorption columns to select the CD34-positive (stem cell) fraction from peripheral blood progenitor cell or autologous bone marrow collections, to support high-dose treatment in haematological and other malignancies.

Table 9.11 **Biological therapies**

Drug	Function	Malignancy
Imatinib	Tyrosine kinase inhibitor	Stromal cell tumour Chronic myeloid leukaemia
Gefitinib	Tyrosine kinase inhibitor	Non-small-cell lung cancer
Dallizumab	Anti-CD25	Leukaemia/lymphoma
Alemtuzumab	Anti-CD52	Chronic lymphocytic leukaemia
Trastuzumab	Anti-HER-2 protein	Breast cancer
Bortezomib	Proteosome inhibitor	Leukaemia Myeloma

- As direct treatment for B cell non-Hodgkin's lymphoma (e.g. Rituximab anti-CD20 surface antigen). Tumour cell lysis occurs by both complement- and antibody-dependent cellular cytotoxicity.
- *As a carrier molecule* to target toxins or radioisotopes to the tumour cells, e.g. anti-CD20 conjugated to radioactive iodine is being used as treatment for non-Hodgkin's lymphoma.
- As anti-growth factor agents added to chemotherapy, e.g. trastuzumab against the Her2/ Neu or c-erbB2 antigen, a member of the epidermal growth factor receptor family, to increase the apoptotic response to cytotoxics with improved survival in metastatic breast cancer or with bevacizumab in colorectal cancer.

Immunotherapy

Activation of the immune system using bacille Calmette–Guérin (BCG) for bladder cancer or interleukin-2 for renal cancer induces responses in 60% and 10% of patients respectively. Certain antigens that are specific to cancer cells, such as sequences of tumour immunoglobulin from B cell lymphomas or melanoma antigens have been used as tumour vaccines. Antigen-presenting cells (dendritic cells) from the patient can be genetically engineered to present both antigen and cytokines such as interleukin-2 or granulocyte–macrophage colony-stimulating factor, and clinical responses have been observed. Another approach has used dendritic cells to further improve the vaccination strategy by engineering them to display the full range of HLA and B7 costimulatory molecules.

The use of non-myeloablative haemopoietic stem cell and donor lymphocyte infusions, while losing some of the specificity, has produced the strongest evidence for the efficacy of immunotherapy at the risk of the greatest toxicity.

Gene therapy

Antisense oligonucleotides are short sequences of DNA bases which specifically inhibit complementary sequences of either DNA or RNA. As a result, they can be generated against genetic sequences which are specific for tumour

cells. Their clinical development has been hampered by poor uptake by tumour cells and rapid degradation by natural endonucleases. However, one antisense sequence directed against the *Bcl*-2 oncogene has been shown to have an antitumour effect in patients with non-Hodgkin's lymphoma. Creation of reliable vectors for the transfection of tumour cells in vivo still forms a major barrier to the greater application of this modality.

Intracellular signal inhibitors

The recognition that many cancer cells are transformed by the activity of the protein products of oncogenes has led to the search for peptides or other compounds which inhibit these proteins, or their intracellular signal pathways. An example is the tyrosine kinase inhibitor imatinib, which specifically inhibits the fusion oncoprotein BCR-ABL. This compound is an extremely effective treatment for chronic myeloid leukaemia, a disease characterized by the presence of the BCR-ABL fusion protein. Many other similar molecules, inhibiting enzymes involved in cell cycling or cytokine signalling, are in preclinical or early clinical development. Examples include farnesyl transferase inhibitors, which inhibit ras proteins, inhibitors of the platelet-derived growth factor receptor, and drugs which inhibit matrix metalloproteinases.

PRINCIPLES OF RADIATION THERAPY

Radiation delivers energy to tissues, causing ionization and excitation of atoms and molecules. The biological effect is exerted through the generation of single- and double-strand DNA breaks, inducing apoptosis of cells as they progress through the cell cycle, and through the generation of short-lived free radicles, particularly from oxygen, which damage proteins and membranes.

The most commonly used form of radiotherapy is *external beam* or *teletherapy* from a linear accelerator source which provides X-rays, the energy of which is transmitted as photons. Cobalt-60 generators can also provide gamma rays and high-energy photons.

Brachytherapy is the use of radiation sources in close contact with the tissue to provide intense exposure over a short distance to a restricted volume.

Systemic radionuclides, e.g. iodine-131, or radioisotope-labelled monoclonal antibodies and hormones can be administered by intravenous or intracavitary routes to provide radiation targeted to particular tissue uptake via surface antigens or receptors.

The radiation dose is measured in grays (Gy), where 1 gray = 1 joule absorbed per kilogram of absorbing tissue and 1 centigray = 1 rad. The biological effect is dependent upon the dose rate, duration, volume irradiated, and the tissue sensitivity. Sensitivity to photon damage is greatest during the G_2–M phase of the cell cycle and is also dependent upon the DNA repair capacity of the cell. Fractionation is the delivery of the radiation dose in increments separated by at least 4–6 hours to try to exploit any advantage in DNA repair between normal and malignant cells. Radiation dose is thus described by three factors:

- total dose in cGy
- number of fractions
- time for completion.

Most treatments are delivered in 150–200 cGy fractions daily for 5 days per week, although a regimen of two fractions daily (hyperfractionation) had improved survival benefit in a lung cancer trial.

The radiation effect will also depend upon the intensity of the radiation source, measured as the linear energy transfer or frequency of ionizing events per unit of path, which is subject to the inverse square law as the energy diminishes with the distance from the source.

The generation of free radicles depends upon the degree of oxygenation/hypoxia in the target tissues. This can affect the biological effect by up to threefold and is the subject of continuing research for hypoxic cell sensitizers.

The depth of penetration of biological tissues by the photons depends upon the energy of the beam. Low-energy photons from an 85 kV source are suitable for superficial treatments, while high-energy 35 MeV sources produce a beam with deeper penetration, less scatter both at the initial skin boundary (skin sparing) and at the margins of the beam, and less absorption by bone. Superficial radiation may be also delivered by electron beams from a linear accelerator that has had the target electrode that generates the X-rays removed.

Radiotherapy treatment planning involves both detailed physics of the applied dose and knowledge of the biology of the cancer and whether the intention is to treat the tumour site alone, or include the likely loco-regional patterns of spread. Normal tissue tolerance will determine the extent of the side-effects, and a balanced decision is made according to the curative or palliative intent of the treatment and the likely early or late side-effects.

The cancers for which radiotherapy is usually employed as primary curative when the tumour is anatomically localized are listed in Table 9.12 along with those in which radiotherapy has curative potential when used in addition to surgery (adjuvant radiotherapy). Palliative treatments are frequently used to provide relief of symptoms to improve quality if not duration of survival (Box 9.4).

Side-effects of radiotherapy

Radiotherapy side-effects may occur early within days to weeks of treatment when they are usually self-limiting but associated with general systemic disturbance (Table 9.13). The side-effects will depend upon tissue sensitivity, fraction size and treatment volume and are managed with supportive measures until normal tissue repair occurs. The toxicity may also be enhanced by exposure to other radiation-sensitizing agents, especially some cytotoxics, e.g. bleomycin, actinomycin, anthracyclines, cisplatin and 5-fluorouracil.

Table 9.12 Curative radiotherapy treatment

Primary modality

Rectum
Testis-seminoma
Sarcoma

Box 9.4 Palliative benefits of radiotherapy

- Pain relief, e.g. bone metastases
- Reduction of headache and vomiting in raised intracranial pressure from CNS metastases
- Relief of obstruction of bronchus, oesophagus, ureter, and lymphatics
- Preservation of skeletal integrity from metastases in weight-bearing bones
- Reversal of neurological impairment from spinal cord or optic nerve compression by metastases

Later side-effects occur from months to years later, unrelated to the severity of the acute effects because of their different mechanism. Late effects reflect both the loss of slowly proliferating cells and a local endarteritis which produces ischaemia and proliferative fibrosis.

Growth may be arrested if bony epiphyses are not yet fused and are irradiated, leading to distorted skeletal growth in later life.

Secondary malignancies following radiotherapy typically appear 10–20 years after the cure of the primary cancer. Haematological malignancies tend to occur sooner than solid tumours from the irradiated tissues. The latter are very dependent upon the status of the tissue at the time of treatment, e.g. the pubertal breast is up to 300 times more sensitive to malignant transformation than the breast tissues of a woman in her thirties. Patients who smoke are more liable to develop lung cancer. Treatment of these secondary cancers can be successful providing there is normal bone marrow to reconstitute the haemopoietic system or the whole tissue at risk (e.g. thyroid after mantle radiotherapy for lymphoma) can be resected.

Table 9.13 Side-effects of radiotherapy

Acute side-effects	
Anorexia, nausea, malaise	
Mucositis, oesophagitis, diarrhoea	
Alopecia	
Myelosuppression	
Late side-effects	
Skin	Ischaemia, ulceration
Bone	Necrosis, fracture, sarcoma
Mouth	Xerostomia, sialitis, ulceration
Bowel	Stenosis, fistula, diarrhoea
Bladder	Cystitis
Vagina	Dyspareunia, stenosis
Lung	Fibrosis
Heart	Pericardial fibrosis, cardiomyopathy
CNS	Myelopathy
Gonads	Infertility, menopause
Second malignancies,	e.g. Leukaemia Cancer, e.g. thyroid

HAEMATOLOGICAL MALIGNANCIES

The leukaemias, the lymphomas and multiple myeloma are an interrelated spectrum of malignancies of the myeloid and lymphoid systems. They are uncommon but not rare, the lymphomas alone being the seventh commonest cancer in the UK. The aetiology of these diseases is unknown, although viruses, irradiation, cytotoxic poisons and immune suppression have been implicated in a small proportion of cases (p. 501). The pathogenesis involves at least one or usually more molecular abnormalities, and non-random chromosomal abnormalities have been detected in several leukaemias and lymphomas. Classification has become increasingly complex, with the universally applied WHO scheme demanding morphological, cytogenetic and sometimes molecular criteria to be fulfilled. Treatment options are multiple. Patients need to be supported through treatment involving prolonged myelosuppression and immunosuppression. These are potentially life-threatening but can also be curative. This has given rise to the need for highly skilled staff and specialist facilities, and patients should be referred to these centres for treatment.

Large multicentre Phase III trials have validated single centre data and show that curative therapy can be delivered in the community.

In the management of these diseases it is critical that patients are appraised of the natural history, its potential modification by treatment and the risks of both severe morbidity and mortality. It must be made clear from the outset whether a curative or palliative strategy is most appropriate and why. If cure is to be pursued, the patient must be appraised of the approximate probability of success and its potential price. The possibility of failure needs to be addressed at the outset and not at the last minute.

THE LEUKAEMIAS

These are relatively rare diseases with an incidence of about 10 per 100 000 per year. They are classified as being acute (short natural history) or chronic (long natural history), and of myeloid or lymphoid origin. More than half of the leukaemias present acutely (ALL, AML) with the remainder being chronic types (CLL, CML). The type of leukaemia varies with age; acute lymphoblastic leukaemia (ALL) is mainly seen in childhood and chronic lymphocytic leukaemia is a disease of the elderly. The myelodysplastic syndromes are considered pre-leukaemic and are discussed on page 453. Leukaemia can be diagnosed by examination of a stained slide of peripheral blood and bone marrow, with immune phenotyping, cytogenetics and molecular genetics being essential for complete subclassification and prognostication.

General classification

The characteristics of leukaemic cells can be assessed by light microscopy, expression of cytosolic enzymes and expression of surface antigens. These will reflect the lineage and degree of maturity of the leukaemic clone. Thus, leukaemia can be divided on the basis of the speed of evolution of the disease into acute or chronic. Each of these is then further subdivided into myeloid or lymphoid, according to the cell type involved.

- acute myeloid leukaemia (AML)
- acute lymphoblastic leukaemia (ALL)
- chronic myeloid leukaemia (CML)
- chronic lymphocytic leukaemia (CLL).

Aetiology

This is unknown but several factors have been associated:

- *Radiation*. This can induce genetic damage to haemopoietic precursors and ALL, AML and CML have been seen in increased incidences in survivors of Hiroshima and Nagasaki and in patients treated with ionizing radiation.
- *Chemical and drugs*. Exposure to benzene used in industry, may lead to marrow damage. AML occurs after treatment with alkylating agents, e.g. melphalan.
- *Genetic*. The incidence of leukaemia is increased in identical twins and in syndromes of somatic cell chromosomal aneuploidy, e.g. Down's syndrome, Klinefelter's syndrome.
- *Viruses*. Leukaemias are associated with human T cell lymphotropic virus type 1 (HTLV-1), which is found particularly in Japan and the Caribbean.

Genetic abnormalities in leukaemia

Leukaemic cells often have a somatically acquired cytogenetic abnormality, which may be of prognostic, as well as diagnostic, importance.

These genetic alterations change the normal cell regulating process by interfering with the control of normal proliferation, blocking differentiation, maintaining an unlimited capacity for self-renewal and lastly, promoting resistance to death signals, i.e. decreased apoptosis.

The first non-random chromosomal abnormality to be described was the Philadelphia (Ph) chromosome, which is associated with chronic myeloid leukaemia (CML) in 97% of cases. The Ph chromosome is also found in ALL, the incidence in the latter illness increasing with age. The translocation is shown schematically in Figure 9.5. The Ph chromosome is an abnormal chromosome 22, resulting from a reciprocal translocation between part of the long arm of chromosome 22 and chromosome 9. The resulting karyotype is described as t(9;22)(q34;q11). The molecular consequences of the translocation are that part of the Abelson proto-oncogene (c-*ABL*) normally present on chromosome 9 is translocated to chromosome 22, where it comes into juxtaposition with a region of chromosome 22 named the 'breakpoint cluster region' (BCR). The translocation creates a hybrid transcription unit consisting of the 5' end of the *BCR* gene and the c-*ABL* proto-oncogene.

The new 'fusion' gene *BCR-ABL* is capable of being expressed as a chimeric messenger RNA which has been identified in cells from patients with CML. When translated, this produces a fusion protein that has tyrosine kinase activity and enhanced phosphorylating activity compared with the normal protein, resulting in altered cell growth, stromal attachment and apoptosis. The breakpoint differs in CML and Ph-positive ALL, leading to the production of two different tyrosine kinase proteins with molecular weights of 210 kDa and 190 kDa respectively. It is unclear whether the presence of *BCR-ABL* is sufficient for the development of the disease. It has recently been shown that normal subjects can carry low levels of the *BCR-ABL* fusion gene in their blood without developing leukaemia.

Almost all patients with acute promyelocytic leukaemia (APML), a subtype of acute myelogenous leukaemia,

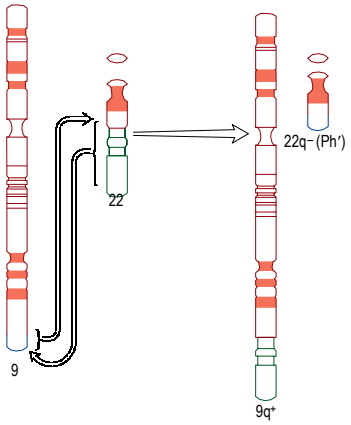

Fig. 9.5 **The Philadelphia chromosome (Ph)**. The long arm (q) of chromosome 22 has been shortened by the reciprocal translocation with chromosome 9.

have the t(15;17) reciprocal translocation, which occurs at the q25 band on chromosome 15 and the q22 band on chromosome 17. The breakpoint on chromosome 17 occurs in the gene encoding the retinoic acid receptor, fusing it with part of the *PML* gene. This is to some extent the explanation for the responsiveness of patients with APML to all-*trans*-retinoic acid (ATRA, see p. 504). Other genetic and cytogenetic abnormalities are often seen in leukaemic cells (see Table 9.14).

Cell surface markers

These can be used to classify acute leukaemias. Immature myeloid cells have cell surface markers, e.g. CD13, CD14, CD33, CD34, which can be identified using monoclonal antibodies. The majority of patients with ALL (60%), for example, show the common ALL antigen (CALLA – CD10).

ACUTE LEUKAEMIAS

The acute leukaemias are predominantly diseases of adulthood, increasing in incidence with advancing age. Acute myeloid (myeloblastic, myelogenous) leukaemia (AML) has a median age at presentation of 65 years and may arise 'de novo' or against a background of myelodysplasia, either of unknown aetiology or related to cytotoxic chemotherapy. Acute lymphoid (lymphoblastic) leukaemia (ALL) has a substantially lower median age at presentation and in addition is the commonest malignancy in childhood. The WHO classification is shown in Table 9.14.

Clinical features

The majority of patients with acute leukaemia, regardless of subtype present with symptoms arising from:

- anaemia – shortness of breath on effort; excessive tiredness, weakness
- leucopoenia – recurrent infections
- thrombocytopenia – bleeding and bruising (particularly acute promyelocytic leukaemia)
- marrow infiltration – bone pain.

Examination may be unremarkable, but features include:

- pallor
- fever (due to infection, not the disease itself)
- petechiae, purpura, bruises, fundal haemorrhage (particularly acute promyelocytic leukaemia)
- lymphadenopathy, hepatosplenomegaly (more notable in lymphoblastic leukaemia)
- violacious skin lesions (acute myelomonocytic leukaemia)
- testicular enlargement (acute lymphoblastic leukaemia)
- cranial nerve palsies occasionally found (acute lymphoblastic leukaemia).

Investigations

Confirmation of diagnosis (Fig. 9.6)

- **Blood count**. Hb low, WBC raised usually (sometimes low), platelets low.
- **Blood film**. Blast cells almost invariably seen, (Fig. 9.6a), lineage identified morphologically, confirmed with immunophenotyping.
- **Bone marrow aspirate**. Increased cellularity, reduced erythropoiesis, reduced megakaryocytes, sometimes trilineage dysplasia. Blast cells > 20% (often approaching 100%) (Fig. 9.6b). Lineage confirmation by immunophenotyping (FISH), cytogenetic and molecular genetics.
- **Chest X-ray**. Mediastinal widening often present in T lymphoblastic leukaemia.

Table 9.14 **WHO classification of acute leukaemia**

(a) Acute myeloid leukaemia

AML with recurrent genetic abnormalities

AML with t(8;21)(q22;q22), (AML1/ETO)
AML with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), (CBFβ/MYH1 1)
Acute promyelocytic leukaemia with t(15;17)(q22;q12), PML/RAR-alpha and variants
AML with 11q23 (MLL) abnormalities

AML with multilineage dysplasia

Following MDS or MDS/MDP
Without antecedent MDS or MDS/MDP, but with dysplasia in at least 50% of cells in two or more myeloid lineages

AML and myelodysplastic syndromes, therapy related

Alkylating agent/radiation-related type
Topoisomerase II inhibitor-related type
Other

AML, not otherwise categorized*

AML, minimally differentiated
AML without maturation
AML with maturation
Acute myelomonocytic leukaemia
Acute monoblastic/acute monocytic leukaemia
Acute erythroid leukaemia (erythroid/myeloid and pure erythroleukaemia variants)
Acute megakaryoblastic leukaemia
Acute basophilic leukaemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma

(b) Acute lymphoid leukaemia

Precursor B cell acute lymphoblastic leukaemia
t(9;22)(q34;q11); BCR/ABC fusion gene
t(4;11)(q21;q23); MLL-AF4 fusion gene
t(1;19)(q23;p13.3); E2A/PBX1 fusion gene
t(12;21)(p13;q22); TEL/AML1
Precursor T cell acute lymphoblastic leukaemia
Burkitt-cell leukaemia

* The entities included in this group are defined almost identically to the corresponding entity in the French–American–British (FAB) classification
MDS, myelodysplastic syndromes; MPD, myeloproliferative diseases

For planning therapy

- Biochemistry, serum urate, renal and liver biochemistry.
- Cardiac function; ECG and direct tests of left ventricular function, e.g. echocardiogram or MUGA scan (p. 756).

Principles of management

Untreated acute leukaemia is invariably fatal, most often within months, though with judicious palliative care it may be extended to perhaps a year. Treatment with curative intent may be successful, or may fail, either because the leukaemia cannot be eradicated or because the patient cannot sustain the therapy, death occurring as early as if treatment had not been initiated.

At initial presentation, acute leukaemias range from being probably curable (most favourable risk – childhood acute lymphoblastic leukaemia) through possibly curable (de novo low-risk AML) to probably incurable (AML with adverse cytogenetic features in the elderly, secondary AML, recurrent acute leukaemia). Since curative treatment even for 'low-risk' acute leukaemia carries considerable morbidity and potential mortality and that for 'high-risk' acute leukaemia even more, it is essential that the 'risk/benefit' ratio is clearly understood by physician and patient alike.

In AML, patients with t(15;17) t(8;17) or inv(16) (or its variant t16;16), i.e. low risk, do not benefit from allogeneic stem cell transplantation during their first complete remission because the risks outweigh benefits. Patients with adverse factors (high risk) – (5/del5q), -7, abnormal 3q, t(9;22) or a complex karyotype – should have transplantation because they respond poorly to conventional chemotherapy. Other poor prognostic factors (high risk) include developing the disease over 60 years of age, leukaemia following myelodysplastic syndrome (MDS), relapsed disease, secondary leukaemia and extramedullary disease.

Palliative therapy

The patient must understand that the decision to manage palliatively does not mean 'no therapy', or abandonment, but rather the recognition of a different goal from prolongation of life, though this may also be achieved to some degree. Every attempt should be made to ensure that the patients are at home as much as possible, whilst making available the full range of supportive care. Palliation may well include both chemotherapy and irradiation in addition to blood product support. 'Moral' support is invaluable.

Curative therapy

The decision to treat with curative intent, particularly if successful, implies severe disruption of normality for the patient and family for at least 6 months and often up to a year, and, regardless of success, life is never quite the same again. In the short term, it may demand transfer to another hospital, as acute leukaemia should only be treated in units seeing at least 10 such cases per year. It is highly likely to involve admission to hospital for up to a month in the first instance, with further, partly predictable, subsequent admissions of several days' to weeks' duration, requiring discussions and decisions about work or education.

The decision to treat with curative intent implies that cure is possible, and that the chance of cure justifies the risks of the therapy. It does not imply that cure is guaranteed or even expected. The failure rate may be high, and the patient must know that he or she will be told if cure becomes an unrealistic goal. Treating with curative intent may well involve rapid decisions about resuscitation with transfer to the intensive care unit, the possibility of which is discussed in advance.

Active therapy

Supportive care

This forms the basis of treatment whether for cure or palliation:

- Avoidance of symptoms of anaemia (haemoglobin > 10 g/dL) – repeated transfusion of packed red cells (sometimes irradiation of cells is required).
- Prevention or control of bleeding (platelet count < 10×10^9/L in the uninfected, and 20×10^9/L in the infected patient).
- Treatment of infection:
  (a) *Prophylactically.* Education of patients, relatives and staff about hand washing and isolation facilities. The use of selected antibiotics and antifungals.

(b) *Therapeutically.* Management of fever with protocol/algorithm of antibiotic and antifungal combinations.

- Control of hyperuricaemia with hydration, prophylactic allopurinol and very occasionally rasburicase (p. 492).

Specific treatment

The initial requirement of therapy is to return the peripheral blood and bone marrow to normal (complete remission; CR) with 'induction chemotherapy' tailored to the particular leukaemia and the individual patient's risk factors. Since this treatment is not leukaemia specific but also impairs normal bone marrow function, it leads to a major risk of life-threatening infection, which increases the risk of early death in the short term. Since infection is the major problem, it is necessary to conduct the early therapy in hospital, the patient sleeping in a single room with en-suite lavatory and washing facilities ('some' isolation).

Successful remission induction is always followed by further treatment (consolidation), the details being determined by the type of leukaemia and the patient's risk factors (and the patient's tolerance of treatment). Recurrence is almost invariable if 'consolidation' therapy is not given. This reflects the lack of sensitivity of the definition of 'complete remission', which has until very recently been solely morphological. Cytogenetics and molecular genetic techniques can identify residual leukaemic cells not detected morphologically, and they are highly predictive of recurrence. Recommendations have recently been made to modify the definition of remission to reflect this. Failure to achieve morphological CR with two cycles of therapy carries almost as bad a prognosis as the leukaemia untreated. If CR can be achieved, e.g. by new experimental approaches, cure may still be possible with stem cell transplantation (p. 496).

Acute myeloid leukaemia (AML; excluding APML, p. 504)

Treatment with curative intent is undertaken in the majority of adults below the age of 60 years, provided there is no significant co-morbidity. Risk of failure is based on the cytogenetic pattern (p. 503). Those at 'low risk' are treated with moderately intensive combination chemotherapy always including an anthracycline antibiotic such as daunorubicin and cytosine arabinoside (cytarabine) and consolidation with a minimum of four cycles of treatment given at 3- to 4-week intervals. Those at 'high risk' may only be treated with curative intent if an HLA-identified sibling is available for stem cell transplantation.

Those at ' intermediate risk' are a heterogeneous group but when possible they should be given consolidating chemotherapy to induce remission followed by sibling matched allogeneic transplantation, despite its attendant risks.

The initial treatment of the older patient is much more contentious. Intuitively, biological age should determine the management of the individual patient. Unfortunately 'high risk AML' is commoner with increasing age, but is only curable with allogeneic transplantation, and the toxicity of this treatment increases dramatically with age.

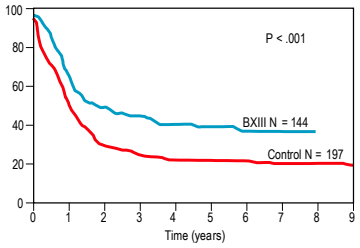

Fig. 9.7 **Acute myeloid leukaemia: overall survival with or without myeloablative therapy.** BXIII = treatment group. (from Rohatiner AZS et al. (2000) *Annals of Oncology* **11**: 1007–1015 with permission).

Complete remission will be achieved in about three-quarters of patients under the age of 60, failure being due to either resistant leukaemia or death due to infection or (rarely) bleeding. It may be expected that approximately 50% of those entering complete remission will be cured. (i.e. approximately 30% overall) (Fig. 9.7). The management of recurrence is undertaken on an individual basis, since the overall prognosis is very poor despite the fact that second remissions may be achieved. Long survival following recurrence is rarely achieved without allogeneic transplantation. Experimental therapy should be considered.

Acute promyelocytic leukaemia (APML)

This is an uncommon variant of AML characterized by the translocation t(15;17) (p. 501). There is an almost invariable coagulopathy, which was a major cause of death. The empirical discovery that all-*trans*-retinoic acid (ATRA) causes differentiation of promyelocytes and rapid reversal of the bleeding tendency was a major breakthrough. It is now conventional to treat APML with ATRA combined with chemotherapy and to follow successful remission induction with maintenance ATRA. Allogeneic transplantation may be necessary either if the leukaemia is not eliminated at the molecular level, or following a second remission after recurrence. Arsenic trioxide, which induces apoptosis via activation of the caspase cascade (p. 162) is also effective.

Complete remission and molecular remission occur in at least 80% of younger adults with APML (it is uncommon in the elderly). At least 60% will expect to be cured. In contrast to the other subtypes of AML, the prognosis after recurrence is quite favourable with prolonged second remissions being possible with further blocks of ATRA and chemotherapy even if allogeneic transplant is not performed, though it is the treatment of choice.

Acute lymphoblastic leukaemia (ALL)

The overall strategy for the treatment of ALL differs in detail from that for AML (Fig. 9.8). Remission induction is undertaken with combination chemotherapy including vincristine, prednisolone, asparaginase (crisantaspase) and usually an anthracycline antibiotic, e.g. doxorubicin. Once remission is achieved, the details of consolidation will be determined by the anticipated risk of failure.

Allogeneic transplantation is only recommended for those at highest risk, i.e. those with t(9;22) since this is otherwise incurable with conventional therapy. It is unclear yet what the role of imatinib (see below) will be in this setting. Patients with certain subtypes receive maintenance therapy for 2 years.

The other major difference between therapy for ALL and AML is the need for central nervous system directed therapy. Prophylaxis should be given with intrathecal chemotherapy under platelet cover if necessary, as soon as blasts are cleared from the blood. Depending upon risk this may be continued for up to 2 years, and complemented by high doses of systemic cytosine arabinoside (cytarabine) or methotrexate. Cranial irradiation previously given to all patients is reserved for those at very high risk and those who are symptomatic (Fig. 9.8).

Prognosis

The prognosis of ALL in childhood is now excellent: complete remission is achieved in almost all, with up to 80% being alive without recurrence at 5 years. Failure occurs most frequently in those with high blast count and t(9;22) translocation.

The situation is far less satisfactory for adults, the prognosis getting worse with advancing years. Co-morbidity and t(9;22) translocation increases in frequency with age. Overall the complete remission rate is 70–80%, failure being due partly to resistant leukaemia and partly to failure of supportive care. Failure to achieve complete remission with first-line therapy carries a very poor prognosis. If CR can be achieved with new therapies, it should be consolidated with sibling or possibly even unrelated donor transplantation despite the high risk of graft-versus-host disease. Thirty to 40% of patients continue in durable first remissions, resulting in approximately 25–30% overall patient cure.

As with AML, most recurrences occur within the first 3 years and the outcome is extremely poor. Second remissions, though usually achieved, are rarely durable except following allogeneic transplantation. Isolated extramedullary recurrences, however, may be cured.

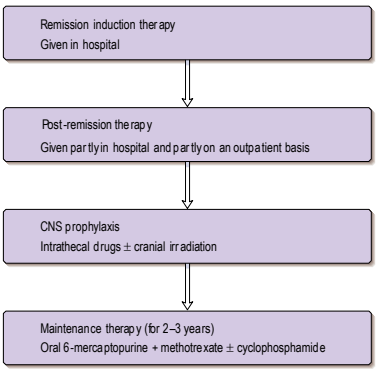

Fig. 9.8 **Treatment regimen for acute lymphoblastic leukaemia.**

CHRONIC LEUKAEMIAS

Chronic myeloid leukaemia (CML)

Chronic myeloid leukaemia (CML) accounts for about 14% of all leukaemias, is almost exclusively a disease of adults with the peak of presentation being at 40–60 years and is characterized by the presence of the Philadelphia chromosome (Fig. 9.9). Unlike the acute leukaemias which are either rapidly reversed or rapidly fatal, CML has a more slowly progressive course which if not initially cured will be followed eventually by blast crisis (90% myeloid, 20% lymphoid) or myelofibrosis and death after 3–4 years.

Clinical features

CML usually presents in the chronic phase and some patients have no symptoms. Symptoms include:

- shortness of breath due to anaemia
- abdominal discomfort due to splenomegaly
- weight loss
- fever, sweats, NOT due to infection

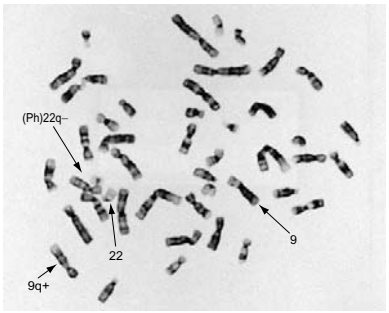

Fig. 9.9 **Philadelphia chromosome**. This is formed by a reciprocal translocation of part of the long arm (q) of chromosome 22 to chromosome 9. It is seen in 90–95% of patients with chronic myeloid leukaemia. The karyotype is expressed as 46XX, (9;22)(q34;q11).

- headache (occasionally) due to hyperleucocytosis
- bruising, bleeding (uncommon).

Signs

- Pallor
- Splenomegaly, often massive
- Lymphadenopathy, at times of blast crisis
- Retinal haemorrhage due to leucostasis.

Investigations

- **Blood count**. Hb low or normal, WBC raised, platelets low, normal or raised.
- **Blood film**. Neutrophilia with the whole spectrum of myeloid precursors including occasional blasts.
- **Bone marrow aspirate**. Increased cellularity, increased myeloid precursors. Cytogenetics reveals t(9;22) translocation (the Philadelphia chromosome) (Fig. 9.9)
- **Fluorescein-in-situ hybridization** (FISH), reverse transcriptase polymerase chain reaction (RT-PCR) or microarray expression may be needed to demonstrate the cytogenetic/molecular abnormality.
- **LAP is usually reduced.**

Management

Imatinib, a *tyrosine kinase inhibitor* that specifically blocks the enzymatic action of the BCR-ABL fusion protein is first-line treatment *for the chronic phase*. It has replaced alpha-interferon. Imatinib produces a complete haematological response in over 95% of patient, and 70–80% of these have no detectable BCR-ABL transcripts in the blood. Event-free, and overall, survival appear to be better than for other treatments. Imatinib can be continued indefinitely.

In the acute phase (blast transformation) most patients have only a short-lived response to imatinib, and other treatments (see below) will be necessary.

Side-effects of imatinib, which usually are well tolerated, include nausea, headaches, rashes and cytopenia. Resistance to imatinib as a single agent has developed and further clinical studies are necessary.

Stem cell transplantation (SCT)

Allogeneic haemopoietic stem cell transplantation can cure approximately 70% of chronic phase CML patients but with a risk of complications and death due to graft-versus-host disease (GVHD) and opportunistic infections.

Factors making complications more likely include:

- increasing age
- SCT in acute phase
- degree of histocompatibility between donor and recipient.

Graft-versus-leukaemia effect plays a role in the increased survival following SCT so that reduced-intensity transplantation is being more frequently used.

The exact role of SCT in the imatinib era is unclear but failure to respond to that agent is an indication. Monitoring of patients following either SCT or imatinib is by measuring BCR-ABL transcripts using the reverse transcriptase PCR.

Chronic lymphocytic leukaemia (CLL)

This is the commonest leukaemia, occurring predominantly in later life and increasing in frequency with advancing years. It is almost invariably B lymphocytic in origin. In many patients it is a chance finding with no symptoms, while others present with the features of marrow failure or immunosuppression. The median survival may be 10 years, and may be found to correlate with various presentation features (Table 9.15). It is becoming increasingly recognized that cytogenic and molecular abnormalities carry prognostic significance (see below).

Clinical features

Common symptoms are:

- recurrent infection because of (functional) leucopenia and immune failure (reduced immunoglobulins)
- anaemia due to haemolysis or marrow infiltration
- painless lymphadenopathy
- splenic discomfort.

The commonest findings on examination are:

- anaemia
- fever (due to infection)
- generalized lymphadenopathy
- hepatosplenomegaly, sometimes massive.

However, none of these may be present.

Investigations

- **Blood count**. Hb normal or low; WBC raised, and may be very high; platelets normal or low.
- **Blood film**. Lymphocytes increased above 5×10^9/L.
- **Bone marrow**. Reflects peripheral blood, often very heavily infiltrated with lymphocytes.
- **Immunophenotyping** shows mainly CD19/20 + $CD5^+$ B cells. They may weakly express surface immunoglobulin.
- **Cytogenetics** can help assess prognosis. Abnormalities include deletions at trisomy 12 (40%) 13q14 (60%), long arms of 6, 11 and 13 and abnormalities in the *p53* gene. There are mutations of IgVH (on B cells) which help in assessing prognosis. IgVH is difficult to measure. However, intracellular ZAP-70 (zeta-associated protein) which correlates closely with the IgVH mutated status can be measured by flow cytometry in a general laboratory.
- **Coombs' test**. May be positive if there is haemolysis.
- **Immunoglobulins**. Low or normal.

Management

In CLL, the major consideration is when to treat. Treatment depends on the 'stage' (Table 9.15) of the disease, although the cytogenic markers are being increasingly used. In particular, low levels of ZAP-70 indicate a good prognosis with no treatment necessary. Conversely unmutated IgVH (high levels of ZAP-70) indicate a poor prognosis.

Early-stage disease is usually managed expectantly, advanced-stage disease is always treated immediately

Table 9.15 The Rai and Binet staging systems for chronic lymphocytic leukaemia*

System and stage	Risk	Manifestations	Percent of patients	Median survival	Recommended treatment
Rai staging system					
0	Low	Lymphocytosis	31	> 10	Watch and wait
I	Intermediate	Lymphadenopathy	35	9	Treat only with progression†
II	Intermediate	Splenomegaly, lymphadenopathy, or both	26	7	Treat only with progression†
III	High	Anaemia, organomegaly,	6	5	Treatment indicated in most cases
IV	High	One or more of the following: anaemia, thrombocytopenia and organomegaly	2	5	Treatment indicated in most cases
Binet staging system					
A	Low	Lymphocytosis, < 3 lymphoid areas enlarged‡	63§	> 10	Watch and wait
B	Intermediate	≥ 3 Lymphoid areas enlarged‡	30	7	Treatment indicated in most cases
C	High	Anaemia, thrombocytopenia or both	7	5	Treatment indicated in most cases

* Lymphocytosis is present in all stages of the disease
† Progression is defined by weight loss, fatigue, fever, massive organomegaly and a rapidly increasing lymphocyte count
‡ Enlarged lymphoid areas may include the cervical, axillary and inguinal lymph nodes; the spleen or liver may be enlarged
§ Stage A includes all patients with Rai stage 0 disease, two-thirds of patients with Rai stage I disease and one-third of those with Rai stage II
From Dighiero G, Binet JL (2000) *New England Journal of Medicine* **343**: 1800

and the approach to the intermediate stage is variable. The absolute indication for treatments are:

- anaemia (especially due to haemolysis)
- recurrent infection
- splenic discomfort
- progressive disease manifest by doubling of the lymphocyte count in 6 months.

General/supportive treatment

Anaemia due to haemolysis is treated with steroids. If it is refractory or recurrent, or if splenic discomfort is a problem, a splenectomy is performed. Anaemia due to marrow infiltration is treated with chemotherapy and, when necessary, blood transfusion. Erythropoietin (p. 422) may avoid the need for transfusions, particularly in patients receiving chemotherapy.

Infection is treated with antibiotics, with prophylactic therapy being given during periods of chemotherapy. Immunoglobulin replacement may be helpful.

Allopurinol is given to prevent hyperuricaemia.

Specific treatment

Chlorambucil, given in modest doses, usually reduces the blood count and decreases lymphadenopathy and splenomegaly, and successfully palliates the disease. The bone marrow rarely returns to normal. Treatment is usually limited to a few months' duration and then withheld until progression.

Since the introduction of the purine analogues, fludarabine alone or in combination with cyclophosphamide or mitoxantrone (with or without steroids), treatment has had a much greater impact on the bone marrow and can induce complete or molecular complete remission. More recently, the addition of rituximab (relatively ineffective alone) in combination therapy has been reported to result in a dramatic improvement in the response rate. Myeloblative chemotherapy with autologous stem cell rescue and allogeneic stem cell transplantation with myeloablative or non-myeloablative condition regimens are currently undergoing trials.

Outcome

Survival correlates closely with cytogenetic findings and Rai or Binet stage at any time. The median survival from diagnosis is very variable with normal life expectancy in some groups and rapid progression in others. Poor prognostic factors include a high Rai and Binet stage, a short lymphocyte doubling time (< 12 months), diffuse bone marrow infiltration, cytogenetic abnormalities involving *p53* dysfunction, *11q23*, trisomy 12 and CD38/ZAP-70 positivity, male gender and developing the disease over 60 years of age. Intervention, when indicated, usually causes improvement in symptoms and in the blood count. The effect on survival is unclear. More aggressive treatments, particularly combinations of cytotoxic chemotherapy with antibody therapy, result in better quality remission of longer duration. These improvements may translate into a survival advantage, to accompany the improvement in quality of life afforded by good supportive care.

Hairy cell leukaemia (HCL)

HCL is a clonal proliferation of abnormal B (or very rarely T) cells which, as in CLL, accumulate in the bone marrow

and spleen. It is a rare disease, median age at presentation is 52 years old and the male to female ratio is 4 : 1. The bizarre name relates to the appearance of the cells on a blood film and in the bone marrow – they have an irregular outline owing to the presence of filament-like cytoplasmic projections. They show a strong acid phosphatase reaction that is resistant to tartaric acid. The cells express many cellular differentiation markers including CD19, 20 and 103 but not CD21 or 5.

Clinical features include anaemia, fever and weight loss. Splenomegaly occurs in 80%, lymphadenopathy is uncommon. Anaemia, neutropenia, thrombocytopenia and low monocyte counts are found.

Treatment

The purine analogues 2-chloroadenosine acetate (2-CDA) (cladribine) and pentostatin have specific activity in this condition; complete remission is achieved in 90% with just one cycle of treatment. The remissions sometimes last for several years and patients can be retreated. Rituximab is used in cases who do not respond to the above drugs.

Prolymphocytic leukaemia

Prolymphocytic leukaemia is another rare disorder, often mistaken for CLL. It may be of B or of T cell lineage. It is characterized by bone marrow failure (anaemia, neutropenia and thrombocytopenia) and – as in HCL – splenomegaly. Treatment generally comprises chlorambucil as for CLL, although splenectomy may be indicated and fludarabine can be useful.

THE LYMPHOMAS

The lymphomas are commoner than the leukaemias and are increasing in incidence for reasons which are unclear. They arise as the result of abnormal proliferation of the lymphoid system, and hence occur at any site where lymphoid tissue is found. Most commonly they are manifest by the development of lymphadenopathy at single or multiple sites, although primary extranodal presentations account for up to 20% of non-Hodgkin's lymphoma. The prognosis is determined by the specific subtype of lymphoma and the anatomical extent of disease and its bulk, the clinical course ranging from months to years.

The guiding principles of management are broadly the same as for the leukaemias. The precise diagnosis is established, appropriate further investigation is conducted to allow a management plan to be formulated, both for the short and long term, and the situation is clearly explained to the patient.

Lymphomas are currently classified on the basis of histological appearance into:

- Hodgkin's lymphoma
- non-Hodgkin's lymphoma.

The distinction between lymphoid leukaemia and lymphoma is not always clear.

HODGKIN'S LYMPHOMA (HL)

This is a rare disease involving primarily the lymph nodes. The incidence in the UK is approximately 2.5/100 000 with a male to female ratio of 1.3 : 1. Its peak incidence is in the third decade. The incidence is stable.

Aetiology

There is epidemiological evidence linking previous infective mononucleosis with HL and up to 40% of patients with HL have increased EBV antibody titres at the time of diagnosis and several years prior to the clinical development of HL. EBV DNA has been demonstrated in tissue from patients with HL. These data suggest a role for EBV in pathogenesis. Other viruses have not been detected. Other environmental and occupational exposure to pathogens have been postulated.

Pathology

The hallmark of HL is the Reed–Sternberg cell (Fig. 9.10) which is usually derived from germinal centre B cells or, rarely, peripheral T cells. CD30 and CD25 are almost always expressed in the majority of cases of classical HL.

The WHO classification of HL is shown in Table 9.16. Classical HL can be divided into:

Table 9.16 Pathological classification of Hodgkin's lymphoma

Nodular lymphocyte-predominant Hodgkin's lymphoma
Classical Hodgkin's lymphoma
Nodular sclerosis HL
Lymphocyte-rich HL
Mixed cellularity HL
Lymphocyte-depleted HL

From Harris NL et al. (1999) *Journal of Clinical Oncology* **17**: 3835–3849

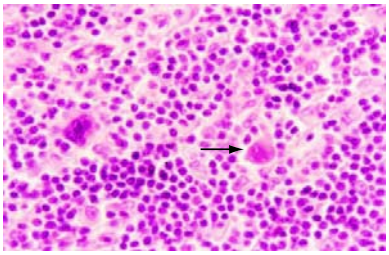

Fig. 9.10 **Histological appearance of Hodgkin's lymphoma**. There is a background rich in benign small lymphocytes and histiocytes together with scattered mononuclear Hodgkin's cells and a classical malignant binucleate Reed–Sternberg cell (arrow) to the right of centre. Courtesy of Dr AJ Norton.

- *Nodular sclerosing HL* (70% of cases) where many fibrotic bands are present. This type is typically seen in young females, involving particularly lymph nodes in the mediastinum and neck.
- *Lymphocyte-rich HL* appears in 5% and is characterized by an infiltrate of many small lymphocytes and Reed–Sternberg cells. It often occurs in peripheral lymph nodes. It is often an indolent disease.
- *Mixed cellularity HL*. Approximately 25% of cases have mixed cellularity with lymphocytes, eosinophils, neutrophils and histiocytes. Reed–Sternberg cells are present but no fibrotic bands. It is more common in men and is associated with B symptoms.
- *Lymphocyte-depleted HL* is rare and there is lack of cellular infiltrate with numerous Reed–Sternberg cells. It is seen in HL associated with HIV.

In addition to classical HL, *nodular lymphocyte-predominant HL* (5% of cases) contains malignant L and H cells (lymphocytic and/or histiocytic Reed–Sternberg cell variants, also called 'popcorn' cells) which are positive for CD20, CD45, BCL6, CD79a without expressing CD15 or CD30.

Pathogenesis

This remains unclear but several factors have been identified in classical HL:

B cells. There is a lack of expression of surface immunoglobulin (or BCR) in the Hodgkin and Reed–Sternberg cell. This may be due to destructive mutations or non-functional rearrangements in the immunoglobulin genes, and/or a lack of immunoglobulin-specific transcription factors.

Resistance to apoptosis. The malignant lymphoma cell may have acquired a Fas-resistant phenotype that prevents its death in the germinal centre. Destruction mutations have been found in the Fas gene inactivating the Fas pathway.

Development of non-regulatory growth signals. It has been suggested that the transforming Reed–Sternberg cell may acquire self-sufficiency in growth signals and develop non-regulated, permanent transcription activity by NFκB. Mutations have been reported in the *Ik*βα gene

Environmental. A delayed exposure to ubiquitous infections in childhood may suggest that HL is a late infection with a common virus. See EBV above.

Genetic factors. Monozygotic twins have a 100 times greater risk of concordantly developing HL. No increase has been seen in dizygotic twins.

It is clear that several pathways may lead to HL but the central issue must be that lymphocytes of the B-cell lineage not expressing immunoglobulins somehow escape apoptosis.

Clinical features

- Lymph node enlargement, most often of the cervical nodes (other causes are shown in Table 9.17); these are usually painless and with a rubbery consistency.
- Enlargement of the spleen/liver.
- 'B' symptoms: fever, (25%) drenching night sweats, weight loss of > 10% bodyweight (see Table 9.18).
- Other constitutional symptoms, such as pruritus, fatigue, anorexia and, occasionally, alcohol-induced pain at the site of enlarged lymph nodes.
- Symptoms due to involvement of other organs (e.g. lung – cough and breathlessness).

Investigations

- **Blood count** may be normal, or there can be a normochromic, normocytic anaemia. Lymphopenia and occasionally eosinophilia are present.
- **Erythrocyte sedimentation rate** (ESR) is usually raised and is an indicator of disease activity.
- **Liver biochemistry** is often abnormal, with or without liver involvement.
- **Serum lactate dehydrogenase**; raised level is adverse prognostic factor.
- **Uric acid** is normal or raised.
- **Chest X-ray** may show mediastinal widening, with or without lung involvement.
- **CT scans** show involvement of intrathoracic nodes in 70% of cases. Abdominal or pelvic lymph nodes are also found. It is the investigation of choice for staging

Miscellaneous

Kawasaki's syndrome

(Table 9.18), although PET scanning is increasingly being used.

- **Bone marrow aspirate and trephine biopsy** are seldom done but show involvement in patients with advanced disease. This is unusual at initial presentation.
- **Lymph node biopsy** is required for a definitive diagnosis (Fig. 9.10).

A typical chest X-ray and CT scan in one patient are shown in Figure 9.11.

Management

Treatment is almost always recommended and undertaken with curative intent and considerable expectation of success (Figs 9.12 and 9.13). Expectant management may be reasonable in some cases of lymphocyte-predominant Hodgkin's lymphoma, although the rationale for this must be made clear to the patient and there needs to be close early surveillance.

Specific treatment is based otherwise on the anatomical distribution of disease, its 'bulk' and the presence or absence of 'B' symptoms. ('stage': Table 9.18).

'Early stage' (I^A, II^A no bulk)

The treatment of choice now is brief chemotherapy followed by involved field irradiation. Extended field megavoltage irradiation was used with 70% of patients being cured, and probably half of those in whom it failed were 'salvageable' with combination chemotherapy. Large field irradiation has come under recent criticism because of a significantly increased incidence of breast cancer in young women, lung cancer in smokers and cardiac disease following supradiaphragmatic 'mantle' field irradiation. 'Moderate' chemotherapy ABVD (Table 9.10), 2–4 cycles (i.e. non sterilizing and low secondary cancer risk) followed by involved field irradiation (20–30 Gy) has become standard care. Current trials are evaluating the role of PET scanning to see if patients who become 'PET' negative can be spared irradiation altogether.

Table 9.18 Cotswolds modification of Ann Arbor staging classification

Stage	Description
Stage I	Involvement of a single lymph-node region or lymphoid structure (e.g. spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site
Stage II	Involvement of two or more lymph-node regions on the same side of the diaphragm (hilar nodes, when involved on both sides, constitute stage II disease); localized contiguous involvement of only one extranodal organ or site and lymph-node region(s) on the same side of the diaphragm (IIE). The number of anatomic regions involved should be indicated by a subscript (e.g. II_3)
Stage III	Involvement of lymph-node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (IIIS) or by localized involvement of only one extranodal organ site (IIIE) or both (IIISE)
III1	With or without involvement of splenic, hilar, coeliac, or portal nodes
III2	With involvement of para-aortic, iliac, and mesenteric nodes
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph-node involvement
Designations applicable to any disease state	
A	No symptoms
B	Fever (temperature > 38°C), drenching night sweats, unexplained loss of more than 10% of body weight within the previous 6 months
X	Bulky disease (a widening of the mediastinum by more than one-third of the presence of a nodal mass with a maximal dimension greater than 10 cm)
E	Involvement of a singe extranodal site that is contiguous or proximal to the known nodal site

From Diehl V et al. (2004) Hodgkin's lymphoma – diagnosis and treatment. Reprinted with permission from Elsevier (*Lancet Oncology* **5**: 19–26).

Advanced disease

This is also curable for a significant proportion of patients, the median survival exceeding 5 years. Cyclical combination chemotherapy with or without irradiation to sites of 'bulk' disease is the treatment of choice for all these patients. The 'gold standard' combination is ABVD (Table 9.10) given to a total of 6–8 cycles each month, the blood count permitting. All patients with mediastinal bulk receive irradiation whether or not the CT scan returns to normal. It may well be that in the future PET scanning, as for those with early disease, may reduce the need for irradiation. This approach will be curative for approximately 50–60% of those with advanced disease, the major potential toxicity in the short term being

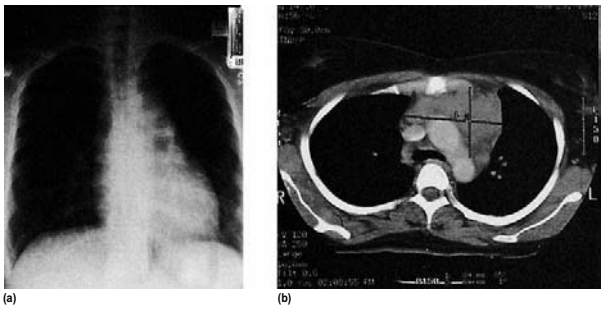

Fig. 9.11 **(a) Chest X-ray of a large mediastinal mass that is due to Hodgkin's lymphoma. (b) CT scan of the same patient.** The mass is indicated here by crossed lines.

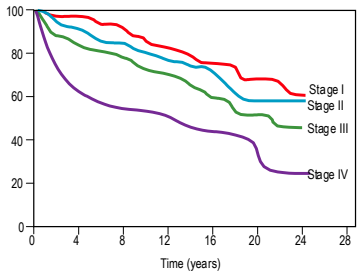

Fig. 9.12 **Survival in Hodgkin's lymphoma related to Ann Arbor stage at presentation.**

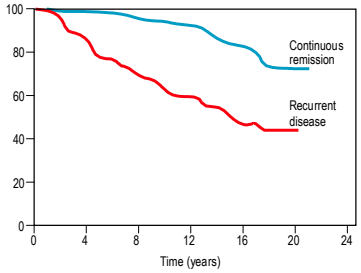

Fig. 9.13 **Survival of patients with Hodgkin's lymphoma.** From Oza AM et al. (1993) Patterns of survival in patients with Hodgkin's disease: long follow-up in a single centre. From Oza AM et al. (1993) *Annals of Oncology* **4**: 385–392, with permission.

myelosuppression with a mortality of ~ 1%. In the long term the risks are to the heart and lungs. Infertility and second malignancy are much less common than following the previous gold standard therapy MOPP (or MVPP). The 15-year survival of this group of patients is approximately 65%.

Twenty-five per cent of patients fail to achieve remission of advanced Hodgkin's lymphoma with the initial ABVD chemotherapy. 'Intensification' of treatment by increasing the number of drugs, alternating combinations, or hybrids may have reduced this proportion in resistant patients. Recently two schedules, one given cyclically with many drugs, some in high doses, and the other as a continuous 12-week programme of chemotherapy (both complemented with significant amounts of irradiation) have been reported to reduce the failure rate substantially in the short term. Confirmation of these results with longer follow-up is awaited. Clearly, the development of a prognostic index to identify these resistant patients prospectively would be a major step forward, although the highest-risk group is very small. The alternative to the strategy of overtreating some for the benefit of the few, is to undertreat the few to the advantage of the many, and then 'salvage' the failures. Limited success with myeloablative chemotherapy with haemopoietic stem cell rescue has been reported in those with 'refractory disease'.

Recurrent Hodgkin's lymphoma, certainly after 'conventional'-dose chemotherapy is potentially very serious though not necessarily fatal. The median survival from the first recurrence is more than 10 years; it may be influenced by the duration of first remission: it may not be so good if failure occurs after more intensive initial therapy. Second, and third remissions are achieved more often than not with 'appropriate' re-induction chemotherapy. It is conventional to consolidate remission in this group when possible, with high-dose therapy and peripheral blood cell progenitor rescue (PBPCR). Registry data suggest that this may be curative in up to 50%, although follow-up does not extend beyond 15 years.

Experimental approaches for recurrent and refractory disease include new cytotoxic drugs, monoclonal antibodies and reduced-intensity allogeneic transplantation.

Thomas RK et al. (2004) Hodgkin's lymphoma – molecular biology of Hodgkin and Reed–Sternberg cells. *Lancet Oncology* **5**: 11–18.

NON-HODGKIN'S LYMPHOMA (NHL)

These are malignant tumours of the lymphoid system classified separately from Hodgkin's lymphoma. Most (70%) are of B cell origin although T cell tumours are increasingly being recognized.

The incidence of these tumours is approximately 15/100 000 per year in developed countries, an incidence which has increased over the last 20–30 years. There is a slight male predominance. The median age of presentation is 55–75 years.

Aetiology

The cause is unknown. There is wide geographical variation which probably reflects different environmental factors. NHL is associated with the EBV virus (Burkitt's lymphoma) and the human T cell lymphotropic virus which is prevalent in Japan, Africa, South America and the Caribbean. Herpesvirus 8 is associated with primary effusion lymphomas and Castleman's disease; there is an increase in lymphoma in patients with AIDS. *Helicobacter pylori* is an aetiological factor in gastric MALT lymphoma.

Lymphomas also occur in congenital immunodeficiency, post-transplantation and in autosomal family cancer syndromes (Table 9.3). Other causes, e.g. occupation, dietary and exposure to chemicals, have been linked to the increasing incidence but the evidence is unconfirmed.

Pathogenesis

There is a malignant clonal expansion of lymphocytes which might occur at a different stage of lymphocyte development. In general, neoplasms of non-dividing mature lymphocytes are indolent whereas those of proliferating cells (e.g. lymphoblasts, immunoblasts) are much more aggressive. This malignant transformation is usually due to errors in gene rearrangements which occur during the class switch, or gene recombinations for immunoglobulins and T cell receptors. Thus, many of the errors occur within immunoglobulin loci or T cell receptor loci. For example, an abnormal gene translocation may lead to the activation of a proto-oncogene next to a promoter sequence for the immunoglobulin heavy chains (Ig-H).

Cytogenetic features (Table 9.19)

Burkitt's lymphoma was the first tumour in which a cytogenetic change was shown to involve the translocation of a specific gene. The most frequent change is a translocation between chromosomes 8 and 14 in which the *myc* oncogene moves from chromosome 8 to a position near the constant region of the immunoglobulin heavy chain gene on chromosome 14, resulting in upregulation of *myc*. Similar rearrangements involving the light chain loci are seen in the alternative Burkitt's lymphoma translocations between chromosome 8 and either chromosome 2 or 22. Other somatic cytogenetic abnormalities associated with human lymphoma are the t(14;18) in follicular lymphoma, involving upregulation of the *Bcl-2* gene, or the upregulation of *Bcl-1* (also called cyclin D1) as a result of t(11;14) in mantle cell lymphoma.

Immunophenotypes

All NHL B cells express CD20 and surface immunoglobulin. Individual lymphomas vary in their expression, e.g. follicular lymphomas express CD10, mantle cell CD43, while the diffuse large B cell lymphoma expresses both CD10 and CD43. They can be used in the classification. T cell lymphomas do not express CD20 but variably express CD3, 4, 8 and 30.

Classification

The WHO classification (2001) which is based on the Revised European American Lymphoma (REAL) system is shown in Table 9.20. Previous classifications have divided lymphomas into indolent (or low grade) and aggressive (or high grade), and the WHO classification has been modified to include aggressive or highly aggressive lymphomas.

Clinical features

- *Peripheral lymphadenopathy.* Most patients present with painless, superficial lymph node enlargement.
- *Systemic symptoms (B symptoms).* Fever, sweats, anorexia and weight loss.
- *Extranodal presentation.* This is more common than in HL and may involve the gastrointestinal tract, lung,

Table 9.19 **Chromosome translocations in non-Hodgkin's lymphoma**

Type	Translocation	Genes	Function
Follicular	t(14;18)	*Bcl-2*/*IgH*	Suppresses apoptosis
Lymphoplasmacytic	t(9;14)	*PAX5*	Transcription factor
Mantle cell	t(11;14)	*Bcl-1* (cyclin D1)	Cell cycle regulator
Diffuse large B cell	t(3;4)	*Bcl-6*	Cell cycle regulator
Burkitt's	t(8;14) t(2;8)	*c-myc* and Ig	Transcription factor

T/NK cell lymphomas	
Precursor T cell lymphoma	Precursor T cell lymphoblastic leukaemia/lymphoma (*highly aggressive*)
	Blastic NK cell lymphoma
Mature T/NK cell lymphoma	Adult T cell leukaemia/lymphoma (*very aggressive*)
	Extranodal NK/T cell lymphoma, nasal type
	Enteropathy-type T cell lymphoma
	Hepatosplenic T cell lymphoma
	Subcutaneous panniculitis-like T cell lymphoma
	Mycosis fungoides
	Sézary syndrome
	Primary cutaneous anaplastic large cell lymphoma
	Peripheral T cell lymphoma, unspecified (*aggressive*)
	Angioimmunoblastic T cell lymphoma
	Anaplastic large cell lymphoma (*aggressive*)

NK, natural killer
Modified from Jaffe ES, Harris NL, Stein H, Vardiman JW (eds) (2001) *World Health Organization Classification of Tumours. Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues*. Lyon: IARC Press

brain, testes, thyroid and skin. Abdominal involvement may reveal hepatosplenomegaly. Skin involvement (T cell lymphomas) presents as mycosis fungoides (p. 1352) and Sézary syndrome (p. 1353).

- *Oropharyngeal involvement* occurs rarely.
- HIV predisposes to NHL.

Investigations

- **Full blood count**. Normochromic, normocytic anaemia, an elevated white cell count or neutropenia and thrombocytopenia are suggestive of bone marrow infiltration.
- **ESR** may be elevated.
- **Urea and electrolytes**. Patients may have renal impairment as a consequence of ureteric obstruction secondary to intra-abdominal or pelvic lymph node enlargement.
- **Serum uric acid level** may be raised.
- **Liver biochemistry**. This may be abnormal if there is hepatic involvement.
- **Serum lactate dehydrogenase and β_2-microglobulin** are prognostic indicators.
- **Serum immunoglobulins** – decreased levels may occur with paraproteinaemia.
- **Chest X-ray, CT scans** of chest, abdomen and pelvis. **PET and gallium scans** help in staging.
- **Bone marrow aspirate** and trephine biopsy are always performed.
- **Lymph node biopsy** (or Trucut needle biopsy, often under radiological guidance, in the case of surgically inaccessible nodes). Immunophenotyping and cytogenetic/molecular analysis (DNA micro-array analysis), to distinguish type of NHL.

Follicular lymphoma

These comprise 20% of all B cell lymphomas. Most patients with follicular lymphoma present feeling well but with painless lymphadenopathy. Investigation usually reveals multiple sites of disease: involvement of the bone marrow is common. Managed conservatively it is a remitting and recurring disease with a clinical course running over a median of 10 (1–20 years) years during which there will be about three 'episodes' of relapse. Death occurs because of resistant disease, transformation to diffuse large B cell lymphoma (LBCL) or the effects of therapy.

The 'well' patient should be managed with no specific therapy until progression is documented. Repeat biopsy should be performed at this time in case there has been histological transformation to LBCL as this has specific implications for therapy.

The indications for the initiation of therapy are:

- *Stage 1 presentation (10–15%).* This is treated with 'involved' field irradiation, which almost invariably induces 'complete remission'. The median time to progression is 10–15 years. Some patients may be cured. There is no evidence that mortality is affected by treatment, but the therapy has a low morbidity and mortality.
- *Advanced disease* with:
  - constitutional 'B' symptoms
  - 'organ impairment', i.e. bone marrow failure
  - 'bulky' disease, i.e. lymph node mass > 10 cm
  - progressive disease after expectant management, documented if necessary on two scans 3 months apart

– histological transformation.
- *Philosophy of patient and physician.*

A specific follicular lymphoma international prognostic index (FLIPI) has been formulated, defining 'low', 'intermediate' and 'high' risk groups. This may provide a more objective basis for the decision to begin therapy, and with what.

A recent study showed that survival can be predicted by the different genes expressed on accompanying T cells and dendritic cells (not tumour cells) identified by DNA micro-array analysis of tumour tissue.

Treatment options

Standard initial treatment in the UK is with an alkylating agent, e.g. chlorambucil, or a combination containing an alkylating agent, e.g. COP (cyclophosphamide, vincristine and prednisolone), given usually over 3–6 months. The overall response rate is high (~ 80%), but the proportion of complete remissions is low. It may be possible to push those patients for whom the first treatment fails into remission with a second therapy. Progression is the rule after a median of 2–3 years: there is no evidence of cure. Provided transformation has not occurred, further remissions (an average of three) can be achieved with the same or other single agents or combination of drugs. The remission becomes significantly shorter after the third, and death supervenes. Quality of life, except during treatment (and often during treatment), is normal until the disease becomes refractory.

Thus, managed conventionally, follicular lymphoma is a paradigm for the 'indolent' but incurable malignancy. Whilst this overall approach is acceptable for the elderly it is manifestly unsatisfactory for the younger patient.

Other therapies

- Aggressive combination chemotherapy gives high complete remission rates and molecular remission.
- High-dose chemotherapy with PBPCR. Open Phase II trials, comparing outcome with historical controls and now Phase III trials suggest an advantage over conventional therapy in first or second remission (molecular remission also occurs).
- Antibody therapy. The monoclonal antibody rituximab induces remission (partial) in 30–70% of patients, almost without toxicity. Molecular remissions are observed. Complications include the cytokine release syndrome, with fever, vomiting and allergic reactions (angio-oedema, bronchospasm and dyspnoea).
- Rituximab/chemotherapy combination. These have now been reported to improve the complete remission rate (with disappearance of Bcl-2 positive cells from the bone marrow in 100% of patients), freedom from progression and event-free survival, even though there is (as yet) no effect on overall survival. This may become the standard therapy for CD20 positive lymphoma.
- Antibody-targeted irradiation. This short-term therapy using anti-CD20 to deliver either ^{131}I or ^{90}Y yields 'durable' complete remission.

In addition, two major additional biological therapies are under evaluation:

- vaccine therapy
- reduced intensity allogeneic transplantation.

The median survival of follicular lymphoma appears to have been extended from 5 years to 10 years following the introduction of alkylating agent chemotherapy. There are grounds for optimism that the new approaches outlined above will improve it further or even result in cure. The challenge, beyond giving the best current advice to the patient today is to devise the initial strategy which will convert follicular lymphoma from a treatable to a curable disease. If the strategy brings greater potential toxicity, the risks have to be weighed carefully against *potential* long-term benefits. The same strategy will not be right for all patients.

Lymphoplasmacytic lymphoma

This is an uncommon B cell lymphoma often presenting with heavy bone marrow infiltration, and is almost the only lymphoma to be diagnosed on bone marrow biopsy alone. There is frequently splenomegaly and anaemia, and in some an associated paraprotein IgM with associated immune paresis (Waldenström's macroglobulinaemia; WM) occurs. Patients in this group are usually older and commonly present with the symptoms of bone marrow failure or hyperviscosity. It may be a chance diagnosis.

Management may be expectant, the indications for treatment being:

- symptomatic anaemia
- recurrent infection
- symptoms of hyperviscosity, e.g. headache, visual disturbance
- progression.

Treatment is supportive in the first instance. Transfusion and/or erythropoietin is given for the anaemia, particularly if chemotherapy is being given. Plasmapheresis is an excellent means of controlling the paraproteinaemia both in the short and longer term.

Chlorambucil is the conventional treatment, the 'response criteria' for WM being different from those of the rest of the lymphomas. The paraprotein will be reduced by 50% (response) in 50–70% of cases in the short term. Progression is the rule and as with follicular lymphoma there may be further response. The purine analogue fludarabine is also 'effective'.

It is not clear how much the use of chemotherapy has actually influenced overall survival, and quality of life is poorly recorded. The median survival is several years.

A heightened awareness of this relatively uncommon but symptomatic lymphoma has led to more enthusiastic exploration of the new therapies being tested on the other B cell lymphomas (see above).

Mantle cell lymphoma

This is an uncommon lymphoma (6% of non-Hodgkin's

lymphoma) with a median survival of 3–4 years. It occurs predominantly in the elderly and is almost always widely disseminated at presentation, with lymphadenopathy and frequent involvement of the bone marrow and gastrointestinal tract. Treatment is often compromised by co-morbidity.

Combination chemotherapy is the most usual first-line therapy, if possible: the response rate may be above 50% but the complete remission rate is low. The addition of rituximab has been reported to improve this. Intensifying chemotherapy appears to improve the results, but recurrence is almost invariable. New approaches are greatly needed.

Large B cell lymphoma (DLBCL)

This is the commonest lymphoma and is almost invariably fatal without therapy within months, and was previously classified as aggressive or high-grade lymphoma. Now > 50% of young patients are cured. The only indications for a palliative approach at the initial presentation are extreme co-morbidity and the will of the patient. Expectant management is inappropriate. Patients present with rapidly progressive lymphadenopathy and progressive infiltration of many organs, e.g. spinal cord, gastrointestinal tract.

Treatment

Treatment decisions are based on the stage and may be tailored by the International Prognostic Index (Box 9.5).

In the absence of relevant co-morbidity all patients should receive cyclical combination chemo-immunotherapy, the gold standard being cyclophosphamide, hydroxydaunorubicin, vincristine, prednisolone and rituximab (CHOP + R). Sixty to seventy percent of those with early stage disease (I, II_A without bulk) may expect to be cured either with 6 cycles or 3 cycles followed by involved field irradiation. Those with more extensive disease conventionally receive 6–8 cycles. There has been a suggestion that decreasing the interval between cycles may be feasible (with growth factor support), and this may improve the results. There are conflicting reports about the advantages of increasing the intensity of initial treatment for those perceived to be at 'high risk'. There is also controversy about the indications for central nervous system prophylaxis and which form it should take.

For those with advanced disease the cure fraction, which was about 30%, has been increased with the incorporation of rituximab as standard therapy, by 15%.

Box 9.5 **Prognostic factors in non-Hodgkin's lymphoma**

Adverse factors:
- Age > 60 years
- Stage III or IV, i.e. advanced disease
- High serum lactate dehydrogenase level
- Performance status (ECOG 2 or more)
- More than one extranodal site involved

ECOG, Eastern Cooperative Oncology Group

Progression during therapy or failure of the initial treatment to achieve complete remission has a very poor prognosis. Second-line therapy e.g. platinum or gemcitabine should be initiated with a view, if possible, to high-dose therapy and PBPCR if further response is achieved. This is not usually possible and long-term success is rare. Proper consideration should be given to palliation or experimental therapy. In contrast, recurrence after a disease-free interval is potentially still curable. The complete remission rate after a second treatment is 40–50%: it is conventional to consolidate such remissions with high-dose therapy which will cure perhaps half (i.e. 25% 'cure' overall of the selected younger patients in whom curative therapy is attempted).

Burkitt's lymphoma

This is an uncommon lymphoma in the western world. It is endemic to Africa in the mosquito belt: there is a close association with the Epstein–Barr virus and it is a disease with a very high proliferative index which is very rapidly fatal without therapy.

The clinical presentation worldwide is usually that of lymphadenopathy, often with an abdominal mass and frequently with bone marrow infiltration (and 'leukaemia'). Central nervous system involvement is common, up to 30% having meningitis at the time of presentation. In Africa, by far the two commonest presentations are the abdominal mass or a large tumour involving the jaw (Fig. 9.14); the bone marrow and central nervous system are also frequently involved.

Treatment

Treatment, whilst undoubtedly toxic with both morbidity and mortality, is much less dangerous than the disease. It relieves symptoms and is potentially curative in a high proportion of cases.

Supportive care is with hydration and prevention of hyperuricaemia with allopurinol associated with rapid tumour lysis. Rasburicase is a major advance.

Fig. 9.14 **A child with Burkitt's lymphoma.**

Drug therapy

The management of the newly diagnosed case in Europe is straightforward but in Africa it may be very difficult.

Cyclical combination chemotherapy, incorporating at least high doses of cyclophosphamide and methotrexate as well as vincristine and doxorubicin, is followed by further cycles including high-dose cytarabine depending on the extent of disease at presentation. Up to six cycles must be given at about monthly intervals. While both the high-dose systemic methotrexate and cytarabine cross the blood–brain barrier in tumoricidal doses, many prefer to supplement them with intrathecal chemotherapy also. The role of cranial irradiation is unclear. In Africa, treatment can be difficult to coordinate but is based on the same principles.

This treatment will be tolerated quite well by the majority of patients, who tend to be young. The reported complete remission rate is very high, 70–90% depending on age (and excluding those with concurrent HIV infection), with very few recurrences occurring after 1 year. Hence 60–70% may be cured. Demonstrating improvements on this will be difficult but rituximab may have a role.

The management of progression despite treatment is difficult and rarely successful. Remission induction with alternative therapy, possibly including cisplatin, is the first line of attack. If achieved, it is consolidated with high-dose therapy or allogeneic transplantation.

T Cell lymphomas

These are much less common than the B cell counterparts. In the main, the overall treatment strategies are the same, but success is much more limited.

Primary extranodal lymphoma

The WHO classification does not distinguish between primarily nodal or extranodal at the time of presentation if the histological picture is the same.

Primary cerebral lymphoma

This is a very aggressive disease with survival untreated measured in months. It is particularly dangerous within the setting of HIV infection. Irradiation plus corticosteroids has, until recently, been the treatment of first choice. It is rarely curative, and may be associated with severe cerebral toxicity when given in high enough doses to eliminate lymphoma, particularly in the elderly. Even following irradiation, the median time to progression is less than a year. Subsequent management is palliative.

Recent data suggest that a very aggressive approach, involving sequential very high doses of methotrexate followed by cytarabine may obviate the need for irradiation and be curative in a proportion of cases. Followed by irradiation this treatment may eliminate lymphoma in an even higher proportion of cases, but the potential central nervous system toxicity is considered by most to be unacceptable.

Primary gastric lymphoma

In a high proportion of cases, particularly in Northern Italy, lymphoma is associated with *Helicobacter pylori* infection (p. 283). Biopsy of the gastric lesion usually shows lymphoma ('low-grade' B cell pathologically, of extranodal marginal zone type) and *H. pylori* is usually detected. Treatment to eradicate *H. pylori* is with antibiotics (and a proton pump inhibitor) for 2 weeks. Symptomatic relief is usually rapid. Provided there is no evidence of disease outside the stomach, further treatment is not given but surveillance endoscopy is performed, first at 3 months then 6-monthly. Partial or complete remission is the rule, but may take many months to achieve. Treatment of progression (always confirmed by biopsy) is with more antibiotics initially. Both irradiation and alkylating agent therapy are effective. Rituximab is being investigated. There is no role for surgery in the management of gastric lymphoma.

Primary cutaneous lymphoma (see p. 1352)

This is much commoner than generally perceived. It must be carefully distinguished from cutaneous infiltration with lymphocytes in a patient with nodal disease. It is usually of T cell origin (Sézary syndrome, mycosis fungoides). It is often multifocal and responds well to local therapy even when it appears histologically aggressive. Survival may be very long without chemotherapy, and in many cases treatment may only serve to disrupt the quality of life.

MYELOMA

Myeloma is a malignant disease of the plasma cells of bone marrow, accounting for 1% of all malignant disease. There is a clonal expansion of abnormal, proliferating plasma cells producing a monoclonal paraprotein, mainly IgG (55%) or IgA (20%) and rarely IgD. The paraproteinaemia may be associated with excretion of light chains in the urine (Bence Jones protein), which are either kappa or lambda. In approximately 20% there is no paraproteinaemia, only light chains in the urine.

Clinicopathological features

Myeloma is a disease of the elderly, the median age at presentation being over 60 years. It is rare under 40 years of age. The annual incidence is 4 per 100 000 and it is commoner in males and in black Africans but less common in Asians. There is:

- *Bone destruction*, often causing fractures of long bones or vertebral collapse (which can cause spinal cord compression) and hypercalcaemia
- *Bone marrow infiltration* with plasma cells, resulting in anaemia, neutropenia, thrombocytopenia, together with production of the paraprotein which may (rarely) result in symptoms of hyperviscosity
- *Renal impairment* (p. 637) owing to a combination of factors – deposition of light chains in the renal tubules, hypercalcaemia, hyperuricaemia, use of NSAIDs and (rarely) in patients who have had the disease for some time, deposition of amyloid.

In addition there is a reduction in the normal immunoglobulin levels (immune paresis), contributing to the tendency for patients with myeloma to have recurrent infections, particularly of the respiratory tract.

Cytogenetics

Abnormalities of chromosomes were found in only 50% of patients with old techniques. However, with fluorescent in situ hybridization and microarray techniques abnormalities are found in most. Abnormalities of chromosome 13 and hypodiploidy have been shown to be associated with poor survival, as have t(4;14), t(14;16) and p53 deletions.

Bone metastases

There is dysregulation of bone remodelling which leads to the typical lytic lesions, e.g. spine, skull. In myeloma there is increased osteoclastic activity with no increased osteoblast formation of bone. Bisphosphonates that inhibit osteoclast activity are useful in myeloma but surprisingly there is no increase in bone deposition (see below).

Adhesion of stromal cells to myeloma cells stimulates the production of RANKL, IL-6, and also VEGF (which plays a role in angiogenesis). RANKL also stimulates osteoclast formation and the lytic lesions (see Fig. 9.1). Myeloma cells also produce dickkopf-1 (DKK1) which *inhibits* osteoblast activity and therefore production of new bone. This occurs because DKK1 binds to the Wnt co-receptor, lipoprotein receptor-related protein 5 (LRP5), inhibiting Wnt signalling and osteoblast differentiation.

Symptoms

- Bone pain – most commonly backache owing to vertebral involvement (60%)
- Symptoms of anaemia
- Recurrent infections
- Symptoms of renal failure (20–30%)
- Symptoms of hypercalcaemia
- Rarely, symptoms of hyperviscosity and bleeding due to thrombocytopenia.

Patients can be asymptomatic, the diagnosis being suspected by 'routine' abnormal blood tests. Life-threatening complications are shown in Box 9.6.

***Box 9.6* Life-threatening complications of myeloma**

- Renal impairment – often a consequence of hypercalcaemia – requires urgent attention and patients may need to be considered for long-term peritoneal or haemodialysis.
- Hypercalcaemia should be treated by rehydration and use of bisphosphonates such as pamidronate.
- Spinal cord compression due to myeloma is treated with dexamethasone, followed by radiotherapy to the lesion delineated by a magnetic resonance imaging (MRI) scan.
- Hyperviscosity due to high circulating levels of paraprotein may be corrected by plasmapheresis.

Investigations

- **Full blood count**. Hb is normal or low. WCC is normal or low. The platelet count is normal or low.
- **ESR**. This is almost always high.
- **C-reactive protein** is always raised.
- **Blood film**. There may be rouleaux formation as a consequence of the paraprotein.
- **Urea and electrolytes**. There may be evidence of renal failure (see above)
- **Serum β_2-microglobulin** > 2.5 mg/L } useful in
- **Serum lactate dehydrogenase (LDH)** } prognosis.
- **Serum calcium** is normal or raised.
- **Serum alkaline phosphatase** is usually normal.
- **Total protein** is normal or raised.
- **Serum albumin** is normal or low.
- **Serum protein electrophoresis or immunofixation** characteristically shows a monoclonal band.
- **Uric acid** is normal or raised.
- **Skeletal survey**. This may show characteristic lytic lesions, most easily seen in the skull (Fig. 9.15). CT,

Fig. 9.15 **Myeloma affecting the skull**. Note the rounded lytic translucencies produced by infiltration of the skull with myeloma cells.

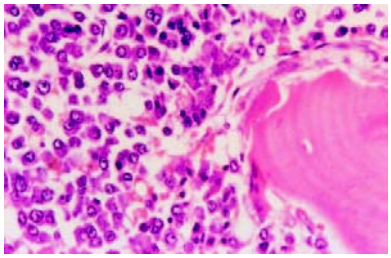

Fig. 9.16 **Multiple myeloma**. Histology shows replacement of the medullary cavity by abnormal plasma cells with some binucleate forms. A residual bony trabeculum is present towards the right. Courtesy of Dr AJ Norton.

MRI and PET are used in plasmacytomas (bone lesions without plasma cells in the blood).

- **DXA scanning** is valuable for follow-up of treatment.
- **24-hour urine immunofixation** is used for assessment of light-chain excretion.
- **Bone marrow aspirate** or trephine shows characteristic infiltration by plasma cells (Fig. 9.16). Amyloid may be found.

Diagnosis

Two out of three diagnostic features should be present:

- paraproteinaemia or Bence Jones protein
- radiological evidence of lytic bone lesions
- an increase in bone marrow plasma cells.

An international prognostic index which would help in staging the disease is being developed; the Durie–Salmon criteria are no longer used.

Monoclonal gammopathy of unknown significance (MGUS). MGUS describes an isolated finding of a monoclonal paraprotein in the serum, usually in the elderly; 20–30% go on to develop multiple myeloma.

Treatment

With good supportive care and chemotherapy with autologous or allogeneic stem cell transplantation, median survival is now 5 years with some patients surviving to 10 years. Young patients receiving more intensive therapy may live longer.

Supportive therapy

- Anaemia should be corrected; blood transfusion may be required. Erythropoietin often helps.
- Infection should be treated promptly with antibiotics. Give yearly flu vaccinations.
- Bone pain can be helped most quickly by radiotherapy. NSAIDs are also useful (beware of use in renal involvement).
- Pathological fractures may also be prevented by prompt orthopaedic surgery (kyphoplasty) with pinning of lytic bone lesions seen on the skeletal survey.

Specific therapy

Conventional treatment, incorporating first-class supportive care including long-term bisphosphonates, e.g. zoledronate or clodronate, which inhibit osteoclast activity, reduces progression of bone disease. Initial chemotherapy with melphalan and prednisolone has a response rate of approximately 50%. Complete remission is never attained and all patients will relapse without further treatment. High-dose melphalan therapy and peripheral blood stem cell rescue (autotransplantation) has undoubtedly improved the duration of remission and overall survival of younger patients, even if cure has not been attained. 'Reduced-intensity' allogeneic stem cell transplants are also used, with a reduction of mortality over normal-intensity allogeneic transplants, but still with graft-versus-myeloma effect.

'New' approaches are showing considerable promise and may lead to greater improvements:

- *Thalidomide.* This anti-angiogenesis agent has been shown, outside the context of pregnancy, to reduce the paraprotein in heavily pretreated patients with myeloma. Phase III trials in combination with chemotherapy are in progress and new analogues are becoming available.
- *Bortazemab*. This proteosome inhibitor has now been licensed in the USA on the basis of single agent data. As with thalidomide, Phase II trials with chemotherapy have been most encouraging and Phase III trials are underway.

COMMON SOLID TUMOUR TREATMENT

Common solid cancer mortality is listed in Table 9.1; the improvements over the past 10 years have come from advances in the prevention, diagnosis, and treatment. The presentation, diagnosis, and natural history of the common cancers are described in the relevant organ system chapters. In this section the systemic therapy of the common cancers is described, and in addition the treatment of germ cell tumours illustrates what can be achieved when chemotherapy resistance is overcome. The decision to treat and the aim of that treatment whether for palliation or cure, require knowledge of the disease, prognostic factors, the patient's performance status, and the potential efficacy of treatment. Management should be carried out by multidisciplinary teams, usually led by an oncologist.

Lung cancer (p. 947)

Prognostic factors

Presentation, diagnosis and surgery are discussed on p. 948.

Lung cancer histology is divided into two main types; small-cell (neuroendocrine) lung cancers (SCLC) and non-small-cell lung cancers (NSCLC). In addition, tumour stage and patient performance status are used in selecting treatment and predicting response and prognosis. While overall 5-year survival has remained approximately 15%, treatment is beginning to have an impact in selected groups and the multidisciplinary team can greatly aid in the appropriate application of treatment and the avoidance of nihilism.

Non-small-cell lung cancer

Prognostic factors

The staging is classified according to the TNM system (Table 9.5), by which the disease can be divided into local, locally advanced, and advanced stages with 5-year survival varying from 55–67%, to 23–40%, to 1–3% respectively. The addition of CT and PET scanning has increased the accuracy of staging and improved the selection of patients for surgery and adjuvant therapy.

Treatment

In *operable disease* stages T1N0 to T3N2 (stage I to IIIa) adjuvant radiotherapy and chemotherapy are still of uncertain benefit, although recently the international adjuvant lung cancer trial showed that cisplatin-based combination chemotherapy produced an improvement in 5-year survival of 4% from 40.4% to 44.5%. Uracil and tegafur given for 2 years after complete resection can improve survival in stage I adenocarcinoma.

For *unresectable disease,* the combination of concurrent cisplatin with radiotherapy when compared with radiotherapy alone has increased the resection rate and 3-year survival from 11% to 23% at the expense of greater oesophageal toxicity.

In *advanced disease* cisplatin or carboplatin in combination with one other drug such as paclitaxel or gemcitabine for 12 weeks produces a symptomatic improvement in 40%, and increases median survival from 6 to 10 months compared with best supportive care, with 10–20% alive at 1 year.

Small-cell lung cancer

Prognostic factors

The staging of small-cell lung cancer is divided into limited and extensive disease according to whether or not it is confined to a single anatomical area or radiation field.

Treatment

Limited disease is present in approximately 30% of patients and is best treated with concurrent chemo- and radiotherapy using a combination of cisplatin and etoposide or irinotecan, which increases the survival at 5 years from 15% to 25% compared with radiotherapy alone. A similar degree of improvement can also be achieved with hyperfractionated radiotherapy. Prophylactic whole-brain radiation to prevent cerebral metastases can reduce symptomatic CNS disease and improve overall survival by 5%.

Extensive disease can be palliated with the combination of carboplatin and etoposide or irinotecan, which when compared with best supportive care can increase median survival from 6 months to 9–13 months and 2-year survival to 20%.

Breast cancer

Breast cancer is the most common cancer in women who do not smoke. The screening programme in the UK, with mammography every 3 years in women aged 50–64 and improvements in multimodality treatment have improved overall survival and rates of cure, while breast-conserving surgery has greatly ameliorated the psychosexual impact of the disease.

Symptoms and signs

Most women present with a painless increasing mass which may also be associated with nipple discharge, skin tethering, ulceration and, in inflammatory cancers, oedema and erythema. In developing countries, 80% present with advanced disease.

Investigations

The triple assessment of any symptomatic breast mass by palpation, radiology (mammography, ultrasound and MRI scan) and fine-needle aspiration cytology is the most reliable way to differentiate breast cancer from the 15 times more common benign breast masses. Assessment should be carried out in a dedicated one-stop clinic able to provide the appropriate support and referral accordingly. Staging is both surgical with respect to tumour size and axillary lymph node status and, in advanced disease, by investigation of common sites of metastasis by chest X-ray, bone and liver scan. At present, only 20% of patients are diagnosed with no evidence of microscopic nodal metastases.

Prognostic factors

The size of the primary tumour, the histological subtype (most are infiltrating ductal carcinoma), histological grade/differentiation, oestrogen and progesterone receptor status, patient age and menopausal status are all significant independent predictors of risk of recurrence. Expression of c-*erbB2* is linked to the above and a predictor of treatment response.

Early breast cancer

The prognosis (10-year survival) can be predicted from the independent prognostic factors in Box 9.7. Survival

***Box 9.7* Poor prognostic factors for breast cancer**

- Young age
- Premenopausal
- Large tumour size
- High tumour grade
- Oestrogen and progesterone receptor negative
- Positive nodes

will vary from 90% for small (< 1 cm) low-grade node-negative tumours to 20% for large high-grade tumours with more than three axillary nodes involved and no adjuvant therapy.

Local treatment

Surgery with wide local excision and breast conservation, or mastectomy with or without reconstruction, is dictated by the location and extent of the breast mass, and patient preferences. Surgery of the axilla may require full dissection or sentinel lymph node guided sampling in order to gain local control and provide prognostic information to guide adjuvant treatment if there are clinically involved nodes. The greater the amount of axillary surgery the more the risk of post-operative lymphoedema. Radiotherapy is given to the conserved breast after wide local excision to reduce local recurrence, and after mastectomy if there are risk factors such as proximity to surgical margins or lymph node metastases, to complete the local control measures. Adjuvant radiotherapy reduces the risk of local recurrence by 25% and improves 10-year survival by 3%. Recent data suggest that women over 70 years with oestrogen receptor positive cancers up to 2 cm may be offered surgery and tamoxifen alone without radiotherapy, without compromising outcome.

Adjuvant systemic treatment

Tamoxifen (p. 497) adjuvant therapy immediately following surgery for oestrogen and/or progesterone receptor-positive disease has reduced the 10-year relative risk of women dying from breast cancer by about 25% and the absolute 10-year death rate by 12%. A meta-analysis of all randomized trials of adjuvant therapy in breast cancer has shown that for *premenopausal women* with axillary lymph node metastases or other high-risk features (Box 9.7), adjuvant chemotherapy with CMF (cyclophosphamide, 5-fluorouracil plus methotrexate) or more effective regimens with epirubicin, or ataxane (Epi-CMF or FEC) for 6 months, reduces the absolute 10-year death rate by about 10% and the relative risk of death by 20%. Ovarian ablation is equally effective as CMF chemotherapy. The effects of tamoxifen and chemotherapy are additive and most effective given serially, not concurrently.

For *postmenopausal women* with oestrogen and/or progesterone receptor-positive disease, adjuvant tamoxifen or aromatase inhibitors given for 5 years reduces the risk of death from breast cancer by a similar 25%. Aromatase inhibitors avoid the adverse effects of tamoxifen on the uterus and venous thromboembolism but add risks of osteoporosis. Menopausal status does not affect the relative efficacy of tamoxifen or chemotherapy; however, since the risk of recurrence is lower after the menopause, the absolute improvement in survival is less. Toxicity may also be higher in this age group so that treatment decisions may need to be more individualized in discussion between the patient and her doctors. The combined effect of radiotherapy, chemotherapy and tamoxifen or aromatase inhibitor halves the risk of dying of breast cancer for appropriately selected patients.

Advanced breast cancer

Patients with established metastatic disease may require endocrine therapy, chemotherapy or radiotherapy. The treatment is not curative but may be of great palliative benefit and consistent often with many years of good-quality life. Little additional benefit has been gained by adding endocrine and chemotherapy together, although the addition of anti-HER2 (antibodies) to chemotherapy has produced a modest survival advantage. In general, therefore, the serial use of intermittent courses of the different hormonal and chemotherapies seems most consistent with maintaining a good quality of life for as long as possible.

Endocrine therapy (p. 497)

Women who have high levels of oestrogen receptors and progesterone receptors in their tumour have a greater chance of responding to endocrine treatments. In addition, certain clinical features can predict the likelihood of responding to hormonal manipulations (Box 9.8).

Endocrine therapy is usually tried first in those patients who have characteristics suggesting they are likely to respond and who do not have immediately life-threatening disease. Remission lasts on average 2 years and is consistent with an excellent quality of life. When relapse occurs, further treatment with alternative agents may produce another remission. A range of hormonal manipulations is available (Table 9.21).

Chemotherapy (p. 492)

Chemotherapy is considered for patients who are unlikely to respond to hormonal treatment or who fail to respond to endocrine therapy or who require a rapid response if at risk of, for example, liver or respiratory failure. If chosen carefully, chemotherapy can provide

Box 9.8 Clinical features that increase the likelihood of response to endocrine treatment for metastatic disease

- Oestrogen or progesterone receptor positive (60% vs 10% response in oestrogen receptor (ER) negative disease)
- Long interval (more than 2 years) from initial surgery to time of relapse

Table 9.21 Endocrine therapy of metastatic breast cancer

For premenopausal patients

(a) Suppression of ovarian function by means of oophorectomy, radiation-induced ovarian ablation or a GnRH analogue, e.g. goserelin
(b) Oestrogen receptor antagonist, tamoxifen, fulvestrant
(c) Progesterone

For postmenopausal patients

(a) Oestrogen receptor antagonists, tamoxifen, fulvestrant
(b) Progesterone
(c) Aromatase inhibitors (e.g. anastrozole, letrozole and exemestane)

good-quality palliation and prolongation of life. The most common regimens used include:

- CMF (cyclophosphamide, methotrexate, 5-fluorouracil)
- MM (mitoxantrone (mitozantrone) and methotrexate)
- doxorubicin and cyclophosphamide
- paclitaxel or docetaxel used as single agents or in combination with an anthracycline or capecitabine
- vinorelbine
- capecitabine.

There is very little difference in efficacy between the different regimens for metastatic disease, with response rates varying from 40% to 60% for median duration of 8 months. More recently, the addition of trastuzumab (p. 498) monoclonal antibody to the cytotoxic drugs has significantly improved survival for those women whose tumour over-expresses the c-*erbB2/Her2* oncogene. The addition of capecitabine to docetaxel or trastuzumab, has also improved survival in metastatic breast cancer. The regimens do differ in toxicity with MM being one of the least toxic. The multiple regimens provide the possibility of avoiding drug resistance over several episodes of treatment interspersed with treatment-free periods so that the disease can be palliated, often for several years.

Gastrointestinal cancer

Presentation, diagnosis and local treatments are described in Chapter 6.

Oesophageal cancer

Histology, stage, age and performance status are critical to treatment decisions, which should be made by a multidisciplinary team in designated units. The prognosis for the majority of symptomatic patients is poor, 50% have distant metastases at the time of diagnosis and the majority of the remainder will have loco-regional spread into mediastinal structures.

Treatment

Neoadjuvant therapy for potentially resectable squamous carcinomas with cisplatin, 5-fluorouracil and concurrent radiotherapy achieves complete remission in 20–40% with 25–35% of patients alive 5-years after surgery. There is an increased perioperative mortality. Postoperative chemotherapy for adenocarcinomas has failed to improve overall survival.

Locally advanced or metastatic disease can be palliated with 5-fluorouracil chemotherapy in approximately 30%, increasing to 45–55% with the addition of oxaliplatin or irinotecan for a median duration of 6–8 months.

Gastric cancer

Presentation and diagnosis are described on page 288.

Prognostic factors

The histological grade and staging with respect to the presence of serosal involvement (T3) and nodal involvement (N1–2) are the main factors in prognosis. For the majority of patients with node-positive disease the 5-year survival is only 20% following surgery alone.

Treatment

A recent study of combined chemo-radiotherapy with cisplatin and 5-fluorouracil compared with surgery alone showed significantly increased median survival from 28 to 35 months and 3-year survival from 41% to 50%. This was achieved mainly through improvement in loco-regional control but is suitable only for good performance status patients.

Advanced disease may be palliated with chemotherapy such as epirubicin, cisplatin, and infusional 5-fluorouracil in 40–50% of patients for a median of 8–10 months but is suitable only for the younger fitter patient.

Colorectal cancer

Presentation and diagnosis are described on page 329.

The site of the disease, above or below the pelvic peritoneal reflection, and TNM stage are the main prognostic factors (see Table 6.17).

Treatment

Local therapy is discussed on page 330.

Adjuvant chemotherapy with 5-fluorouracil and folinic acid for rectal and colonic adenocarcinoma significantly increases 5-year survival for node-positive disease stage III (Dukes' C) by 5% from 40% to 45%. A further 6% improvement in a recent trial was achieved by the addition of oxaliplatin, and trials are examining the addition of monoclonal antibody to the EGF receptor (cetuximab) or VEGF (bevacizumab).

Advanced colorectal cancer is successfully palliated with little toxicity by 5-fluorouracil and folinic acid regimens in approximately 30% of patients for a median of 12–14 months. The addition of irinotecan or oxaliplatin increases the proportion who benefit to 55% but with increased toxicity. The monoclonal antibody bevacizumab (and possibly cetuximab) increases the response rate to chemotherapy and in one trial the median survival from 14 to 21 months.

Epithelial ovarian cancer

Epithelial ovarian cancer comprises 80% of all ovarian cancers, the remainder being of germ cell or stromal origin.

Symptoms and signs

Ovarian cancer typically causes few specific symptoms, sometimes there is a sensation of a pelvic mass, which may become (acutely) painful, often there is only vague abdominal distension and epigastric discomfort.

Investigation

Pelvic examination should be complemented by a transvaginal ultrasound and serum CA125. Magnetic resonance imaging is the definitive imaging technique for the pelvis.

Prognostic factors

Histological subtype, grade/differentiation stage, and extent of residual disease following surgery are all significant independent prognostic factors for survival.

Treatment

Surgery (with total abdominal hysterectomy, bilateral salpingo-oophorectomy and omentectomy) has a major role in the treatment of ovarian cancer. For patients in whom the disease is confined to the ovary, the surgery can be curative in 80–90% if the histology is well to moderately differentiated. For patients with poorly differentiated or more advanced disease, with spread throughout the peritoneal cavity, surgery still has a major role in staging the patient and improving survival when it is possible to debulk optimally to < 1 cm residual. Primary chemotherapy and delayed surgery is an alternative approach currently under investigation.

Drugs used to treat ovarian cancer are cisplatin and its analogue carboplatin, which is associated with fewer side-effects. Response is achieved in approximately two-thirds of patients. Paclitaxel has been shown to improve the survival of many patients when added to a platinum-based treatment.

Adjuvant treatment with carboplatin and paclitaxel for stage I high-risk disease increases the absolute 5-year survival by 9% from 70% to 79%. In advanced disease 75% of patients will respond to combination chemotherapy and the median survival is approximately 3 years. Up to 30% of those with metastatic disease may be alive after 5 years, although this falls to 5–10% if the cancer is not able to be debulked at operation or has spread outside the peritoneal cavity.

Prostate cancer

Early prostate cancer

Presentation and diagnosis are described on page 685.

Prognostic factors

The histological appearances are graded and accorded a Gleason Score which together with the height of the serum PSA plus accurate staging of the local extent of disease with pelvic MRI and transrectal ultrasound can identify prognostic groups. This allows the selection of patients with good prognosis who may reasonably choose to be kept under surveillance with no active treatment and, like 75% of men over the age of 80, die with, but not because of, their prostate cancer.

Treatment

Curative surgery (radical prostatectomy) and either external beam radiotherapy or brachytherapy can achieve equivalent survival rates but differ in the spectrum of unwanted side-effects with respect to incontinence and sexual dysfunction. In appropriately selected series of patients a 5-year survival of 85% can be achieved. Discussion between patient and clinician is vital before treatment is started.

Adjuvant androgen deprivation treatment such as monthly depot goserelin has not improved the survival from surgery but when given before and during radiotherapy can improve the overall survival at 3 years from 62% to 78%.

Advanced prostate cancer

Treatment

Metastatic prostate cancer with either local or skeletal spread is rapidly and effectively palliated in 70% of patients by androgen deprivation. The median duration of response is 2 years and, on the development of hormone resistance, mitoxantrone or docetaxel possibly with estramustine, chemotherapy can be guided by PSA response to provide some further months' palliation when compared with best supportive care. Radiotherapy provides a very effective palliation of painful skeletal metastases and can be delivered systemically by intravenous bone-seeking strontium-labelled bisphosphonate for patients with multiple affected sites.

Testicular and ovarian germ cell tumours

Germ cell tumours are the most common cancers in men aged 15–35 years but comprise only 1–2% of all cancers. They are much less common in women. There are two main histological types, seminoma (dysgerminoma in women) and teratoma. Teratomas may comprise varying proportions of mature and immature elements. Germ cell tumours may rarely occur in extragonadal sites in the midline from pituitary, mediastinum or retroperitoneum but should be treated in a similar manner.

Symptoms and signs

Most men present with a testicular mass which is often painful, some with symptoms of metastases to the paraaortic lymph nodes with back pain. In women the mass presents with vague pelvic symptoms but at a younger age than the more common epithelial ovarian cancers.

Investigations

Ultrasound scanning of the testicle or ovary is required, with assay of serum tumour markers, α-fetoprotein (AFP) and β-human chorionic gonadotrophin (β-HCG), and lactic dehydrogenase (LDH), followed by CT or MRI scan for distant metastases. Surgery for men is by the inguinal approach to avoid spillage of highly metastatic tumour in the scrotum. Surgery for diagnosis and staging should be conservative in women with preservation of fertility because of the efficacy of chemotherapy.

Treatment

Seminomas

Seminomas are the least common of these tumours and are very radiosensitive and chemosensitive. Seminomas are associated with a raised serum LDH but only rarely a mildly raised HCG and never a raised AFP. Stage I disease limited to the gonad is associated with a 30% risk

of recurrence with surgery alone. Adjuvant therapy with either chemo- or radiotherapy leads to greater than 95% cure in early-stage disease but chemotherapy with single-agent cisplatin or carboplatin does not have the long-term risks of secondary malignancy associated with radiotherapy. Combination chemotherapy (e.g. cisplatin, etoposide and bleomycin) will cure 90% of those with metastatic disease.

Teratomas

The risk of relapse with stage I disease varies from 5% to 40% depending upon the histological differentiation and extent of local invasion. Adjuvant chemotherapy for those at moderate to high risk (e.g. cisplatin, etoposide and bleomycin) leads to a 95% cure rate. Metastatic disease commonly involves para-aortic lymph nodes and lungs but may spread rapidly, especially if there are trophoblastic (HCG-producing) elements present. HCG can be associated with gynaecomastia and can be tested for in any young male with a urinary pregnancy test to enable rapid institution of potentially life-saving treatment. About 80% of teratomas will express either HCG or AFP and almost all metastatic disease will be associated with an elevation of the less-specific serum marker lactate dehydrogenase (LDH). Chemotherapy cure for metastatic teratoma varies from over 90% for those with small-volume to 40% for those with large-volume metastases and associated rises of AFP > 10 000 and β-HCG > 100 000 IU/L.

Although approximately 20% of men will be infertile due to azoospermia at the time of diagnosis, the majority of the remainder will retain their fertility after chemotherapy and be able to father normal children. Similarly, most women retain their fertility, although less is known about the association with infertility at presentation owing to the much lower frequency of germ cell tumours in women.

Cancer with unknown primary

Patients presenting with symptoms of their metastases without a clinically obvious primary after investigation represent a common clinical problem and comprise 5–10% of patients in a specialist oncological centre. As a result of several systematic studies, some with post-mortem follow-up, the following guidance should aid the choice of appropriate investigation and treatment.

Diagnosis

Diagnosis requires histology first and foremost, as it will lead to the identification of several distinct groups.

1. *Squamous cancers* – mostly presenting in the lymph nodes of the cervical region, 80% will be associated with an occult head and neck primary, the remainder arising from the lung. Inguinal nodes point usually to a primary of the genital tract or anal canal. Treatment with radiotherapy and chemotherapy may have curative potential.
2. *Poorly differentiated or anaplastic cancers* – this group will contain the majority of the curable cancers such as high-grade lymphomas and germ cell tumours identifiable by their immunocytochemistry and tumour markers. Treatment and prognosis is as outlined in the respective primary sites.
3. *Adenocarcinomas* form the majority, and their investigation should be guided by the desire to identify the most treatable options and the knowledge that the largest proportion will have arisen from the lung or pancreas, with relatively poor treatment prospects (Box 9.9). Investigations should therefore comprise a chest X-ray and abdominal CT scan with, in men, serum PSA and rectal ultrasound to identify prostate cancers, and in women, mammography to identify occult breast cancer, and pelvic CT or MRI to identify ovarian cancer. Tumour markers for other solid cancers, although highly sensitive, are too non-specific to be useful as diagnostic aids in this situation.

***Box 9.9* Adenocarcinoma with unknown primary: primary sites with major treatment benefits**

- Breast, e.g. isolated axillary lymphadenopathy
- Ovary, e.g. peritoneal carcinomatosis
- Prostate, e.g. pelvic lymphadenopathy

Further investigation may require MRI for breast and ovarian masses, PET for head and neck, lung and possibly other primaries, and radioisotope scans for thyroid and carcinoid tumours.

For good prognosis patients wishing to have palliative chemotherapy, investigations such as endoscopy to identify lung, colon or stomach primaries are indicated to guide the choice of chemotherapy agents.

Prognosis

The histological type and extent of the disease, and performance status of the patient are the key factors. Most large series report an overall median survival of 12 weeks but considerably better survival amongst the special subgroups below.

Patients presenting with isolated nodal metastases do have a significantly better prognosis than the majority with visceral and/or bone metastases and may warrant more extensive investigation.

Treatment

In women, an isolated axillary lymph node metastasis should be treated as for lymph-node-positive breast cancer. Malignant ascites in women should have a trial of chemotherapy as for epithelial ovarian cancer. The prognosis for those responding to the therapeutic trial is similar to the disease of known primary origin. For men, the occasional occult prostatic cancer found from a raised serum PSA offers some palliative treatment prospects. An increasing choice of chemotherapy agents for gastrointestinal cancers has potential to improve the palliation of patients with liver metastases. If after all efforts, no primary has been identified, palliative chemotherapy treatment can achieve responses in 20–40% in highly selected series, with

median survivals of 9–10 months and 5–10% surviving to 5 years.

PALLIATIVE MEDICINE AND SYMPTOM CONTROL

Palliative care may be defined as the active, total care of patients whose disease is no longer responsive to curative treatment. The goal of this care is to achieve the best possible quality of life for patients and their families by controlling physical symptoms as well as recognizing psychological, social and spiritual problems. Death is accepted as a normal process, which should neither be hastened nor postponed and the need to provide a support system for the family in bereavement is also recognized.

Many symptoms suffered in incurable illness have a complex aetiology in which the physical component may be overlaid by psychosocial issues. For such patients considerable input from a multidisciplinary team of specialist palliative care professionals may be needed to resolve the symptoms. There is good evidence that integration of palliative care and antitumour management early in the course of disease will reduce long-term distress and difficulty in symptom management. This view moves away from the traditional concentration on the provision of palliative care at the end of life.

The most appropriate first step in providing care in complex situations is often to deal with physical symptoms.

Pain

The symptom most feared by cancer patients is pain, although only two-thirds suffer significant pain throughout the course of their disease. Those patients who suffer pain may present with several pains of differing aetiology, with cancer being directly responsible for about 70%. Pain may be related to associated problems such as rapid weight loss or pressure sores, or may have a separate, non-malignant cause, such as arthritis. The principles of pain relief are careful assessment and diagnosis of the cause of pain, use of analgesics according to the analgesic ladder, and regular review of the effectiveness of the prescribed drugs (Fig. 9.17).

The analgesic ladder

The cancer pain relief programme of the World Health Organization groups drugs into three main classes:

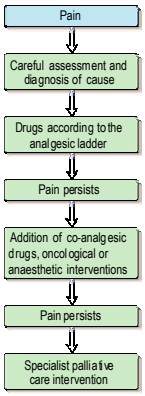

Fig. 9.17 **Management of cancer pain.**

1. non-opioid drugs, such as paracetamol or aspirin and other non-steroidal anti-inflammatory medications
2. weak opioid drugs, such as codeine, dextropropoxyphene and combinations of codeine with paracetamol
3. strong opioid drugs, such as morphine and diamorphine.

The analgesic ladder states that, if optimal use of a drug from the non-opioid class (e.g. 1000 mg of paracetamol 6-hourly) does not result in satisfactory pain relief, the prescription should be increased up one step to a weak opioid. If the equivalent of codeine 60 mg 4-hourly is not sufficient to control pain, the patient will require a strong opioid. Adjuvant, co-analgesic drugs may be added to each step of the ladder.

Strong opioid drugs

Morphine is the drug of choice and in most circumstances should be given regularly by mouth. The dose can be tailored to the individual patient's needs by the addition of 'as required' doses; morphine has no ceiling analgesic effect. A suitable starting dose of morphine is 10 mg 4-hourly, or 5 mg if the patient is elderly or frail. Patients with renal failure will have impaired excretion of morphine metabolites; they should receive a single dose of morphine and be carefully observed for the return of pain in order to determine the approximate rate of excretion of the metabolites.

If a 10 mg dose of morphine relieves the pain but the relief does not last for 4 hours, a 50% increase in the dose should be made (i.e. 10, 15, 20, 30, 45, 60, 90, 120, 180 mg) until satisfactory pain control is achieved.

When the patient's 24-hour morphine requirement has been established, the prescription may be converted to a

controlled-release preparation. There are both 12-hour and 24-hour release preparations available. The appropriate dose may be calculated by simple addition. For example:

20 mg morphine elixir 4-hourly
= 120 mg morphine per day
= 60 mg twice-daily of a 12-hour preparation
or 120 mg daily of a 24-hour preparation.

If the patient is unable to take oral medication because of nausea or vomiting, gastrointestinal obstruction or altering levels of consciousness, the opioid should be given rectally or parentally. For cancer patients who need long-term analgesia, continuous subcutaneous infusion is the preferred route. Diamorphine is used in this situation because of its greater solubility. By subcutaneous or intramuscular injection, diamorphine is approximately twice as potent as morphine orally. Hence the conversion from oral morphine may be calculated as follows:

30 mg oral morphine 4-hourly
= 180 mg morphine per day
= 90 mg diamorphine subcutaneously over 24 hours.

Side-effects. *Constipation* caused by analgesic drugs is almost universal. The prescription of a stimulant laxative such as dantron 1–3 capsules at night should be mandatory at the same time as morphine is started. No tolerance develops to this side-effect and laxative medication must be continued as long as analgesics are prescribed.

Nausea or vomiting may occur in 30–60% of patients first started on morphine. However, for those who have worked up the analgesic ladder and who have no other cause for vomiting, the prescription of an 'as required' centrally acting antiemetic is usually sufficient. Tolerance will develop to this side-effect, usually within 4–5 days.

Confusion, nightmares and hallucinations occur in a small percentage of patients. Tolerance to these side-effects does not develop and a change of opiate drug is usually required.

Pain not responsive to opioids

Not all cancer pains are relieved by opioids. In some situations the addition of co-analgesic drugs will result in improved pain control. An increasing number of different classes of drugs have been used in this setting. Some of the most common include the following.

Non-steroidal anti-inflammatory drugs used in addition to a weak or strong opioid for bone pain. Published studies have most frequently used naproxen (500 mg twice-daily) but there is no clear evidence of any one drug being superior in effect. It may be that idiosyncratic side-effects require a trial of a different NSAID.

Pains of nerve destruction called dysaesthetic or deafferentation pain are generally only marginally improved by strong opiates. Several classes of drug, including steroids, have been found to be helpful in reducing the symptoms. In cases of constant burning dysaesthesia, the tricyclic antidepressants are helpful. Amitriptyline 10 mg at night increasing incrementally to 75–100 mg is usually sufficient (compare with the doses required for mood elevation) and the response, if achieved, can be expected in about a week. Anticonvulsant drugs are useful in the management of lancinating, neuropathic pains. Carbamazepine starting at a dose of 100 mg twice-daily is most commonly used, but sodium valproate 300 mg twice-daily may cause fewer adverse side-effects. Gabapentin and pregabalin are of benefit in some forms of neuropathic pain.

In addition to drugs, many other techniques such as radiotherapy, anaesthetic and neurosurgical intervention are employed for the treatment of specific pains.

Regular review of the patient is necessary to achieve optimal pain control. Pain is a complex experience unique to each individual and its perception is modulated by the psychosocial and spiritual situation of the patient. If pain is proving difficult to control, it will be necessary to pay further attention to these other significant factors.

Gastrointestinal symptoms

Anorexia, malaise and weakness are among the most frequently troublesome symptoms in advanced cancer. Endogenously produced cytokines (e.g. tumour necrosis factor and interleukins) are mediators of the anorexia/cachexia syndrome. There is at present no specific therapy, but the approach to treatment depends on adequate management of associated symptoms. Care should be given to addressing the psychological distress caused by a change in body image, with attention to nutrition including dietary advice and the judicious use of steroids.

Nausea and vomiting occur in up to two-thirds of cancer patients in the last 6 weeks of life. The approach to treatment should be similar to that required for pain, involving careful assessment and diagnosis of the cause. It may, however, be more difficult to reach a diagnosis and a somewhat empirical approach to treatment is often adopted. In order to ensure adequate absorption of the antiemetic, parenteral administration, preferably by the subcutaneous route, may be helpful for the first 24–48 hours.

Antiemetics are classified according to their affinities for neurotransmitter receptor sites. A gastrokinetic dopamine antagonist such as metoclopramide 10 mg every 6–8 hours would be helpful in vomiting related to upper gastrointestinal tract stasis or to liver metastases. Metoclopramide should be avoided in cases of intestinal obstruction as it increases peristalsis in the upper bowel. Centrally acting antiemetics such as the phenothiazines, e.g. prochlorperazine 10 mg 8-hourly, cyclizine 50 mg 8-hourly, or the dopamine antagonist butyrophenone, haloperidol 1.5 mg 8-hourly are the drugs of choice in vomiting caused by drugs or metabolic disturbance. As with the prescription of analgesics, antiemetics will be most effective if prescribed on a regular rather than 'as-required' basis.

Bowel obstruction

Bowel obstruction may present acutely or in a more chronic manner and the cause is often multifactorial.

A small number of patients may benefit from surgical intervention, so consideration must be given to this modality of treatment in every case. Most patients will not be suitable for surgery and can be managed medically. The active medical management of malignant bowel obstruction includes:

- the relief of intestinal colic using an antispasmodic such as hyoscine butylbromide 60–80 mg daily; loperamide is sometimes helpful
- treating continuous pain with adequate analgesia such as diamorphine
- treating vomiting if nausea is a problem with a centrally acting antiemetic such as cyclizine 150 mg daily or haloperidol 5–10 mg daily.

It will be necessary to administer all of these medicines parenterally and the subcutaneous route is most appropriate.

Evidence suggests that the use of corticosteroids or the somatostatin analogue octreotide may shorten the length of episodes of obstruction. Octreotide also reduces the volume of fluids secreted into the bowel, thus reducing the volume of nasogastric aspirate or vomit.

Patients may be allowed to drink and eat low-residue diets which are mostly absorbed in the proximal gastrointestinal tract. It is usually possible, with adequate mouth care, to prevent a sensation of thirst, and routine parenteral fluids are not required. A few patients with intractable vomiting due to a high intestinal block may benefit from continuous nasogastric aspiration or gastrostomy drainage.

Respiratory symptoms

Respiratory symptoms, in particular breathlessness, cause great distress to patients and their carers. Management is based on an accurate diagnosis of the cause and active treatment of all potentially reversible situations. Infections should be treated, pleural and pericardial effusions drained and symptomatic anaemic patients transfused. Radiotherapy, cytotoxic agents and local laser therapy or stent insertions may relieve specific areas of bronchial tree obstruction. The place of oxygen in managing breathlessness is not clear, but it may be helpful in patients with correctable hypoxia.

The sensation of breathlessness and a cycle of respiratory panic may be partially relieved by the prescription of regular benzodiazepines. Regular doses of short-acting opioids 5–20 mg 4-hourly are also helpful, as they are postulated to have a local as well as a central effect. Nebulization of a morphine solution may reduce the sensation of breathlessness in a proportion of patients.

Persistent unproductive cough is a very troublesome symptom. Opiates, codeine, methadone or morphine elixir are helpful as antitussive agents. Antitumour therapy may be required to alleviate pressure on a large airway. Nebulized local anaesthetic may also be helpful in the prevention of cough.

Other physical symptoms

Patients with cancer may develop a large number of physical symptoms. These may be related directly to the presence of the tumour (e.g. vaginal blood loss from a cervix carcinoma) or to the treatment received (e.g. lymphoedema of the arm following breast surgery and radiotherapy). Management of these symptoms will be specific and may require the intervention of other specialists.

Patients may also develop symptoms as a reflection of their debility, such as pressure sores, urinary incontinence, jaundice or recurrent infections. These symptoms may be managed according to the overall expectations and requirements of the patient and their family. These situations of multiple symptomatology in frail patients put considerable demands on the expertise and creativity of clinicians as they present a great challenge for the maintenance of the best possible quality of life.

Psychological symptoms

Effective communication with all patients and their families is a fundamental tenet of clinical practice but is particularly necessary in the stressful situations which surround fatal disease. Basic communication skills include allowing time for the patient to talk, using language which is appropriate to the circumstances, being prepared to repeat information, and being aware that both the patient and the family may receive bad news by blocking or denying it. Remember that it is not always necessary to have an answer or a solution to every problem that is presented, but that considerable support may be given by sympathetic listening.

Care of cancer patients should be designed to allow them to spend as much time as possible in their own homes. Effective liaison between the cancer centre, the palliative care team and the primary healthcare team is essential to ensure total care. You must avoid misinterpretation of any information that may be given regarding treatment and prognosis.

Approximately 60% of cancer patients will die in general hospital wards under the care of the physician or surgeon who first diagnosed their tumour, although many are transferred to hospice care. Every clinician should develop some basic skills in symptom control and the ability to recognize those patients who require more specialist intervention. Caring for this group of patients demands detailed attention to alleviating physical symptoms and the establishment of a secure environment for the patient and family to obtain information and support.

The practice of specialist palliative medicine has traditionally been confined to patients with cancer, although most services cover HIV and AIDS and some of the rapidly fatal neurological diseases. These are all conditions in which the clinical situation is changing

rapidly and where difficult symptoms exist. There are undoubtedly patients with non-malignant disease such as end-stage renal or cardiac failure who benefit from a similar multidisciplinary approach to their care. Expansion of specialist palliative medicine into non-malignant situations is being actively pursued. The patient-orientated principles of palliative medicine can, however, be usefully applied throughout all medical practice.

Rheumatology and bone disease

RHEUMATOLOGICAL AND MUSCULOSKELETAL DISORDERS

Many common locomotor problems are short-lived and self-limiting or settle with a course of simple analgesia and/or physical treatment; for example, physiotherapy or osteopathy. Nonetheless, they represent 20-30% of the workload of the primary care physician. Recognition and appropriate early treatment of many painful rheumatic conditions may help reduce the incidence of chronic pain disorders. Early recognition and subsequent treatment of inflammatory arthritis by specialist multidisciplinary teams leads to better symptom control and prevents long-term joint damage and disability. A wide selection of pamphlets offer helpful advice for patients, and their use should be encouraged. Most of the musculoskeletal diseases are seen world-wide, although the prevalence of individual conditions varies.

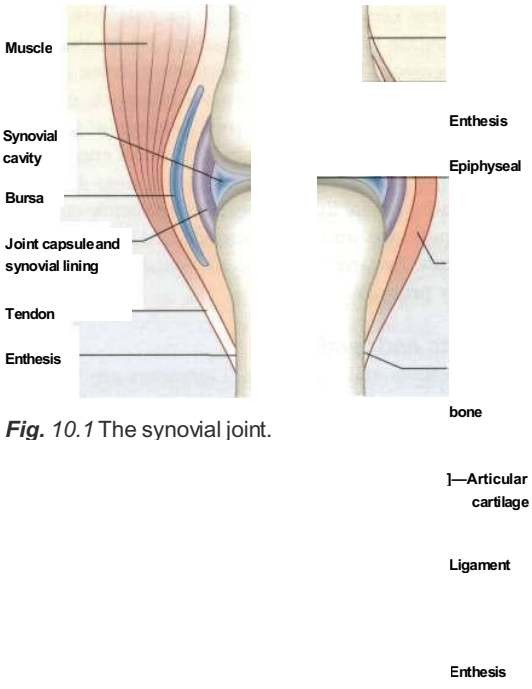

***Fig.** 10.1* The synovial joint.

THE NORMAL JOINT

There are two types of joints - synovial and fibrocartilaginous.

Synovial joints (Fig. 10.1)
These include the ball-and-socket joints (e.g. hip) and the hinge joints (e.g. interphalangeal).

They possess a cavity and permit the opposed cartilaginous articular surfaces to move painlessly over each other. Movement is restricted to a required range, and stability is maintained during use. The load is distributed across the surface, thus preventing damage by overloading or disuse.

Synovium and synovial fluid
Normal synovium is a few cells thick and vascular. Its surface is smooth and non-adherent and is permeable to proteins and crystalloids. As there are no macroscopic gaps, it is able to retain normal joint fluid even under pressure. The surface layer comprises macrophages and

fibroblast-like cells. The fibroblasts release hyaluronan into the joint space, which helps to retain fluid in the joint. Synovial fluid is a highly viscous fluid secreted by the synovial cells and has a similar consistency to plasma. Glycoproteins ensure a low coefficient of friction between the cartilaginous surfaces. Tendon sheaths and bursa are also lined by synovium.

Fibrocartilaginous joints

These include the intervertebral discs, the sacroiliac joints, the pubic symphysis and the costochondral joints.

Juxta-articular bone

The bone which abuts a joint (epiphyseal bone) differs structurally from the shaft (metaphysis). It is highly vascular and comprises a light framework of mineralized collagen enclosed in a thin coating of tougher, cortical bone. The ability of this structure to withstand pressure is low and it collapses and fractures when the normal intra-articular covering of hyaline cartilage is worn away - as, for example, in osteoarthritis (OA). Loss of surface cartilage also leads to the abnormalities of bone growth and remodelling typical of OA (see p. 551).

Hyaline cartilage

This forms the articular surface and is avascular. It relies on diffusion from synovial fluid for its nutrition. It is rich in type II collagen that forms a meshwork enclosing giant macromolecular aggregates of proteoglycan. These heterogeneous macromolecules comprise protein chains (aggrecans) to which are attached side-chains of the carbohydrates keratan and chondroitin sulphate. These molecules retain water in the structure by producing a dynamic tension between the retaining force of the collagen matrix and the expansive effect of osmotic pressure. Intermittent pressure from 'loading' of the joint is essential to normal cartilage function and encourages movement of water, minerals and nutrients between cartilage and synovial fluid. Chondrocytes secrete collagen and proteoglycans and are embedded in the cartilage. They migrate towards the joint surface along with the matrix they produce.

Ligaments and tendons

These structures stabilize joints. Ligaments are variably elastic and this contributes to the degree of stiffness or laxity of joints (see p. 587). Tendons are inelastic and transmit muscle power to bones. The joint capsule is formed by intermeshing tendons and ligaments. The point where a tendon or ligament joins a bone is called an *enthesis* and may be the site of inflammation.

Components of extracellular matrix

All connective tissues contain an extracellular matrix of macromolecules - collagens, elastins, non-collagenous glycoproteins and proteoglycans - in addition to cells, e.g. fibroblasts. There are several different types of cell surface receptors that bind extracellular matrix proteins including the integrins, CD44 and the proeoglycan-family of receptors e.g. syndecans.

Collagens

Collagens consist of three polypeptide chains (alpha chains) wound into a triple helix These alpha chains contain repeating sequences of *Gly—x—y* triplets, where *x* and *y* are often prolyl and hydroxyprolyl residues. Collagen fibres show considerable genetic heterogeneity, with genes on at least 12 chromosomes. The majority of collagen in the body is type I - the major component of bone, tendon, ligament, skin, sclera, cornea, blood vessels and the hollow organs. Types III, V and VI are also present in most tissues although little collagen type III is found in bone or cartilage. Other types of collagen are tissue specific, i.e. types II, IX, X and XI are found in hyaline cartilage, type IV in basement membrane and type VII in anchoring structures at junctions between epithelium and mesenchyme. There are several classes of collagen genes, based on their protein structures, and abnormalities of these may lead to specific diseases (see p. 602).

Elastin

Elastin is an insoluble protein polymer and is the main component of elastic fibres. Tropoelastin, its precursor, is synthesized by vascular smooth muscle cells and skin fibroblasts. Cross-linkages with desmosine and iso-desmosine are specific to elastin fibres.

Glycoproteins

Fibronectin is the major non-collagenous glycoprotein in the extracellular matrix. Its molecule contains a number of functional domains, or cell recognition sites that bind ligands and are involved in cellular adhesion. A peptide sequence *(Arg-Gly-Asp),* which mimics some of the functions of fibronectin, is also found in other adhesion proteins (e.g. vitronectin, laminin and collagen type VI). Fibronectin plays a major role in tissue remodelling. Its production is stimulated by interferon-gamma and by transforming growth factor-beta and inhibited by tumour necrosis factor and interleukin-1.

Proteoglycans

These proteins contain glycosaminoglycan (GAG) side-chains and are of variable form and size. Many have been identified at different sites in connective tissue, e.g. aggrecan, biglycan, fibromodulin, decorin (in extra-cellular matrix), syndecan, CD44, fibroglycan (on cell surfaces), cerebroglycan (in brain), serglycan (in intra-cellular tissues) and perglycan (in basement membranes). Their function is to bind extracellular matrix together, retain soluble molecules in the matrix and assist with cell binding. Abnormalities of any of these structures may lead to periarticular or articular symptoms and/or pre-dispose to the development of arthritis.

Joint sensation

The ligaments, periosteum, synovial tissue and capsule of the joint are richly supplied by blood vessels and nerves. Pain usually derives from inflammation of these sites because the synovial membrane is relatively insensitive.

CLINICAL APPROACH TO THE PATIENT

TAKING A MUSCULOSKELETAL HISTORY

The following questions are helpful in assessing the problem and making a diagnosis. A history, taken carefully, can often lead to a diagnosis. Pattern recognition is the key to accurate diagnosis in rheumatic diseases.

Pain

- *Where is it? Is it localized or generalized?* The pattern of joint involvement is a useful clue to the diagnosis (e.g. distal interphalangeal joints in osteoarthritis).
- 7s *it arising from joints, the spine, muscles or bone?* Soft tissue lesions and inflamed joints are locally tender.
- *Could it be referred from another site?* Joint pain is localized but may radiate distally - shoulder to upper arm; hip to thigh and knee.
- Is *it constant, intermittent or episodic? How severe is it - aching or agonizing?* For example, the pain of gout, or of septic arthritis in a previously fit, non-immunocompromised patient is agonizing. Joint pain lasting a day or so may indicate palindromic rheumatism, whilst longer bouts of a few days are typical of untreated gout or pseudogout. Constant pain, especially pain at night, may be due to an underlying malignancy.
- *Are there aggravating or precipitating factors ?* For example:
  - Mechanical problems are made worse by activity and eased by rest.
  - Inflammatory joint and spine pain are worse after rest and improve with activity.
  - Trauma is a common cause of musculoskeletal pain.
- *Are there any associated neurological features ?* Numbness, pins and needles and/or loss of power suggest 'nerve' pain. Consider carpal tunnel syndrome (see p. 539), a spinal problem such as disc prolapse (p. 542) or spondylosis (p. 541), or neurological disease. Nerve root pain, such as that due to a disc prolapse, reflects the anatomical distribution of the affected root.

Stiffness

- 7s *it generalized or localized?* Spine or joint stiffness is common after injury.
- *Does it affect the limb girdles or periphery?*
- *Is it worse in the morning and relieved by activity?* Joints that are stiff for more than 15 minutes each morning are usually inflamed - think of rheumatoid arthritis (RA) (see p. 555) or another cause of inflammatory arthritis. Spinal stiffness and pain which is much worse in the morning may indicate ankylosing spondylitis (p. 564), especially in patients in their twenties or thirties. Shoulder and pelvic girdle stiffness and pain, which are worse in the morning in a patient over 55 years, may be polymyalgia rheumatica (p. 582).

Swelling

- 7s *it of one joint, or of several?* Look for symmetry or asymmetry, and/or a peripheral or proximal pattern; these are important clues to the type of arthritis. Rheumatoid arthritis is typically polyarticular. An acute monarthritis may be due to trauma, gout (in a middle-aged male) or sepsis (fever or immunosuppression).
- 7s *it constant or episodic?*
- *Are episodes of swelling short-lived, or longer?*
- 7s *there associated inflammation (redness and warmth)?*

Gender

Gout (see p. 568), reactive arthritis (p. 566) and ankylosing spondylitis (p. 564) are more common in men. Rheumatoid arthritis and other autoimmune connective tissue diseases are more common in women.

Age

- 7s *the person young, middle-aged or older?* Injury is common in young people but can occur at any age.
- *How old was the patient when the problem first started?* Osteoarthritis (see p. 550) and polymyalgia rheumatica (p. 582) rarely affect the under-fifties. Rheumatoid arthritis starts most commonly in women aged 20-50 years.

General health

- 7s *there any associated ill-health or other worrying feature, such as weight loss or fever?* Systemic illness is a common feature of many rheumatic diseases. If there is weight loss and/or fever, think of autoimmune rheumatic disease, sepsis (joint infection may be due to septicaemia and is a medical emergency) or malignancy.
- *Are there other associated medical conditions that may be relevant?* Psoriasis (see p. 1331) or inflammatory bowel disease is associated with asymmetrical arthritis. Charcot's joints (p. 589) are seen in diabetics.

Medication

Could a drug be a cause? Diuretics may precipitate gout in men and older women. Hormone replacement therapy or the oral contraceptive pill may precipitate systemic lupus erythematosus (SLE) (p. 574). Steroids can cause avascular necrosis. Some drugs cause a lupus-like syndrome (p. 576).

Race

7s *this relevant?* Sickle cell disease causes joint pain in young black Africans, but osteoporosis (see p. 594) is uncommon in older black Africans.

Past history

Have there been any similar episodes or is this the first? Are there any clues from previous medical conditions? Gout is recurrent; the episodes settle without treatment in about 10 days. Acute episodes of palindromic rheumatism may predate the onset of rheumatoid arthritis (see p. 557).

Family history

Does anyone in the family have a similar problem or another related disorder? Osteoarthritis may be familial. Sero-

negative spondyloarthropathies (see p. 564) is seen in families with a history of arthritis, psoriasis, ankylosing spondylitis, iritis or inflammatory bowel disease. Autoimmunity has a familial tendency.

Occupational history

What job does the patient do? This can be a factor in soft tissue problems and osteoarthritis (e.g. in heavy labourers and dancers). Work-related problems are becoming more common and are complained of more.

Psychosocial history

- *Has there been an injury for which a legal case for compensation is pending?*

u *Has there been any recent major stress in family or working life? Could this be relevant?* Stress rarely causes rheumatic disease but may precipitate a flare-up of inflammatory arthritis. Stress also tends to reduce a person's ability to cope with pain or disability. Remember that the diagnosis of a chronic arthritis has a major influence on the lifestyle of patients and their families. **The** extent of disability should be noted.

Extent of disability

The World Health Organization describes the impact of disease on an individual in terms of:

- *Impairment:* any loss or abnormality of psychological or anatomical structure or function
- *Disability* (activity limitation): any restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being
- *Handicap* (participation restriction): a disadvantage for an individual resulting from an impairment or dis ability that limits or prevents the fulfilment of a role that is normal for that individual.

The patient's own perception of limitation must be taken into account during assessment, as well as the impact of physical causes due to disease. Subjective and objective assessments must be made. Quality of life (QoL) involves physical and psychosocial factors. The aim of treatment is to reduce or cure physical and/or psychological disease and to reduce the impact of any impairment or disability on the individual. A variety of different standard questionnaires can be used to assess pain, disease impact and outcome (e.g. Health Assessment Questionnaire (HAQ), Arthritis Impact Measurement Scale (AIMS)).

EXAMINATION OF THE JOINTS

Always observe a patient, looking for disabilities, as he or she walks into the room and sits down. General and neurological examinations are often necessary. Guidelines for rapid examinations of the limbs and spine are shown in Practical box 10.1.

Examining an individual joint involves three stages - looking, feeling and moving:

- *Appearance.* Look at it for swelling, rash or erythema, muscle wasting, deformity such as a distal bone displaced laterally as in knock knees (genu valgus) or bowed legs (genu varus), fixed flexion or hyperextension, loss of normal range and lack of fluidity of movement, and any pain caused by movement. *Feel* it for tenderness, warmth (indicates inflammation) and swelling which may be due to fluid, soft tissue or

Practical Box 10.1
Rapid examinations of the limb and spine

Rapid examination of the upper limbs

r *Raise arms sideways to the ears (abduction).* ***Reach behind neck and back.*** Difficulties with these movements indicate a shoulder or rotator cuff problem. *Hold the arms forward, with elbows straight and fingers apart, palm up and palm down.* Fixed flexion at the elbow indicates an elbow problem. Examine the hands for swelling, wasting and deformity. *Place the hands in the 'prayer' position with the elbows apart.* Flexion deformities of the fingers may be due to arthritis, flexor tenosynovitis or skin disease. Painful restriction of the wrist limits the person's ability to move the elbows out with the hands held together. *Make a tight fist.* Difficulty with this indicates a loss of flexion or grip. Grip strength can be measured.

Rapid examination of the lower limbs

Ask the patient to walk a short distance away from and towards you, and to stand still. Look for abnormal posture or stance.

t *Ask the patient to stand on each leg.* Severe hip disease causes the pelvis on the non-weight-bearing side to sag (positive Trendelenburg test). *Watch the patient stand and sit,* looking for hip and/or knee problems. *Ask the patient to straighten and flex each knee. Ask the patient to place each foot in turn on the opposite knee with the hip externally rotated.* This tests for painful restriction of hip or knee. Abnormal hips or knees must be examined lying. *Move each ankle up and down.* Examine the ankle joint and tendons, medial arch and toes whilst standing.

Rapid examination of **the spine**

Stand behind the patient.

- *Ask the patient to (a) bend forwards to touch the toes with straight knees, (b) extend backwards, (c) flex sideways, and (d) look over each shoulder, flexing and extending and side-flexing the neck.* Observe abnormal spinal curves - scoliosis (lateral curve), kyphosis (forward bending) or lordosis (backward bending). A cervical and lumbar lordosis and a thoracic kyphosis are normal. Muscle spasm is worse whilst standing and bending. Leg length inequality leads to a scoliosis which decreases on sitting or lying (the lengths are measured lying).

," *Ask the patient to lie supine.* Examine any restriction of straight-leg raising (see disc prolapse, p. 542). *Ask the patient to lie prone.* Examine for anterior thigh pain during a femoral stretch test (flexing knee whilst prone), which indicates a high lumbar disc problem. *Palpate* the spine and buttocks for tender areas.

bone. Common descriptors are 'fluctuant' (fluid), 'firm' or 'boggy' (swelling of the synovium), and 'hard' (bony).

- *Movement.* Move it to assess the passive range of movement (e.g. flexion, extension, abduction, adduction and rotation), any instability, or the production of pain and crepitus (grating) seen with cartilage damage. The normal range varies between individuals. Comparing right with left and asking the patient about any change in range help to assess whether the endpoints are normal or not. A screening examination of the locomotor system, known by the acronym GALS (global assessment of the locomotor system) has been devised.

X-ray of the joint often forms an integral part of the examination.

INVESTIGATIONS

Investigations are unnecessary in many of the common regional musculoskeletal problems and osteoarthritis (OA); the diagnosis is clear from the history and examination findings. Tests help to exclude another condition and to reassure the patient or their primary care physician.

Useful blood screening tests

- **Full blood count**
  Haemoglobin. Normochromic, normocytic anaemia occurs in chronic inflammatory and autoimmune diseases. Hypochromic, microcytic anaemia indicates iron deficiency, often due to non-steroidal anti-inflammatory drug (NSAID) induced gastrointestinal bleeding.
  White cell count. Neutrophilia is seen in bacterial infection (e.g. septic arthritis). It also occurs with corticosteroid treatment. Lymphopenia occurs with viral illnesses or active systemic lupus erythematosus (SLE). Neutropenia may reflect drug-induced bone marrow suppression. Eosinophilia is seen in the Churg-Strauss syndrome (p. 938). *Platelets.* Thrombocythaemia occurs with chronic inflammation. Thrombocytopenia is seen in drug-induced bone marrow suppression.
- **Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).** An increase reflects inflammation. Plasma viscosity is also raised in inflammatory disease and measured in some laboratories in place of the sedimentation rate.
- **Bone and liver biochemistry.** A raised serum alkaline phosphatase may indicate liver or bone disease. A rise in liver enzymes is seen with drug-induced toxicity. For other investigations of bone, see page 593.

Other blood and urine tests

- *Protein electrophoretic strip and urinary Bence Jones protein* - to exclude myeloma as a cause of a raised ESR.
- *Serum uric acid* — for gout.
- *Antistreptolysin-O titre* - in rheumatic fever.

Serum autoantibody studies

Rheumatoid factors (RFs)

IgM rheumatoid factors are detected by agglutination tests using IgG-coated latex particles (the Rose-Waaler test) or sensitized sheep red cells (sheep cell agglutination test or SCAT). They are antibodies (usually IgM, but occasionally IgG or IgA) against the Fc portion of IgG and are detected in 70% of patients with rheumatoid arthritis (RA), but are not diagnostic. A high titre in early RA indicates a poor prognosis. Positive titres occasionally predate the onset of RA. Titres may fluctuate. RFs are detected in many autoimmune rheumatic disorders (e.g. SLE), in chronic infections, and in asymptomatic older people (Table 10.1).

Citrullinated cyclic peptide (CCP) antibodies

These are measured by an ELISA technique and have a high specificity for RA (90% with a sensitivity of 60%). They are helpful in early disease to distinguish it from acute transient synovitis (see Box 10.7, p. 557).

Antinuclear antibodies (ANAs)

These are detected by indirect immunofluorescent staining of fresh-frozen sections of rat liver or kidney or Hep-2 cell lines. Different patterns reflect a variety of antigenic specificities that occur with different clinical pictures (for example, anti-DNA/histone (homogeneous) antibodies suggest active SLE; anticentromere antibodies suggest systemic sclerosis) and are detected in many autoimmune diseases. ANA is used as a screening test for SLE, but low titres occur in RA and chronic infections and in normal individuals, especially the elderly (Table 10.2). Hep-2 staining patterns are a guide to likely antigenic specificity, and some such as anticentromere are unequivocal. Antinucleolar staining patterns are associated with several hallmarks of systemic sclerosis reactivities (see below).

Table 10.1 **Conditions in which rheumatoid factor is found in the serum**

Autoimmune rheumatic diseases	RF **(IgM)** %
Rheumatoid arthritis	70
Systemic lupus erythematosus	25
Sjdgren's syndrome	90
Systemic sclerosis	30
Polymyositis/dermatomyositis	50
Juvenile idiopathic arthritis	Variable
Viral infections	**Hyperglobinaemias**
Hepatitis	Chronic liver disease
Infectious mononucleosis	Sarcoidosis
	Cryoglobulinaemia
Chronic infections	**Normal population**
Tuberculosis	Elderly
Leprosy	Relatives of patients with RA
Infective endocarditis	
Syphilis	

Table 10.2 Conditions in which serum antinuclear antibodies (%) are found

Systemic lupus erythematosus	95
Systemic sclerosis	70
Sjogren's syndrome	80
Polymyositis and dermatomyositis	40
Rheumatoid arthritis	30
Juvenile idiopathic arthritis	Variable
Other diseases	
Autoimmune hepatitis	100
Drug-induced lupus	>95
Myasthenia gravis	50
Fibrosing alveolitis	30
Diabetes mellitus	25
Infectious mononucleosis	5-10
Normal population	8

Anti-double-stranded-DNA (dsDNA) antibodies

These are usually detected by a precipitation test (Farr assay), by ELBA, or by an immunofluorescent test using *Crithidia luciliae* (which contains double-stranded DNA). They are diagnostic of active SLE but may be negative in mild or inactive disease. High titres of IgG anti-dsDNA indicate a poor prognosis and are specific to SLE. Anti-single-stranded DNA antibodies are non-specific.

Anti-extractable nuclear antigen (ENA) antibodies

These produce a speckled ANA fluorescent pattern and can be distinguished by ELISA:

- anti-Ro (SS-A) - SLE + Sjogren's syndrome
- anti-La (SS-B) - Sjogren's syndrome
- anti-Sm - SLE
- anti-Ul-RNP - a range of diseases, including SLE, overlap syndrome.

Anti Jo-1 antibodies

These antibodies to the enzyme histidyl tRNA synthase block its amino-acylation and are found in polymyositis and dermatomyositis.

Anti-topoisomerase 1 (ScL-70) antibodies

These are seen in systemic sclerosis.

Anti-neutrophil cytoplasmic antibodies (ANCAs) (see p. 634)

These are detected on fixed human neutrophils. Two major ANCA patterns are recognized:

- proteinase 3 (PR3-ANCA), formerly called cytoplasmic or cANCA
- myeloperoxidase (MPO-ANCA), formerly called perinuclear or pANCA.

PR3-ANCA is present in up to 90% of serum from patients with Wegener's granulomatosis. MPO-ANCA is found in up to 60% of other vasculitides, such as microscopic polyarteritis (polyangiitis) and Churg-Strauss syndrome. An MPO-ANCA is found in inflammatory bowel disease and rheumatic disease, which is not associated with vasculitis.

Antiphospholipid antibodies

These are detected in the antiphospholipid syndrome and SLE (p. 577).

The principal autoantigen is pVglycoprotein 1 (apolipoprotein H), which binds to cardiolipin and other anionic phospholipids. Anticardiolipin antibody and (3_2-glycoprotein are measured by ELISA. The lupus anticoagulants are antibodies against pVgty^{co}P^{ro}t^{em} 1 as well as prothrombin and annexin. They are detected by coagulation tests, such as prolongation of the activated partial thromboplastin time (APTT), as some of these antibodies interfere with phospholipid-dependent clotting systems in vitro.

Anti-RNA polymerase antibodies I, II and III

I and III are present in systemic sclerosis (see p. 579).

Immune complexes

Immune complexes are infrequently measured, largely because of variability between assays and difficulty in interpreting their meaning. Assays based on the polyethylene glycol precipitation method (PEG) or Clq binding are available commercially.

Complement

Low complement levels indicate consumption and suggest an active disease process in SLE.

Joint aspiration (Practical box io.2)

Examination of joint (or bursa) fluid is used mainly to diagnose septic, reactive or crystal arthritis. The nature of the fluid is an indicator of the level of inflammation. Clear

Practical Box 10.2
Joint aspiration

This is a sterile procedure which should be carried out in a clean environment

Explain the procedure to the patient; obtain consent

1. Decide on the site to insert the needle and mark it.
2. Clean the skin and your hands scrupulously; remove rings and wristwatch. Gloves are not obligatory, but many prefer to use them.
3. Draw up local anaesthetic (and corticosteroid if it is being used) and then use a new needle.
4. Warn the patient, insert the needle, injecting local anaesthetic as it advances and, if a joint effusion is suspected, attempt to aspirate as you advance it.
5. If fluid is obtained, change syringes and aspirate fully.
6. Examine the fluid in the syringe and decide whether or not to proceed with a corticosteroid injection.
7. Cover the injection site and advise the patient to rest the affected area for a few days. Warn the patient that the pain may increase initially but to report urgently if this persists beyond a few days, if the swelling worsens, or if they become febrile, since this might indicate an infected joint.

fluid indicates little inflammation in the joint, whereas translucent or opaque fluid indicates increasing cellularity and underlying inflammation. Purulent fluid is seen in septic arthritis, but crystal arthritis and reactive arthritis may also produce a highly cellular effusion. The procedure is often undertaken in combination with injection of a corticosteroid. Aspiration alone is therapeutic in crystal arthritis.

Diagnostic imaging and visualization

X-rays can be diagnostic in certain conditions (e.g. rheumatoid arthritis), but remember the following points:

(a) In acute low back pain, X-rays are indicated only if the pain is persistent, recurrent, associated with neurological symptoms or signs, or worse at night. They should also be performed if the pain is associated with such symptoms as fever or weight loss, which might indicate a more sinister underlying pathology.

(b) Radiological changes are common in older people and may not indicate symptomatic osteoarthritis or spondylosis.

(c) X-rays are of little diagnostic value in early inflammatory arthritis but are useful as a baseline from which to judge later change. **Ultrasound (US)** is particularly useful for periarticular structures, soft tissue swellings and tendons. It is increasingly used to examine the shoulder and other structures during movement. This visualizes shoulder impingement syndrome (see p. 538). US can be used to guide local injections. Quantitative ultrasound of the heel may prove a convenient and portable means of assessing bone density.

Magnetic resonance imaging (MRI) shows bone changes and intra-articular structures in striking detail. It is more sensitive than X-rays in the early detection of articular disease. It is the investigation of choice for most spinal disorders but is inappropriate in uncomplicated mechanical low back pain. Gadolinium injection enhances inflamed tissue. MRI can also detect muscle changes, e.g. myositis.

Computerized axial tomography (CT) is useful for detecting changes in calcified structures. **Bone scintigraphy** utilizes radionuclides, usually ^{99m}Tc, and detects abnormal bone turnover and blood circulation and, although non-specific, helps in detecting areas of inflammation, infection or malignancy. It is best used in combination with other anatomical imaging techniques.

DXA scanning uses very low doses of X-irradiation to measure bone density and is used in the screening and monitoring of osteoporosis.

Positron emission tomography (PET) scanning uses radionuclides which decay by emission of positrons. Fluorine-18 in deoxyglucose indicates areas of increased glucose metabolism, locates tumours, demonstrates large vessel vasculitis, e.g. Takayasu's arteritis (see p. 869). PET scans are combined with CT or MRI to improve anatomical details.

■ **Arthroscopy** is a direct means of visualizing a joint, particularly the knee or shoulder. Biopsies can be taken, surgery performed in certain conditions (e.g. repair or trimming of meniscal tears), and loose bodies removed.

Examination of synovial fluid

This is described in Box 10.1.

COMMON REGIONAL MUSCULOSKELETAL PROBLEMS (Rg.io.2)

Analgesic and anti-inflammatory drugs used for treatment of musculoskeletal problems are discussed on page 549.

Box 10.1 **Examination of synovial fluid**

The fluid can be examined directly in a clear syringe or sterile pot. The characteristics of synovial fluid show a trend from clear to purulent which indicates roughly the type of arthritis.

Colour	Diagnosis	WCC per mm^3
Clear, yellow and viscous	OA	<3000
Translucent and thin	RA	
Very cloudy	Seronegative arthritis Reiter's disease Crystal arthritis	■3000-40 000
Purulent	′ Sepsis	750 000

Polarized light microscopy with a red filter needs to be undertaken by an expert:

Gout - negatively birefringent, needle-shaped crystals of sodium urate

Pyrophosphate arthropathy (pseudogout) -rhomboidal, weakly positively birefringent crystals of calcium pyrophosphate.

Gram staining is essential if septic arthritis is suspected and may identify the organism immediately. Joint fluid should be cultured and antibiotic sensitivities requested.

RA, rheumatoid arthritis; OA, osteoarthritis

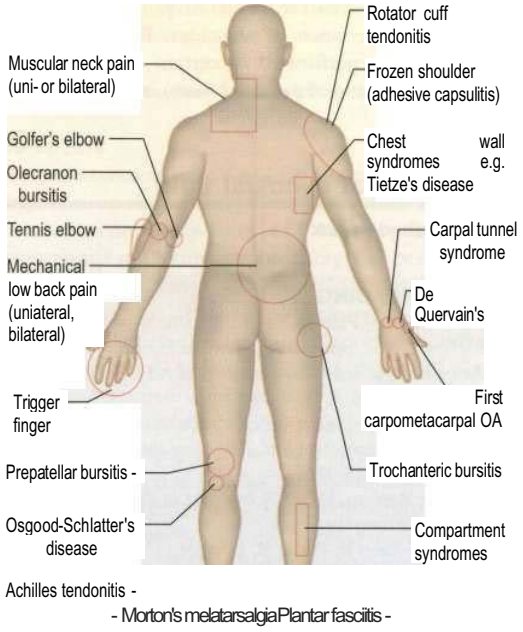

Fig. 10.2 **Common regional musculoskeletal problems.**

PAIN IN THE NECK AND SHOULDER

(Table 10.3)

Mechanical or muscular neck pain (shoulder girdle pain)

Unilateral or bilateral muscular-pattern neck pain is common and usually self-limiting. It can follow injury, falling asleep in an awkward position, or prolonged keyboard working. Chronic burning neck pain occurs because of muscle tension from anxiety and stress.

Spondylosis (see p. 1264) seen on X-ray increases after the age of 40 years, but it is not always causal. Spondylosis can, however, cause stiffness and increases the risk of mechanical or muscular neck pain. Muscle spasm can be palpable, is tender and may lead to abnormal neck posture (e.g. acute torticollis). Muscular-pattern neck pain is not localized but affects the trapezius muscle, the C7 spinous process and the paracervical musculature (shoulder girdle pain). Pain often radiates upwards to the occiput but rarely laterally to the tip of the shoulder. It is commonly associated with unilateral or bilateral tension headaches; pain radiating over the head to the temple and eye, described as like a pressure or tight band. These features are also seen in fibromyalgia (see p.547).

Table 10.3 **Pain in the neck and shoulder**

Trauma (for example, a fall)
Mechanical or muscular neck pain
Whiplash injury
Disc prolapse - nerve root entrapment (p. 1265)
Ankylosing spondylitis
Shoulder lesions:
Rotator cuff tendonitis Calcific tendonitis or bursitis Impingement syndrome or rotator cuff tear Adhesive capsulitis (true 'frozen' shoulder) Inflammatory arthritis or osteoarthritis
Polymyalgia rheumatica
Fibromyalgia
Chronic (work-related) upper limb pain syndrome
Tumour

Treatment

Patients are given short courses of analgesic therapy along with reassurance and explanation. Physiotherapists can help to relieve spasm and pain, teach exercises and relaxation techniques, and improve posture. An occupational therapist can advise about the ergonomics of the workplace if the problem is work-related (see p. 548).

Nerve root entrapment

This is caused by an acute cervical disc prolapse or pressure on the root from spondylotic osteophytes narrowing the root canal.

Acute cervical disc prolapse presents with unilateral pain in the neck, radiating to the interscapular and shoulder regions. This diffuse, aching dural pain is followed by sharp, electric shock-like pain down the arm, in a nerve root distribution, often with pins and needles, numbness, weakness and loss of reflexes (see Table 10.4).

Cervical spondylosis occurs in the older patient with posterior osteophytes compressing the nerve root and causing root pain (see Fig. 21.42, p. 1265), commonly at

Table 10.4 **Cervical nerve root entrapment - symptoms and signs**

Nerve root	Sensory changes	Reflex loss	Weakness
C5	Lateral arm	Biceps	Shoulder abduction Elbow flexion
C6	Lateral forearm Thumb and index finger	Biceps Supinator	Elbow flexion Wrist extension
C7	Middle finger	Triceps	Elbow extension
C8	Medial forearm Little and ring fingers	None	Finger flexion
T1	Medial upper arm	None	Finger ab- and addi

Fig. 10.3 **MRI of cervical spine,** showing a large central disc prolapse impinging on the spinal cord (arrow) at the C6/7 level.

C5/C6 or C6/C7; it is seen on oblique radiographs of the neck. An MRI scan shows facet joint OA and any associated disc prolapse clearly.

Treatment

A support collar, rest, analgesia and sedation are used as necessary. Patients should be advised not to carry heavy items. It usually recovers in 6-12 weeks. MRI is the investigation of choice if surgery is being considered or the diagnosis is uncertain (Fig. 10.3). A cervical root block administered under direct vision by an experienced pain specialist may relieve pain while the disc recovers. Neurosurgical referral is essential if the pain persists or if the neurological signs of weakness or numbness are severe or bilateral. Bilateral root pain is a neurosurgical emergency because a central disc prolapse may compress the cervical spinal cord.

Whiplash injury

Whiplash injury results from acceleration-deceleration forces applied to the neck, usually in a road traffic accident when the car of a person wearing a seat belt is struck from behind. Delayed recovery depends in part upon the severity of the initial injury. A simple decision plan based on clinical criteria helps to distinguish those most at risk and who warrant radiography. There is a low probability of serious bony injury if there is no midline cervical tenderness, no focal neurological deficit, normal alertness, no intoxication and no painful distracting injury. CT scans are reserved for those with bony injury. MRI scans occasionally show severe soft tissue injury. Whiplash injuries commonly lead to litigation.

Whiplash injury is a common cause of chronic neck pain, although most people recover within a few weeks or months. The pattern of chronic neck pain is often complex, involving pain in the neck, shoulder and arm. Headache, dizziness, and loss of memory and poor concentration sometimes accompany this. The subjective nature of these symptoms has led to controversy about their cause. The problem is more commonly seen in industrialized countries. It has often been suggested that the syndrome is caused in part by the prospect of financial compensation. This may not be wholly conscious and may be contributed to in part by the conflictive nature of the compensation process. There appears to be a direct relationship between poor prognosis and potential for compensation - elimination of compensation for pain and suffering due to this type of injury may lead to an improved prognosis.

Treatment is with reassurance (as the patient may be very anxious), analgesia, a short-term collar and physiotherapy. Pain may take a few weeks or months to settle and the patient should be warned of this.

PAIN IN THE SHOULDER

The shoulder is a shallow joint with a large range of movement. The humeral head is held in place by the rotator cuff (Fig. 10.4) which is part of the joint capsule. It comprises the tendons of infraspinatus and teres minor posteriorly, supraspinatus superiorly and teres major and subscapularis anteriorly. The rotator cuff (particularly

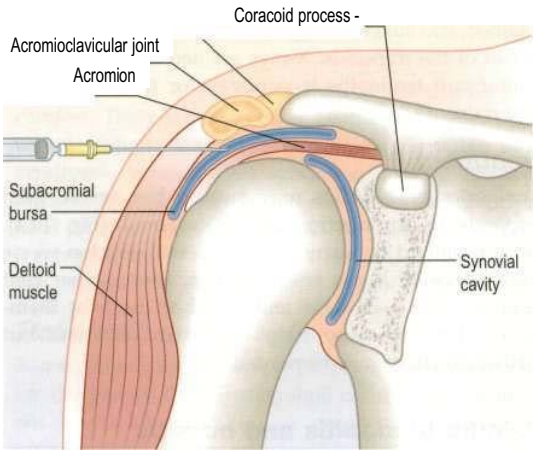

Fig. 10.4 **The shoulder region,** showing site of injection and subacromial space.

Rotator cuff

Box 10.2 **Differential diagnosis of 'shoulder' pain**

Rotator cuff tendonitis pain is worse at night and radiates to the upper arm.
Painful shoulders produce secondary muscular neck pain.
Muscular neck pain (also known as shoulder girdle pain) does not radiate to the upper arm.
Cervical nerve root pain is usually associated with pins and needles or neurological signs in the arm.

supraspinatus) prevents the humeral head blocking against the acromion during abduction; the deltoid pulls up and the supraspinatus pulls in to produce a turning moment. This permits the greater tuberosity to glide under the acromion without impingement.

Pain in the shoulder can sometimes be due to problems in the neck. The differential diagnosis of this is shown in Box 10.2. Although the term 'frozen shoulder' is commonly used for any painful stiff shoulder, true frozen shoulder (adhesive capsulitis) is uncommon - see below. A painful, stiff shoulder can result from rotator cuff lesions and is also seen following hemiplegia, chest or breast surgery or myocardial infarction. Painful shoulders may also be the initial presentation of RA, less commonly a seronegative spondyloarthropathy, and of polymyalgia rheumatica in the elderly.

Rotator cuff (supraspinatus) tendonitis

This is a common cause of painful restriction of the shoulder at all ages. It follows trauma in 30% of cases and is bilateral in under 5%. The pain radiates to the upper arm and is made worse by arm abduction and elevation, which are often limited. The pain is often worse during the middle of the range of abduction, reducing as the arm is raised fully and the painful part of the tendon rotates through to the proximal side of the acromion - a so-called painful arc syndrome. When examined from behind, the scapula rotates earlier during elevation. Passive elevation reduces impingement and is less painful. Severe pain virtually immobilizes the joint, although some rotation is retained (cf. adhesive capsulitis). There is also painful spasm of the trapezius. X-rays are necessary only when rotator cuff tendonitis is persistent or the diagnosis is uncertain.

Treatment

Analgesics or NSAIDs may suffice, but severe pain responds to an injection of corticosteroid (Fig. 10.4). Patients should be warned that 10% will develop worse pain for 24^18 hours after injection. Seventy per cent improve over 5-20 days and mobilize the joint themselves. Physiotherapy helps persistent stiffness but further injections may be needed.

Calcific tendonitis and bursitis

Calcium pyrophosphate deposits in the tendon are visible on X-ray, but they are not always symptomatic. The pathogenesis is unclear, although the part of the tendon affected is likely to be affected by relative ischaemia. The deposit is usually just proximal to the greater tuberosity. It may lead to acute or chronic recurrent shoulder pain and restriction of movement. A local corticosteroid injection may relieve the pain. The calcification may persist or resolve. Aspiration of the deposit under X-ray or ultrasound control may be required for persistent pain. Rarely, arthroscopic removal is necessary.

Shedding of crystals into the subacromial bursa causes severe pain and shoulder restriction. The shoulder feels hot and is swollen, and an X-ray will show a diffuse opacity in the bursa. The differential diagnosis of calcific bursitis is gout, pseudogout or septic arthritis.

Aspiration and injection with corticosteroid can help.

Torn rotator cuff

This is caused by trauma in the young but also occurs spontaneously in the elderly and in rheumatoid arthritis (RA). It prevents active abduction of the arm, but patients learn to initiate elevation using the unaffected arm. Once elevated, the arm can be held in place by the deltoid muscle. In younger people, the tear is repaired surgically but this is rarely possible in the elderly or in RA. Repeated trauma of the cuff between humerus and acromion/acromioclavicular joint causes osteophyte and cyst formation.

Shoulder impingement syndrome causes pain and crepitus on abduction and rotation. Some patients require arthroscopic surgery.

Adhesive capsulitis (true 'frozen' shoulder)

This is uncommon. Severe shoulder pain is associated with complete loss of all shoulder movements, including rotation. High doses of NSAIDs and intra-articular injections of corticosteroids are helpful. Once the pain settles, a manipulation under anaesthetic is advisable. When untreated, it recovers in 1-2 years.

Ultrasound examination can distinguish the above shoulder problems accurately and allows a guided corticosteroid injection.

PAIN IN THE ELBOW

Pain in the elbow can be due to epicondylitis, inflammatory arthritis or occasionally osteoarthritis.

Epicondylitis

Two common sites where the insertions of tendons into bone become inflamed *(enthesitis)* are the insertions of the

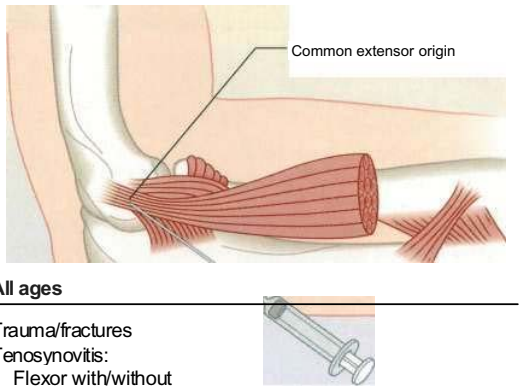

Fig. 10.5 **Injection for tennis elbow.**

wrist extensor tendon into the lateral epicondyle ('tennis elbow') and the wrist flexor tendon into the medial epicondyle ('golfer's elbow'). Both are usually unrelated to either sporting activity.

There is local tenderness. Pain radiates into the forearm on using the affected muscles - typically, holding a heavy bag in tennis elbow or carrying a tray in golfer's elbow. Pain at rest also occurs.

Treatment

Advise rest and arrange review by a physiotherapist. A local injection of corticosteroid at the point of maximum tenderness is helpful when the pain is severe (Fig. 10.5). Avoid the ulnar nerve when injecting golfer's elbow. Both conditions settle spontaneously eventually, but occasionally become disabling.

PAIN IN THE HAND AND WRIST (Table 10 5)

Hand pain is commonly caused by injury or repetitive work-related use. When associated with pins and needles or numbness it suggests a neurological cause arising at the wrist, elbow or neck. Pain and stiffness that are worse in the morning are due to tenosynovitis or inflammatory arthritis. The distribution of hand pain often indicates the diagnosis.

DIPs, PIPs, distal and proximal interphalangeal joints

Tenosynovitis

The finger flexor tendons run through a series of synovial sheaths and under loops which hold them in place. Inflammation occurs with repeated or unaccustomed use, or in inflammatory arthritis when the thickened sheaths are often palpable.

Flexor tenosynovitis causes finger pain when gripping and stiffness of the fingers in the morning. Occasionally a tendon causes a trigger finger, when the finger remains flexed after gripping and has to be pulled straight. A tendon nodule is palpable, usually in the distal palm.

Dorsal tenosynovitis is less common except in rheumatoid arthritis. The swelling is on the back of the hand and wrist.

De Quervain's tenosynovitis causes pain and swelling around the radial styloid where the abductor pollicis longus tendon is held in place by a retaining band. There is local tenderness, and the pain at the styloid is worsened by flexing the thumb into the palm.

Treatment

Therapeutic ultrasound helps some people. Usually corticosteroid is injected alongside the tendon under low pressure (not into the tendon itself). Occasionally surgery is needed.

Other conditions causing pain

Carpal tunnel syndrome

This is due to thickened tendons or synovitis in the carpal tunnel and the causes are discussed on page 1260. The history is usually typical and diagnostic with the patient waking with numbness, tingling and pain in a median nerve distribution. The pain radiates to the forearm. The fingers feel swollen but usually are not. Wasting of the abductor pollicis brevis develops with sensory loss in the palm and radial three and a half fingers. Tinel's sign may be positive, i.e. reproduction of the pain on tapping the nerve in the carpal tunnel.

Treatment is with a splint to hold the wrist in dorsiflexion overnight. This relieves the symptoms and is diagnostic; used nightly for several weeks it may produce full recovery. If it does not, a corticosteroid injection into the carpal tunnel helps in about 70% of cases, although it may recur. Persistent symptoms or nerve damage requires nerve conduction studies and surgical decompression of the carpal tunnel.

Inflammatory arthritis

This may present with pain, swelling and stiffness of the hands. In RA the wrists, proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints are affected symmetrically. In psoriatic arthritis and Reiter's disease a finger may be swollen (dactylitis) or the distal interphalangeal (DIP) joints are affected asymmetrically.

Nodal osteoarthritis

This affects the DIP and less commonly PIP joints, which are initially swollen and red. The inflammation and pain

settle but bony swellings remain. There is often a strong family history and it rarely presents before 50 years of age. Reassurance and local treatment are all that is needed.

First carpometacarpal osteoarthritis

This causes pain at the base of the thumb when gripping, or painless stiffness at the base of the thumb.

Scaphoid fractures

These cause pain in the anatomical snuffbox. They may not be seen immediately on X-ray. Untreated scaphoid fractures eventually cause pain because of failed union.

Ganglion

A ganglion is a jelly-filled, often painless swelling caused by a partial tear of the joint capsule. The wrist is a common site. Treatment is not essential as many resolve or cause little trouble. They rarely respond to injection, and surgical excision is possibly the best option.

Dupuytren's contracture

This is a painless, palpable fibrosis of the palmar aponeurosis, with fibroblasts invading the dermis. It causes puckering of the skin and gradual flexion of the affected fingers, usually the ring and little fingers. It is more common in males, Caucasians, in diabetes mellitus and in those who abuse alcohol. It is associated with Peyronie's disease of the penis - a painful inflammatory disorder of the corpora cavernosa, leading eventually to painless fibrosis and angulation of the penis during erection. Plastic surgical release of the contracture is restricted to those with severe deformity of the fingers.

PAIN IN THE LOWER BACK ^ _ ^

Low back pain is a common symptom, it is often traumatic and work-related, although lifting apparatus and other mechanical devices are used to avoid it. Episodes are generally short-lived and self-limiting, and patients attend a physiotherapist or osteopath more often than a doctor. Chronic back pain is the cause of 14% of long-term disability in the UK. The causes are listed in Table 10.6, and the management of back pain is summarized in Box 10.3.

Box 10.3 **Management of back pain**

Most back pain presenting to a primary care physician needs no investigation.
Pain between ages 20 and 55 years is likely to be mechanical and is managed with analgesia, brief rest and physiotherapy.
Patients should stay active within the limits of their pain.
Early treatment of the acute episode, advice and exercise programmes reduce long-term problems and prevent chronic pain syndromes.
Physical manipulation of uncomplicated back pain produces short-term relief and enjoys high patient satisfaction ratings.
Psychological and social factors may influence the time of presentation.
Appropriate early management reduces long-term disability.

Investigations

- **Spinal X-rays** are required only if the pain is associated with certain 'red flag' symptoms or signs, which indicate a high risk of more serious underlying problems:
  (a) starts before the age of 20 or after 50 years
  (b) is persistent and a serious cause is suspected
  (c) is worse at night or in the morning, when an inflammatory arthritis (e.g. ankylosing spondylitis), infection or a spinal tumour may be the cause
  (d) is associated with a systemic illness, fever or weight loss
  (e) is associated with neurological symptoms or signs.
- **MRI** is preferable to CT scanning when neurological signs and symptoms are present.
- **Bone scans** are useful in infective and malignant lesions but are also positive in degenerative lesions.
- **Full blood count, ESR and biochemical tests** are required only when the pain is likely to be due to malignancy, infection or a metabolic cause.

Mechanical low back pain

Mechanical low back pain starts suddenly, may be recurrent and is helped by rest. Mechanical back pain is often pre-

cipitated by an injury and may be unilateral or bilateral. It is usually short-lived.

Examination

The back is stiff and a scoliosis may be present when the patient is standing. Muscular spasm is visible and palpable and causes local pain and tenderness. It lessens when sitting or lying. Patients with spondylosis on X-ray probably have an increased risk of developing mechanical back pain but changes are often absent in the young and may be coincidental in the elderly. Pain relief and physiotherapy are helpful. The patient needs to be re-educated in lifting and shown exercises to prevent recurrent attacks of chronic pain. Once a patient has presented to a general practitioner with low back pain, although the episode itself is usually self-limiting, there is a significantly increased risk of further back pain episodes. Risk factors for recurrent back pain include female sex, increasing age, pre-existing chronic widespread pain (fibromyalgia) and such psychosocial factors as high levels of psychological distress, poor self-rated health and dissatisfaction with employment. Chronic low back pain is a major cause of disability and time off work and is reduced by appropriate early management.

Spinal movement occurs at the disc and the posterior facet joints, and stability is normally achieved by a complex mechanism of spinal ligaments and muscles. Any of these structures may be a source of pain. An exact anatomical diagnosis is difficult, but some typical syndromes are recognized (see below). They are often associated with radiological spondylosis (see p. 1265).

Postural back pain develops in individuals who sit in poorly designed, unsupportive chairs.

Fibrositic nodulosis

This causes unilateral or bilateral low back pain, radiating to the buttock and upper posterior thigh. There are tender nodules in the upper buttock and along the iliac crest. Such nodules are relevant only if they are tender and associated with pain. They are probably traumatic. Local, intralesional corticosteroid injections help.

Postural back pain and sway back of pregnancy

Low back pain is common in pregnancy and reflects altered spinal posture and increased ligamentous laxity. There is usually a hyperlordosis on examining the patient standing. Weight control and pre- and postnatal exercises are helpful, and the pain usually settles after delivery. Analgesics and NSAIDs are best avoided during pregnancy and breast-feeding. Epidurals during delivery are not associated with an increased incidence of subsequent back pain. Poor posture causes a similar syndrome in the non-pregnant, owing to obesity or muscular weakness. Poor sitting posture at work is a frequent cause of chronic low back pain.

Lumbar spondylosis

The fundamental lesion in spondylosis is in an intervertebral disc, a fibrous joint whose tough capsule inserts into the rim of the adjacent vertebrae. This capsule encloses a fibrous outer zone and a gel-like inner zone. The disc allows rotation and bending.

Changes in the discs may start in teenage years or early twenties and increase with age. The gel changes chemically, breaks up, shrinks and loses its compliance. The surrounding fibrous zones develop circumferential or radial fissures. In the majority this is initially asymptomatic but visible on MRI as decreased hydration. Later the discs become thinner and less compliant. These changes cause circumferential bulging of the intervertebral ligaments.

Reactive changes develop in adjacent vertebrae; the bone becomes sclerotic and osteophytes form around the rim of the vertebra (Fig. 10.6). The most common sites of lumbar spondylosis are L5/S1 and L4/L5. Disc prolapse through an adjacent vertebral endplate to produce a Schmorl's node on X-ray is painless but may accelerate disc degeneration.

Spondylosis may be symptomless, but it can cause:

- episodic mechanical spinal pain
- progressive spinal stiffening
- facet joint pain
- acute disc prolapse, with or without nerve root irritation
- spinal stenosis
- spondylolisthesis.

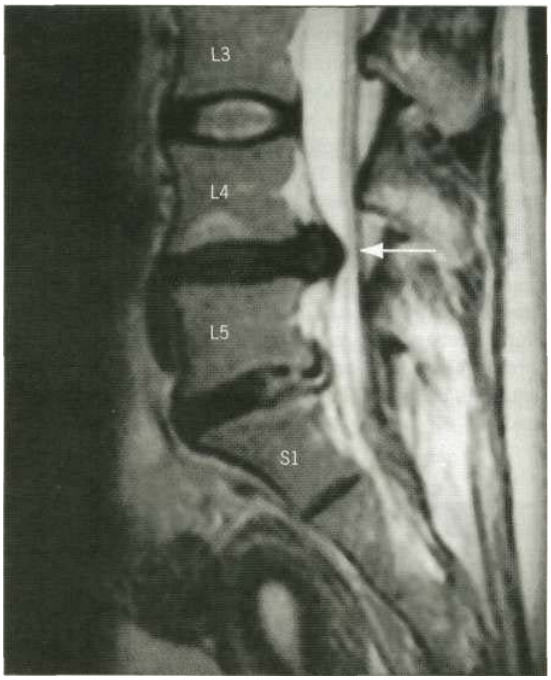

Fig. 10.6 **MRI of lumbar spine,** showing a central disc prolapse at the L4/L5 level (arrow). The signal from the L4/L5 and L5/S1 discs indicates dehydration, while the L3/L4 signal appearance is normal.

Facet joint syndrome

Lumbar spondylosis also causes secondary osteoarthritis of the facet joints. Pain is typically worse on bending backwards and when straightening from flexion. It is lumbar in site, unilateral or bilateral and radiates to the buttock. The facet joints are well seen on MR1 and may show osteoarthritis, an effusion or a ganglion. Diagnostic local anaesthetic injections into the joints (under X-ray vision) can be followed by a corticosteroid injection. The long-term value of this is unclear but many patients find the procedure helpful. Physiotherapy to reduce hyperlordosis and reducing weight are helpful.

Treatment of mechanical back pain

Adequate analgesia to allow normal mobility and avoid bed rest is best, combined with physical treatments. The evidence base for physiotherapy, back muscle training regimens and manipulation is not good. Manipulation produces more rapid pain relief in some patients. A positive approach probably reduces the development of chronic pain. A comfortable sleeping position should be adopted using a mattress of medium (not hard) firmness.

Acute lumbar disc prolapse

The central disc gel may extrude into a fissure in the surrounding fibrous zone and cause acute pain and muscle spasm, which in turn leads to a forwards and sideways tilt when standing. These events are often self-limiting. A disc prolapse occurs when the extrusion extends beyond the limits of the fibrous zone (Fig. 10.6). The weakest point is posterolateral, where the disc may impinge on emerging spinal nerve roots in the root canal. The episode starts dramatically during lifting, twisting or bending and produces a typical combination of low back pain and muscle spasm, and severe, lancinating pains, paraesthesia, numbness and neurological signs in one leg (rarely both). The back pain is diffuse, usually unilateral and radiates into the buttock. The muscle spasm leads to a scoliosis that reduces when lying down. The nerve root pain develops with, or soon after, the onset. The site of the pain and other symptoms is determined by the root affected (Table 10.7). A central high lumbar disc prolapse may cause spinal cord compression and long tract signs (i.e. upper motor neurone). Below L2/L3 it produces lower motor neurone lesions.

On examination, the back often shows a marked scoliosis and muscle spasm. The lying, straight-leg-raising test is positive in a lower lumbar disc prolapse - raising the straight leg beyond 30 degrees produces pain in the leg; slight limitation or pain in the back limiting the movement is not significant. Pain in the affected leg produced by a straight raise of the other leg suggests a large or central disc prolapse. Look for perianal sensory loss, which might indicate a cauda equina lesion - a neurosurgical emergency. An upper lumbar disc prolapse produces a positive femoral stretch test - pain in the anterior thigh when the knee is flexed in the prone position.

Treatment

Advise a short period (2-3 days) of bed rest - lying flat for a lower disc but semi-reclining for a high lumbar disc - and prescribe analgesia and muscle relaxants. Once the pain is tolerable, encourage the patient to mobilize and refer to a physiotherapist for exercises and preventative advice. An X-ray-guided epidural or nerve root canal injection by a pain specialist reduces pain, although the evidence that it speeds resolution or prevents surgery is unclear. Caudal epidural injections are less effective than lumbar ones. Resuscitation equipment must be available for these procedures. Referral to a surgeon for possible microdiscectomy or hemilaminectomy is necessary if the neurological signs are severe, if the pain persists and is severe for more than 6-10 weeks, or if the disc is central. If bladder or anal sphincter tone is affected it becomes a neurosurgical emergency.

Spinal and root canal stenosis

Progressive loss of disc height, OA of the facet joints, posterolateral osteophytes and hypertrophy of the ligamentum flavum all contribute to root canal stenosis. This causes nerve root pain or spinal root claudication - pain and paraesthesiae in a root distribution brought on by walking and relieved slowly by rest. The associated sensory symptoms, slow recovery when the patient rests and presence of normal foot pulses distinguish this from peripheral arterial claudication.

Spinal canal stenosis at more than one level is often associated with a congenitally narrow spinal canal. It causes buttock and bilateral leg pain, paraesthesiae and numbness when walking. Rest helps, as does bending forwards, a manoeuvre that opens the spinal canal. Specialist surgical advice is necessary.

Table 10.7 **Lumbar nerve root entrapment - symptoms and signs**

Nerve root	Sensory changes	Reflex loss	Weakness	Usual disc prolapse
L2	Front of thigh	None	Hip flexion/ adduction	L2/3
L3	Inner thigh and knee	Knee	Knee extension	
L4	Inner calf	Knee	Knee extension	L3/4
L5	Outer calf Upper, inner foot	None	Inversion of foot Dorsiflexion of toes	L4/5
S1	Posterior calf Lateral border of foot	Ankle	Plantar flexion of foot	L5/S1

Spondylolisthesis

This occurs in adolescents and young adults when bilateral congenital pars interarticularis defects cause instability and permit the vertebra to slip, with or without preceding injury. Rarely a cauda equina syndrome with loss of bladder and anal sphincter control and saddle-distribution anaesthesia develops (p. 1265). It is diagnosed radiologically. Low back pain in adolescents warrants investigation, and spondylolisthesis requires orthopaedic assessment. It needs careful monitoring during the growth spurt.

A degenerative spondylolisthesis may also develop in older people with lumbar spondylosis.

Diffuse idiopathic skeletal hyperostosis (DISH)

DISH (Forrestier's disease) affects the spine and extra-spinal locations. It causes bony overgrowths and ligamentous ossification and is characterized by flowing calcification over the anterolateral aspects of the vertebrae. The spine is stiff but not always painful, despite the dramatic X-ray changes. Ossification at muscle insertions around the pelvis produces radiological 'whiskering'. Similar changes occur at the patella and in the feet.

Treatment is with analgesics or NSAIDs for pain, and exercise to retain movement and muscle strength.

Osteoporotic crush fracture of the spine

Osteoporosis is asymptomatic but leads to an increased risk of fracture of peripheral bones, particularly neck of femur and wrist, and thoracic or lumbar vertebral crush fractures. Such vertebral fractures develop without trauma, after minimal trauma, or as part of a major accident. They may develop painlessly or cause agonizing localized pain that radiates around the ribs and abdomen. Multiple fractures lead to an increased thoracic kyphosis ('widow's stoop'). The diagnosis is confirmed by X-rays, showing loss of anterior vertebral body height and wedging, with sparing of the vertebral end-plates and pedicles (see Fig. 10.37, p. 595).

Treatment

Advise bed rest and analgesia until the severe pain subsides over a few weeks, then gradual mobilization. It may warrant hospitalization. There may be some residual pain. Bone density measurement and preventative treatment of osteoporosis are essential (see p. 596).

Ankylosing spondylitis (see also p. 564)

Buttock pain and low-back stiffness in a young adult suggests ankylosing spondylitis, especially if it is worse at night and in the morning.

Polymyalgia rheumatica	Lumbar spine, buttocks and thighs

AS, ankylosing spondylitis

PAIN IN THE HIP (Table 10.8)

'Hip' refers to a wide area between the upper buttock, trochanter and groin. It is useful to ask the patient to point to the site of pain and its field of radiation. Pain arising from the hip joint itself is felt in the groin, lower buttock and anterior thigh, and may radiate to the knee. Occasionally and inexplicably, hip arthritis causes pain only in the knee.

Osteoarthritis (OA) (see also p. 552) OA is the most common cause of hip joint pain in a person over the age of 50 years. It causes pain in the buttock and groin on standing and walking. Stiff hip movements cause difficulty in putting on a sock and may produce a limp.

Trochanteric bursitis and gluteus medius tendinopathy

This may be due to trauma or unaccustomed exercise, but sometimes has an unknown cause. It also occurs in inflammatory arthritis. The pain over the trochanter is worse going up stairs and when abducting the hip, and the trochanter is tender to lie on. A local corticosteroid injection onto the surface of the trochanter is helpful. A tear of the gluteus medius tendon at its insertion into the trochanter causes a syndrome that is similar but does not respond to injection. MRI scans have demonstrated this new syndrome. Its best management is unclear.

Meralgia paraesthetica (see also p. 1260) This causes numbness and burning dysaesthesia (increased sensitivity to light touch) over the anterolateral thigh and may be precipitated by a sudden increase in weight, an injury or during pelvic surgery. It is usually self-limiting but can be helped by amitriptyline 10 mg at night or gabapentin starting with 300 mg.

Fracture of the femoral neck

This usually occurs after a fall, occasionally spontaneously. There is pain in the groin and thigh, weight-

bearing is painful or impossible, and the leg is shortened and externally rotated. Occasionally a fracture is not displaced and remains undetected. X-rays are diagnostic. Anyone with a hip fracture, especially after minimal trauma, should be reviewed for osteoporosis (see p. 595).

Avascular necrosis (osteonecrosis) of the femoral head

This is uncommon but occurs at any age. There is severe hip pain. X-rays are diagnostic after a few weeks, when a well-demarcated area of increased bone density is visible. In the femur this lies at the upper pole of the femoral head. The affected bone may collapse. Early, the X-ray is normal but bone scintigraphy or MRI demonstrate the lesion. Risk factors include treatment with corticosteroids or heparin, exposure to high barometric pressures (divers and tunnellers), excessive alcohol consumption, and sickle cell disease.

Inflammatory arthritis of the hip

This produces pain in the groin and stiffness, which are worse in the morning. Rheumatoid arthritis (RA) rarely presents with hip pain, although the hip is involved eventually in severe RA. Ankylosing spondylitis and other seronegative spondyloarthropathies cause inflammatory hip arthritis in younger people.

Polymyalgia rheumatica (see also p. 582) Bilateral hip, buttock and thigh pain and stiffness that are worse in the morning in an elderly patient may be attributable to polymyalgia rheumatica.

PAIN IN THE KNEE (Table 10.9)

The knee depends on ligaments and quadriceps muscle strength for stability. It is frequently injured, particularly during sports. Trauma or overuse of the knee leads to a variety of peri- and intra-articular problems. Some are self-limiting, others require physiotherapy, local corticosteroid injections or surgery.

The knee is also a common site of inflammatory arthritis and osteoarthritis. Minor radiographic changes of osteoarthritis (see Fig. 10.9, p. 551) are common in the over-fifties and often coincidental, the cause of the pain being periarticular. Knee pain should not be attributed to osteoarthritis until other causes have been excluded. Symptomatic osteoarthritis of the knee correlates poorly with the severity of the radiological changes.

Table 10.9 **Pain in the knee**

- Trauma and overuse:
  - Periarticular problems:
    - Anterior knee pain or medial knee pain Internal derangements - meniscal tears or cruciate ligament tears
- Osteoarthritis
- Inflammatory arthritis:
  - Acute monarthritis:
    - Gout, pseudogout, Reiter's disease or septic arthritis
  - Pauciarticular (< 4 joints):
    - Seronegative spondyloarthropathy or atypical rheumatoid arthritis
  - Polyarticular: Rheumatoid arthritis
- Popliteal (Baker's) cyst/ruptured cyst
- Osteochondritis dissecans Hypermobility
- syndrome Referred from hip joint

Common periarticular knee lesions

Medialknee pain

There may be medial or lateral ligament strain, but the medial ligament is more commonly affected. There is pain at the ligament's insertion into the upper medial tibia, which is worsened by standing or stressing the affected ligament.

Anserine bursitis causes pain and localized tenderness 2-3 cm below the posteromedial joint line in the upper part of the tibia at the site of the bursa. It occurs in obese women, often with valgus deformities, and in breast-stroke swimmers.

Treatment is with physiotherapy and a local corticosteroid injection.

Anterior knee pain

Anterior knee pain is common in adolescence. In many cases no specific cause is found despite careful investigation. This is called 'anterior knee pain syndrome' and settles with time. Isometric quadriceps exercises and avoidance of high heels both help the condition. Patient and parents often need firm reassurance. Abnormal patellar tracking may be a cause and need surgical treatment.

Pre- and infrapatellar bursitis are caused by unaccustomed kneeling ('housemaid's knee'). There is local pain, tenderness and fluctuant swelling. Avoidance of kneeling and a local corticosteroid injection are helpful. Septic bursitis can occur.

Chondromalacia patellae is diagnosed arthroscopically. The retropatellar cartilage is fibrillated. In most cases the pain settles eventually. When there is patellar misalignment it may need surgery, as does recurrent patellar dislocation in adolescent girls.

Osgood-Schlatter's disease causes pain and swelling over the tibial tubercle. It is a traction apophysitis of the patellar tendon and occurs in enthusiastic teenage sports players.

Hypermobility of joints causes joint pain (see also p. 587).

Common intra-articular traumatic lesions of the knee

Torn meniscus

The menisci are partially attached fibrocartilages that stabilize the rounded femoral condyles on the flat tibial plateaux. In the young they are resilient but this decreases

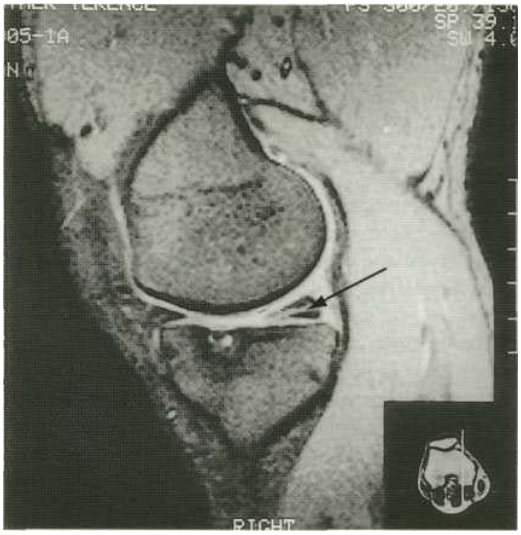

Fig. 10.7 MRI of a knee, showing a complete tear of the posterior horn of the medial meniscus, extending to its lower surface (arrow).

with age. They can be torn by a twisting injury, commonly in sports that involve twisting and bending. The history is usually diagnostic. There is immediate medial or lateral knee pain and dramatic swelling within a few hours. The affected side is tender. If the tear is large the knee may lock flexed. The immediate treatment is to apply ice. MRI demonstrates the tear (Fig. 10.7). In most circumstances, especially in active sportsmen, early arthroscopic repair or trimming of the torn meniscus is essential. Surgical intervention reduces recurrent pain, swelling and locking but not the risk of secondary osteoarthritis. The long-term benefit of repairing tears is not yet known. Post-surgical quadriceps exercises aid a return to sport.

Torn cruciate ligaments

Torn cruciate ligaments account for around 70% of knee haemarthroses in young people. They often coexist with a meniscal tear. Partial cruciate tears are difficult to diagnose clinically. On flexing the knee to 90 degrees, a torn anterior cruciate allows the tibia to be pulled forwards on the femur. MRI is the investigation of choice. Such injuries need urgent orthopaedic referral. There is a significant incidence of secondary OA.

Osteochondritis dissecans

This occasionally causes knee pain and swelling in adolescents and young adults, more commonly males. It is probably traumatic, possibly with hereditary predisposing factors. A fragment of bone and its attached cartilage detach by shearing, most commonly from the lateral aspect of the medial femoral condyle.

There is aching pain after activity and, if the fragment becomes loose, locking or 'giving way' occurs. The lesion is seen on a tunnel-view X-ray, but MRI is more sensitive, especially if the fragment is undisplaced. Undisplaced lesions are treated with rest, then isometric quadriceps exercises. Loose fragments can be fixed arthroscopically or removed. A similar lesion affecting the lateral femoral condyle occurs in older people.

Knee joint effusions

An effusion of the knee causes swelling, stiffness and pain. The pain is more severe with an acute onset and with increasing inflammation, because of stretching of the capsule that contains the pain receptors. A full clinical history and examination must include a past medical, family and drug history.

Inflammatory arthritis affects the knees and causes warmth and swelling. An acute inflammatory monarthritis of the knee is a common presentation of a seronegative spondyloarthropathy and occasionally is the first sign ofRA.

Monarthritis of the knee, associated with severe pain and marked redness, may be due to septic arthritis, or gout in the middle-aged male, or to gout or pseudogout in an older male or female. A cool, clear, viscous effusion is seen in elderly patients with moderate or severe symptomatic OA.

Examination

A large and tense effusion is easily seen and felt on each side of the patella and in the suprapatellar pouch, and is fluctuant. The effusion delays the patella tapping against the femur when it is pressed firmly and quickly (the 'patellar tap' sign). Small effusions also demonstrate the 'bulge' sign when the patient is lying with the quadriceps relaxed. For this, apply a gentle sweeping pressure, first to the medial side of the joint and then, watching the medial dimple, to the lateral side. Slightly delayed bulging of the medial dimple indicates fluid in the joint.

Investigations

These are (a) blood biochemistry, and (b) aspiration and examination of the knee effusion. The basic technique of aspiration is described in Practical box 10.2 on page 534. If there is a flexion deformity, externally rotate the leg or support the knee. Stand on the side opposite the joint and insert the needle between the patella, just proximal to its mid point, and the medial femoral condyle. Angle the needle slightly backwards and inject small volumes of local anaesthetic, advancing until aspiration detects fluid. Then change the syringe for a larger one and aspirate as much fluid as possible. Examine the fluid (see Box 10.1, p. 535) and decide whether to inject corticosteroid or arrange microbiological tests.

Haemarthrosis of the knee

This is caused by:

- trauma - meniscal, cruciate or synovial lining tear
- clotting or bleeding disorders, such as haemophilia, sickle cell disease or von Willebrand's disease.

Popliteal cyst (Baker's cyst)

In approximately 5% of patients with a knee effusion, a swollen, painful popliteal cyst develops. This is usually

due to a bursa (usually the semimembranosus bursa), which in some individuals has a valve-like connection to the knee. This allows the effusion to flow into the bursa but not back. Occasionally there is a synovial herniation through the posterior joint capsule. The cyst is best seen and felt in the popliteal fossa with the patient standing.

Ruptured popliteal cyst

A popliteal cyst may rupture if the patient is mobile, particularly on standing up quickly or climbing stairs. Fluid escapes into the soft tissue of the popliteal fossa and upper calf, causing sudden and severe pain, swelling and tenderness of the upper calf. Dependent oedema of the ankle develops and the knee effusion reduces dramatically in size and may be undetectable.

A history of previous knee problems and the sudden onset of pain and tenderness high in the calf suggest a ruptured cyst rather than a deep vein thrombosis (DVT). However, the diagnosis is often missed and treated inappropriately with anticoagulants. A diagnostic ultrasound examination distinguishes a ruptured cyst from a DVT (see p. 870). Analgesics or NSAIDs, rest with the leg elevated, and aspiration and injection with corticosteroids into the knee joint are required.

PAIN IN THE FOOT AND HEEL (Table 10.10)

The feet are subjected to extreme pressures by weight-bearing and inappropriate shoes. They are commonly painful. Broad, deep, thick-soled shoes are essential for sporting activities, prolonged walking or standing, and in people with congenitally flat or arthritic feet. There are two common types of foot deformity:

- flat feet stress the ankle and throw the hindfoot into a valgus (everted) position - a flat foot is rigid and inflexible
- high-arched feet place pressure on the lateral border and ball of the foot.

The foot is affected by a variety of inflammatory arthritic conditions. After the hand, the foot joints are the most commonly affected by rheumatoid arthritis. The diagnosis depends upon careful assessment of the distribution of the joints affected, the pattern of other joint problems, or by finding the associated condition (e.g. psoriasis, see p. 1331).

Table 10.10 Pain in the foot and heel - causes

Structural (flat (pronated) or high arched (supinated))	
Hallux valgus/rigidus (+ OA)	
Metatarsalgia	
Morton's neuroma	
Stress fracture	
Inflammatory arthritis	
Acute, monarticular - gout	
Chronic, polyarticular - RA	
Chronic, pauciarticular - seronegative spondyloarthropathy	
Tarsal tunnel syndrome	
Heel pain	
Plantar fasciitis	Below heel
Plantar spur	Below heel
Achilles tendonitis/bursitis	Behind heel
Sever's disease	Behind heel
Arthritis of ankle/subtaloid joints	

Hallux valgus

The great toe migrates laterally. In the congenital form the first metatarsal is displaced medially (metatarsus primus varus). The shape of modern shoes causes later onset of hallux valgus. It is a common complication of RA.

Hallux rigidus

Osteoarthritis of the first MTP joint in a normally aligned or valgus joint causes hallux rigidus - a stiff, dorsiflexed and painful great toe. Careful choice of footwear and the help of a podiatrist suffice for most cases, but some require surgery.

Metatarsalgia

This is common, especially in women who wear high heels, after trauma and in those with hammer toes. The ball of the foot is painful to walk and stand on. Callosities and pressure-induced bursae develop under the metatarsal heads. Rheumatoid arthritis causes misalignment of the metatarsal bones and severe metatarsalgia.

Treatment is with podiatry and the wearing of appropriate shoes. Surgery is occasionally needed, particularly in the rheumatoid forefoot.

Morton's metatarsalgia is due to a neuroma, usually between the third and fourth toes. It causes pain, burning and numbness in the adjacent surfaces of the affected toes when walking. It is helped by wearing wider, cushioned-soled shoes. Occasionally a steroid injection is necessary.

Stress (march) fractures

These cause sudden, severe weight-bearing pain in the distal shaft of the fractured metatarsal bone. They occur after unaccustomed walking or with new shoes. There is local tenderness and swelling, but initially X-rays are normal and diagnosis delayed. A radioisotope bone scan reveals the fracture earlier than X-rays. Reduced weight-bearing for a few weeks usually suffices.

Tarsal tunnel syndrome

This is an entrapment neuropathy of the posterior tibial nerve as it rounds the medial maleolus. It produces burning, tingling and numbness of the toes, sole and medial arch. The nerve is tender below the maleolus and, when tapped, produces a shock-like pain (Tinel's sign). A local steroid injection under the retinaculum, between the medial maleolus and calcaneum, is helpful.

Pain under the heel

Plantar fasciitis is an enthesitis at the insertion of the tendon into the calcaneum. It produces localized pain when standing and walking, and tenderness in the midline. It occurs alone or in seronegative spondyloarthropathy.

Plantar spurs are traction lesions at the insertion of the plantar fascia in older people and are usually asymptomatic. They become painful after trauma.

Calcaneal bursitis is a pressure-induced (adventitious) bursa that produces diffuse pain and tenderness under the heel. Compression of the heel pad from the sides is painful, which distinguishes it from plantar fascia pain.

Whatever the cause, the pain is always worse in the morning as soon as weight is placed on the foot.

All of these lesions are treated with heel pads, and reduced walking; they are often self-limiting. A splint at night to hold the foot dorsiflexed and to stretch the plantar fascia is preferable to a local corticosteroid injection in plantar fasciitis. When an injection is necessary, a medial approach is used, rather than through the heel pad, under a posterior tibial nerve block.

Pain behind the heel and leg

Sever s *disease* is a traction apophysitis of the Achilles tendon in young people (cf. Osgood-Schlatter's disease p.588).

Achilles tendonitis is an *enthesitis* at the insertion of the tendon into the calcaneum. This is traumatic or it can complicate seronegative spondyloarthropathy. Raising the shoe heel reduces pain. Occasionally a low-pressure corticosteroid injection near the enthesis is necessary.

Achilles tendonosis causes a painful, tender swelling a few centimetres above the tendon's insertion. Advise against walking barefoot and jumping. Therapeutic ultrasound is helpful. (Caution - a local injection may cause the tendon to rupture.)

Achilles' bursitis lies clearly anterior to the tendon and can be safely injected with corticosteroid.

Compartment syndromes

The muscles of the lower leg are enclosed in fascial compartments, with little room for expansion to occur. Compartment syndromes can be acute and severe, such as following exercise.

In the *anterior tibial syndrome* there is severe pain in the front of the shin, occasionally with foot drop. Immediate surgical decompression to prevent muscle necrosis is sometimes required.

Chronic compartment syndrome produces pain in the lower leg that is aggravated by exercise and may therefore be mistaken for a vascular or neurological disorder.

PAIN IN THE CHEST

Musculoskeletal conditions are sometimes a cause of chest pain. An example is Tietze's disease. In this condition, pain arises from the costosternal junctions. It is usually unilateral and affects one, two or three ribs. There is local tenderness, which helps to make the diagnosis. The condition is benign and self-limiting. It often responds well to anti-inflammatory drugs. Other causes of chest wall pain include rib fractures due to trauma or osteoporosis or a malignant deposit. Costochondral pain occurs in ankylosing spondylitis (see p. 565).

CHRONIC PAIN SYNDROMES

(see also p. 1282)

Chronic pain syndromes are difficult to manage. Psychological factors are at least as important as inflammation or damage in determining a patient's perception of pain. It is essential to be objective and non-judgmental when dealing with them, discussing physical, psychological and social factors without assuming which is primary. Chronic pain syndromes are difficult to explain scientifically and it is all too easy for a doctor to 'blame' the patient for this lack of explanation. Some chronic pain states may be caused partly by the process of litigation that may follow an injury.

Any chronic painful condition can change the way a person copes. Some people with chronic diseases or chronic pain cope well, but others adopt coping strategies and patterns of behaviour which make things worse. They become anxious, depressed or socially isolated, and their quality of life is reduced. In chronic pain syndromes patients need help to lead a more normal life despite their pain, and are best referred to a specialist, multidisciplinary pain service.

Psychological states such as depression and anxiety produce physical symptoms, of which one is pain, while people with frank physical diseases are often understandably anxious and depressed.

Fibromyalgia (fibrositis syndrome)

'Fibromyalgia' (p. 1282) is a useful diagnosis of exclusion although it is not universally accepted as a diagnosis. Patients value a name to explain symptoms previously dismissed or attributed simply to psychological or social problems. A typical feature of fibromyalgia is tender trigger points. The tenderness is not 'all over', a point which distinguishes it from anxiety states. The patient is usually a middle-aged woman who struggles on with her work and/or housework despite the pain. Such individuals are difficult to live with and there is often family discord. Many patients have sleep disturbances, so they awake unrefreshed and have poor concentration. It can occur at any age and is increasingly recognized in teenagers.

The pain is a widespread, unremitting, aching discomfort. There are often other health problems, such as chronic fatigue syndrome (see below), irritable bowel syndrome, premenstrual syndrome, tension headache, anxiety and depression; doctors sometimes inappropriately label them 'heart sink' patients. The patient's frustration is compounded by the fact that most tests are normal, and they fear doctors believe it is 'all in their mind'.

Treatment

A sympathetic approach is appropriate, with reassurance for the patient that fibromyalgia often improves and is not inevitably disabling. A graded aerobic exercise regimen over 3 months is safe and effective. When depression is present, it should be treated, but potentially addictive anxiolytic agents are best avoided. A behavioural

psychologist may persuade the person to pace their life more effectively and to cope better, although patients often resist referral for psychological help.

Drugs

Analgesics or NSAIDs help in some cases but are best used intermittently.

Low doses of sedative antidepressant drugs, such as amitriptyline or dosulepin, help when taken a few hours before bedtime. They act by increasing the levels of serotonin in the CNS. It should be explained that these doses are analgesic and not antidepressant, and their side-effects should be outlined.

Trigger-point injections with local anaesthetic, corticosteroids or acupuncture are sometimes helpful.

Oral corticosteroids are not helpful.

Chronic fatigue syndrome

Diffuse muscular pain and stiffness is common in this condition, which is described on page 1281.

Chronic (work-related) upper-limb pain syndrome

This name is preferred to 'repetitive strain injury' (RSI). The predominant symptoms are pain in all or part of one or both arms. A specific lesion, such as tennis elbow or carpal tunnel syndrome, or muscular-pattern neck pain often develops first, and early recognition and treatment may prevent chronicity. After a variable period, the pain becomes more diffuse and no longer simply work-related, and there is often severe distress. It is seen in keyboard workers and others who perform the same task without breaks for prolonged periods, and in musicians. When it arises at work, it is often at a time of changing work practices, shortage of staff or disharmony. Middle managers find it difficult to deal with and this compounds the stress.

It is seen throughout the developed world. It peaked in incidence in Australia in the 1970s and 1980s but has largely disappeared there, apparently because of changes in work practices, improvements in early medical management, changes in workers' compensation legislation, and reduced media discussion of the problem.

Treatment

If possible there should be a brief period off work and a gradual return to activity once the pain has settled. Cautious use of analgesia and NSAIDs, with physiotherapy, is helpful during the initial phase to prevent a vicious circle developing.

A review of working practices and the positioning of screen, keyboard and chair are essential, as is support of the patient by their manager. Musicians are helped by expert advice on playing technique and should reduce playing times temporarily, but not stop completely.

Temporomandibular pain dysfunction syndrome

This is a disorder of the temporomandibular joint associated with nocturnal tooth grinding or abnormalities of bite. It particularly occurs in anxious people. It gives rise to pain in one or both temporomandibular joints.

Dental correction of the bite helps a few but when no dental cause is found, low-dose tricyclic antidepressant therapy is used. Many patients are exposed to much unnecessary dental treatment.

Chronic regional pain syndrome type 1 (previously called reflex sympathetic dystrophy or Sudek's atrophy)

This is defined as 'a complex disorder or group of disorders that may develop as a consequence of trauma affecting the limbs, with or without obvious nerve lesions'. It may also develop after central nervous system lesions (e.g. strokes) or without cause. It occurred in 1.5% of soldiers injured in Vietnam. Its features are pain and other sensory abnormalities, including hyperaesthesia, autonomic vasomotor dysfunction, leading to abnormal blood flow and sweating, and motor system abnormalities. This leads to structural changes of superficial and deep tissues (trophic changes). Not all components need be present. The sensory, motor and sympathetic nerve changes are not restricted to the distribution of a single nerve and may be remote from the site of injury. The early phase - with pain, swelling and increased skin temperature - is difficult to diagnose but potentially reversible.

After a period of weeks or months, a second, still painful, dystrophic phase develops, characterized by articular stiffness, cold skin and trophic changes, often with localized osteoporosis.

A late phase involves continued pain, skin and muscle atrophy, and muscle contractures, and is extremely disabling.

Diagnosis is initially clinical - a high index of suspicion and recognizing the unusual distribution of the pain. A three-phase bone scan shows diffuse or patchy increase in uptake in the affected limb in all three phases: early (a few seconds - arterial); middle (a few minutes - soft tissue); and late (several hours - mineral). The bone phase abnormalities appear early and well before demineralization is seen on X-ray. There is never loss of joint space, which distinguishes the appearances from the periarticular osteoporosis of inflammatory joint disease.

Treatment

Management is difficult and the problem often very disabling. The evidence base to treatment is poor, as in many rare disorders. Early diagnosis, effective pain relief and general care of the patient are essential. NSAIDs and corticosteroids are used in the early phase, together with active exercise of the limb. Calcitonin or intravenous disodium pamidronate may also help at this stage. If pain persists despite initial treatment, a phentolamine test is

used to test for evidence of sympathetically maintained pain (i.v. infusion of up to 40 mg with careful cardiac monitoring). If this is positive, a stellate ganglion block is used for upper limb and a sympathetic chain block for lower limb involvement. Guanethidine (an alpha-blocking agent) or lidocaine administered to the limb under tourniquet is also useful. Referral to a pain management clinic is advisable.

Chronic regional pain syndrome type II is discussed on page 1198.

ANALGESIC AND ANTI-INFLAMMATORY DRUGS FOR MUSCULOSKELETAL PROBLEMS

The key to using drugs, particularly in chronic disorders and the elderly, is to balance risk and benefit and constantly to review their appropriateness. Box 10.4 shows the main drugs available.

Simple and compound analgesic agents

Simple agents such as paracetamol, aspirin, or codeine compounds (or combination preparations), used when necessary or regularly, relieve pain and improve function. Paracetamol with dextropropoxyphene (co-proximal) should not be prescribed and is being withdrawn. Sleep may also be improved. Side-effects are relatively infrequent, although drowsiness and constipation occur with codeine preparations, especially in the elderly.

Stronger analgesics, such as dihydrocodeine or morphine derivatives, should be used only with severe pain.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs have anti-inflammatory and centrally acting analgesic properties. They inhibit cyclo-oxygenase (COX), a key enzyme in the formation of prostaglandins, prostacyclins and thromboxanes (see Fig. 14.32). There are three specific cyclo-oxygenase enzymes: COX-1, the constitutive form; COX-2, the form mainly induced by inflammation; and COX-3 found in the brain. Most of the older NSAIDs block all three enzymes but with variable specificity; their therapeutic effect depends on blocking COX-2 and their side-effects mainly on blocking COX-1.

COX-1 is a constitutive enzyme present in many normal tissues. Inhibition of the enzyme by NSAIDs produces side-effects caused, for example, by the loss of gastric mucosal protection and a decrease in renal blood flow.

COX-2 is induced in response to pro-inflammatory cytokines and is not found in most normal tissues. It is associated with oedema and the nociceptive and pyretic effects of inflammation. COX-2 appears to be constitutive in the kidney. COX-2 specific NSAIDs are available, but see page 550.

COX-3 is present in the brain and is responsible for pain and hyperpyrexia. It is blocked weakly by paracetamol and by COX non-specific drugs. COX-2 specific drugs appear not to block COX-3, an observation which may explain their weaker analgesic action.

Uses

- *Short courses* of NSAIDs are used occasionally in osteoarthritis and spondylosis, even when there is minimal inflammation. They are commonly used in musculoskeletal pain but simple analgesia is often more appropriate.
- *In crystal synovitis,* NSAIDs have a true anti-inflammatory effect (see p. 570).
- *In chronic inflammatory synovitis,* NSAIDs do not alter the chronic inflammatory process, nor decrease the risk of joint damage, but they do reduce pain and stiffness.

© ***Box 10.4*** **Analgesics and NSAIDs**

Analgesics (in order of potency)

Advise that they be taken *only* if needed. Maximum doses are indicated here.

Paracetamol	500-1000 mg	6-hourly
Paracetamol with codeine	1-2 tablets	6-hourly
Paracetamol with dihydrocodeine	1-2 tablets	Every 6-8 hours
Dihydrocodeine	30-60 mg	Every 6-8 hours

Non-steroidal anti-inflammatory drugs (NSAIDs)

Always to be taken with food. Use slow-release preparations in inflammatory conditions or if more regular pain control is needed. Examples:

Ibuprofen	200-400 mg	Every 6-8 hours
Ibuprofen slow release	600-800 mg	Every 1-3 days
Diclofenac	25-50 mg	8-hourly
Diclofenac slow release	75-100 mg	x 1-2 daily
Celecoxib*	100-200 mg	x 2 daily

*COX-2-specific NSAID

- Slow-release preparations are useful for *inflammatory arthritis* and when more constant pain control is needed.
- NSAID gels have some value in chronic arthritis.

Side-effects

The most common with COX non-specific NSAIDs are indigestion or skin rashes. Gastric erosions and peptic ulceration with perforation and bleeding also occur. Proton-pump inhibitors are probably the best drugs to protect those at high risk from serious gastrointestinal events. H_2 blockers also help as gastroprotective agents. The value of prostaglandin E_2 analogues is limited by their tendency to cause nausea and diarrhoea. In the elderly, NSAIDs may cause gastric mucosal damage and gastrointestinal bleeding without warning symptoms, thereby causing significant morbidity and mortality. They may also reduce renal function, especially in the elderly. They should only be prescribed with a proton pump inhibitor in this group.

COX-2 specific NSAIDs produce fewer gastrointestinal side-effects (6% compared to 16% in one trial) but renal complications and fluid retention still occur. Rofecoxib has been withdrawn because of an increase in cardiovascular events with prolonged use. Celecoxib has also been implicated suggesting that this may be a 'class' phenomenon. Cox-2 specific NSAID should therefore only be used in patients with a high risk of gastrointestinal disease and with no cardiovascular risk.

OSTEOARTHRITIS (OA)

Osteoarthritis is a disease of synovial joints characterized by cartilage loss with an accompanying periarticular bone response. There is no simple definition of OA as it requires consideration of three overlapping areas - pathological changes, radiological features and clinical consequences. Pathologically, there is an alteration in cartilage structure, radiologically there are osteophytes and joint space narrowing, and clinically some patients complain of pain and disability.

Epidemiology

Osteoarthritis is the most common type of arthritis. The prevalence increases with age, and most people over 60 years will have some radiological evidence of it. It occurs world-wide, although OA of the hip is less common in black Africans and Chinese populations than in Caucasians. Most epidemiological studies have been based on radiological evidence, which is much more frequent than symptomatic OA. Women over 55 years are affected more commonly than are men of a similar age. There is a familial pattern of inheritance with distal interphalangeal joint involvement as the hallmark (nodal OA) and also with primary generalized OA. OA has a variable distribution (Fig. 10.8). The resulting disabilities have major socio-economic resource implications, particularly in the developed world.

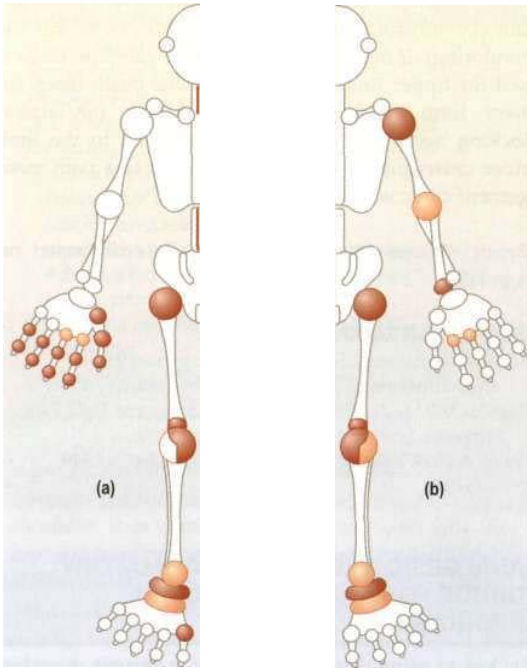

Fig. 10.8 Typical distribution of affected joints in (a) primary generalized OA and (b) pyrophosphate arthropathy. •, more commonly affected; , less commonly affected.

Aetiology

Genes that encode collagen type II have been proposed as candidate genes for familial OA. Osteoarthritis is the result of active, sometimes inflammatory but potentially reparative processes rather than the inevitable result of trauma and ageing. Focal destruction of the articular cartilage is the common pathological feature. The spectrum of OA ranges from atrophic disease in which cartilage destruction occurs without any subchondral bone response, to hypertrophic disease in which there is massive new bone formation at the joint margins.

Cartilage is a matrix of collagen fibres (mainly type II, see p. 530), enclosing a mixture of proteoglycans and water. Proteoglycans are present mainly as large molecular aggrecans, which consist of a protein core with attached chondroitin sulphate and keratan sulphate chains. The gene for human aggrecan has been cloned,

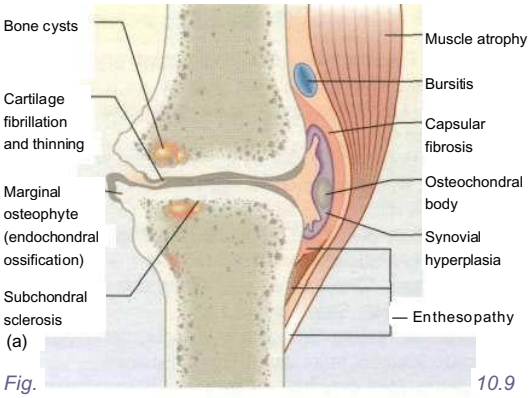
and polymorphisms of the gene have been correlated with OA of the hand in older men.

Cartilage is smooth-surfaced and shock-absorbing. Under normal circumstances there is a dynamic balance between cartilage degradation by wear and its production by chondrocytes. Early in the development of OA this balance is lost and, despite increased synthesis of extracellular matrix, the cartilage becomes oedematous. Focal erosion of cartilage develops. Chondrocytes die and, although repair is attempted from adjacent cartilage, the process is disordered. Eventually the synthesis of extracellular matrix fails and the surface becomes fibrillated and fissured. Cartilage ulceration exposes underlying bone to increased stress, producing micro-fractures and cysts. The bone attempts repair but produces abnormal sclerotic subchondral bone and overgrowths at the joint margins, called *osteophytes* (Fig. 10.9). There is some secondary inflammation.

Pathogenesis

Several mechanisms have been suggested for the pathogenesis:

- Matrix loss is caused by the action of matrix metalloproteinases such as collagenase (MMP-1), gelatinase (MMP-2) and stromelysin (MMP-3). These are secreted by chrondrocytes in an inactive form. Extracellular activation then leads to the degradation of collagen and proteoglycans.
- Tissue inhibitors of metalloproteinases (TIMPs) regulate the MMPs. Disturbance of this regulation may lead to increased cartilage degradation and contribute to the development of OA.
- There is synovial inflammation in OA, producing interleukin-1 (IL-1) and tumour necrosis factor (TNF-a). These cytokines stimulate metalloproteinase production and IL-1 inhibits type II collagen production.
- Growth factors, including insulin-like growth factor (IGF-1) and transforming growth factor (TGF-fS), are involved in collagen synthesis, and their deficiency may play a role in impairing matrix repair.
- Vascular endothelial growth factor from macrophages is a potent stimulator of angiogenesis and may contribute to inflammation and neovascularization in OA.
- Mutations in the gene for type II collagen (COL2A1) have been associated with early polyarticular OA.
- Twin studies suggest a strong hereditary element underlying OA, and further studies may reveal genetic markers for the disease. The influence of genetic factors is estimated at 35-65%.
- In the Caucasian population there is an inverse relationship between the risk of developing OA and osteoporosis.
- A large population study has suggested that a high intake of vitamin C and other antioxidants may reduce the risk of OA. The lack of antioxidants is thought to contribute to many ageing processes.
- In women, weight-bearing sports produce a two- to threefold increase in risk of OA of the hip and knee.



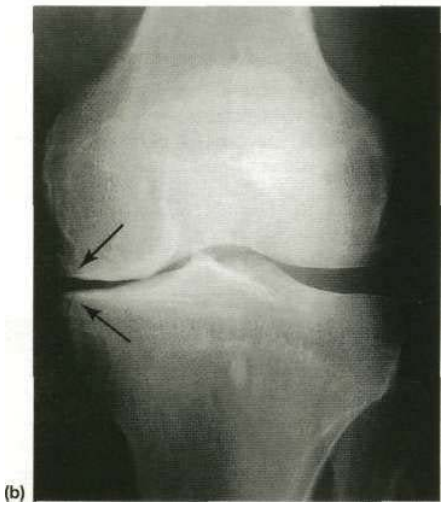


Fig. 10.9 Diagram and X-ray of a knee, showing early osteoarthritis. There is a medial compartment narrowing owing to cartilage thinning with subarticular sclerosis and marginal osteophyte formation (arrows).

- In men, there is an association between hip OA and certain occupations - farming and labouring.
- Obesity is a risk factor for developing OA in later life.

The term primary OA is sometimes used when there is no obvious known predisposing factor.

Box 10.5 shows some of the predisposing factors for the development of OA, whilst Table 10.11 shows other conditions that sometimes cause secondary arthritis.

Clinical features

Osteoarthritis affects many joints, with diverse clinical patterns. Hip and knee OA is the major cause of disability. Early OA is rarely symptomatic unless accompanied by a joint effusion, whilst advanced radiological and pathological OA is not always symptomatic.

Some flare-ups are due to inflammation but are not associated with an increased ESR or CRP. Focal synovitis

Box 10.5 Factors predisposing to osteoarthritis

- *Obesity* - Predicts later risk of radiological and symptomatic OA in population studies.
- *Heredity* - Familial tendency to develop nodal and generalized OA.
- *Gender* - Polyarticular OA is more common in women; a higher prevalence after the menopause suggests a role for sex hormones.
- *Hypermobility* (see p. 587) - Increased range of joint motion and reduced stability lead to OA.
- *Osteoporosis* - There is reduced risk of OA.
- Other diseases - See Table 10.11.
- *Trauma* - A fracture through any joint. Meniscal and cruciate ligament tears cause OA of the knee.
- *Congenital joint dysplasia* - Alters joint biomechanics and leads to OA. Mild acetabular dysplasia is common and leads to earlier onset of hip OA.
- *Joint congruity* - Congenital dislocation of the hip or a slipped femoral epiphysis or Perthes' disease; osteonecrosis of the femoral head (see p. 588) in children and adolescents causes early-onset OA.
- *Occupation* - Miners develop OA of the hip, knee and shoulder, cotton workers OA of the hand, and farmers OA of the hip.
- *Sport* - Repetitive use and injury in some sports causes a high incidence of lower-limb OA.

Table 10.11 Causes of osteoarthritis

Primary OA	No known cause
Secondary OA	Pre-existing joint damage:
	Rheumatoid arthritis
	Gout
	Seronegative spondyloarthropathy Septic arthritis Paget's disease Avascular necrosis, e.g. corticosteroid therapy
	Metabolic disease: Chondrocalcinosis
	Hereditary haemochromatosis Acromegaly
	Systemic diseases:
	Haemophilia - recurrent haemarthrosis
	Haemoglobinopathies, e.g. sickle cell disease
	Neuropathies

is caused by fragments of shed bone or cartilage. Radiological OA is usually, but not inevitably, progressive. This progression may be stepwise or continual. Radiological improvement is uncommon but has been observed, suggesting that repair is possible. This may be the basis for effective drug treatments in the future.

Symptoms

- Joint pain
- Joint gelling (stiffening and pain after immobility)
- Joint instability
- Loss of function.

Table 10.12 Features of nodal OA

Familial
Has a higher incidence in women
Typical pattern of polyarticular involvement of the hand joints
Develops in late middle age Has a generally good long-term functional outcome Associated with OA of the knee, hip and spine

Signs

- Joint tenderness
- Crepitus on movement
- Limitation of range of movement
- Joint instability
- Joint effusion and variable levels of inflammation
- Bony swelling
- Wasting of muscles.

Clinical subsets

Localized OA

Nodal OA (Table 10.12)

Joints of the hand are usually affected one at a time over several years, with the distal interphalangeal joints (DIPs) being more often involved than the proximal interphalangeal joints (PIPs). The onset may be painful and associated with tenderness, swelling and inflammation and impairment of hand function. The inflammation often occurs around the female menopause. PIP-predominant nodal OA has a superficial similarity to early rheumatoid arthritis. Even if a weakly positive rheumatoid factor is found, it is of no significance. The inflammatory phase settles after some months or years, leaving painless bony swellings posterolaterally - Heberden's nodes (DIPs) and Bouchard's nodes (PIPs), along with stiffness and deformity (Fig. 10.10). Functional impairment is slight for most, although PIP osteoarthritis restricts gripping more than DIP involvement. On X-ray, the nodes are marginal osteophytes and there is joint space loss.

Carpometacarpal and metacarpophalangeal OA of the thumb coexist with nodal OA and cause pain, which decreases as the joint stiffens. The 'squared' hand in OA is caused by bony swelling of the carpometacarpal joint and fixed adduction of the thumb. Function is rarely severely compromised.

Polyarticular hand OA is associated with a slightly increased frequency of OA at other sites.

Hip OA

Hip OA affects 7-25% of white adult Caucasians but is significantly less common in black African populations. There are two major subgroups defined by the radiological appearance. The most common is *superior-pole hip OA,* where joint space narrowing and sclerosis predominantly affect the weight-bearing upper surface of the femoral head and adjacent acetabulum. This is most common in men and unilateral at presentation, although both hips may become involved because the disease is progressive. Early onset of hip OA is associated with acetabular dysplasia. Less commonly, *medial cartilage loss*

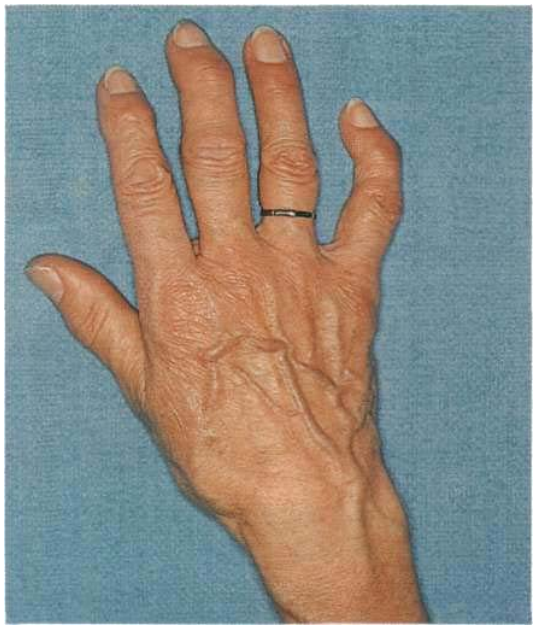

***Fig. 10.10* Severe nodal osteoarthritis.** The DIP joints demonstrate Heberden's nodes. The middle finger DIP joint is deformed and unstable. The thumb is adducted and the bony swelling of the first carpometacarpal joint is clearly shown - 'the squared hand of nodal OA'.

occurs. This is most common in women and associated with hand involvement (nodal generalized OA- NGOA), and is usually bilateral. It is more rapidly disabling.

Knee OA

The prevalence of knee OA is 40% in individuals aged over 75 years. It is commoner in women than in men. There is a strong relationship with obesity. The disease is generally bilateral and strongly associated with *polyarticular OA of the hand* in elderly women. The medial compartment is most commonly affected and leads to a varus (bow-legged) deformity. There is often also retropatellar OA. Previous trauma, meniscal and cruciate ligament tears are risk factors for developing knee OA.

Primary generalized OA

This is less common than nodal OA of the hands but is usually seen in combination. It is also called 'nodal generalized OA' (NGOA). The other joints affected are the knees, first MTP, hip, and intervertebral (spondylosis). There is a female preponderance and a strong familial tendency. NGOA is associated with immune complex deposition and may have an autoimmune cause. Its onset is often sudden and severe.

Erosive OA

This is rare. The DIPs and PIPs are inflamed and equally affected. In contrast to nodal OA, the functional outcome is poor. Radiologically, there are marked subchondral cysts. Erosive OA may develop into RA and may not be a true subset of OA.

Crystal-associated OA

This is most commonly seen with calcium pyrophosphate deposition in the cartilage (chondrocalcinosis). *Chondrocalcinosis* increases in frequency with age, but is usually asymptomatic. The joints most commonly affected are the knees (hyaline cartilage and fibrocartilage) and wrists (triangular fibrocartilage). There is patchy linear calcification on X-ray (Fig. 10.11).

A chronic arthropathy (pseudo-OA) occurs, predominantly in elderly women with severe chondrocalcinosis. There is a florid inflammatory component and marked osteophyte and cyst formation visible on X-rays. The joints affected differ from NGOA - being predominantly the knees, then wrists and shoulders, but also elbows, ankles and hips. Chondrocalcinosis is associated with pseudogout, an acute crystal-induced arthritis (see p. 571).

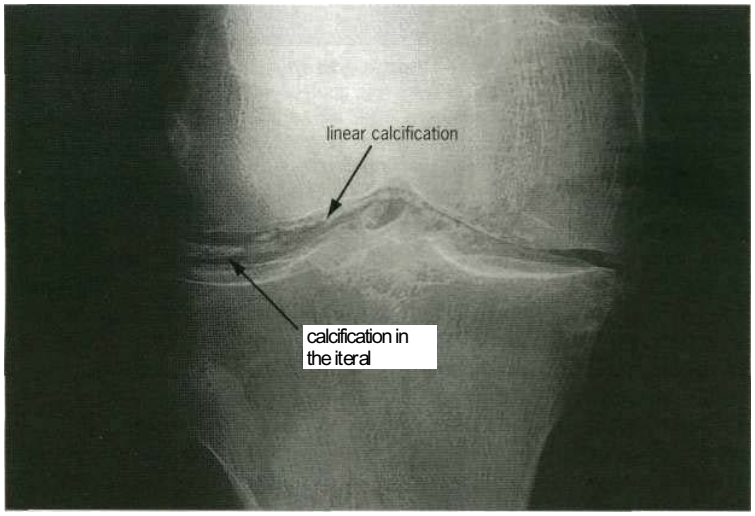

Fig. 10.11 Chondrocalcinosis of **the** knee. Note the linear calcification in the hyaline cartilage and calcification of the lateral meniscus (plus mild secondary OA).

A rare, rapidly destructive arthritis in elderly women, affecting shoulders, hips and knees, is associated with finding crystals of calcium apatite in a bloody joint effusion. The outlook is poor and joints require early surgical replacement.

Investigations in OA

- **Blood tests.** There is no specific test; the ESR and CRP are normal. Rheumatoid factor and antinuclear antibodies are negative.
- **X-rays** are abnormal only when the damage is advanced.
- **MRI** demonstrates early cartilage and subchondral bone changes.
- **Arthroscopy** reveals early fissuring and surface erosion of the cartilage.

Treatment

The guiding principle is to treat the symptoms and disability, not the radiological appearances; depression and poor quadriceps strength are better predictors of pain than is radiological severity in OA of the knee. Education of the individual about the disease and its effects reduces pain, distress and disability and increases compliance with treatment. Psychological or social factors alter the impact of the disease.

Physical measures

Weight loss and exercises for strength and stability are useful. Hydrotherapy helps, especially in lower-limb OA. Local heat, ice packs, massage and rubifacients or local NSAID gels are all used, although the value of NSAID gels is probably marginal.

Complementary medicine is commonly used and, despite lack of scientific evidence, little is lost in trying it since a number of patients do seem to be helped.

Medication

Balance the potential benefit against potential side-effects. Drugs usually should be used only in severe disease. Patients should be prescribed short courses of simple analgesics before NSAIDs (see Box 10.4). NSAIDs should be used intermittently. It has been suggested that some NSAIDs may increase the cartilage damage, while others are 'chondroprotective', but these claims remain unproven.

Intra-articular corticosteroid injections produce short-term improvement when there is a painful joint effusion. Frequent injections into the same joint should be avoided.

The role of chondroitin sulphate and glycosaminoglycan (sold as food supplements) is still under investigation and unproven. They appear to do no harm and some patients benefit.

Surgery

Total replacement arthroplasty has transformed the management of severe OA. The safety of hip and knee replacements is now equal, with a complication rate of about 1%; loosening, and late blood-borne infection are the most serious. Unicompartmental knee replacement is a less major procedure and appropriate for some patients. These slight but definite risks make it essential that the patient is certain that surgery is wanted, when all else has been tried. For the vast majority, a total hip or knee replacement reduces pain and stiffness and greatly increases function.

Other surgical procedures include realignment osteotomy of the knee or hip, excision arthroplasty of the first MTP and base of the thumb, and fusion of a first MTP joint.

INFLAMMATORY ARTHRITIS

Inflammatory arthritis includes a large number of arthritic conditions in which the predominant feature is synovial inflammation. This disparate group includes postviral arthritis, rheumatoid arthritis, seronegative spondyloarthropathy, crystal arthritis and Lyme arthritis. The diagnosis of these conditions is helped by the pattern of joint involvement (Table 10.13), along with any non-articular disease; a past and family history may be helpful. The distribution of the affected joints (symmetrical or asymmetrical; large or small) as well as the periodicity of the arthritis (single acute, relapsing, chronic and progressive) may also help in the diagnosis.

Certain nonarticular diseases - for example, psoriasis, iritis, inflammatory bowel disease, non-specific urethritis or recent dysentery - may suggest a seronegative spondyloarthropathy. There may be evidence of recent viral illness (rubella, hepatitis B or parvovirus), of rheumatic fever, or of a tick bite and skin rash (Lyme

Table 10.13 **Pattern of joint involvement in inflammatory arthritis**

disease). In early arthritis it may not be possible to make a specific diagnosis until the disease has evolved.

There is a distinct genetic separation of rheumatoid-pattern synovitis and the seronegative group; RA (see below) is associated with a genetic marker in the class II major histocompatibility genes, whilst seronegative spondyloarthropathy shares certain alleles in the B locus of class I MHC genes, usually B27 (see p. 564).

In general the pain and stiffness of inflammatory arthritis are worse in the morning and after rest. This early-morning exacerbation may last several hours, in contrast to the much shorter post-rest gelling of OA. Inflammatory markers (ESR and CRP) are often raised in inflammatory arthritis, and there is often a normochromic, normocytic anaemia. Specific types of arthritis are discussed below.

RHEUMATOID ARTHRITIS (RA)

Rheumatoid arthritis is a chronic symmetrical polyarthritis of unexplained cause. It is a systemic disorder characterized by chronic inflammatory synovitis of mainly peripheral joints. Its course is extremely variable and it is associated with nonarticular features.

Aetiology and pathogenesis

- *Geographical.* RA has a world-wide distribution and affects 0.5-3% (depending on the definition) of the population. It is a significant cause of disability and mortality and carries a high socio-economic cost.
- *Age.* RA presents from early childhood (when it is rare) to late old age. The most common age of onset is between 30 and 50 years.
- *Gender.* Women before the menopause are affected three times more often than men. After the menopause the frequency of onset is similar between the sexes, suggesting an aetiological role for sex hormones. The use of oral contraceptives may delay the onset of RA but does not reduce the risk of developing it.
- *Familial.* The disease is familial but sporadic. In occasional families it affects several generations. It is estimated to account for 50% of disease susceptibility.
- *HLA types.* There is a strong association between susceptibility to RA and certain HLA haplotypes. HLA-DR4, which occurs in 50-75% of patients, correlates with a poor prognosis, as does HLA-DRfil* 0404/0401. The possession of a specific pentapeptide (QK/RAA) in the third allelic hypervariable region of HLA-DRpi increases susceptibility. Combined with a positive rheumatoid factor it identifies individuals with a 13 times greater risk for developing bone erosions in early disease.
- *Anti-CCP (anti-citrullinated cyclic peptide) antibodies* react with proteins where arginine has been replaced by citrulline. They predate the clinical disease by several years. They help distinguish early RA from transient polyarthritis.

Immunology

The chronic synovial inflammation may be caused by ongoing *T cell activation.* Alternatively it may be maintained by the local production of rheumatoid factors and *continuous stimulation of macrophages* via IgG Fc receptors. Considering the extent of synovial inflammation and lymphocytic infiltration, there are only minimal amounts of factors normally produced by T cells (interferon and interleukin-2 and -4). Conversely, the cytokines (IL-1, IL-8, TNF-a, granulocyte-macrophage colony-stimulating factor) and chemokines produced by macrophages (macrophage inflammatory protein (MIP) and monocyte chemoattractant protein (MCP)) and fibroblasts (producing IL-6) are abundant. Activated mast cells which release histamine and TNF-a may also play a role.

CD4-specific antibodies, when used therapeutically, produce a specific helper T-cell lymphopenia but do not significantly alter the disease, raising the possibility that T cells play a lesser role.

Temporary B cell ablation (a technique used for treating B cell lymphomas) induces remission, reinforcing the central place of rheumatoid factor production in maintaining the chronic inflammation of RA.

Antibodies to TNF-a, IL-1 or specific blocking agents produce marked short-term improvement in synovitis, indicating the pivotal role of these cytokines in the chronic synovitis (see p. 562). They also reduce the malaise felt in active RA.

Synovial fibroblasts have high levels of the *adhesion molecule,* vascular cell adhesion molecule (VCAM-1), a molecule which supports B lymphocyte survival and differentiation, and of decay accelerating factor (DAF), a factor that prevents complement-induced cell lysis. These molecules may facilitate the formation of ectopic lymphoid tissue in synovium. High-affinity antibodies are not a feature of RA, unlike other autoimmune diseases.

The triggering antigen remains unclear, although it is suggested that the glycosylation pattern of immunoglobulins may be abnormal in RA and lead to their becoming potentially antigenic. There is little evidence that collagen type II is the triggering antigen, although it is a cause of arthritis in animal models of RA.

Bacterial or slow virus infections have been implicated but are unproven. It has been suggested that an immune response to any pathogen is to produce autoantibodies by B cell clonal expansion. In susceptible individuals such clones may persist.

Pathology

Rheumatoid arthritis is typified by widespread persisting synovitis (inflammation of the synovial lining of joints, tendon sheaths or bursae). The cause of this is unclear, but the production of rheumatoid factors (RFs, see below) by plasma cells in the synovium and the local formation of immune complexes play a part. In RA, the normal synovium becomes greatly thickened to the extent that it is palpable as a 'boggy' swelling around the joints and tendons. There is proliferation of the synovium into folds and fronds, and it is infiltrated by a variety of inflam-

matory cells, including polymorphs, which transit through the tissue into the joint fluid, and lymphocytes and plasma cells. There are disorganized lymphoid follicles that are responsive to exogenous antigens. The normally sparse surface layer of lining cells becomes hyperplastic and thickened (Fig. 10.12). There is marked vascular proliferation. Increased permeability of blood vessels and the synovial lining layer leads to joint effusions that contain lymphocytes and dying polymorphs.

The hyperplastic synovium spreads from the joint margins on to the cartilage surface. This 'pannus' of inflamed synovium damages the underlying cartilage by blocking its normal route for nutrition and by the direct effects of cytokines on the chondrocytes. The cartilage becomes thinned and the underlying bone exposed. Local cytokine production and joint disuse combine to cause juxta-articular osteoporosis during active synovitis.

Fibroblasts from the proliferating synovium also grow along the course of blood vessels between the synovial margins and the epiphyseal bone cavity and damage the bone. This is shown by MRI to occur in the first 3-6 months following onset of the arthritis, and before the diagnostic, ill-defined juxta-articular bony 'erosions' appear on X-ray (Fig. 10.13). This early damage justifies the use of DMARDs (see p. 561) within 3-6 months of onset of the arthritis. Low-dose steroids delay and anti-TNF-a agents halt or even reverse erosion formation. Erosions lead to a variety of deformities and contribute to long-term disability.

***Fig.** 10.13* X-ray of early RA, showing typical erosions at the thumb and middle MCP joints and at the ulnar styloid.

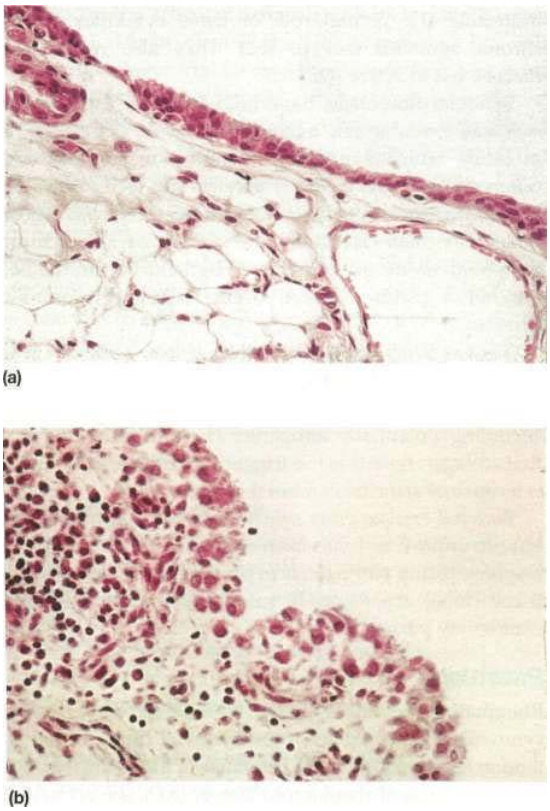

Fig. 10.12 Histological appearance of RA synovium. (a) Normal synovium. (b) Synovial appearances in established RA, showing marked hypertrophy of the tissues with infiltration by lymphocytes and plasma cells. From Shipley M (1993) *Colour Atlas of Rheumatology,* 3rd edn. Wolfe Mosby, with permission.

Rheumatoid factors (RFs)

These are circulating autoantibodies, which have the Fc portion of IgG as their antigen. The nature of the antigen means that they self-aggregate into immune complexes and thus activate complement and stimulate inflammation, causing chronic synovitis. Transient production of RFs is an essential part of the body's normal mechanism for removing immune complexes, but in RA they show a much higher affinity and their production is persistent and occurs in the joints. They may be of any immunoglobulin class (IgM, IgG or IgA), but the most common tests employed clinically detect IgM rheumatoid factor. Around 70% of patients with polyarticular RA have IgM rheumatoid factor in the serum.

The term seronegative RA is used for patients in whom the standard tests for IgM rheumatoid factor are persistently negative. They tend to have a more limited pattern of synovitis.

IgM rheumatoid factor is not diagnostic of RA, nor does its absence rule the disease out; but it is a useful predictor of prognosis. A persistently high titre in early disease implies more persistently active synovitis, more joint damage and greater disability eventually, and justifies earlier use of DMARDs.

M

RF and the antibody to CCP (see p. 533) together are more specific, and anti-CCP indicates a worse prognosis.

CLINICAL FEATURES OF RA

Typical presentation

The most typical presentation of rheumatoid arthritis (approximately 70% of cases) begins as a slowly progressive, symmetrical, peripheral polyarthritis, evolving over a period of a few weeks or months. Women are affected three times more often than are men. The patient is usually in her thirties to fifties, but the disease can occur at any age. Less commonly (15%) a rapid onset can occur over a few days (or explosively overnight) with a severe symmetrical polyarticular involvement. These patients often have a better prognosis. A worse than average prognosis (with a predictive accuracy of about 80%) is indicated by being female, a gradual onset over a few months, and a positive IgM rheumatoid factor, and/or anaemia within 3 months of onset. The differential diagnosis of early RA is shown in Box 10.6.

Symptoms and signs

The majority of patients complain of pain and stiffness of the small joints of the hands (metacarpophalangeal, MCP), proximal and distal interphalangeal (PIP, DIP) and feet (metatarsophalangeal, MTP). The wrists, elbows, shoulders, knees and ankles are also affected. In most cases many joints are involved, but 10% present with a monarthritis of the knee or shoulder or with a carpal tunnel syndrome. The hips are rarely affected early in the disease.

The patient feels tired and unwell and the pain and stiffness are significantly worse in the morning and may improve with gentle activity. Sleep is disturbed.

The joints are usually warm and tender with some joint swelling. There is limitation of movement and muscle wasting. Deformities develop as the disease progresses. Nonarticular features develop (see below).

Other presentations

The presentation and progression of RA is variable. Presentations are shown in Box 10.7. Relapses and remissions occur either spontaneously or in response to drug therapy. In some patients the disease remains active, producing progressive joint damage. Rarely the process may cease ('burnt-out RA').

A *seronegative, limited synovitis* initially affects the wrists more often than the fingers and has a less symmetrical joint involvement. It has a better long-term prognosis, but some cases progress to severe disability. This form can be confused with psoriatic arthropathy, which has a similar distribution. There may be a family history of psoriasis or the patient may develop psoriasis later.

Palindromic rheumatism is unusual (5%) and consists of short-lived (24—72 h) episodes of acute monarthritis. The joint becomes acutely painful, swollen and red, but resolves completely. Further attacks occur in the same or other joints. About 50% go on to develop typical chronic rheumatoid synovitis after a delay of months or years. The rest remit or continue to have acute episodic arthritis. The detection of IgM rheumatoid factor predicts conversion to chronic, destructive synovitis.

Box *10.6* Differential diagnosis of early rheumatoid arthritis

Postviral arthritis - rubella, hepatitis B or parvovirus
Seronegative spondyloarthropathies Polymyalgia rheumatica Acute nodal osteoarthritis (PIPs and DIPs involved)

mm *Box 10.7* Typical presentations of rheumatoid ^■^ arthritis

Palindromic - Monarticular attacks lasting 24-48 hours; 50% progress to other types of RA. **Transient** - A self-limiting disease, lasting less than 12 months and leaving no permanent joint damage. Usually seronegative for IgM rheumatoid factor. Some of these may be undetected postviral arthritis. **Remitting** - There is a period of several years during which the arthritis is active but then remits, leaving minimal damage. **Chronic, persistent** - The most typical form, it may be seropositive or seronegative for IgM rheumatoid factor. The disease follows a relapsing and remitting course over many years. Seropositive patients tend to develop greater joint damage and long-term disability. They warrant earlier and more aggressive treatment with disease-modifying agents. **Rapidly progressive** - The disease progresses remorselessly over a few years and leads rapidly to severe joint damage and disability. It is usually seropositive, has a high incidence of systemic complications and is difficult to treat.

Complications (Table 10.14)

Septic arthritis

This is a serious complication with significant morbidity and mortality. The joint (or joints) may be hot and inflamed with accompanying fever and a neutrophil leucocytosis in the blood. However, these signs are often absent, and any effusion, particularly of sudden onset, should be aspirated. *Staphylococcus aureus* is the most common organism. Treatment is with systemic antibiotics (see p. 571) and drainage.

***Table 10.14* Complications of rheumatoid arthritis**

Complications of the condition
Ruptured tendons
Ruptured joints (Baker's cysts)
Joint infection
Spinal cord compression (atlantoaxial or upper cervical spine) Amyloidosis (rare)
Side-effects of therapy
See Table 10.15

Amyloidosis (see p. 1142)
Amyloidosis is found in a very small number of people with severe rheumatoid arthritis. RA is the most common cause of secondary amyloidosis. Primary amyloidosis causes a polyarthritis that resembles RA in distribution and is also often associated with carpal tunnel syndrome and subcutaneous nodules.

Joint involvement in RA

Hands and wrists
The impact of RA on the hands is severe. In early disease the fingers are swollen, painful and stiff. Inflamed flexor tendon sheaths increase functional impairment and may cause carpal tunnel syndrome. Joint damage causes a variety of typical deformities. Most typical is a combination of ulnar drift and palmar subluxation of the MCPs (Fig. 10.14). This leads to unsightly deformity, but function may be remarkably good once the patient has learned to adapt, and pain is controlled. Fixed flexion (buttonhole or boutonniere deformity) or fixed hyperextension (swan-neck deformity) of the PIP joints impairs hand function.

Swelling and dorsal subluxation of the ulnar styloid leads to wrist pain and may cause rupture of the finger extensor tendons, leading in turn to a sudden onset of finger drop of the little and ring fingers predominantly, which needs urgent surgical repair.

Shoulders
RA commonly affects the shoulders. Initially the symptoms mimic rotator cuff tendonitis (see p. 538) with a painful arc syndrome and pain in the upper arms at night. As the joints become more damaged, global stiffening occurs. Late in **the** disease rotator cuff tears are common (see p. 538) and interfere with dressing, feeding and personal toilet.

Elbows
Synovitis of the elbows causes swelling and a painful fixed flexion deformity. In late disease flexion may be lost and severe difficulties with feeding result, especially combined with shoulder, hand and wrist deformities.

Feet
One of the earliest manifestations of RA is painful swelling of the MTP joints. The foot becomes broader and a hammer-toe deformity develops. Exposure of **the** metatarsal heads to pressure by the forwards migration of the protective fibrofatty pad (Fig. 10.15) causes pain. Ulcers or callouses may develop over the metatarsal heads and the dorsum of the toes. Mid- and hindfoot RA causes a flat medial arch and loss of flexibility of the foot. The ankle often assumes a valgus position. Appropriate broad, deep shoes are essential but rarely wholly adequate, and walking is often painful and limited. Podiatry helps and surgery may be required.

Knees
Massive synovitis and knee effusions occur, but respond well to aspiration and steroid injection (see p. 534). A

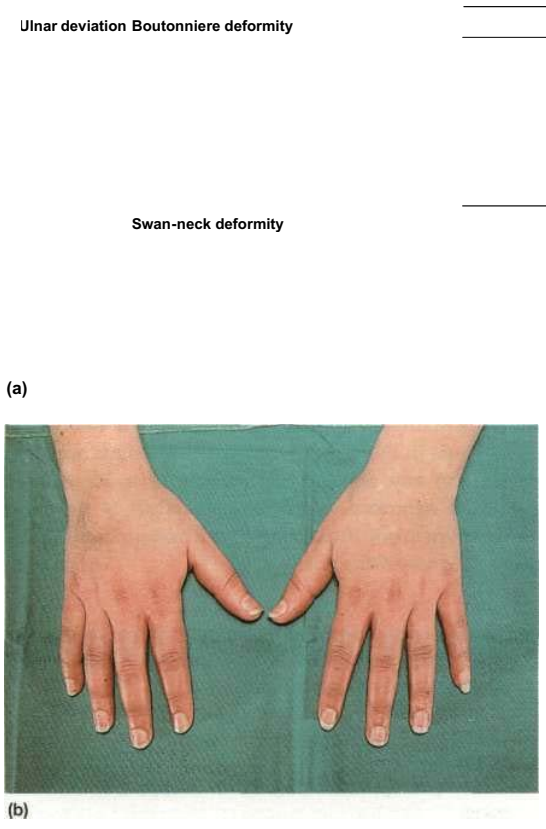

Fig. 10.14 **(a) Characteristic hand deformities in RA. (b) Early rheumatoid arthritis** - dorsal tenosynovitis of the right wrist and small joints of both hands with spindling of the fingers.

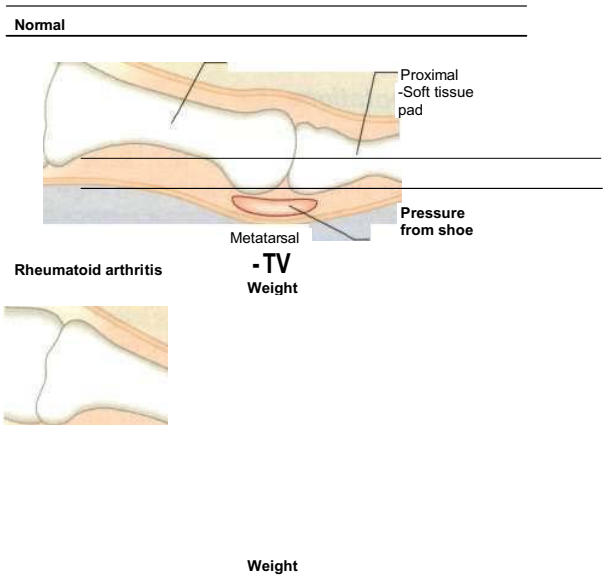

Fig. 10.15 **The toes in RA,** showing exposure of the metatarsal heads with forward migration of the soft tissue pad.

persistent effusion increases the risk of popliteal cyst formation and rupture (see p. 546). In later disease, erosion of cartilage and bone causes loss of joint space on X-ray and damage to the medial and/ or lateral and/or retropatellar compartments of the knees. Depending on the pattern of involvement, the knees may develop a varus or valgus deformity. Secondary OA follows. Total knee replacement is often the only way to restore mobility and relieve pain.

Hips

The hips are rarely affected in early RA and are less commonly affected than the knees at all stages of the disease. Pain and stiffness are accompanied by radiological loss of joint space and juxta-articular osteoporosis. The latter may permit medial migration of the acetabulum (protrusio acetabulae). Later, secondary OA develops. Hip replacement is usually necessary.

Cervical spine

Painful stiffness of the neck in RA is often muscular, but it may be due to rheumatoid synovitis affecting the synovial joints of the upper cervical spine and the bursae which separate the odontoid peg from the anterior arch of the atlas and from its retaining ligaments. This synovitis leads to bone destruction, damages the ligaments and causes atlantoaxial or upper cervical instability. Subluxation and local synovial swelling may damage the spinal cord, producing pyramidal and sensory signs. MRI is the best way of visualizing this, but lateral flexed and extended neck X-rays can demonstrate instability. In late RA, difficulty walking which cannot be explained by articular disease, weakness of the legs or loss of control of bowel or bladder may be due to spinal cord compression and is a neurosurgical emergency. Image the cervical spine in flexion and extension in patients with RA before surgery or upper gastrointestinal endoscopy to check for instability and reduce the risk of cord injury during intubation. .. ,.

Other joints ■ . , ■

The temporomandibular, acromioclavicular, sternoclavicular, cricoarytenoid and any other synovial joint can be affected.

Nonarticular manifestations (Fig. 10.16)

Soft tissue surrounding joints

Subcutaneous nodules are firm, intradermal and generally occur over pressure points, typically the elbows, the finger joints and the Achilles tendon. They may ulcerate and become infected, but usually resolve when the disease comes under control. The nodules can be removed surgically or injected with corticosteroids if causing a problem. They tend to recur. Histologically there is a necrotic centre surrounded by rows of activated macrophages. This resembles synovitis without a synovial space. The olecranon and other bursae may be swollen *(bursitis).* .

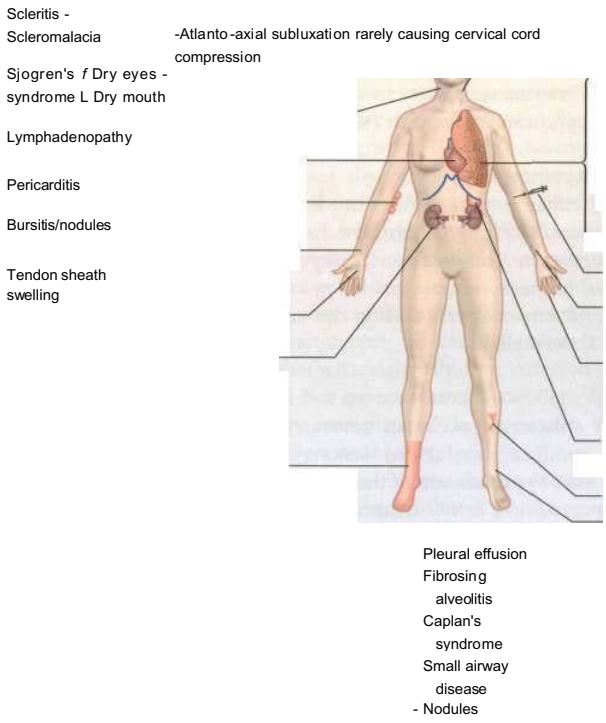

Fig. 10.16 Nonarticular manifestations of RA.

Tenosynovitis of affected flexor tendons in the hand can cause a trigger finger. Swelling of the extensor tendon sheath over the dorsum of the wrist is common.

Muscle wasting around joints is common. Muscle enzyme concentrations are normal; myositis is extremely rare. Corticosteroid-induced myopathy may occur.

Lungs (see also p. 937) '

Peripheral, intrapulmonary nodules are usually asymptomatic but may cavitate. When pneumoconiosis is present (Caplan's syndrome), large cavitating lung nodules develop.

Other manifestations are:

- serositis causing pleural effusion
- pleural nodules
- fibrosing alveolitis
- obstructive bronchiolitis.

Vasculitis

Vasculitis (see p. 581) is caused by immune complex deposition in arterial walls. It is uncommon. Smoking is a risk factor. Other manifestations are:

- nail-fold infarcts due to cutaneous vasculitis -
- widespread cutaneous vasculitis with necrosis of the skin (seen in patients with very active, strongly seropositive disease)

- mononeuritis multiplex (p. 1260)
- bowel infarction due to necrotizing arteritis of the mesenteric vessels (this may be indistinguishable from polyarteritis nodosa).

The heart and peripheral vessels

Clinical pericarditis is rare. In strongly seropositive RA, echocardiogram or post-mortem studies, however,

show that 30-40% of patients have pericardial involvement.

Endocarditis and myocardial disease are rarely seen clinically, although found at post-mortem in approximately 20% of cases. These are secondary to vasculitis.

Raynaud's syndrome may occur (see p. 869).

The nervous system

Neuropathies, either mononeuritis multiplex or a sensory loss in a glove and stocking pattern, are due to vasculitis of the vasa nervorum. Compression neuropathies such as carpal or tarsal tunnel syndrome are due to local synovial hypertrophy. Atlantoaxial subluxation can cause serious neurological abnormalities.

The eyes

Scleritis and episcleritis occur in severe, seropositive disease and produce painful red lesions in the eye. Scleritis may lead to perforation of the eye (scleromalacia perforans) and requires active treatment with local and systemic corticosteroids.

Sicca syndrome causes dry mouth and eyes (see Sjogren's syndrome, p. 581).

The kidneys

Amyloidosis causes the nephrotic syndrome and renal failure. Presentation is with proteinuria. It occurs rarely in severe, long-standing rheumatoid disease and is due to the deposition of highly stable serum amyloid A protein (SAP) in the intercellular matrix of a variety of organs. SAP is an acute-phase reactant, produced normally in the liver. It is rare, and proteinuria in RA is more commonly due to DMARDs.

The spleen, lymph nodes and blood

Felty's syndrome is splenomegaly and neutropenia in a patient with RA. Leg ulcers or sepsis are complications. HLA-DR4 is found in 95% of patients, compared with 50-75% of patients with RA alone.

The lymph nodes may be palpable, usually in the distribution of affected joints. There may be peripheral lymphoedema of the arm or leg.

Anaemia is almost universal and is usually the normochromic, normocytic anaemia of chronic disease. It may be iron-deficient owing to gastrointestinal blood loss from NSAID ingestion, or rarely haemolytic (Coombs' positive). There may be a pancytopenia due to hypersplenism in Felty's syndrome or as a complication of DMARD treatment. A high platelet count occurs with active disease.

DIAGNOSIS AND INVESTIGATIONS

The diagnosis relies on the clinical features described above. The American College of Rheumatology (ACR) criteria are shown in Box 10.8 and are useful for epidemiological and investigative studies but are unhelpful in early disease.

Initial investigations include:

- **Blood count.** Anaemia may be present. The ESR and/or CRP are raised in proportion to the activity of the inflammatory process and are useful in monitoring treatment.
- Serology. Rheumatoid factor is present in approximately 70% of cases and ANA at low titre in 30%.
- **X-rays** of the affected joint(s) to establish a baseline. Only soft tissue swelling is seen in early disease. MRI demonstrates early erosions but is rarely warranted.
- **Aspiration of the joint** if an effusion is present. The aspirate looks cloudy owing to white cells. In a suddenly painful joint septic arthritis should be suspected (see p. 571).

Other investigations will depend on the clinical picture as outlined above. In severe disease extensive imaging of joints may be required. MRI is the technique of choice, especially for the knee and cervical spine.

Box 10.8 **Criteria for the diagnosis of rheumatoid arthritis (American College of Rheumatology, 1987 revision)**

Morning stiffness > 1 hour	For 6 weeks or more
Arthritis of three or more joints *i*	
Arthritis of hand joints and wrists •	
Symmetrical arthritis	
Subcutaneous nodules	
A positive serum rheumatoid factor	
Typical radiological changes (erosions and/or periarticular osteopenia)	

Four or more criteria are necessary for diagnosis.

MANAGEMENT OF RA (Box 10.9)

The diagnosis of RA inevitably causes concern and fear in the patient and requires a lot of explanation and reassurance. The doctor and therapist should retain a positive approach and remind the patient that with the help of drugs most will continue to lead a more or less normal life despite their arthritis; 25% will recover completely. The earliest years are often the most difficult and people should try to stay at work during this phase.

Sox *10.9* Management of rheumatoid arthritis

Establish the diagnosis clinically.
Use NSAIDs and analgesics to control symptoms.
Try to induce remission with i.m. depot methylprednisolone 80-120 mg if synovitis persists beyond 6 weeks.
If synovitis recurs, refer to a rheumatologist to start sulfasalazine or methotrexate. Give a second dose of i.m. depot methylprednisolone.
Refer for physiotherapy and general advice through a specialist team.
If there is no significant improvement in 6-12 weeks as measured by less pain, less morning stiffness and reduced acute-phase response, use a combination of methotrexate and sulfasalazine.
If no better, use an alternative agent, such as gold, d-penicillamine, leflunamide or anti-TNF-a therapy

Uncertainty about when the disease will remit and flare, when and if drugs will work, and whether they may produce side-effects, makes planning from day to day difficult. People learn to adjust remarkably but this takes time and support. A rheumatology unit will have a team, including doctors, specialist nurses and physiotherapists, to help the patient learn to cope. Leaflets give helpful advice, as do local patient groups. Patients from socially deprived backgrounds and smokers have a worse prognosis. Statins have been shown to be of benefit in reducing cardiovascular risk and possibly inflammation whatever the cholesterol level; more studies are required.

Drug therapy

There is no curative agent available for RA. Symptoms are controlled with analgesia and NSAIDs. Recent data support the use of DMARDs early in the disease to prevent the long-term irreversible damaging effects of inflammation of the joints, and TNF-a blocking drugs are revolutionizing the management of RA.

Non-steroidal anti-inflammatory drugs (NSAIDs)

Most patients with RA are unable to cope without an NSAID to relieve night pain and morning stiffness. NSAIDs do not reduce the underlying inflammatory process. They all act on the cyclo-oxygenase (COX) pathway (see Fig. 14.32). The individual response to NSAIDs varies greatly. It is desirable therefore to try several different drugs for a particular patient in order to find the best (see Box 10.4). Each compound should be given for at least a week. Start with an inexpensive NSAID with few side-effects and with which you are familiar. Regular doses are needed to be effective. The major side-effects of NSAIDs are discussed on page 549. If gastrointestinal side-effects are prominent,or the patient is over 65 years, add a proton pump inhibitor. Slow-release preparations (e.g. slow-release diclofenac, 75 mg, taken after supper), or a suppository at bedtime, usually work well and can be given in addition to daytime therapy if necessary. For additional relief a simple analgesic is taken as required (e.g. paracetamol or a combination of dihydrocodeine and paracetamol). Many patients need night sedation.

Disease-modifying anti-rheumatic drugs

(Table 10.15)

DMARDs, which mainly act through cytokine inhibition, reduce inflammation, as reflected by a reduction of joint swelling, a fall in the plasma acute-phase reactants and slowing of the development of joint erosions and irreversible damage. Their beneficial effect is not immediate (hence 'slow-acting agents') and may be partial or transient. The problem with many DMARDs is that their effect is often only partial, achieving between 20-50% improvement by ACR criteria for disease remission. Drugs which achieve 70% improvement are required and TNF-a blocking agents are close to achieving this goal in around 20% of patients. There is good evidence that DMARDs control symptoms and signs of joint inflammation and that their withdrawal leads to a flare. Methotrexate, sulfasalazine, leflunamide, TNF-a blockers and ciclosporin have all been shown to reduce the rate of progressive joint damage in early and late disease.

Generally DMARDs are used after symptomatic treatment. However, in patients positive for RF and anti-CCP with a poor prognosis they should be used early, and certainly before the appearance of erosions on X-rays of hands and feet. The early use of depot injections of a corticosteroid at 6-12 weeks may induce remission. Studies of early RA suggest that intervention with DMARDs at 6 weeks to 6 months improves the outcome. The use of combinations of three or four drugs (steroids, methotrexate, sulfasalazine and hydroxychloroquine) in early RA (the inverted pyramid approach), reducing the number of agents once remission has been achieved, is more controversial and its long-term efficacy is yet to be proven. Toxicity appears to be reduced with such combinations, possibly because inflammation is controlled effectively. You must not overtreat people who are not going to develop erosions. Most prognostic assessments in early disease are only 80% accurate for risk of erosion and subsequent disability, and clinical judgement retains a central place in managing RA. DMARDs are usually prescribed by a rheumatologist (Table 10.15).

Sulfasalazine

This is a combination of sulfapyridine and 5-aminosalicylic acid. Sulfapyridine is probably the active component. It is well tolerated and for many is the first-choice DMARD, especially in younger patients. It produces a response in about half the patients in the first 3-6 months. Serious side-effects are rare, being mainly leucopenia and thrombocytopenia.

Methotrexate

This is considered by many to be the drug of choice. It should not be used in pregnancy. Conception should be delayed for at least 3 months off the drug for either partner. It is given at an initial weekly dose of 2.5-7.5 mg orally, increased up to 15-25 mg if necessary. It is well tolerated and this therapy can be introduced early in the disease. Nausea or poor absorption may limit its efficacy. It can be self-administered by subcutaneous injection. Oral folic acid should be given in addition to reduce side-effects, although it may marginally reduce efficacy. Full blood counts and liver biochemistry should be monitored carefully. It usually works within 1-2 months. More patients remain on this agent than on most other DMARDs, indicating that it is effective and has relatively few side-effects. . . ■

Leflunamide

This DMARD exerts an immunomodulatory effect by preventing pyrimidine production in proliferating lymphocytes through blockade of the enzyme dihydro-orotate dehydrogenase. Most cells are able to bypass this blockade but T cells cannot - thus it has a specific effect to

Table 10.15 **Disease-modifying anti-rheumatic drugs (DMARDs)**

Drug	Dose	Side-effects	Monitoring
Sulfasalazine (enteric coated)	500 mg daily after food, increasing to 2-3 g daily	Nausea Skin rashes and mouth ulcers Neutropenia and/or thrombocytopenia Abnormal liver biochemistry	Initial, fortnightly, then 4-monthly Initial, monthly, then 4-monthly
Methotrexate	2.5 mg increasing to 25 mg weekly, orally or s.c.	Nausea, mouth ulcers and diarrhoea Abnormal liver biochemistry Neutropenia and/or thrombocytopenia Renal impairment Pulmonary fibrosis (rare) Diarrhoea Neutropenia and/or thrombocytopenia Abnormal liver biochemistry Alopecia Hypertension Infections including tuberculosis, septicaemia Hypersensitivity reactions	Initial, fortnightly, then monthly Initial, weekly, then monthly Initial, then every 3-6 months Baseline chest X-ray Initial, then fortnightly; monthly at 6 months Initial, then fortnightly; monthly at 6 months See British Society of Rheumatology guideline Stop if no response after 3 months
Leflunamide	100 mg daily for 1-3 days, then 20 (or 10) mg daily or 10-20 mg daily		
TNF-a blockade Etanercept. Infliximab and adalimumab (used with methotrexate)	For use in specialist centre - central registry of patients		
Less commonly used			
Sodium aurothiomalate	10 mg test dose i.m., then 20-50 mg weekly Monthly with improvement	Skin rashes and mouth ulcers Neutropenia and/or thrombocytopenia Renal impairment Skin rashes Corneal deposits Retinal damage (very rare before 6 years' therapy) Nausea or loss of taste Skin rashes and mouth ulcers Neutropenia and/or thrombocytopenia Renal impairment Lupus-like syndrome Nausea Neutropenia and/or thrombocytopenia Abnormal liver biochemistry Renal impairment Hypertension Headache, infections, neutropenia	Initial and with each injection Test urine for blood/protein weekly Test visual fields at 6 months and fundoscopy if abnormal Initial, fortnightly, then monthly Test urine for blood/protein weekly Initial, then weekly, then monthly Initial, then monthly Initial, then fortnightly, then monthly Initial, then fortnightly, then monthly Initial, then monthly
Hydroxychloroquine	200-400 mg daily, reduce to 5 days/week		
D-penicillamine	125 mg, increasing slowly to 500-1000 mg daily before food		
Azathioprine	25 mg, increasing to 150 mg daily (max 2.5 mg/kg/day)		
Ciclosporin	2.5 mg/kg/day for 6 weeks, then 4 mg/kg/day. Reduce if creatinine doubles or BP rises 100 mg		
Anakinra	x 1 daily sc		

block clonal expansion of T cells by slowing progression through the maturation phases G to SI. It is 80% absorbed by mouth and there is no significant interaction with food. It has a long half-life of 4-28 days. The loading dose is 100 mg daily for 1-3 days, then 20 mg daily (10 mg if diarrhoea is a problem). The main side-effects are diarrhoea, nausea, alopecia and rash. Diarrhoea diminishes with time. Blood monitoring is obligatory. Its onset of action is 4 weeks compared with 6 weeks for methotrexate. The initial response is similar to sulfasalazine but improvement continues and is better sustained at 2 years.

Leflunamide works in some patients who have failed to respond to methotrexate, or it can be administered with methotrexate to enhance the response. It is probably more effective when given without folate supplements. It needs a 'washout' of 2 years before conception (3 months in men) so is best avoided in premenopausal women.

Tumour necrosis factor (TNF-a), IL-1 blockers and new therapies

The availability of agents that block TNF-a has significantly changed the traditional use of DMARDs. They are

used after at least two DMARDs (usually sulfasalazine and methotrexate) have been tried (NICE guidelines).

- *Etanercept* is a fully humanized p75 TNF-a receptor IgGl fusion protein given by subcutaneous injection. Around 65% of patients respond well. Some develop an injection reaction.
- *Infliximab* is a monoclonal antibody against TNF-a, given intravenously and co-prescribed with metho trexate to prevent loss of efficacy because of antibody formation.
- *Adalimumab* is a fully human monoclonal antibody against TNF-a given along with methotrexate.

These products slow or halt erosion formation in up to 70% of patients with RA and produce healing in a few. Patients often comment that their malaise and tiredness improve in a manner that is not seen with other DMARDs. They represent a major therapeutic advance in the treatment of RA and juvenile idiopathic arthritis. There is no evidence to date of increased tumour development. Some people become ANA positive and develop a reversible lupus-like syndrome. Reactivation of old TB may occur. These agents are extremely expensive when compared with traditional DMARDs and will cause funding problems for most healthcare systems even if they save costs in the longer term by reducing disability and the need for hospitalization. Their use should be restricted to specialist centres, and patients should be included in long-term cohort studies to unequivocally prove efficiency and to search for potential serious late-onset side-effects.

Anakinra is a human recombinant IL-1 receptor antagonist which, in combination with methotrexate, is licensed for use in RA.

Anti-citrullinated peptide has been shown to slow the development of RA erosions. Cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) is promising in trials.

Rituximab (p. 498), which causes lysis of B cells, has been shown to produce significant short-term improvement when used alone or in combination with cyclophosphamide or methotrexate.

Corticosteroids

The use of oral corticosteroids has a number of problems (Box 10.10). They are powerful disease-controlling drugs, but are avoided in the long term because side-effects are inevitable. Early intensive short-term regimens are used in some centres. Others use doses of 5-7.5 mg as maintenance therapy. There is some evidence that increased physical activity because of better symptom control reduces the risk of osteoporosis. Corticosteroids are also invaluable to patients with severe disease with extra-articular manifestations such as vasculitis.

Intra-articular injections with semicrystalline steroid preparations have a powerful but sometimes only short-lived effect.

Intramuscular depot injections (40-120 mg depot methylprednisolone) help to control severe disease flares, or can be used before a holiday or other life event, but should be used with caution and also infrequently.

Box 10.10 Problems associated with the use of corticosteroids

Patients are increasingly anxious about the use of corticosteroids because of adverse publicity about their potential side-effects. This must be discussed frankly and the risks of not using corticosteroids in treatment should be described and balanced against the risks of the drugs themselves. Patients must be warned to avoid sugars and saturated fats and to eat less because of the risk of weight gain.
The skin becomes thin and easily damaged. Monitor for diabetes and hypertension. Cataract formation may be accelerated. Osteoporosis develops within 6 months on doses above 7.5 mg daily, monitor with DXA scan and treat with calcium and vitamin D and bisphosphonate (see p. 597).

Drugs used less commonly

Gold (sodium aurothiomalate) is given by deep intramuscular injection. A test dose of 10 mg is followed by weekly doses of 50 mg until response occurs, usually in about 3 months. If there is no remission after a total dose of 1 g, treatment should be stopped. If a response is obtained, the interval between injections is increased to 4 weeks, continued for up to 5 years. Side-effects occur in a third of patients on i.m. gold. Rare side-effects include pulmonary fibrosis, colitis, polyneuropathy and cholestatic jaundice. Gold-induced glomerulonephritis can occur, particularly in patients who are HLA-DR3 positive, and routine urinalysis for proteinuria is performed.

The antimalarial, hydroxychloroquine is well tolerated. It is used alone in mild disease or as an adjunct to other DMARDs. Retinopathy is the most serious side-effect, but this is rare before 6 years of treatment. Patients should have 6-monthly checks of macular function with an Amsler chart, as retinopathy is irreversible.

D-penicillamine is given *before food* and for at least 3 months before improvement occurs. Penicillamine should not be continued if there is no improvement within 1 year. If proteinuria exceeds 2 g/24 h the drug must be stopped. Loss of taste is reversible. Other rare side-effects include a lupus erythematosus-like syndrome and a myasthenia gravis-like syndrome.

Azathioprine at a maximum dose of 2.5mg/kg and cyclophosphamide 1-2mg/kg have been used, usually when other DMARDs have been ineffective. They are often used when extra-articular features are severe, particularly with vasculitis. They are also used in patients who have been treated with corticosteroids and who have developed the severe side-effects of those agents.

Ciclosporin 2.5^1 mg/kg is used for active rheumatoid arthritis when conventional therapy has been ineffective. Side-effects include a rise in creatinine level and hypertension.

Physical measures

Patients with RA need constant advice and support from

physiotherapists and nurse specialists, especially while they are learning to adjust. A combination of rest for active arthritis and exercises to maintain joint range and muscle power is essential. Exercise in a hydrotherapy pool is popular and effective. Advice about managing activities of daily living despite the arthritis, and about gadgets, seating or structural changes in the home or at work are helpful.

Surgery

Surgery has a useful role in the long-term approach to patient management. Its main objectives are prophylactic, to prevent joint destruction and deformity, and reconstructive, to restore function.

Single-joint disease can be treated by surgical synovectomy to reduce the bulk of inflamed tissue and prevent damage. Excision arthroplasty of the ulnar styloid reduces pain and the risk of extensor tendon damage. Excision arthroplasties of the metatarsal heads reduce metatarsal pain and relieve pressure points. The major surgical advance has been the development of total replacement arthroplasty of the hip, knee, finger joints, elbows and shoulders. Such procedures need careful planning and preparation, and the expected outcomes and risks should be explained to the patient.

SERONEGATIVE SPONDYLOARTHROPATHIES

This awkward title describes a group of conditions affecting the spine and peripheral joints, which cluster in families and are linked to certain type 1 HLA antigens (Table 10.16).

The joint involvement is more limited than that seen in RA and its distribution is different. There are associated extra-articular and genetic features. These diseases occasionally present in childhood.

Histologically the synovitis itself is difficult to distinguish from that of RA, but there is no production of rheumatoid factors - hence 'seronegative'. Inflammation of the enthesis (junction of ligament or tendon and bone) and joint ankylosis develop more commonly than in RA.

Table 10.16 **Seronegative spondyloarthropathies**

Ankylosing spondylitis (AS)
Psoriatic arthritis
Reactive arthritis
Sexually acquired (Reiter's disease)
Post-dysenteric reactive arthritis
Enteropathic arthritis (ulcerative colitis/Crohn's disease)

All are associated with an increased frequency of sacroiliitis and an increased frequency of HLA-B27.

Aetiology

The common aetiological thread of these disorders is their striking association with HLA-B27, particularly ankylosing spondylitis (AS). This was the first demonstrated disease association of any HLA type (B27 is present in > 90% of Caucasians with AS but only 8% of controls). Its aetiological relevance remains unclear. The role of class I HLA antigens in pathogenesis is supported by the fact that HLA-B27 transgenic mice spontaneously develop arthritis, skin, gut and genitourinary lesions.

There are clues that infections play a role, possibly by molecular mimicry, with parts of the organism which are structurally similar to the HLA molecule triggering cross-reactive antibody formation. This is unproven. AIDS is increasing the prevalence of reactive arthritis and spondylitis in sub-Saharan Africa even in the absence of HLA-B27. The explanation for this changing epidemiology is unclear.

The types of arthritis that follow a precipitating infection are called reactive arthritis (p. 566).

The specialized immune systems of the gut and genitourinary mucous membranes may also play a causal role, perhaps reacting to local infections or to antigens which cross the damaged mucosa.

ANKYLOSING SPONDYLITIS (AS)

This is an inflammatory disorder of the spine affecting mainly young adults. The frequency of AS in different populations is roughly paralleled by the incidence of HLA-B27; Africans and Japanese have a low incidence of both HLA-B27 and ankylosing spondylitis, while the North American Haida Indians have a high incidence of both. There are at least 11 subtypes of HLA-B27 (B*2701-B*2711). Some appear to increase risk; others have a protective role. Twin studies indicate a much higher disease concordance in HLA-B27-positive monozygotic twins than in dizygotic twins. Other genetic loci appear to be involved. The disease occurs in men and women (2.5 : 1). It is milder in women, so men are more likely to present with symptoms of the disease (in a ratio of 4 : 1). There is lymphocyte and plasma cell infiltration and local erosion of bone at the attachments of the intervertebral and other ligaments (enthesitis). This heals with new bone (syndesmophyte) formation.

Box 10.11 **Nonarticular problems in seronegative spondyloarthropathies**

Uveitis, in all types
Cutaneous lesions in reactive arthritis (keratoderma blenorrhagica), histologically identical to pustular psoriasis
Nail dystrophy, in psoriasis and reactive arthritis
Aortitis, occasionally in AS and reactive arthritis

Clinical features

Episodic inflammation of the sacroiliac joints in the late teenage years or early twenties is the first manifestation of AS. Pain in one or both buttocks and low back pain and stiffness are typically worse in the morning and relieved by exercise. Initially the diagnosis is often missed because the patient is asymptomatic between episodes and radiological abnormalities are absent. Retention of the lumbar lordosis during spinal flexion is an early sign. Later, paraspinal muscle wasting develops. Spinal stiffness can be measured by Schoeber's test - a tape measure is placed in the midline 10 cm above the dimples of Venus. Any movement of a marker at 15 cm during flexion is recorded. A reading of less than 5 cm implies spinal stiffness. Individuals may be able to touch the floor with a stiff back if they have good hip movements but serial movement of the finger tip to floor distance highlights any change. Non-spinal complications (uveitis or costochondritis) suggest the diagnosis (Box 10.11). Costochondral junction inflammation causes anterior chest pain. Measurable reduction of chest expansion is due to costovertebral joint involvement.

Peripheral joint involvement is asymmetrical and affects a few, predominantly large joints. Hip involvement leads to fixed flexion deformities of the hips and further deterioration of the posture. Young teenage boys occasionally present with a lower-limb monarthritis (see p. 587).

Acute anterior uveitis is strongly associated with HLA-B27 in AS and related diseases and is occasionally the presenting complaint. Severe eye pain, photophobia and blurred vision are an emergency (see p. 1169). Overall clinical assessment is based on pain, tenderness, stiffness and fatigue using, for example, the Bath Ankylosing Spondylitis Disease Activity Index.

Investigations

- **Blood.** The ESR and CRP are usually raised.
- **HLA testing** is rarely of value because of the high frequency of HLA-B27 in the population, but may give supporting evidence in a difficult case.
- **X-rays.** The medial and lateral cortical margins of both sacroiliac joints lose definition owing to erosions and eventually become sclerotic (Fig. 10.17). The earliest radiological appearances in the spine are blurring of the upper or lower vertebral rims at the thoracolumbar junction (best seen on a lateral X-ray) caused by an enthesitis at the insertion of the intervertebral ligaments. These changes may eventually affect the whole spine. Persistent inflammatory enthesitis causes bony spurs (syndesmophytes). Syndesmophytes are more vertically oriented than the beak-like osteophytes of spondylosis and the disc is preserved, unlike in spondylosis (see p. 541). Syndesmophytes cause bony ankylosis and permanent stiffening. The sacroiliac joints eventually fuse, as may the costovertebral joints, reducing chest expansion. Calcification of the intervertebral ligaments and fusion of the spinal facet joints and syndesmophytes leads to what is often called a 'bamboo' spine (Fig. 10.18).

Fig. 10.17 **X-ray of ankylosing spondylitis.** The sacroiliac joints are eroded and show marginal sclerosis (white arrows). There is bridging syndesmophyte formation at the thoracolumbar junction (black arrows).

Treatment

The key to effective management of AS is early diagnosis so that a regimen of preventative exercises is started before syndesmophytes have formed. Morning exercises aim to maintain spinal mobility, posture and chest expansion. Failure to control pain and to encourage regular spinal and chest exercises leads to an irreversible dorsal kyphosis and wasted paraspinal muscles. This, along with stiffening of the cervical spine, makes forward vision difficult.

When the inflammation is active, the morning pain and stiffness are too severe to permit effective exercise. An evening dose of a long-acting or slow-release NSAID or an NSAID suppository improves sleep, pain control and exercise compliance. Peripheral arthritis and

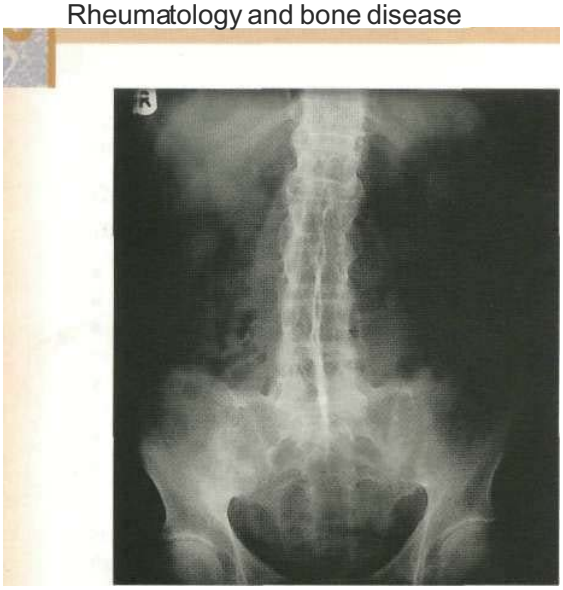

***Fig. 10.18* X-ray of bamboo spine in ankylosing spondylitis.** In advanced disease there is calcification of the interspinous ligaments and fusion of the facet joints as well as syndesmophytes at all levels. The sacroiliac joints fuse.

enthesitis are managed with NSAIDs or local steroid injections. Sulfasalazine or methotrexate may help the peripheral arthritis but there is little evidence that they control spinal disease.

TNF-cx blocking drugs are effective in severe disease and help both spinal and peripheral joint inflammation in the short term. Relapse occurs on stopping therapy.

Prognosis

With exercise and pain relief, the prognosis is excellent and over 80% of patients are fully employed. The back may be stiff, but disability is minimal unless the hips are involved.

Most patients with AS are HLA-B27 positive and they should be made aware that they risk passing the gene to 50% of their children. HLA-B27 positive offspring then have a 30% risk of developing AS.

The term 'psoriatic arthritis' describes a variety of different patterns of arthritis and enthesitis seen in people with psoriasis or with a family history of psoriasis. Five to eight per cent of individuals with psoriasis develop one of several different patterns of arthritis for which there is no serological marker. Activated CD4+ T lymphocytes appear to cause the lesions. Different subtypes of activated lymphocyte migrate to skin or joint, accounting for the skin and joint disease flaring at different times. There is compelling evidence that this is a reaction to organisms, such as group A streptococci, producing an autoimmune response in psoriatic skin plaques. These activated T lymphocytes release cytokines (interleukin 1, TNF-p" and interferon).

Clinical features

The arthritis is typically more limited in distribution and less severe than in RA. The skin disease can be mild and may develop after the arthritis.

The most typical pattern of joint involvement in psoriasis is distal interphalangeal arthritis. It is unsightly, but rarely disabling, and there is often adjacent nail dystrophy. Cutaneous lesions, interphalangeal joint synovitis and tenosynovitis causing a 'sausage' finger or toe (dactylitis) are seen in pauciarticular psoriatic arthritis (and in reactive arthritis).

A seronegative symmetrical polyarthritis similar to rheumatoid arthritis also occurs.

Radiologically, psoriatic arthritis is erosive but the erosions are central in the joint, not juxta-articular, and produce a 'pencil in cup' appearance (Fig. 10.19).

Arthritis mutilans affects about 5% of patients with psoriatic arthritis and causes marked periarticular osteolysis and bone shortening ('telescopic' fingers) (Fig. 10.20), in which, despite the deformity, pain may be mild and function often surprisingly good.

Individuals with psoriasis may develop unilateral or bilateral sacroiliitis and typical AS, but with early involvement of the neck; only 50% are HLA-B27 positive.

Treatment and prognosis

NSAIDs and/or analgesics help the pain but they can occasionally worsen the skin lesions. Local synovitis responds to intra-articular corticosteroid injections.

In milder, polyarticular cases, sulfasalazine slows the development of joint damage.

When the disease is severe, methotrexate or ciclosporin is given because they control both the skin lesions and the arthritis. Anti-TNF-a agents, e.g. etanercept (see p. 563), are highly effective and safe for severe skin and joint disease. Corticosteroids orally may destabilize the skin disease and are best avoided.

The prognosis for the joint involvement is generally better than in RA.

REACTIVE ARTHRITIS

Reactive arthritis is a sterile synovitis, which occurs following an infection (see also post-streptococcal arthritis, p. 587). -

Seronegative spondyloarthropathy develops in 1-2% of patients after an acute attack of dysentery, or a sexually acquired infection - non-specific urethritis (NSU) in the male, non-specific cervicitis in the female. In male patients who are HLA-B27 positive the relative risk is 30-50. Being HLA-B27 positive is not obligatory, however. Women are less commonly affected.

Aetiology

A variety of organisms can be the trigger, including some strains of *Salmonella* or *Shigella* spp. in bacillary dysentery. *Yersinia enterocolitica* causes diarrhoea and a reactive arthritis. In NSU the organisms are *Chlamydia trachomatis* or *Ureaplasma urealyticum.*

Fig. 10.20 Hand showing psoriatic arthritis mutilans. All the fingers are shortened and the joints unstable, owing to underlying osteolysis.

Fig. 10.19 X-ray of psoriatic arthritis. There is osteolysis of the metatarsal heads and central erosion of the proximal phalanges to produce the 'pencil in cup' appearance (circle). All the lesser toes are subluxed.

These are not mutually exclusive.

There are other organisms that also trigger reactive arthritis but have a different genetic basis; see post-streptococcal arthritis (p. 587), gonococcal arthritis (p. 572) and brucellosis (p. 572). In these, the borderline between reactive arthritis and septic arthritis is more indistinct and they can cause both.

Clinical features (Fig. 10.21)

The arthritis is typically an acute, asymmetrical, lower-limb arthritis, occurring a few days to a couple of weeks

Fig. 10.21 Clinical features of reactive arthritis.

Bacterial antigens or bacterial DNA have been found in the inflamed synovium of affected joints, suggesting that this persistent antigenic material is driving the inflammatory process. Other environmental factors may explain why even in susceptible individuals, repeated infections do not necessarily produce a reactive arthritis. The methods by which HLA-B27 increases susceptibility to reactive arthritis may include:

- T cell receptor repertoire selection
- molecular mimicry causing autoimmunity against HLA-B27 and/ or other self antigens
- mode of presentation of bacteria-derived peptides to T lymphocytes.

after the infection. The arthritis may be the presenting complaint if the infection is mild or asymptomatic. Enthesitis is common, causing plantar fasciitis or Achilles tendonitis (see p. 546). Seventy per cent recover fully within 6 months but many have a relapse.

In susceptible individuals with reactive arthritis, sacroiliitis and spondylitis may also develop. Acute anterior uveitis may complicate more severe or relapsing disease but is not synchronous with the arthritis.

The skin lesions resemble psoriasis:

- *Circinate balanitis* in the uncircumcised male causes painless superficial ulceration of the glans penis. In the circumcised male the lesion is raised, red and scaly. Both heal without scarring.
- *Keratoderma blenorrhagica* - the skin of the feet and hands develops painless, red and often confluent raised plaques and pustules histologically similar to pustular psoriasis.
- *Nail dystrophy* may occur.

Other features
These include:

- bilateral conjunctivitis occurs in 30%
- the classically described triad of Reiter's disease - urethritis, arthritis and conjunctivitis.

Treatment

There is some evidence that treating persisting infection with antibiotics will alter the course of the arthritis, once it has developed. Cultures should be taken and any infection treated. Sexual partners may require specialist advice about, and treatment for, sexually acquired diseases.

Pain responds well to NSAIDs and local corticosteroid injections. The majority of individuals with reactive arthritis have a single attack which settles, but a few develop a disabling relapsing and remitting arthritis. Relapsing cases are sometimes treated with sulfasalazine or methotrexate (see Table 10.15). There is a likely but unproven role for TNF-oc blocking agents in severe disease.

ENTEROPATHIC ARTHRITIS ASSOCIATED WITH INFLAMMATORY BOWEL DISEASE

Enteropathic synovia's occurs in approximately 10—15% of patients with ulcerative colitis and Crohn's disease (see p. 312). The link between the bowel disease and the inflammatory arthritis is not clear. Selective mucosal leakiness may expose the individual to antigens that trigger synovitis.

The arthritis is asymmetrical and predominantly affects lower-limb joints. An HLA-B27-associated sacroiliitis or spondylitis is seen in 5% of patients with inflammatory bowel disease and is independent of disease activity. The joint symptoms may predate the development of bowel disease and lead to its diagnosis.

Remission of ulcerative colitis or total colectomy usually leads to remission of the joint disease, but arthritis may persist even in well-controlled Crohn's disease.

Treatment

The inflammatory bowel disease should be treated (see p. 314). In all cases of enteropathic arthritis, the joint disease should be managed symptomatically with NSAIDs, although they may make diarrhoea worse. A monoarthritis is best treated by intra-articular corticosteroids. Sulfasalazine is frequently prescribed as this may help both bowel and joint disease. TNF-a blocking drugs are effective in inducing remission in Crohn's disease but not in ulcerative colitis.

CRYSTAL ARTHRITIS

Aetiology

Two main types of crystal account for the majority of crystal-induced arthritis. They are sodium urate and calcium pyrophosphate and are distinguished by their different shapes and refringence properties under polarized light with a red filter (Fig. 10.22). Rarely, crystals of calcium apatite (see p. 554) or cholesterol cause acute synovitis.

Neutrophils ingest the crystals and release pro-inflammatory enzymes from their phagosomes into the joint, thus triggering complement activation and attracting more neutrophils. Crystals may be found in asymptomatic joints. Why they initiate an attack is unclear. In pseudogout (p. 571), crystal shedding from the cartilage causes an attack.

GOUT AND HYPERURICAEMIA

Gout is an inflammatory arthritis associated with hyperuricaemia.

Epidemiology

The prevalence of gout in Europe and the USA is approximately 0.2%, although hyperuricaemia in this population occurs in about 5%. The prevalence of gout is increasing and is mainly seen in developed countries. Gout develops in men more than women (10 : 1) and rarely occurs before young adulthood (when it suggests a specific enzyme defect), and seldom in premenopausal females. The prevalence in older females is increasing with increased diuretic use. Hyperuricaemia is common in certain ethnic groups (e.g. Maoris).

Uric acid levels start to rise after puberty and are higher in men than in women until the female menopause. There is a normal distribution of serum uric acid in the population with a skewed distribution at the upper end of the range. Hyperuricaemia is defined as a serum uric acid level greater than two standard deviations from the mean (420 umol/L in males, 360 umol/L in females). This is close to the limit of urate solubility.

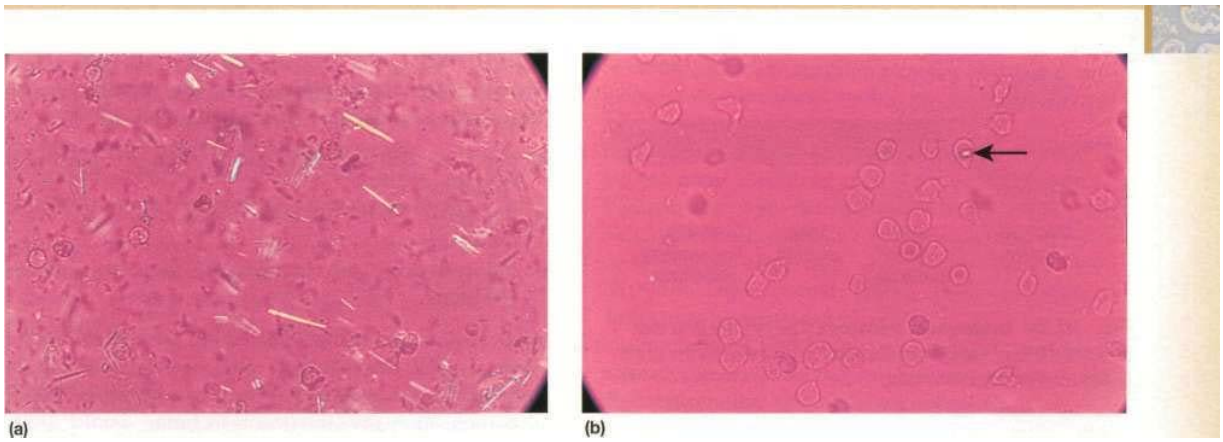

Fig. 10.22 **(a) Needle-shaped urate crystals,** viewed under polarized light with a red filter, **(b) A small intracellular pyrophosphate crystal,** viewed under polarized light with a red filter.

Most people with hyperuricaemia are asymptomatic. The range for gouty individuals is higher than for normals, but the curves overlap (Fig. 10.23). Serum uric acid levels increase with age, obesity, a high-protein diet, a high alcohol consumption (particularly beer drinkers), combined hyperlipidaemia, diabetes mellitus, ischaemic heart disease and hypertension. There is often a family history of gout.

Pathogenesis

Causes of hyperuricaemia are shown in Table 10.17. In many patients with gout there is no obvious cause. Hyperuricaemia is the major determinant for developing gout.

Uric acid levels in the blood depend on the balance between purine synthesis and the ingestion of dietary purines, and the elimination of urate by the kidney and intestine. The body pool is about 1000 mg and 60% is turned over daily.

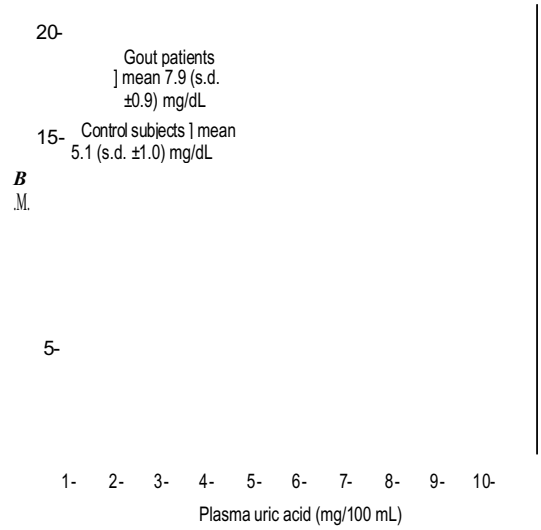

Fig. 10.23 **Serum uric acid levels in normals and in patients with gout.** 7.9 mg/dL is equivalent to 474 umol/L, 5.1 mg/dL is equivalent to 306 umol/L. From Snaith ML, Scott JT (1977) *Annals of Rheumatic Disease,* with permission.

Table 10.17 **Causes of hyperuricaemia**

Impaired excretion of uric acid
Chronic renal disease (clinical gout unusual)
Drug therapy, e.g. thiazide diuretics, low-dose aspirin
Hypertension
Lead toxicity
Primary hyperparathyroidism
Hypothyroidism
Increased lactic acid production from alcohol, exercise, starvation Glucose-6-phosphatase deficiency (interferes with renal excretion)

Increased production of uric acid
Increased purine synthesis de novo due to: Hypoxanthine-guanine-phosphoribosyl transferase (HGPRT) reduction (an X-linked inborn error causing the Lesch-Nyhan syndrome)
Phosphoribosyl-pyrophosphate synthase overactivity
Glucose-6-phosphatase deficiency with glycogen storage disease type 1 (patients who survive develop hyperuricaemia due to increased production as well as decreased excretion) Increased turnover of purines due to: Myeloproliferative disorders, e.g. polycythaemia vera
Lymphoproliferative disorders, e.g. leukaemia Others, e.g. carcinoma, severe psoriasis

Uric acid synthesis. Uric acid is the last step in the breakdown pathway of purines. The last two steps, the conversion of hypoxanthine to xanthine and of xanthine to uric acid, are catalysed by the enzyme xanthine oxidase. Humans lack the enzyme uricase.

Uric acid excretion (Fig. 10.24). Uric acid is completely filtered by the glomerulus; 98-100% is then reabsorbed in the proximal tubule and 50% is secreted by the distal tubule. Some post-secretory reabsorption also takes place. Low-dose aspirin blocks urate secretion. High-dose aspirin also blocks its reabsorption, leading to increased

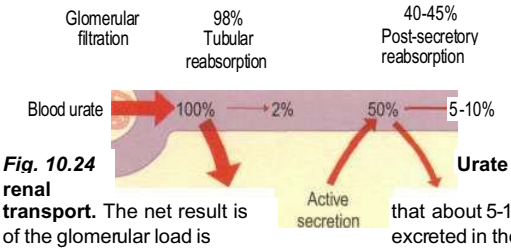

Fig. 10.24 **Urate renal transport.** The net result is that about 5-10% of the glomerular load is excreted in the urine under normal circumstances.

net excretion. Insulin resistance enhances urate resorption. Ninety per cent of patients with gout have impaired excretion of urate, 10% have increased production also and in less than 1% an inborn error of metabolism leads to purine overproduction. One-third of uric acid is eliminated in the faeces.

Clinical features

Hyperuricaemia causes four clinical syndromes:

- acute urate synovitis - gout
- chronic polyarticular gout
- chronic tophaceous gout
- urate renal stone formation (p. 649).

Acute gout presents typically in a middle-aged male with sudden onset of agonizing pain, swelling and redness of the first MTP joint. The attack occurs at any time, but may be precipitated by too much food or alcohol, by dehydration or by starting a diuretic. Untreated attacks last about 7 days. Recovery is typically associated with desquamation of the overlying skin. In 25% of attacks, a joint other than the great toe is affected.

In severe attacks, overlying crystal cellulitis makes gout difficult to distinguish clinically from infective cellulitis. A family or personal history of gout and the finding of a raised serum urate suggest the diagnosis but, if in doubt, blood and other cultures should be taken.

Chronic polyarticular gout is unusual, except in elderly people on long-standing diuretic treatment, in renal failure, or occasionally in men who have been started on treatment with allopurinol too soon after an acute attack.

Chronic tophaceous gout (see below).

Investigations

The clinical picture is often diagnostic, as is the rapid response to NSAIDs.

- **Joint fluid microscopy** is the most specific and diagnostic test but is technically difficult.
- **Serum urate** is usually raised (> 600 umol/L). If it is not, recheck it several weeks after the attack, as the level falls immediately after an acute attack. Acute gout never occurs with a serum uric acid in the lower half of the normal range.
- **Serum urea and creatinine** are monitored for signs of renal impairment.

Treatment

The use of NSAIDs in high doses rapidly reduces the pain and swelling. Initial doses, taken with food, are:

- naproxen: 750 mg immediately, then 500 mg every 8-12 hours
- diclofenac: 75—100 mg immediately, then 50 mg every 6-8 hours
- indometacin: 75 mg immediately, then 50 mg every 6-8 hours.

After 24-48 hours, reduced doses are given for a further week. *Caution:* NSAIDs may cause renal impairment. In individuals with renal impairment or a history of peptic ulceration, alternative treatments include:

- colchicine: 1000 ug immediately, then 500 jig every 6-12 hours, but this causes diarrhoea
- corticosteroids: intramuscular or intra-articular depot methylprednisolone.

Dietary advice

The first attacks may be separated by many months or years and are managed symptomatically. Individuals should be advised to reduce their alcohol intake, especially beer, which is high in purines. A diet which reduces total calorie and cholesterol intake and avoids such foods as offal, some fish and shellfish and spinach, all of which are rich sources of purines, is advised. This can reduce serum urate by 15% and delay the need for drugs that reduce serum urate levels.

Treatment with agents that reduce serum urate levels

Only when the attacks are frequent and severe, despite dietary changes, or associated with renal impairment or tophi, or when the patient finds NSAIDs or colchicine difficult to tolerate should allopurinol be used. It should never be started within a month of an acute attack and always be started under cover of a course of NSAID or colchicine for the first 2^1 weeks before and 4 weeks after starting allopurinol.

Allopurinol (300-600 mg) blocks the enzyme xanthine oxidase, which converts xanthine into urate (see Fig. 15.11). It reduces serum urate levels rapidly and is relatively non-toxic but should be used at low doses (50-100 mg) in renal impairment. Skin rashes are the most common side-effect. Bone marrow suppression is very rare. Allopurinol may induce acute gout when it is first introduced.

Uricosuric agents are no longer routinely available. The angiotensin I-receptor antagonist, losartan, is uricosuric in hypertensive patients on diuretics.

Chronic tophaceous gout

Individuals with very high levels of urate can present with different clinical pictures. In chronic tophaceous gout, sodium urate forms smooth white deposits (tophi) in skin and around joints. They may occur on the ear, the fingers or the Achilles tendon. Large deposits are

unsightly and ulcerate. There is chronic joint pain and sometimes superimposed acute gouty attacks.

Periarticular deposits lead to a halo of radio-opacity and clearly defined ('punched out') bone cysts on X-ray.

Tophaceous gout is often associated with renal impairment and/or the long-term use of diuretics. There may be acute or chronic urate nephropathy or renal stone formation. Whenever possible, stop the diuretics or change to less urate-retaining ones, such as bumetamide.

PSEUDOGOUT (PYROPHOSPHATE IARJTHROP^TJHY)

Calcium pyrophosphate deposits in hyaline and fibrocartilage produce the radiological appearance of chondrocalcinosis (see p. 553). Shedding of crystals into a joint precipitates acute synovitis which resembles gout, except that it is more common in elderly women and usually affects the knee or wrist. The attacks are often very painful. In young people it may be associated with haemochromatosis, hyperparathyroidism, Wilson's disease or alkaptonuria.

Diagnosis

The diagnosis is made by detecting rhomboidal, weakly positively birefringent crystals in joint fluid, or deduced from the presence of chondrocalcinosis on X-ray. The joint fluid looks purulent. Septic arthritis must be excluded and joint fluid should be sent for culture.

The attacks may be associated with fever and a raised white blood cell count.

Treatment

Aspiration of the joint reduces the pain dramatically but it is usually necessary to use an NSAID or colchicine, as for gout. If infection can be excluded, an infra-articular injection of a corticosteroid helps.

INFECTIONS OF JOINTS AND BONES

Joints may become infected by direct injury or by blood-borne infection from an infected skin lesion or other site. Chronically inflamed joints (e.g. in rheumatoid arthritis) are more prone to infection than are normal joints. Individuals who are immunosuppressed, by AIDS or by immunosuppressive agents, are particularly at risk, as are infants, the elderly and those who abuse alcohol. Artificial joints are also potential sites for infection.

SEPTJCARTHRITIS *WKH$*

The organism that most commonly causes septic arthritis is *Staphylococcus aureus.* Other organisms include streptococci, other species of staphylococcus, *Neisseria gonorrhoeae, Haemophilus influenzae* in children, and these and other Gram-negative organisms in the elderly or complicating RA.

Clinical features

Suspected septic arthritis is a medical emergency. In young and previously fit people, the joint is hot, red, swollen, and agonizingly painful and held immobile by muscle spasm. In the elderly and immunosuppressed and in RA the clinical picture is less dramatic, so a high index of suspicion is needed to avoid missing treatable but potentially severely destructive septic arthritis. In 20% the sepsis affects more than one joint.

Investigations

- **Aspirate** the joint and send the fluid for urgent Gram staining and culture. The fluid is usually frankly purulent. The culture techniques should include those for gonococci and anaerobes.
- **Blood cultures** are often positive.
- **Leucocytosis** is usual, unless the person is severely immunosuppressed.
- X-rays are of no value in diagnosis.
- **Skin wound swabs, sputum** and **throat swab or urine** may be positive and indicate the source of infection.

Treatment

This should be started immediately on diagnosis because joint destruction occurs in days. The joint should be immobilized initially and then physiotherapy started early to prevent stiffness and muscle wasting. Intravenous antibiotics should be given for 1-2 weeks. It is usual to give two antibiotics to which the organism is sensitive for 6 weeks, then one for a further 6 weeks orally. Monitor clinically and with the ESR and CRP.

Empirical treatment in septic arthritis

This is started before the results of culture are obtained. Discuss the case with a microbiologist. Intravenous flucloxacillin 1-2 g is given 6-hourly, plus fusidic acid 500 mg orally 8-hourly. If the patient is allergic to penicillin, replace flucloxacillin with erythromycin 1 g i.v. 6-hourly or clindamycin 600 mg i.v. 8-hourly. In immunosuppressed patients, flucloxacillin 1-2 g i.v. 6-hourly plus gentamicin (to cover Gram-negative organisms) should be used. Change the antibiotics if the organism is not sensitive. Drainage of the joint and arthroscopic joint washouts are helpful in relieving pain.

Management of infected prostheses

If chronically infected, the prosthesis is removed and the joint space filled with an antibiotic-impregnated spacer for 3-6 weeks before a new prosthesis is inserted. The whole process is covered by antibiotics.

Prognosis

Surgical drainage may be required if there is joint destruction and osteomyelitis. Patients can start weight-bearing as soon as the inflammation subsides. Resolution

of the septic arthritis with complete recovery can occur in a few days or weeks. It may lead to secondary osteoarthritis (see p. 552).

SPECIFIC TYPES OF BACTERIAL ARTHRITIS

Gonococcal arthritis

This is the most common cause of a septic arthritis in previously fit young adults, more commonly affecting women and homosexual men.

Initially the patient becomes febrile and develops characteristic pustules on the distal limbs. Polyarthralgia and tenosynovitis are common at this stage and about 40% have a gonococcaemia. This phase settles and blood cultures usually become negative. Later, large-joint mon- or pauciarticular arthritis may follow. Culture is usually positive from the genital tract, although the joint fluid may be sterile. It is not clear whether this is simply a septic arthritis - although it responds rapidly to antibiotics - or whether there is also a reactive element to bacterial lipopolysaccharide.

Treatment consists of oral penicillin, ciprofloxacin or doxycycline for 2 weeks, and joint rest.

Tuberculous arthritis

Around 1% of patients with tuberculosis develop joint and/or bone involvement. It occurs as the primary disease in children. In adults, it is usually due to haematogenous spread from secondary pulmonary or renal lesions. The onset is insidious and diagnosis often delayed.

The organism invades the synovium or intervertebral disc. There are caseating granulomas and rapid destruction of cartilage and adjacent bone. Some patients develop a reactive polyarthritis (Poncet's disease).

A hip or knee (30%) is quite commonly affected, but around 50% develop spinal disease. The patient is febrile, has night sweats, is anorexic and loses weight. The usual risk factors for tuberculosis apply - debility, alcohol abuse or immunosuppression. HIV-positive/AIDS patients are at particular risk.

Investigations should include culture of fluid, and culture and biopsy of the synovium. *M. tuberculosis* is the usual organism, but atypical mycobacteria are occasionally implicated. A chest X-ray should be performed. Initially joint or spinal X-rays may be normal but joint-space reduction and bone destruction develop rapidly if treatment is delayed. MRI shows the abnormality earlier in the spine and MRI-guided biopsy from the affected disc is necessary to obtain cultures.

Treatment is as for tuberculosis (see p. 932). The joint should be rested and the spine immobilized in the acute phase.

Meningococcal arthritis

This may complicate a meningococcal septicaemia and presents as a migratory polyarthritis. Organisms can only rarely be cultured from the joint and most cases are due to immune complex deposition. Treatment is with penicillin.

Infective endocarditis

This may present with arthralgia, polymyalgia rheumatica-like symptoms or an infective arthritis. It is discussed on page 828.

Lyme arthritis

A person with Lyme disease (see p. 79) develops a fever and headache, and an expanding, erythematous rash called erythema chronicum migrans. About 25% of cases develop an acute pauciarticular arthritis. This usually resolves but 20% of untreated cases go on to develop a chronic arthritis. It is unclear whether this and other late manifestations are due to chronic infection or are antibody-induced.

Diagnosis is by the detection of IgM antibodies against the spirochaete *Borrelia burgdorferi.*

Treatment with antibiotics (amoxicillin or doxycycline) is highly effective in early disease. The response of chronic arthritis to antibiotic treatment may be delayed for months.

Brucellosis

Brucellosis (see p. *77)* has a world-wide distribution. The most common cause of chronic brucellosis and of arthritis is *Brucella melitensis.* There is usually a peripheral mon- or oligoarticular arthritis, which may be septic or reactive. Arthritis is more common in chronic infections of more than 6 months.

Syphilitic arthritis

Congenital syphilis (see p. 123) can cause an acute painful epiphysitis or osteochondritis sometimes associated with para-articular swelling in the first few weeks of life. Later, at age 8-16 years, painless effusion of the knees may occur (Clutton's joints).

In acquired syphilis, arthralgia and arthritis occur in the secondary stage. Charcot's (neuropathic) joints usually involve the knees in tabes dorsalis (see p. 589).

Actinomycetes infection

Actinomycetes (see p. 90) can affect the mandible or vertebrae.

ARTHRITIS IN VIRAL DISEASE

A transient polyarthritis or arthralgia can occur before, during or after many viral illnesses. These include infectious mononucleosis, chickenpox, mumps, adenovirus, rubella, parvovirus B19, hepatitis B and C, arboviral infections and HIV. In most of these it is due to a direct toxic effect or immune complex deposition.

In *rubella* (see p. 52) the virus can occasionally be isolated from the joint. This arthritis occurs most commonly in up to 50% of young adult females a few

days after rubella infection (6% of men). It is a symmetrical polyarthritis involving the MCP or PIP joints most commonly, but many joints can be affected. It closely resembles rheumatoid arthritis. IgM rubella antibodies are present. It resolves within a few weeks in most cases. A mild arthritis occurs rarely 2-4 weeks after rubella vaccination.

Parvovirus B19 (p. 48) causes an acute, self-limiting arthritis and is associated with erythema infectiosum ('slapped cheek disease').

In *hepatitis B infection* (see p. 366) a sudden symmetrical poly articular arthritis of the small joints of the hands occurs in approximately one-third of patients, often in the prodromal phase and mostly resolving before the onset of jaundice. *Hepatitis C* causes type II mixed cryoglobulinaemia (see p. 628).

Arbovirus infections (see p. 52) which are endemic in many parts of the world give rise to an arthralgia and/ or arthritis. For example, the Ross River virus has caused an epidemic polyarthritis in Australia and the South Pacific; it involves the small joints of the hands and clears in 2-4 weeks. Other viral infections causing epidemic arthritis include chikungunya (p. 53) and O'nyong-nyong (p. 52). . . ,

Musculoskeletal aspects of infection with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS)

The clinical features seen in these patients are due to a number of causes such as opportunistic infections and drug therapy and are not usually caused directly by HIV. Infective arthritis seen in these immunosuppressed patients often has minimal symptoms and signs. Some of the antiviral agents cause an acute arthritis, possibly because of crystallization in the joint.

Arthralgia is common in AIDS. There is a seronegative, predominantly lower-limb arthritis, similar to psoriasis or Reiter's disease. Spondylitis also occurs but is not HLA-B27 associated. Avascular necrosis, possibly associated with corticosteroids or alcohol, is seen.

Nonarticular diseases such as Sjogren's- and lupus-like syndromes, systemic vasculitis of the necrotizing and hypersensitivity types and myositis also occur.

FUNGAL INFECTION

Fungal infections of joints occur rarely. Bone abscesses may be seen. Destructive joint lesions can also occur with blastomycosis. A benign polyarthritis accompanied by erythema nodosum occasionally occurs in coccidioidomycosis and histoplasmosis. Culture of purulent synovial fluid and skin tests for fungi may help the diagnosis.

BONE INFECTIONS

Acute and chronic osteomyelitis

Osteomyelitis can be due either to metastatic haematogenous spread (e.g. from a boil) or to local infection. Malnutrition, debilitating disease and decreased immunity may play a part in the pathogenesis.

Staphylococcus is the organism responsible for 90% of cases of acute osteomyelitis. Other organisms include *Haemophilus influenzae* and salmonella; infection with the latter may occur as a complication of sickle cell anaemia. The classic presentation is with fever and localized pain with overlying erythema. Diagnosis and treatment within a few days carries a good prognosis. Delayed treatment leads to chronic osteomyelitis. In chronic osteomyelitis sinus formation is usual. Subacute osteomyelitis is associated with a chronic abscess within the bone (Brodie's abscess). Symptoms may be limited to local pain.

Treatment of osteomyelitis is with immobilization and antibiotic therapy with flucloxacillin and fusidic acid. Surgical drainage and removal of dead bone (sequestrum) may be possible but recurrence is common.

Tuberculous osteomyelitis

This is usually due to haematogenous spread from a reactivated primary focus in the lungs or gastrointestinal tract. The disease starts in intra-articular bone. The spine is commonly involved (Pott's disease), with damage to the bodies of two neighbouring vertebrae leading to vertebral collapse and acute angulation of the spine (gibbus). Later an abscess forms ('cold abscess'). Pus can track along tissue planes and discharge at a point far from the affected vertebrae. Symptoms consist of local pain and later swelling if pus has collected. Systemic symptoms of malaise, fever and night sweats occur.

Treatment is as for pulmonary tuberculosis (see p. 932) together with initial immobilization.

AUTOIMMUNE DISEASES (CONNECTIVE TISSUE DISORDERS)

Autoimmune diseases are conditions in which the immune system damages specific organs or causes systemic ill-health. Organ-specific autoimmune diseases include Graves' disease, Hashimoto's thyroiditis, pernicious anaemia and insulin-dependent diabetes mellitus. In most of the autoimmune rheumatic diseases it is thought that self-antigens provide the drive, although the trigger may yet prove to be exogenous. They are clinically diverse but are unified by the detection of non-organ-specific autoantibodies in the serum and various tissues. Rheumatoid arthritis (RA, see p. 555) is the most common autoimmune rheumatic disease. .....

Some of the diseases in this section, e.g. systemic lupus erythematosus (SLE), polymyositis and dermatomyositis and systemic sclerosis, are discussed because of their similar pathophysiology. They are sometimes referred to as connective tissue disorders.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

SLE is an inflammatory, multisystem disorder with arthralgia and rashes as the most common clinical features, and cerebral and renal disease as the most serious problems.

Epidemiology

SLE occurs world-wide but the prevalence varies from country to country, with the most common prevalence of 1:250 being in African American women. In other populations the prevalence varies between 1:1000 and 1:10 000. It is about nine times as common in women as in men, with a peak age of onset between 20-40 years.

Aetiology

The cause is unknown but there are several predisposing factors:

- *Heredity.* There is a higher concordance rate in monozygotic twins (up to 25%) compared to dizygotic twins (3%). First-degree relatives have a 3% chance of developing the disease, but approximately 20% have autoantibodies.
- *Genetics.* There is an increased frequency of HLA-B8 and DR3 in Caucasians. There is a stronger association with HLA-DR2 in Japanese lupus patients.
- *Complement.* There is an inherited deficiency of C2 and C4 (which are in linkage disequilibrium with HLA-DR3 and DR2) in some patients. A functional deficiency of Qq has been suggested.
- *Sex hormone status.* Premenopausal women are most frequently affected. In addition, SLE has been seen in males with Klinefelter's syndrome (XXY) (see p. 1064). In New Zealand mice, a lupus-like disease is ameliorated by oophorectomy or treatment with male hormones.

Immunological factors

Loss of 'self-tolerance has several consequences:

- *B cell activation* results in increased autoantibody (mainly IgG) production to a variety (up to 2000) of antigens (nuclear, cytoplasmic and plasma membrane), e.g. ANA, anti-dsDNA.
- Development of and failure to remove *immune complexes* from the circulation leads to deposition of complexes in the tissue, causing vasculitis and disease (e.g. glomerulonephritis). Immune complexes also form in situ and this may play a role in glomerulo nephritis, skin disease and possible cerebral involve ment. Both renal and cerebral lupus are associated with high titre of anti-dsDNA.
- There is impaired T *cell regulation* of the immune response.
- There is *abnormal cytokine production* (IL-1 and IL-2), although its exact role in the pathogenesis is unknown. IL-6 and IL-10 levels are often raised.
- *TNF-a promoter polymorphisms* have also been linked to SLE and appear to be independent of susceptibility alleles.

Environmental triggers

Drugs such as hydralazine, methyldopa, isoniazid, D-penicillamine and minocycline can induce lupus not associated with anti-dsDNA (see below). Flare-ups can be induced by the contraceptive pill and hormone replacement therapy (HRT). Ultraviolet light is another well-recognized trigger, probably via increased apoptosis (see below). Viral aetiology has also been proposed. Increased cell turnover or immunological activation due to environmental agents may be a unifying mechanism.

Pathogenesis

Although much interest has been focused on immunological abnormalities in relation to lupus, there seems to be little wrong with the process itself but rather there is a failure to clear apoptotic material efficiently. Nuclear constituents, e.g. DNA and histones, are released from cells and their inefficient removal may lead to their being present in excess and possibly in some altered form. The nuclear material is then taken up by antigen-presenting cells and presented to T cells which in turn stimulate B cells to produce antibodies directed against nuclear antigens, e.g. Ro, La. The formation of some of these autoantibodies is due to proteases such as granzyme B which are active during apoptosis. Different subsets of autoantibodies may be related to the different clinical patterns.

Pathology

SLE is characterized by a widespread vasculitis affecting capillaries, arterioles and venules. Fibrinoid (an eosinophilic amorphous material) is found along blood vessels and tissue fibres. The synovium of joints may be oedematous and also contain fibrinoid deposits, which contain immune complexes. Haematoxylin bodies (rounded blue homogeneous haematoxylin-stained deposits) are seen in inflammatory infiltrates and are thought to result from the interaction of antinuclear antibodies and cell nuclei.

The pathology of lesions in other organs is described in the appropriate chapters.

Clinical features

SLE is extremely variable in its manifestations and most of the clinical features are due to the consequences of vasculitis. Mild cases may present only with arthralgia and fatigue, and can be difficult to diagnose (Fig. 10.25).

General features

Fever is common in exacerbations, occurring in up to 50% of cases. Patients complain of marked malaise and tiredness and these symptoms do not correlate with disease activity or severity of organ-based complications.

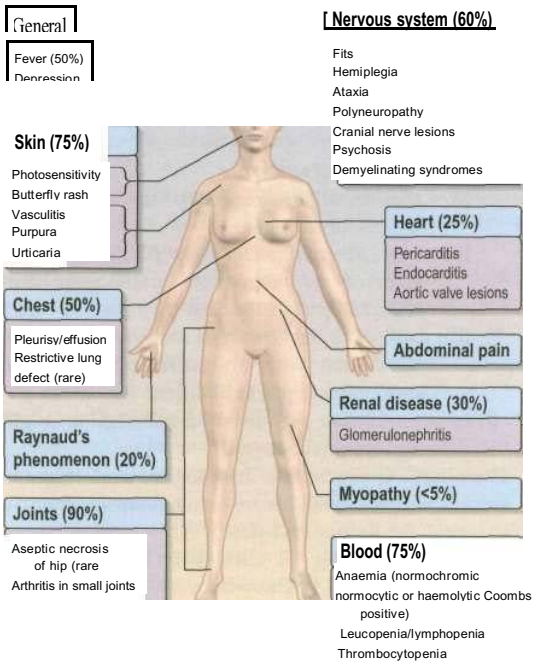

Fig. 10.25 Clinical features of systemic lupus erythematosus (SLE).

The joints and muscles

Joint involvement is the most common clinical feature (> 90%). Patients often present with symptoms resembling RA with symmetrical small joint arthralgia. Joints are painful but characteristically appear clinically normal, although sometimes there is slight soft-tissue swelling surrounding the joint. Deformity because of joint capsule and tendon contraction is rare, as are bony erosions. Rarely, major joint deformity resembling RA (known as Jaccoud's arthropathy) may be seen. Aseptic necrosis affecting the hip or knee is a rare complication of the disease.

Myalgia is present in up to 50% of patients but a true myositis is seen only in < 5%. Overlap connective tissue disease (p. 581) is likely if myositis is prominent.

The skin (see p. 1341)

This is affected in 75% of cases. Erythema, in a 'butterfly' distribution on the cheeks of the face and across the bridge of the nose (see Fig. 23.26) is characteristic. Vasculitic lesions on the finger tips and around the nail folds, purpura and urticaria occur. In one-third of cases there is photosensitivity, and prolonged exposure to sunlight can lead to exacerbations of the disease. Livedo reticularis, palmar and plantar rashes, pigmentation and alopecia may be seen. Raynaud's phenomenon (see p. 869) is common and may precede the development of arthralgia and other clinical problems by years.

Immunofluorescence of 'normal' non-sun-exposed skin, obtained on biopsy (for example from the buttock), will show immunoglobulin and complement deposition at the dermoepidermal junction (known as the positive lupus band test).

Discoid lupus is described on page 1343.

The lungs (see p. **938**)

Up to 50% of patients will have lung involvement sometime during the course of the disease. Recurrent pleurisy and pleural effusions (exudates) are the most common manifestations and are often bilateral. Pneumonitis and atelectasis may be seen; eventually a restrictive lung defect develops with loss of lung volumes and raised hemidiaphragms. This 'shrinking lung syndrome' is poorly understood but may have a neuromuscular basis. Rarely, pulmonary fibrosis occurs, more commonly in overlap syndromes. Intrapulmonary haemorrhage associated with vasculitis is a rare but potentially life-threatening complication.

The heart and cardiovascular system

The heart is involved in 25% of cases. Pericarditis, with small pericardial effusions detected by echocardiography, is common. A mild myocarditis also occurs, giving rise to arrhythmias. Aortic valve lesions and a cardiomyopathy can rarely be present. A non-infective endocarditis involving the mitral valve (Libman-Sacks syndrome) is very rare. Raynaud's, vasculitis, arterial and venous thromboses can occur, especially in association with the antiphospholipid syndrome. There is an increased frequency of atherosclerotic disease in SLE. This partly reflects treatment with corticosteroids but it is likely that SLE itself, perhaps due to effects on endothelial cell activation or sustained elevation in inflammatory proteins, is an independent risk factor for macrovascular disease. Homozygosity for mannan-binding lectin variant (p. 201) is associated with an increased risk of arterial thrombosis in SLE. Trials to assess the benefit of intensive treatment of cardiovascular risk factors in SLE are underway. The benefit of statin therapy in the absence of significant hypercholesterolaemia remains to be proven.

The kidneys

The WHO classification of types of nephritis is on page 627. Autopsy studies suggest that histological changes are very frequent, but clinical renal involvement occurs in only approximately 30% of cases. All patients should have regular screening of urine for blood and protein. Proteinuria should be quantified and haematuria should prompt examination for urinary casts or fragmented red cells that suggest glomerulonephritis. Renal vein thrombosis can occur in nephrotic syndrome or associated with procoagulant antiphospholipid antibodies.

The nervous system

Involvement of the nervous system occurs in up to 60% of cases and symptoms may fluctuate. There may be a mild depression but occasionally more severe psychiatric disturbances occur. Epilepsy, migraines, cerebellar ataxia, aseptic meningitis, cranial nerve lesions, cerebrovascular disease or a polyneuropathy may be seen. The pathogenic

mechanism for cerebral lupus is complex. Lesions may be due to vasculitis or immune-complex deposition, thrombosis or non-inflammatory microvasculopathy. The commonest finding on MRI scan is of increased white matter signal abnormality. In patients with cerebral lupus, infection should be excluded or treated in parallel with administration of corticosteroids and immunosuppression.

The eyes

Retinal vasculitis can cause infarcts (cytoid bodies) which appear as hard exudates, and haemorrhages. There may be episcleritis, conjunctivitis or optic neuritis, but blindness is uncommon. Secondary Sjogren's syndrome may be seen in about 15% of cases.

The gastrointestinal system

SLE causes gastrointestinal symptoms, of which mouth ulcers are the commonest and may be a presenting feature. These may be painless or become secondarily infected and painful. Mesenteric vasculitis can produce inflammatory lesions involving the small bowel (infarction or perforation). Liver involvement is unusual, although lupoid antibodies are described in autoimmune hepatitis. Pancreatitis is uncommon.

Lupus variants

Chronic discoid lupus is a benign variant of the disease, in which skin involvement is often the only feature, although systemic abnormalities may occur with time. The rash is characteristic and appears on the face as well-defined erythematous plaques that progress to scarring and pigmentation (see p. 1343). Subacute cutaneous lupus erythematosus, a rare variant, is described on page 1344.

Drug-induced SLE is usually characterized by arthralgia and mild systemic features, rashes and pericarditis, but seldom renal or cerebral disease. It usually disappears when the drug causing it is stopped. Hydralazine and procainamide are the most likely causes, but other drugs have occasionally been implicated. Anti-histone antibodies are associated.

Overlap syndrome is discussed on page 581.

Antiphospholipid syndrome (see below) was originally described in SLE and the presence of antiphospholipid antibodies partially accounts for the increased tendency to thrombosis.

Investigations

- **Blood:**
  - **(a)** *A full blood count* usually shows a leucopenia, lymphopenia and/or thrombocytopenia. An auto immune haemolytic anaemia occurs. The ESR is raised in proportion to the disease activity. In contrast, the CRP is normal.
  - (b) *Serum antinuclear antibodies* (ANA) are positive in almost all cases. Double-stranded DNA (dsDNA) binding is specific for SLE, although it is only present in 50% of cases, particularly those with severe systemic involvement (e.g. renal disease). Antinucleosome antibodies predate anti-dsDNA antibodies. Antibodies to RNA (ss and ds) anti-Ro and anti-La can also be detected.
  - (c) *Rheumatoid factor* is positive in 25% of the patients.
  - (d) *Serum complement levels* are reduced during active disease. Isolated C4 deficiency may be a genetic variant.
  - (e) *Anti-phospholipid antibodies:*
    - (i) *Anticardiolipin antibodies* are present in 35-45% of the patients.
    - (ii) *Anti /32-glycoprotein 1 antibodies* are also detected in vitro with pathogenic anti-phospholipid antibodies.
  - **(iii)** *Lupus anticoagulant tests* are often positive in association with anticardiolipin and other antiphospholipid antibodies. (f) *Immunoglobulins* are raised (usually IgG and IgM) with a polyclonal pattern.
- **Histology.** Characteristic histological and immunofluorescent abnormalities are seen in biopsies from, for example, the kidney and skin.
- **Diagnostic imaging.** CT scans of the brain sometimes show infarcts or haemorrhage with evidence of cerebral atrophy. MR can detect lesions in white matter which are not seen on CT. However, it can be very difficult to distinguish true vasculitis from small thrombi.

Management

The disease and its management should be discussed, pointing out that the prognosis is much improved, though patients are advised to avoid excessive exposure to sunlight and should reduce cardiovascular risk factors. Drug therapy should be used for active disease. There is no evidence that treatment in remission alters the progression of the disease.

- Arthralgia, arthritis, fever and serositis all respond well to standard doses of NSAIDs. Antimalarial drugs (chloroquine or hydroxychloroquine) (see Table 10.15) help mild skin disease, fatigue and arthralgias that cannot be controlled with NSAIDs. They have been shown to reduce the frequency of flares in SLE and are recommended in all but the mildest cases unless contraindicated. Patients should be warned about visual side-effects but self-monitoring of vision is sufficient for hyroxychloroquine unless there is other ocular pathology.
- Corticosteroids orally or as intravenous boluses are helpful, with dose determined by clinical severity. Immunosuppressive drugs such as azathioprine, cyclophosphamide or mycophenolate mofetil are essential for more severe disease (glomerulonephritis, vasculitis, cerebral disease or blood dyscrasias) and when the symptoms are poorly controlled.
- Newer therapies include anti-CD20 monoclonal antibodies, which are undergoing clinical trials. They deplete subpopulations of B lymphocytes.

Course and prognosis

An episodic course is characteristic, with exacerbations and complete remissions that may last for long periods.

These remissions often occur even in patients with severe organ-based disease. However, SLE can also be a chronic persistent condition. Earlier estimates of the mortality in SLE were exaggerated; 10-year survival rate is about 90%, although much lower if major organ-based complications are present. In most cases the pattern of the disease becomes established in the first 10 years; if serious problems have not developed in this time, they are unlikely to do so. The arthritis is usually intermittent but arthralagia and fatigue are often more persistent. Chronic progressive destruction of joints as seen in RA and OA occurs rarely, but a few patients develop deformities such as ulnar deviation. Increased frequency of macrovascular disease appears to be a significant problem for late-stage SLE.

Pregnancy and SLE

Fertility is usually normal except in severe disease and there is no major contraindication to pregnancy. Barrier methods of contraception rather than the pill are advisable. Recurrent miscarriages occur and these may be associated with antiphospholipid antibodies. Remission and exacerbations can occur during pregnancy with frequent exacerbations of the disease postpartum. The patient's usual treatment should be continued during pregnancy. Hypertension must be controlled. With severe renal disease and high antiphospholipid antibodies, fetal mortality is high (> 25%).

ANTIPHOSPHOLIPID SYNDROME

The antiphospholipid syndrome is associated with autoantibodies which have specificity for negatively charged phospholipids (see p. 534). A small proportion of these patients have SLE. Recurrent arterial and venous thromboses and miscarriages are the hallmark of the syndrome. The paradoxical association between a prothrombotic state and the presence of autoantibodies with in-vitro anticoagulant effects is not fully understood. However, P_2-glycoprotein (P_2GP1) (apolipoprotein H) undergoes a conformational change in the protein, exposing an antigenic epitope which has been identified as the target for both anticardiolipin antibodies and lupus anticoagulant. It is also associated with pathogenic anti-phospholipid antibodies.

Clinical features

Arterial and venous thromboses

Approximately 20% of strokes occurring under the age of 45 years are thought to be due to the antiphospholipid syndrome. Thromboses of different types occur and cause other features of the disease, including the Budd-Chiari syndrome and Addison's disease.

Abortions

Twenty-seven per cent of women who have had more than two spontaneous abortions have the anticardiolipin syndrome. Antiphospholipid antibodies reduce the levels of annexin V, a protein with potent anticoagulant activity found in the placenta and vascular endothelium.

Other features

These include:

- thrombocytopenia
- chorea, migraine and epilepsy
- valvular heart disease
- cutaneous manifestations (e.g. livedo reticularis)
- positive Coombs' test.

The syndrome may also be involved in the development of accelerated atheroma.

Investigations

Anticardiolipin antibodies (detected by ELISA) are diagnostic. Lupus anticoagulant antibodies are found in coagulation assays (p. 534). The ESR is usually normal and antinuclear antibodies are usually negative.

Treatment

Current guidelines recommend aggressive anticoagulation for patients who have suffered thrombosis. High levels of antibody - especially IgG, and particularly if lupus anti-coagulant or anti-(3_2GPl is positive - may warrant treatment even in the absence of thrombosis. Aspirin is most often prescribed, although clopidogel or warfarin is also used in some cases. Heparin and aspirin are given in early pregnancy, because warfarin is toxic to the fetus and because of the adverse effects of high-titre antibodies in pregnancy.

SYSTEMIC SCLEROSIS (SCLERODERMA)

(see p. 1343)

Systemic sclerosis (SSc) is a multisystem disease of unknown cause. It falls within the scleroderma spectrum of diseases but is distinct from the localized scleroderma syndromes that do not involve internal organ disease and are rarely associated with vasospasm (Raynaud's phenomenon). SSc has the highest case-specific mortality of any of the autoimmune rheumatic diseases. SSc occurs world-wide but there may be racial or ethnic differences in clinical features. For example, renal involvement is less frequent in Japanese cases.

The incidence of SSc is 10/million population per year with a 3:1 female to male ratio. The peak incidence is between 30 and 50 years of age. It is rare in children.

Environmental risk factors for scleroderma-like disorders include exposure to vinyl chloride, silica dust, adulterated rapeseed oil and trichlorethylene. Drugs such as bleomycin may also produce a similar picture. Although unusual, familial cases are reported and twin cohorts suggest higher concordance in monozygotic pairs, consistent with genetic determinants of aetiology.

Pathology and pathogenesis

Figure 10.26 shows the pathogenic interaction and mechanisms in systemic sclerosis.

Vascular features

An early lesion is widespread vascular damage involving small arteries, arterioles and capillaries. There is initial

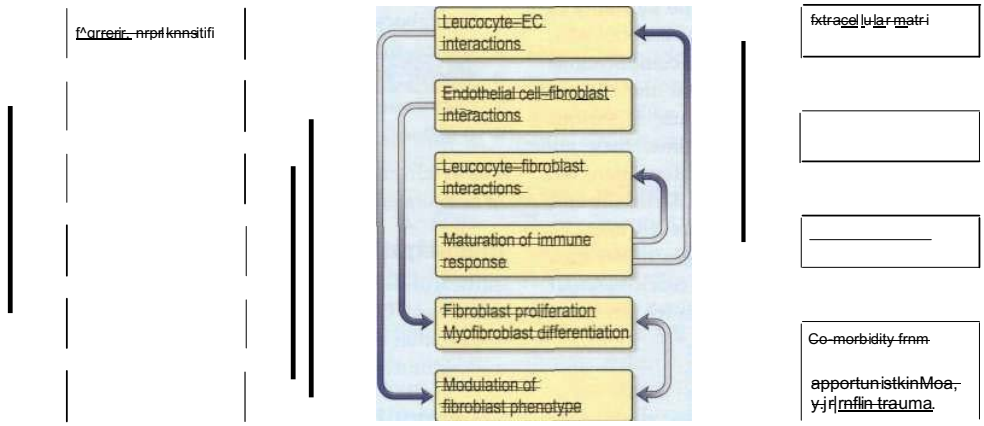

Fig. 10.26 Pathogenic mechanisms in systemic sclerosis. EC, endothelial cell.

endothelial cell damage with release of cytokines including endothelin-1, the latter causing vasoconstriction. There is continued intimal damage with increasing vascular permeability, leading to cellular activation, activation of adhesion molecules (E-selectin, VCAM, ICAM-1) (Table 4.2, p. 198), with migration of cells into the extracellular matrix. Migrating lymphocytes are IL-2-producing cells, expressing surface antigens such as CD3, CD4 and CD5 (Table 4.7, p. 209). All these factors cause release of other mediators (e.g. interleukin-1, -4, -6 and -8, TGF-P and PDGF) (Table 4.5, p. 203) with activation of fibroblasts.

The damage to small blood vessels also produces widespread obliterative arterial lesions and subsequent chronic ischaemia.

Fibrotic features

Fibroblasts synthesize increased quantities of collagen types I and III, as well as fibronectin and glycosaminoglycans, producing fibrosis in the lower dermis of the skin as well as the internal organs.

Humoral immunity

Humoral immunity is also involved because at least 90% of patients have antinuclear antibodies (see below).

Clinical features

Raynaud's phenomenon

Raynaud's phenomenon is seen in almost 100% of cases and can precede the onset of the full-blown disease by many years, especially for limited cutaneous disease (see below).

Limited cutaneous scleroderma (LcSSc) - 70% of cases

This usually starts with Raynaud's phenomenon many years (up to 15) before any skin changes. The skin involvement is limited to the hands, face, feet and forearms. The skin is tight over the fingers and often produces flexion deformities of the fingers. Involvement of the skin of the face produces a characteristic 'beak'-like nose and a small mouth (microstomia). Painful digital ulcers and telangiectasia with dilated nail-fold capillary loops are seen. Digital ischaemia may lead to gangrene. Gastrointestinal tract involvement is common in this group. Pulmonary hypertension develops in 10-15% of this group and pulmonary interstitial disease may occur.

The CREST syndrome (Calcinosis, Raynaud's phenomenon, Esophageal involvement, Sclerodactyly and skin changes in the fingers, Telangiectasia) was the term previously used to describe this syndrome.

Diffuse cutaneous scleroderma (DcSSc) - 30% of cases

Initially oedematous in onset, skin sclerosis rapidly follows. Raynaud's phenomenon usually starts just before or concomitant with the oedema.

Diffuse swelling and stiffness of the fingers is rapidly followed by more extensive sclerosis which can involve most of the body in the severest cases. Later the skin becomes atrophic. Early involvement of other organs occurs with general symptoms of lethargy, anorexia and weight loss.

- Heartburn, reflux or dysphagia due to oesophageal involvement are almost invariable and anal incontinence occurs in many patients. Malabsorption from bacterial overgrowth due to dilatation and atony of the small bowel is not infrequent, and more rarely dilatation and atony of the colon occurs. Pseudo-obstruction is a known complication.
- Renal involvement may be acute or chronic. Acute hypertensive renal crisis used to be the most common cause of death in systemic sclerosis. ACE inhibitors and better care along with dialysis and renal transplantation have changed this.

- Lung disease, both fibrosis and pulmonary hypertension (PHT), contribute significantly to mortality in SSc. PHT can be isolated or secondary to fibrosis, and high plasma levels of endothelin-1 are seen.
- Myocardial fibrosis leads to arrhythmias and conduction defects. Pericarditis is found occasionally.

Sometimes these systemic features occur without skin involvement *(scleroderma sine scleroderma).* Overlap syndromes with additional features of SLE, RA or inflammatory muscle disorder occur.

Investigations

- **Full blood count.** A normochromic, normocytic anaemia may occur and a microangiopathic haemolytic anaemia is seen in some patients with renal disease.
- **Urea and electrolytes.**
- **Autoantibodies:**
  - **(a)** *In LcSSc:* speckled, nucleolar or anticentromere antibodies (ACAs) occur in 70-80% of cases.
  - (b) *In DcSSc:* there are antitopoisomerase-1 antibodies in 30% of cases, and anti-RNA polymerase (I, II and III) antibodies in 20-25%.
  - (c) *Rheumatoid factor* is positive in 30%.
  - (d) *ANA* is positive in 70%.
- **Urine.** Microscopy and, if there is proteinuria, a 24-hour urine collection for protein and creatinine clearance.
- **Imaging:**
  - **(a)** CXR - used to exclude other pathology, changes in cardiac size and established lung disease.
  - (b) Hands - deposits of calcium around fingers (in severe cases, erosion and absorption of the tufts of the distal phalanges - termed acrosteolysis).
  - (c) Barium swallow generally confirms impaired oesophageal motility. Scintigraphy, manometry and upper GI endoscopy are also valuable.
  - (d) High-resolution CT - to demonstrate fibrotic lung involvement. This should be performed prone to exclude dependent fluid changes mimicking very early bibasal fibrosis.
- Other investigations of gastrointestinal tract (e.g. see Fig. 6.4, p. 274), lung, renal and cardiac as appropriate.

Management

Treatment should be organ-based in order to try to control the disease. Currently there is no cure.

- Education, counselling and family support are essential.
- **Regular** exercises and skin lubricants may limit contractures.
- Raynaud's may be improved by hand warmers, oral vasodilators (calcium-channel blockers, ACE inhibitors) and parenteral vasodilators (prostacyclin analogues and calcitonin gene-related peptide). Lumbar sympathectomy can help foot symptoms. Radical microarteriolysis (digital sympathectomy) is indicated in severe digital ischaemia.
- Oesophageal symptoms can almost always be improved by proton-pump inhibitors, and prokinetic drugs are also helpful.
- Symptomatic malabsorption requires nutritional supplements and rotational antibiotics (see p. 304) to treat small intestinal bacterial overgrowth.
- Renal involvement requires intensive control of hypertension. First drug of choice is an ACE inhibitor. Vigilance for hypertensive scleroderma renal crisis (SRC) is critical, especially in early-stage dcSSc with rapidly progressive skin and tendon friction rubs. High-dose corticosteroids (above 10 mg prednisolone daily) may increase the risk of SRC.
- Intermittent or short-term continuous intravenous prostacyclin may be helpful for severe Raynaud's, digital ulceration, critical digital ischaemia.
- Pulmonary hypertension is treated with oral vasodilators, oxygen, warfarin. Advanced cases should receive prostacyclin therapy (inhaled, subcutaneous or intravenous) or the oral endothelin-receptor antagonist bosentan. Right heart failure is treated conventionally and transplantation (heart-lung or single lung) should be considered in eligible cases.
- Pulmonary fibrosis is currently treated with immunosuppression, most often with cyclophosphamide or azathioprine combined with low-dose oral prednisolone.
- No effective anti-fibrotic therapies are yet of proven efficacy.

Prognosis

In limited cutaneous scleroderma the disease is often milder, with much less severe internal organ involvement **and** a 70% 10-year survival. Pulmonary hypertension is a significant later cause of death. Lung fibrosis and severe gut involvement also determine mortality. In diffuse disease, where organ involvement is often severe at an earlier stage, many patients die of pulmonary, cardiac or renal involvement. Overall, pulmonary involvement (vascular or interstitial) accounts for around 50% of scleroderma-related deaths.

Localized forms of scleroderma occur either in patches (morphoea, p. 1343) or linear forms. These are more commonly seen in children and adolescents and do not convert into systemic forms, although ANA may occur in localized scleroderma and very occasionally there is coexistence of localized and systemic forms.

POLYMYOSITIS (PM) AND DERMATOMYOSITIS (DM)

Polymyositis is a rare disorder of unknown cause, in which the clinical picture is dominated by inflammation of striated muscle, causing proximal muscle weakness. When the skin is involved it is called 'dermatomyositis'. These are rare disorders (incidence 2-10/million population per annum) and occur in all races and at all ages. The aetiology is unknown, although viruses (e.g. Coxsackie, rubella, influenza) have been implicated and persons with HLA-B8/DR3 appear to be genetically predisposed.

Clinical features

The clinical subsets are:

- adult polymyositis
- adult dermatomyositis
- adult polymyositis, dermatomyositis with malignancies
- PM/DM in association with other connective tissue diseases
- childhood DM.

Adult polymyositis

Women are affected three times more commonly than men.

The onset can be insidious, over months, but can be acute. General malaise, weight loss and fever can develop during the acute phase.

The major feature of polymyositis is proximal muscle weakness which is progressive. There is wasting of the shoulder and pelvic girdle muscles with weakness. Pain and tenderness are uncommon features. Involvement of pharyngeal, laryngeal and respiratory muscles can lead to dysphagia, dysphonia and respiratory failure. The changes can occur at a frightening speed but are often less rapid. Patients have difficulty squatting, going up stairs, rising from a chair, raising their hands above the head and holding their head up.

Respiratory muscles are affected in severe disease and this compounds the effects of interstitial fibrosis (especially in those with anti-Jo-1 antibodies) and patients may require ventilation. Dysphagia is seen in about 50% owing to oesophageal muscle involvement. Arthralgia is seen in about 25% but is mild and Raynaud's phenomenon occurs in some patients. Antibodies to Jo-1 and other t-RNA synthetases are associated and may predict worse outcome. Hardening and fissuring of skin over the pulp surface of the fingers (mechanic's hands) is typical.

Adult dermatomyositis

This also is more common in women.

Cutaneous features include a heliotrope (purple) discoloration of the eyelids and periorbital oedema. Scaly, purple-red raised vasculitic patches occur over the extensor surfaces of joints and fingers (collodion patches). Ulcerative vasculitis and calcinosis of the subcutaneous tissue occurs in 25% of cases. Muscle weakness is common. Myalgia, polyarthritis and Raynaud's phenomenon occur in this group. In the long term, muscle fibrosis and contractures of joints occur.

Associated with other connective tissue diseases

There is an association with other autoimmune rheumatic diseases (e.g. SLE, RA and systemic sclerosis) with their associated clinical features such as deforming arthritis, malar rash and skin sclerosis.

Association with malignancies

The relative risk of cancer is 2.4 for male and 3.4 for female patients, and a wide variety of cancers have been reported. The onset and clinical picture does not differ from that of typical DM/PM. The associated cancer may not become apparent for 2-3 years, and recurrent or refractory dermatomyositis should prompt a search for occult malignancy.

There is also an association with malignancy (e.g. lung, ovary, breast, stomach), which can predate the onset of myositis. This occurs particularly in males with dermatomyositis.

Childhood dermatomyositis

This most commonly affects children between the ages of 4 and 10 years. The typical rash of dermatomyositis is usually accompanied by muscle weakness. Muscle atrophy, subcutaneous calcification and contractures may be widespread and severe. Ulcerative skin vasculitis is common and recurrent abdominal pain due to vasculitis is also a feature.

Investigations

- **Serum creatine kinase (CK),** aminotransferases and aldolase are usually raised and are useful guides to the muscle damage but may not reflect activity.
- **The ESR** is raised in about 5% of cases.
- **Serum autoantibody studies.** Antinuclear antibody testing is commonly positive in patients with dermato myositis. Rheumatoid factor is present in up to 50% and many myositis-specific antibodies (MSAs) have been recognized and correlate with certain subsets. Antibodies to Jo-1 (antibodies to histidyl tRNA synthase) are predictive of pulmonary fibrosis but are rarely seen in patients with dermatomyositis.
- **Electromyography** (EMG) shows a typical triad of changes with myositis: spontaneous fibrillation poten tials at rest; polyphasic or short-duration potentials on voluntary contraction; and salvos of repetitive potentials on mechanical stimulation of the nerve.
- **MRI** can be used to detect abnormal muscle.
- **Needle muscle biopsy** shows fibre necrosis and regeneration in association with an inflammatory cell infiltrate with lymphocytes around the blood vessels and between muscle fibres. Open biopsy allows more thorough assessment.
- **Screening for malignancy** is usually limited to relatively non-invasive investigation such as CXR mammography, pelvic/abnormal ultrasound, urine microscopy and a search for circulating tumour markers.

Treatment

Bed rest is usually helpful but must be combined with an exercise programme. Prednisolone is the mainstay of treatment; 0.5-1.0 mg/kg bodyweight as initial therapy given for at least 1 month after myositis has become clinically and enzymatically inactive. Tapering of steroids must be slow. Early intervention with steroid-sparing agents such as methotrexate, azathioprine, ciclosporin, cyclophosphamide and mycophenolate mofetil is common. Intravenous immunoglobulin therapy (IVIG) is helpful in some recalcitrant cases.

SJOGREN'S SYNDROME AND KERATOCONJUNCTIVITIS SICCA

The syndrome of dry eyes (keratoconjunctivitis sicca) in the absence of rheumatoid arthritis or any of the autoimmune diseases is known as 'primary Sjogren's syndrome'. There is an association with HLA-B8/DR3. Dryness of the mouth, skin or vagina may also be a problem. Salivary and parotid gland enlargement is seen. Associated systemic features include:

- arthralgia and occasional non-progressive polyarthritis, like that seen in SLE (but much less common)
- Raynaud's phenomenon
- dysphagia and abnormal oesophageal motility as seen in systemic sclerosis (but less common)
- other organ-specific autoimmune disease, including thyroid disease, myasthenia gravis, primary biliary cirrhosis and autoimmune hepatitis
- renal tubular defects (uncommon) causing nephrogenic diabetes insipidus and renal tubular acidosis
- pulmonary diffusion defects and fibrosis
- polyneuropathy, fits and depression
- vasculitis
- increased incidence of non-Hodgkin's B cell lymphoma.

Pathology and investigations

Biopsies of the salivary gland or of the lip show a focal infiltration of lymphocytes and plasma cells.

- **Schirmer tear test.** This is a standard strip of filter paper placed on the inside of the lower eyelid; wetting of < 10 mm in 5 minutes indicates defective tear production.
- **Rose Bengal staining** of the eyes shows punctate or filamentary keratitis.
- **Laboratory abnormalities.** These include raised immunoglobulin levels, circulating immune complexes and many autoantibodies. Rheumatoid factor is usually positive. Antinuclear antibodies are found in 60-70% of cases and antimitochondrial antibodies in 10%. Anti-Ro (SSA) antibodies are found in 70%, compared with 10% of cases of RA and secondary Sjogren's syndrome. This antibody is of particular interest because it can cross the placenta and cause congenital heart block.

Treatment is with artificial tears and saliva-replacement solutions.

'OVERLAP'SYNDROME AND UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE

Patients may present with varied clinical and serologic features not within the accepted boundaries of a single disease entity but sufficiently differentiated to fit more than one diagnosis. Those that have unequivocal evidence for a connective tissue disease but demonstrate features that cross classification criteria for two or more conditions such as SLE, PM, RA or SSc are described as overlap syndromes. Many cases that were previously labelled mixed connective tissue disease (MCTD) are probably better termed overlap connective tissue disease. Some patients demonstrate clinical features suggesting a connective tissue disease such as Raynaud's phenomenon, arthralgia, rash or serological abnormalities including positive ANA. However, they may fail to fulfil classification criteria for a connective tissue disease. These individuals may be operationally labelled as having undifferentiated connective tissue disorder (UCTD). They should be followed up as many develop defined diseases over time.

SYSTEMIC INFLAMMATORY VASCULITIS

Vasculitis is an inflammation of the vessel wall. The classification remains controversial, but is usually based on the type of artery affected (Fig. 10.27 and Table 10.18). There is some overlap and some cases are difficult to classify, partly because in many conditions there is always some vasculitis histologically. Table 10.19 shows other infective and non-infective conditions in which a vasculitis is seen.

The disorders are characterized by inflammation in or through a blood vessel wall, with fibrinoid necrosis with or without granuloma formation. Histologically there are several different patterns: necrotizing vasculitis; giant cell arteritis; and granulomatous angiitis. The clinical

Table 10.18 **Types of systemic vasculitis**

Non-infective

Infective	e.g. Subacute infective endocarditis
Non-infective	Vasculitis with rheumatoid arthritis
	Systemic lupus erythematosus
	Scleroderma
	Polymyositis/dermatomyositis Drug-induced Behc-et's disease
	Goodpasture's syndrome
	Hypocomplementaemia Serum sickness Paraneoplastic syndromes
	Inflammatory bowel disease

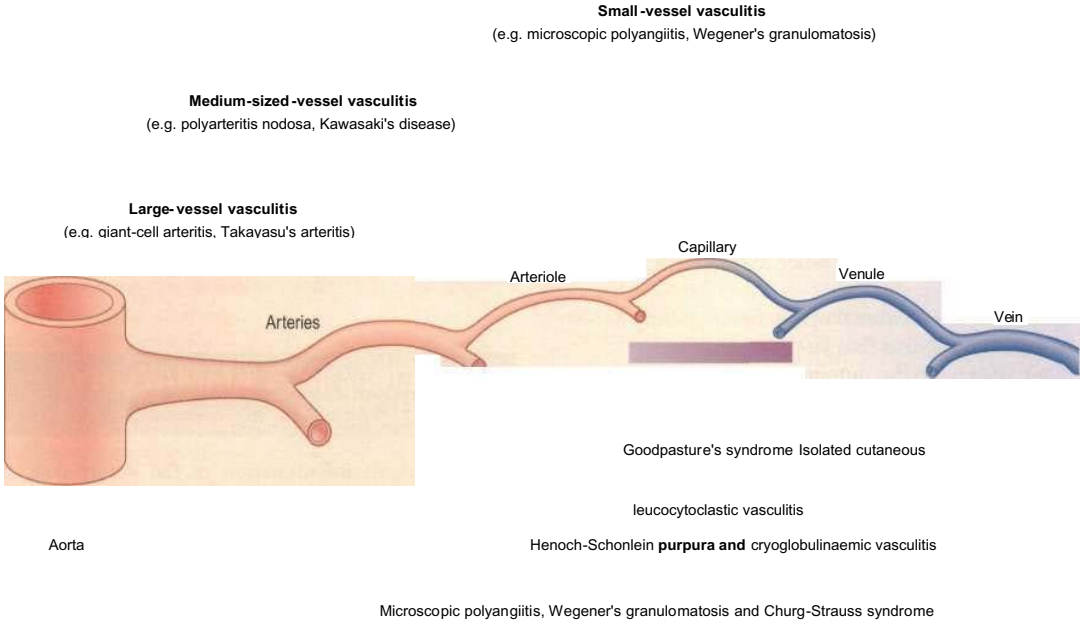

Fig. 10.27 **Sites of vascular involvement by vasculitides.** From Jeanette JC and Falk RJ (1997) *New England Journal of Medicine* **337:** 1512-1523. Copyright © 1997 Massachusetts Medical Society. All rights reserved.

manifestations are due to ischaemic necrosis and vary with the size and type of blood vessel affected. The vasculitides are systemic diseases which affect the skin and musculoskeletal, renal and gastrointestinal systems. Skin lesions are palpable and commonly urticarial. Many types of systemic non-autoimmune vasculitis are associated with antineutrophilic cytoplasmic antibody (ANCA, see p. 633).

- *Large vessel* refers to the aorta and its major tributaries.
- *Medium vessel* refers to medium and small-sized arteries and arterioles.
- *Small vessel* refers to small arteries (ANCA-associated disease only), arterioles, venules and capillaries.

LARGE VESSEL VASCULITIS

Polymyalgia rheumatica (PMR) and giant cell (temporal) arteritis are systemic illnesses of the elderly. Both are associated with the finding of a giant cell arteritis on temporal artery biopsy.

Polymyalgia rheumatica (PMR)

PMR causes a sudden onset of severe pain and stiffness of the shoulders and neck, and of the hips and lumbar spine; a limb girdle pattern. These symptoms are worse in the morning, lasting from 30 minutes to several hours. The clinical history is usually diagnostic and the patient is always over 50 years.

Patients develop systemic features of tiredness, fever, weight loss, depression and occasionally nocturnal sweats if it is not diagnosed and treated early. A differential diagnosis is shown in Box 10.12.

Box 10.12 **Symptom patterns in some muscle disorders**

Polymyositis - proximal muscle ache and weakness
Polymyalgia rheumatica - proximal morning stiffness and pain **Myopathy** - weakness, but no pain or stiffness

Investigation of ***PMR***

- **A raised ESR and/or CRP** is a hallmark of this condition. It is rare to see PMR without an acute-phase response. If it is absent, the diagnosis should be questioned and the tests repeated a few weeks later before treatment is started.
- **Serum alkaline phosphatase and 7-glutamyltranspeptidase** may be raised as markers of the acute phase.
- **Anaemia** (mild normochromic, normocytic) is often present.
- **Temporal artery biopsy** shows giant cell arteritis in 10-30% of cases, but is not usually performed.

Giant cell arteritis (GCA)

GCA is inflammatory granulomatous arteiitis of large arteries which occurs in association with PMR The patient may have current PMR, a history of recent PMR, or be on treatment for PMR. It is extremely rare under 50 years of age. It may present with the symptoms of GCA

with severe headaches, tenderness of the scalp (combing the hair may be painful) or of the temple, claudication of the jaw when eating, tenderness and swelling of one or more temporal or occipital arteries, and can cause sudden painless temporary or permanent visual loss (see p. 1249). Systemic manifestations of severe malaise, tiredness and fever occur.

Investigation of GCA

m **Normochromic, normocytic anaemia.**

- **ESR** is usually raised (in the region of 50-120 mm/h) and the CRP very high.
- **Liver biochemistry.** Abnormalities occur, as in PMR. The albumin may be low.
- **A temporal artery biopsy** from the affected side is the definitive diagnostic test. This should be taken before, or within 7 days of starting, high doses of corticosteroids. Start the drug first if the patient is very ill, in severe pain or has experienced visual loss or stroke. The lesions are patchy and the whole length of the biopsy (> 1 cm long) must be examined.

The histological features of GCA are:

- intimal hypertrophy
- inflammation of the intima and sub-intima
- breaking up of the internal elastic lamina
- giant cells, lymphocytes and plasma cells in the internal elastic lamina.

*Treatment of **PMR** or **GCA***

Corticosteroids produce a dramatic reduction of symptoms within 24-48 hours of starting treatment, provided the dose is adequate. This should reduce the risk of patients with PMR developing GCA. NSAIDs are less effective and should not be used.

In GCA, corticosteroids are obligatory because they significantly reduce the risk of irreversible visual loss and other focal ischaemic lesions, but much higher doses are needed. Both diseases settle after 12-36 months of treatment in about 75% of patients, but the remaining 25% continue to require low doses of corticosteroids for years. Starting doses of prednisolone are:

- **PMR:** 10-15 mg prednisolone as a single dose in the morning
- **GCA:** 60-100 mg prednisolone, usually in divided doses.

With GCA it is best to start at the higher dose, as the response is more dramatic **and** diagnostic. The dose should then be reduced gradually in weekly or monthly steps. While the dose is above 20 mg, the step reductions are 5 mg, reducing the evening doses first. Between 20 mg and 10 mg the reduction can be in 2.5 mg steps, but below 10 mg the rate should be slower and the steps each of 1 mg. Steroid-sparing immunosuppressive agents are used in refractory cases.

Dose reduction (and increases when necessary) are titrated against the response or recurrence of symptoms and a fall or rise in the ESR or CRP.

Calcium and vitamin D supplements and bisphosphonates are necessary to prevent osteoporosis whilst steroids are being used.

Takayasu's arteritis

This is a granulomatous inflammation of the aorta and its major branches and is discussed on page 869.

MEDIUM-SIZED VESSEL VASCULITIS

Polyarteritis nodosa **(PAN)**

Classical PAN **is** a rare condition which, unlike other vasculitic diseases, usually occurs in middle-aged men. It is accompanied by severe systemic manifestations, and its occasional association with hepatitis B antigenaemia suggests a vasculitis secondary to the deposition of immune complexes. Pathologically, there is fibrinoid necrosis of vessel walls with microaneurysm formation, thrombosis and infarction.

Clinical features

These include fever, malaise, weight loss and myalgia. These initial symptoms are followed by dramatic acute features that are due to organ infarction.

- *Neurological* - mononeuritis multiplex is due to arteritis of the vasa nervorum.
- *Abdominal* - pain due to arterial involvement of the abdominal viscera, mimicking acute cholecystitis, pancreatitis or appendicitis. Gastrointestinal haemorrhage occurs because of mucosal ulceration.
- *Renal* - presents with haematuria and proteinuria. Hypertension and acute/chronic renal failure occur.
- *Cardiac* - coronary arteritis causes myocardial infarction and heart failure. Pericarditis may occur.
- *Skin* - subcutaneous haemorrhage and gangrene occur. A persistent livedo reticularis is seen in chronic cases. Cutaneous and subcutaneous palpable nodules occur, but are uncommon.
- *Lung* - involvement is rare.

Investigations and treatment

- **Blood count.** Anaemia, leucocytosis and a raised ESR occur.
- **Biopsy** material from an affected organ shows features listed above.
- **Angiography.** Demonstration of microaneurysms in hepatic, intestinal or renal vessels if necessary.
- **Other investigations** as appropriate (e.g. ECG and abdominal ultrasound), depending on the clinical problem. ANCA is positive only rarely in classic PAN.

Treatment is **with corticosteroids,** usually **in** combination with immunosuppressive drugs such as azathioprine.

Kawasaki's disease

This is an acute systemic vasculitis involving medium-

sized vessels, affecting mainly children under 5 years of age. It is very frequent in Japan, and an infective trigger is suspected. It occurs world-wide and is also seen in adults.

Clinical features and treatment

The clinical features are:

- fever lasting 5 days or more
- bilateral conjunctival congestion 2-4 days after onset
- dryness and redness of the lips and oral cavity 3 days after onset
- acute cervical lymphadenopathy accompanying the fever
- polymorphic rash involving any part of the body
- redness and oedema of the palms and soles 2-5 days after onset.

Five of these six features should be present to make the diagnosis, or four of six if coronary aneurysms can be seen on two-dimensional echocardiography or angiography. Cardiovascular changes in the acute stage include pancarditis and coronary arteritis leading to aneurysms or dilatation. Other features include diarrhoea, albuminuria, aseptic meningitis and arthralgia and, in most, there is a leucocytosis, thrombocytosis and a raised CRP. Anti-endothelial cell autoantibodies are often detectable.

Treatment is with high-dose intravenous immunoglobulin, which prevents the coronary artery disease, followed after the acute phase by aspirin 200-300 mg daily.

SMALL VESSEL VASCULITIS

This can be separated into those that are positive or negative for antineutrophilic cytoplasmic antibody (ANCA) (see p. 633).

The clinical features and diagnosis of small vessel vasculitis are shown in Table 10.20.

ANCA-positive vasculitis

- Wegener's granulomatosis - see page 938.
- Churg-Strauss granulomatosis - see page 938.
- Microscopic polyangiitis - see page 938.

ANCA-negative small-vessel vasculitis

This includes Henoch-Schonlein purpura - see pages 587 and 629.

Cutaneous leucocytoclastic vasculitis

This is the characteristic acute purpuric lesion which histologically involves the dermal post-capillary venules. This lesion affects only the skin and should be differentiated from similar lesions produced in systemic vasculitis. The purpura may be accompanied by arthralgia and glomerulonephritis. Hepatitis C infection is common and may be an aetiological agent. The condition can also be caused by drugs such as sulphonamides and penicillin.

Treatment of small cell vasculitis

Small vessel vasculitis may be self-limiting and requires little treatment. Aggressive therapy with corticosteroids and immunosuppressive agents is required for severe disease.

BEHQET'S DISEASE

Behget's disease is an inflammatory disorder of unknown cause. There is a striking geographical distribution, it being most common in Turkey, Iran and Japan. The prevalence per 100 000 is 10-15 in Japan and 80-300 in

Table 10.20 **Diagnosis and clinical features of small vessel vasculitis**

Modified from Jeanette JC, Falk RJ (1997) Small vessel vasculitis. *New England Journal of Medicine* 337: 1512-1523

Turkey. There is a link to the HLA-B51 allele (a split antigen of B5), with a relative risk of 5-10; this association is not seen in patients in the USA and Europe.

Clinical features

The cardinal clinical feature is recurrent oral ulceration. The international criteria for diagnosis require oral ulceration and any two of the following: genital ulcers, defined eye lesions, defined skin lesions, or a positive skin pathergy test (see below). Oral ulcers can be aphthous or herpetiform. The eye lesions include an anterior or posterior uveitis or retinal vascular lesions. Cutaneous lesions consist of erythema nodosum, pseudofolliculitis and papulopustular lesions.

Other manifestations include a self-limiting peripheral mon- or oligoarthritis affecting knees, ankles, wrists and elbows; gastrointestinal symptoms of diarrhoea, abdominal pain and anorexia; pulmonary and renal lesions; a brainstem syndrome, organic confusional states and a meningoencephalitis. All the common manifestations are self-limiting except for the ocular attacks. Repeated attacks of uveitis can cause blindness.

The pathergy reaction is highly specific to Behcet's disease. Skin injury, by a needle prick for example, leads to papule or pustule formation within 24-48 hours. An intradermal injection of urate crystals is also used.

Treatment

Corticosteroids, immunosuppressant agents and ciclosporin-A are used for chronic uveitis and the rare neurological complications. Colchicine helps erythema nodosum and joint pain. Thalidomide may be useful in some cases although side-effects of drowsiness and peripheral neuropathy are common. It should not be used in pregnant women because of phocomelia (limb abnormalities).

DIFFERENTIAL DIAGNOSIS OF RHEUMATIC COMPLAINTS IN THE ELDERLY (Fig.10.28)

Musculoskeletal problems

These are common at all ages. In the elderly, pain arises from a combination of age-related changes and, injury.

Back and neck pain (see pp. 540 and 536) These are commonly associated with spondylosis on X-ray. Complications include spinal stenosis or nerve root claudication. Look for locally tender areas, which might be injected. Mechanical back pain may be worse in the morning, especially when spondylosis is severe or there is marked deformity; there is a normal ESR and CRP, which distinguishes this from polymyalgia rheumatica. Rarely, elderly women present with previously undiagnosed ankylosing spondylitis.

Osteoporotic fractures

Osteoporotic fractures of the spine cause acute pain or deformity and subsequent postural back pain. The acute pain may warrant a period of bed rest (see p. 596). The management of such problems in the elderly is the same as for younger people but a response to treatment is less predictable. Advice about posture, exercise, general fitness and about medication to reduce the risk of further fractures is necessary but must be tempered by the patient's general health.

Symptomatic osteoarthritis (see p. 552) ; This increases with increasing age and is uncommon below the age of 50 years. It is necessary to look for possible reversible causes of pain and disability, such as periarticular lesions or a joint effusion. Caution about drug treatment is necessary because of the increased risk of side-effects in older patients. Joint replacement surgery

Rheumatoid arthritis

Fig. 10.28 **The differential diagnosis of arthritis in the elderly.**

has transformed the outlook for many older people with OA by offering pain control and increased mobility and independence.

Rheumatoid arthritis (see p. **555)**

RA may present in the elderly as a dramatic onset of symmetrical polyarthritis. This has a reasonable prognosis and responds well to low doses of prednisolone and other drug therapy. RA in the older patient may mimic polymyalgia rheumatica; the synovitis becomes apparent as the corticosteroid dose is reduced. Treat with DMARDs as for RA in order to reduce the corticosteroid dose.

Polymyalgia rheumatica and giant cell arteritis

(see p. 582)

These must be recognized and treated. Failure to respond to adequate doses of prednisolone should trigger a search for an alternative disease, such as RA, vasculitis, infection or malignancy.

Chondrocalcinosis

This increases with increasing age and is seen on over 40% of knee X-rays in the over-80s. It may produce a variety of arthritic conditions (see p. 553).

Pseudogout (see p. **571)**

This causes acute monarthritis of the wrist or knee in older people. It responds well to aspiration and intra-articular corticosteroids or oral NSAIDs.

Gout

Gout causes acute monarthritis in the elderly but may also present as a polyarticular inflammatory arthritis, especially in elderly women on long-term diuretic treatment, or as tophaceous gout (p. 570).

Septic arthritis (see p. **571)**

Septic arthritis in the elderly and frail produces articular symptoms, and signs that may be muted. The patient usually has septicaemia and the best way to ensure its recognition is to retain it in the differential diagnosis of all musculoskeletal presentations in unwell, elderly people.

Treatment

In all cases the management is similar to that described in the main part of the chapter, but special care should be taken to reduce doses of medication where possible and to think about possible adverse drug effects or interactions.

ARTHRITIS IN CHILDREN

Joint and limb pains are common in children but arthritis is fortunately rare. Babies and young children may present with immobility of a joint or a limp, but the diagnosis can be extremely difficult. Figure 10.29 summarizes the differential diagnosis.

For chronic conditions, the child and family often need a great deal of support from physiotherapists, occupational therapists, psychologists, teachers, social workers and orthopaedic surgeons. These are best obtained in specialist paediatric centres.

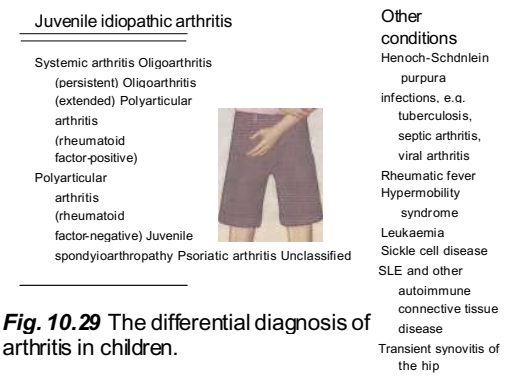

Fig. 10.29 The differential diagnosis of arthritis in children.

JUVENILE IDIOPATHIC ARTHRITIS (JIA)

Systemic arthritis

Still's disease (which accounts for 10% of cases of JIA) affects boys and girls equally up to 5 years of age; then girls are more commonly affected. Adult-onset Still's disease is extremely rare.

Clinical features include a high, swinging, early-evening pyrexia, an evanescent pink maculopapular rash with arthralgia and arthritis, myalgia and generalized lymphadenopathy. Hepatosplenomegaly and pericarditis and pleurisy occur. The differential diagnoses include malignancy, in particular leukaemia and neuroblastoma, and infection. Laboratory tests show a high ESR and CRP, neutrophilia and thrombocytosis. Autoantibodies are negative.

Oligoarthritis (persistent)

This is the most common form of JIA (50-60%) but is still a relatively uncommon condition. It affects, by definition, four or fewer joints - especially knees, ankles and wrists - often in an asymmetrical pattern. It affects mainly girls, with a peak age of 3 years. The prognosis is generally good with most going into remission. Uveitis (often with a positive ANA) occurs and requires regular screening by a 3-monthly slit-lamp examination. Blindness can occur if it is untreated. Prognosis is generally good, with remission occurring eventually in most patients.

Oligoarthritis (extended)

In approximately 25% of patients, oligoarthritis extends to affect many more joints after around 6 months. This form of arthritis can be very destructive.

Polyarticular JIA

The rheumatoid factor-positive form occurs in older girls, usually over 8 years. It is a systemic disease; the arthritis

commonly involves the small joints of the hands, wrists, ankles and feet initially, and eventually larger joints. It can be a very destructive arthritis and needs aggressive treatment.

The rheumatoid factor-negative form is commoner. It usually affects girls under 12 years but can occur at any age. They may be ANA positive, with a risk of chronic uveitis. The arthritis is often asymmetrical, with a distribution similar to that seen in the RF-positive form. It may also affect the cervical spine, temporomandibular joints and elbows.

Enthesitis-related arthritis (juvenile spondyloarthropathy)

This affects teenage and younger boys mainly, producing an asymmetrical arthritis of lower-limb joints and enthesitis. It is associated with HLA-B27 and a risk of acute anterior uveitis. It is the childhood equivalent of adult ankylosing spondylitis but spinal involvement is rare in childhood. Approximately one in three develops spinal disease in adulthood.

Psoriatic arthritis

This may occur in children and is similar in pattern to the adult form. The arthritis may be very destructive. Psoriasis may develop long after the arthritis but is found commonly in a first-degree relative.

Treatment of JIA

JIA should always be referred to a specialist paediatric rheumatology unit with facilities to assess and design treatment plans which aim to prevent long-term disability. These units also need facilities for rehabilitation, education and surgical intervention. NSAIDs reduce pain and stiffness but disease-modifying agents such as methotrexate are used to control moderate and severe disease. Corticosteroids are often required in systemic disease: intravenous pulsed methylprednisolone is used, followed by methotrexate (10-15 mg/m^2) weekly to control disease and prevent growth suppression. Anti-TNF agents (see Table 10.15) are used if methotrexate fails, and are highly effective in all types except systemic-onset disease where the results are variable. Sulfasalazine is used only in enthesitis-related JIA. Aspirin may be a cause of Reye's syndrome and should not be used under the age of 12 years.

Prognosis

Up to 50% of children develop long-term disability; 25% may continue to have active arthritis into adult years. Death may be due to infection or systemic disease with pericarditis or amyloidosis.

OTHER TYPES

Henoch-Schonlein purpura (see also p. 629)

This is the commonest systemic vasculitis seen in children. IgA immune complexes deposit in the small vessels. It often occurs after upper respiratory tract infections. Other manifestations include lower limb purpura, a transient non-migratory polyarthritis, and abdominal pain. Fifty per cent of these patients will have haematuria and proteinuria, due to a glomerulonephritis; treatment of this is discussed on page 629. The prognosis is excellent, although 1% develop chronic renal damage.

Rheumatic fever

Rheumatic fever still occurs occasionally in developed countries but is more common in developing countries. It is described on page 76.

The arthritis affects large joints and migrates between joints, each being affected for a few days at a time. This is unlike Still's disease, where arthritis is usually much more persistent in each affected joint. The fever is persistent but rarely as high as in Still's disease (see above) and the temperature often remains above normal. A child may not volunteer a history of sore throat and the carditis may be silent. Isolated arthritis is the presenting symptom in 14r-42%. The disease is easily missed if not included in the differential diagnosis of acute childhood arthritis.

Treatment is described on page *77*.

Hypermobility syndrome

Five to ten per cent of children are hypermobile. A proportion of them will develop various musculoskeletal complaints in early childhood, such as late walking, flat feet, or nocturnal leg pains, possibly due to hypermobile ankles and knees suffering recurrent sprains and strains after exercise. Joint effusions, subluxation, dislocation and ligamentous injuries may occur throughout childhood. Low back pain may develop in affected adolescents. There may be some risk of the early development of osteoarthritis in adulthood. More severe hypermobility is also seen in Ehlers-Danlos and Marfan's syndromes (see pp. 602 and 1356).

Treatment is with exercise directed at improving the strength of muscles that cross affected joints, as well as overall fitness and endurance. It may be necessary to reduce or change sporting and other activities.

Miscellaneous conditions

Some children develop *idiopathic musculoskeletal pain* that can become chronic. Management of these children requires exclusion of the causes shown in Figure 10.29, but without performing unnecessary laboratory investigations. *Nocturnal musculoskeletal pains* are episodic and may be associated with hypermobility. They may be called 'growing pains'. They often last 15-30 minutes and awaken the child from sleep, and may require physiotherapy and analgesics, together with advice and support to the parents.

Low back pain in children may reflect psychosocial problems at home or school as much as any obvious musculoskeletal pathology. ▪■ ■

Osteochondritis can affect the ossification centre of the ends of bones. A typical condition is *Osgood-Schlatter disease,* which is characterized by localized pain and swelling over the tibial tubercle or at the patellar tendon insertion. It is usually seen in athletic teenagers and responds to local treatment and changes of sporting activities. *Sever's disease* is an osteochondritis of the insertion of the Achilles tendon into the calcaneum.

Perthes' disease is an idiopathic, possibly avascular, necrosis of the proximal femoral epiphysis, of unknown aetiology. It presents as a painless limp, usually in boys aged 3-12 years, and is occasionally bilateral. If severe it may require surgical correction.

Transient synovitis of the hip (irritable hip) causes painful limitation of movement, usually of one hip, after an upper respiratory infection in young children (usually boys). Symptoms usually resolve within a few weeks (2-3% develop Perthes' disease) but other more serious causes of hip pain should be excluded. Treatment is with rest and analgesia until the pain resolves.

Woo R Wedderburn LR (1998) Juvenile chronic arthritis. *Lancet* **351:** 969-973.

RHEUMATOLOGICAL PROBLEMS SEEN IN OTHER DISEASES

Gastrointestinal and liver disease

- *Enteropathic synovitis* - see page 568.
- *Autoimmune hepatitis* (see p. 373) may be accompanied by an arthralgia similar to that seen in systemic lupus erythematosus. Joint pain occurs in a bilateral, symmetrical distribution, with the small joints of the hands being prominently affected. Joints usually look normal but sometimes there is a slight soft-tissue swelling. These patients often have positive tests for antinuclear antibodies.
- *Primary biliary cirrhosis* patients occasionally have a symmetrical arthropathy.
- *Hereditary haemochromatosis* is associated with arthritis in 50% of cases; this is often the first sign of the disease and chondrocalcinosis is common.
- *Whipple's disease* (see p. 305) is accompanied by fever and arthralgia.

Malignant disease

It is not uncommon for malignant diseases to present with musculoskeletal symptoms. Bone pain may be due to multiple myeloma, lymphoma, a primary tumour of bone or secondary deposits. The pain is typically unremitting, worse at night and there are other clinical clues such as weight loss or ill-health. Secondary gout „ occurs in conditions such as chronic myeloid leukaemia.

Table 10.21 **Malignant neoplasms of bone**

Metastases (osteolytic)
Bronchus
Breast
Prostate (often osteosclerotic as well)
Thyroid
Kidney
Multiple myeloma
Primary bone tumours (rare; seen in the young) e.g.
Osteosarcomas
Fibrosarcomas
Chondromas
Ewing's tumour

Neoplastic disease of bone

Malignant tumours of bone are shown in Table 10.21. The most common tumours are metastases from the bronchus, breast and prostate. Metastases from kidney and thyroid are less common. Primary bone tumours are rare and usually seen only in children and young adults.

Symptoms are usually related to the anatomical position of the tumour, with local bone pain. Systemic symptoms (e.g. malaise and pyrexia) and aches and pains occur and are occasionally related to hypercalcaemia (see p. 1092). The diagnosis of metastases can often be made from the history and examination, particularly if the primary tumour has already been diagnosed. Symptoms from bony metastases may, however, be the first presenting feature.

Investigations

Skeletal isotope scans show bony metastases as 'hot' areas before radiological changes occur.

- **X-rays** may show metastases as osteolytic areas with bony destruction. Osteosclerotic metastases are characteristic of prostatic carcinoma.
- **Serum alkaline phosphatase** (from bone) is usually raised.
- **Hypercalcaemia** is seen in 10-20% of patients with malignancies. It is associated chiefly with metastases, but can also result from ectopic parathormone or parathyroid hormone-related protein secretion.
- **Prostate-specific antigen** (PSA) and serum acid phosphate are raised in the presence of prostatic metastases.

Treatment

Treatment is usually with analgesics and anti-inflammatory drugs. Local radiotherapy to bone metastases relieves pain and reduces the risk of pathological fracture. Some tumours respond to chemotherapy; others are hormone-dependent and respond to hormonal therapy. Occasionally pathological fractures require internal fixation.

Hypertrophic pulmonary osteoarthropathy

Hypertrophic osteoarthropathy is most often associated with carcinoma of the bronchus. It is a non-metastatic

complication and may be the presenting feature of the disease. It occurs only rarely with other conditions that also cause clubbing. It is seen most often in middle-aged men, who present with pain and swelling of the wrists and ankles. Other joints are involved occasionally.

The diagnosis is made on the presence of clubbing of the fingers, which is usually gross, and periosteal new bone formation along the shafts of the distal ends of the radius, ulna, tibia and fibula on X-ray. A chest X-ray usually shows the malignancy.

Treatment should be directed at the underlying carcinoma; if this can be removed, the arthropathy disappears. NSAIDs relieve the symptoms.

Paraneoplastic polyarthritis

This is seen with carcinoma of the breast in women and of the lung in men, and also with renal cell carcinoma. The neoplasm may be occult at onset and the diagnosis is then difficult to make.

Skin disease

Psoriatic arthritis

This is discussed on page 566.

Erythema nodosum (p. 1341)

This is accompanied by arthritis in over 50% of cases. The knees and ankles are particularly affected, being swollen, red and tender. The arthritis subsides, along with the skin lesions, within a few months. Treatment is with NSAIDs or occasionally steroids.

Neurological disease

Neuropathic joints (Charcot's joints) are joints damaged by trauma as a result of the loss of the protective pain sensation. They were first described by Charcot in relation to tabes dorsalis. They are also seen in syringomyelia, diabetes mellitus and leprosy. The site of the neuropathic joint depends upon the localization of the pain loss:

- in tabes dorsalis, the knees and ankles are most often affected
- in diabetes mellitus, the joints of the tarsus are involved
- in syringomyelia, the shoulder is involved.

Neuropathic joints are not painful, although there may be painful episodes associated with crystal deposition. Presentation is usually with swelling and instability. Eventually severe deformities develop.

The characteristic finding is a swollen joint with abnormal but painless movement. This is associated with neurological findings that depend upon the underlying disease (e.g. dissociated sensory loss in syringomyelia or polyneuropathy in diabetes). X-ray changes are characteristic, with gross joint disorganization and bony distortion.

Treatment is symptomatic. Surgery may be required in advanced cases.

Blood disease

Arthritis due to haemarthrosis is a common presenting feature of *haemophilia* (see p. 472). Attacks begin in early childhood in most cases and are recurrent. The knee is the most commonly affected joint but the elbows and ankles are sometimes involved. The arthritis can lead to bone destruction and disorganization of joints. Apart from replacement of factor VIII, affected joints require initial immobilization followed by physiotherapy to restore movement and measures to prevent and correct deformities.

Sickle cell crises (p. 443) are often accompanied by joint pain that particularly affects the hands and feet in a bilateral, symmetrical distribution. Affected joints usually look normal but are occasionally swollen. This condition may also be complicated by avascular necrosis (see p. 544) and by osteomyelitis.

Arthritis can also occur in *acute leukaemia;* it may be the presenting feature in childhood. The knee is particularly affected and is very painful, warm and swollen. Treatment is directed at the underlying leukaemia. Arthritis may also occur in *chronic leukaemia,* with leukaemic deposits in and around the joints.

Individuals with *thalassaemia major* (see p. 441) are living longer and are presenting with back pain due to premature disc degeneration, secondary spondylosis and crush fractures due to osteoporosis. There is marked discal calcification.

Endocrine and metabolic disorders

Hypothyroid patients may complain of pain and stiffness of proximal muscles, resembling polymyalgia rheumatica. They may also have carpal tunnel syndrome. Less often, there is an arthritis accompanied by joint effusions, particularly in the knees, wrist and small joints of the hands and feet. These problems respond rapidly to thyroxine.

Hyperparathyroidism may be complicated by chondrocalcinosis and acute pseudogout.

In *acromegaly,* arthralgia occurs in about 50% of patients. It particularly affects the small joints of the hands and knees. There may be carpal tunnel syndrome.

In *Cushing's disease,* back pain is common.

Joint disorders related to diabetes mellitus are described on page 1131.

Familial hypercholesterolaemia is associated with oligo- or polyarthritis usually with tendon xanthomata. Arthritis also occurs in combined hyperlipidaemia.

MISCELLANEOUS ARTHROPATHIES

Familial Mediterranean fever (FMF)

FMF is inherited as an autosomal recessive condition and occurs in certain ethnic groups, particularly Arabs, Turks, Armenians and Sephardic Jews. The gene, called *MEFV,* has been localized to chromosome 16. It encodes for pyrin

or marenostrin, which activate the biosynthesis of a chemotactic-factor inactivator in neutrophils. Failure to produce this leads to FMF attacks.

These are characterized by recurrent attacks of fever, arthritis and serositis. Abdominal or chest pain due to peritonitis or pleurisy occurs. The arthritis is usually monarticular and attacks last up to 1 week. The condition may be mistaken for palindromic rheumatism, but such attacks are not usually accompanied by fever.

The diagnosis can be made by PCR, if available, but usually it is based on the clinical picture and exclusion of other conditions.

Treatment regularly with colchicine 1000-1500 |ig daily can usually prevent the attacks. In general the disorder is benign but in 25% of cases renal amyloidosis develops.

Sarcoidosis (see also p. 935)

The most common type of arthritis is that associated with erythema nodosum, which occurs in 20% of cases of sarcoidosis at or soon after the onset of the disease. The most useful diagnostic test is a chest X-ray, which shows hilar lymphadenopathy in 80% of cases.

Other patterns of arthritis occur later in the disease. These include a transient rheumatoid-like polyarthritis and an acute monarthritis that can be mistaken for gout.

Treatment is with NSAIDs, but if these fail to control the symptoms, corticosteroids are usually very effective.

Osteochondromatosis

In this condition, foci of cartilage form within the synovial membrane. These foci become calcified and then ossified (osteochondromas). They may give rise to loose bodies within the joint. The condition occurs in a single joint of a young adult and X-rays are usually diagnostic.

Treatment involves removal of loose bodies and synovectomy.

Pigmented villonodular synovitis

This is characterized by exuberant synovial proliferation that occurs either in joints or in tendon sheaths. The main manifestation in joints is recurrent haemarthrosis. It may produce progressive local bone destruction but a malignant form is seen occasionally.

Treatment is synovectomy or radiotherapy. In tendon sheaths, the condition gives rise to a nodular mass that requires excision.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory condition of cartilage. It occurs equally in males and females, usually the elderly. Tenderness, inflammation and eventual destruction of cartilage occur, mainly in the ear, nose, larynx or trachea. A seronegative polyarthritis occurs, as well as episcleritis and evidence of a vasculitis (e.g. glomerulonephritis). The diagnosis is clinical with laboratory evidence of acute inflammation.

Treatment involves corticosteroids and immunosuppressive agents.

DISEASES OF BONE

Bone is a specialized connective tissue, serving three major functions:

- *mechanical* - providing structure and muscular attachment for movement
- *metabolic* - as a reserve of calcium and phosphate
- *protective* - enclosing bone marrow and vital organs.

STRUCTURE AND PHYSIOLOGY

Long bones (e.g. femur, tibia, humerus) and flat bones (e.g. skull, scapula, mandible) have different embryological templates, with cortical and trabecular bone in varying proportions (Fig. 10.30).

- *Cortical (compact or lamellar) bone* forms the shaft (diaphysis) of long bones and the outer shell of flat bones. It has mainly mechanical and protective functions.
  Trabecular (cancellous) bone is found at the end of long bones (epiphysis) and inside the cortex of flat bones, consisting of a network of interconnecting trabecular plates and rods. It is the major site of bone remodelling and mineral homeostasis.
- *Woven bone* lacks this organized structure and is characterized by random orientation of collagen fibres. It is formed in the first few years of life, in fracture repair, and in high-turnover bone diseases, e.g. Paget's disease.

Bone comprises cells and a matrix of organic (mainly protein) and inorganic (mineral) elements.

Matrix components

Type I collagen is the main component of bone matrix, forming parallel lamellae in a highly organized structure. In cortical bone, concentric lamellae form around blood vessels in Haversian canals, which communicate via transverse (Volkmann's) canals. Non-collagenous proteins include osteocalcin, osteopontin and fibronectin. Bone mineral consists mainly of calcium hydroxyapatite, which gives bone its resistance to compressive forces.

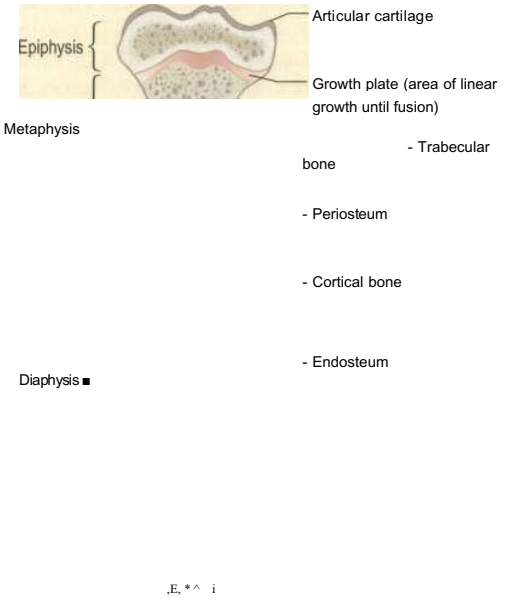

Fig. 10.30 **Diagram of a longitudinal section of a growing long bone.**

Bone cells

Osteocytes

These small cells are embedded within bone and act as transducers of mechanical stress, their cytoplasmic processes communicating with other osteocytes and osteoblastic cells on the bone surface.

Osteoblasts

Derived from local mesenchymal stem cells, osteoblasts are present on the bone surface and synthesize bone matrix (osteoid) and regulate its mineralization, after which a large proportion of the redundant osteoblasts are removed by apoptosis. Some remain as lining cells on the surface or become embedded in newly mineralized bone as osteocytes. Osteoblasts are also critical in the regulation of osteoclast generation and function through production of the stimulatory factor RANK-L (the /igand for receptor activator of nuclear factor fcappa-B) and the inhibitory factor osteoprotegerin (OPG). Osteoblasts are rich in alkaline phosphatase and express many receptors, including those for glucocorticoids, parathyroid hormone (PTH), 1,25-dihydroxyvitamin D_3 (1,25-$(OH)_2D_3$), oestrogen, prostaglandins, interleukins, tumour necrosis factor alpha (TNF-a) and transforming growth factor (TGF)-(5.

Osteoclasts

Osteoclasts develop from haemopoietic stem cells of the macrophage/monocyte lineage. They express receptors for colony-stimulating factor-1 (M-CSF), RANK-L and calcitonin, but not for PTH. They attach to bone, forming a ruffled border to create a series of extracellular lysosomal compartments. Hydrogen ions are secreted into this space, the acid environment dissolving the crystals and exposing the matrix, which is then degraded by cysteine protease enzymes (e.g. cathepsin K) functioning at their optimal pH.

Bone growth and remodelling

Longitudinal growth occurs at the epiphyseal growth plate (between the epiphysis and metaphysis). Cartilage is produced by chondrocytes and ossified until skeletal maturity at 18-21 years of age, when the epiphysis and metaphysis fuse.

In adults, bone is remodelled in basic multicellular units (Fig. 10.31). Osteocytes communicate mechanical strain to osteoblasts on the bone surface via cytoplasmic projections. The osteoblast responds to this or to other signals (PTH, 1,25-$(OH)_2D_3$, cytokines and growth factors) by increasing production of RANK-L and M-CSF and reducing OPG production. This promotes osteoclast formation from circulating monocyte precursors and directs osteoclasts to the area of bone to be resorbed. Unknown inhibitory signals (see p. 486) limit osteoclast recruitment and activity. Macrophages remove apoptotic osteoclasts and prepare the resorbed surface (the cement line). Growth factors drive osteoblast formation from local stem cells (coupling of resorption and formation), producing osteoid which is mineralized to form new bone. The cycle is completed in about 120 days. Remodelling is balanced if there has been no net change in the amount of bone, i.e. the amount formed is the same as the amount resorbed.

The control of bone remodelling is complex and results from the interaction of mechanical stresses, systemic hormones and locally produced cytokines, growth factors, prostaglandins and other factors such as nitric oxide. Genetic factors are also involved. Oestrogen is a major regulator of bone remodelling both in females and males and acts mainly by inhibiting osteoclastogenesis and increasing osteoclast apoptosis.

CALCIUM HOMEOSTASIS AND ITS REGULATION

Calcium homeostasis is regulated by the effects of PTH and 1,25-$(OH)_2D_3$ on gut, kidney and bone. Calcium-sensing receptors are present in the parathyroid gland, kidney, brain and other organs.

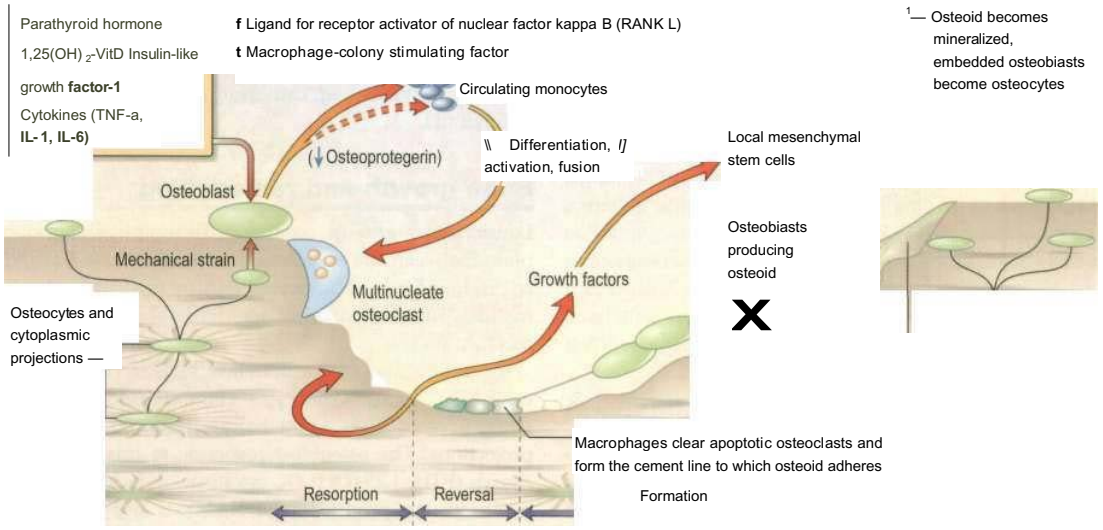

***Fig. 10.31* A diagram of bone remodelling, representing a cross-section of a groove in a flat area of bone at a single time-point.** (Resorption and formation in fact occur simultaneously at different points along the groove or tunnel.) On the left, the multinucleate osteoclast is resorbing bone at the groove's apex, in response to increased RANK-L and M-CSF (and reduced osteoprotegerin) from adjacent osteobiasts which have been activated by hormones, cytokines or by osteocytes under mechanical strain. Macrophages appear in the osteoclasts' wake, clearing apoptotic cells (reversal) and preparing the resorbed bone surface as a 'cement line'. Growth factors released from the bone stimulate differentiation of local stem cells to osteobiasts that form new bone, completing the cycle. TNF, tumour necrosis factor; IL, interleukin.

CALCIUM ABSORPTION AND DISTRIBUTION

(Fig. 10.32)

Daily calcium consumption, primarily from **dairy foods,** should ideally be around 20-25 mmol (800-1000 mg). Dietary calcium deficiency is rarely a significant cause of bone disease. Intestinal absorption of calcium is reduced by vitamin D deficiency and in malabsorptive states.

Vitamin D metabolism (Fig. 10.33) The primary source of vitamin D in humans is photoactivation (in the skin) of 7-dehydrocholesterol to cholecalciferol, which is then converted in the liver to 25-hydroxycholecalciferol (25-(OH)D_3) and further converted by renal loc-hydroxylase to the active metabolite 1,25-dihydroxycholecalciferol (1,25-$(OH)_2D_3$). (This step can occur in lymphomatous and sarcoid tissue, resulting in the hypercalcaemia that may complicate these diseases.) A less active metabolite, 24,25-$(OH)_2D_3$, is formed if vitamin D supplies are adequate. Regulation of this enzyme is by PTH, phosphate and by feedback inhibition by 1,25-$(OH)_2D_3$.

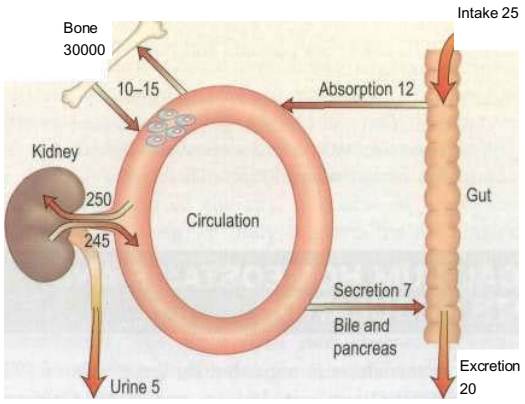

Fig. 10.32 Calcium exchange in the normal human. The amounts are shown in mmol per day.

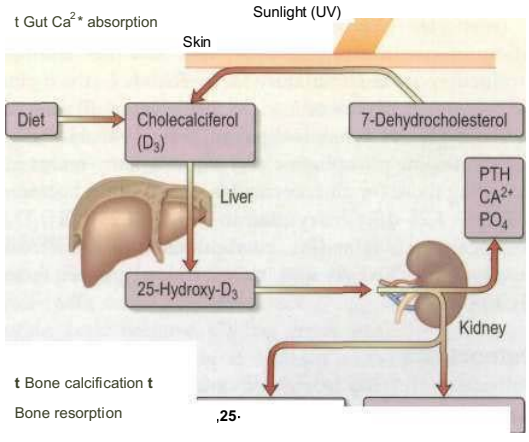

Fig. 10.33 The metabolism and actions of vitamin D.

Parathyroid hormone (PTH)

PTH, an 84-amino-acid hormone, is secreted from the chief cells of the parathyroid glands (normally situated posterior to the thyroid, but occasionally in the neck or mediastinum). PTH increases renal phosphate excretion, and increases plasma calcium by:

- increasing osteoclastic resorption of bone (occurring rapidly)
- increasing intestinal absorption of calcium (a slower response)
- increasing synthesis of 1,25-$(OH)_2D_3$
- increasing renal tubular reabsorption of calcium.

Hypomagnesaemia can suppress the normal PTH response to hypocalcaemia.

Calcitonin

Calcitonin is produced by thyroid C cells. Calcitonin inhibits osteoclastic bone resorption and increases the renal excretion of calcium and phosphate. However, neither total thyroidectomy (absent calcitonin) or medullary carcinoma of the thyroid (excess calcitonin) has significant skeletal effects in humans.

INVESTIGATION OF BONE AND CALCIUM DISORDERS (Rg.10.34)

Total plasma calcium

(reference range 2.2-2.6 mmol/L)

About 40% is ionized and physiologically active; the remainder is complexed or protein-bound, particularly to albumin. Ionized calcium is difficult to measure and not routinely assessed. Total plasma calcium is corrected for protein binding by adding or subtracting 0.02 mmol/L for every gram per litre of a simultaneous albumin level below or above 40g/L. For critical measurements,

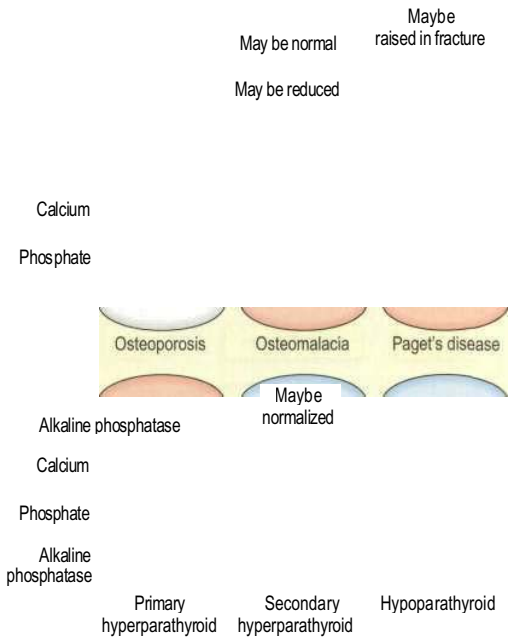

Fig. 10.34 **Changes in serum calcium, phosphate and alkaline phosphatase in main bone disorders.** Shading represents increased (red), reduced (blue) or normal (white) levels.

samples should be taken in the fasting state and without a tourniquet (the latter may increase local plasma protein concentration).

Plasma phosphate (reference range 0.8-1.4 mmol/L) Phosphate is essential to most biological systems. Primary hyperparathyroidism is associated with low levels of plasma phosphate. High levels are found in renal failure or in hypoparathyroidism.

PTH measurements (reference range 10-65 ng/L) The PTH assay measures the intact PTH molecule. Raised levels are found in primary, secondary and tertiary hyperparathyroidism and in familial hypocalciuric hypercalcaemia. Lithium toxicity may also be associated with raised PTH levels. In hypercalcaemia due to other causes, PTH levels are suppressed.

25-hydroxyvitamin D (reference range depends on season of year, but generally levels >20 ng/mL [50 nmol/L] are considered normal) Serum 25-OHD levels provide an assessment of vitamin D status. Vitamin D deficiency or insufficiency is often associated with increased serum PTH levels. Measurements of 1,25-$(OH)_2D_3$ are seldom helpful clinically.

Urinary calcium (normal range 2.5-7.5 mmol/24 h)

This is increased where renal tubular reabsorption of calcium is decreased, or in hypercalcaemia. An exception to the latter is familial hypocalciuric hypercalcaemia, where urinary calcium excretion is inappropriately low in the presence of hypercalcaemia (p. 1094). The main role of urinary calcium assay is in the investigation of renal calculi.

Markers of bone formation

- *Alkaline phosphatase* is derived from liver, bone, pancreas, kidney and placenta. Bone-specific alkaline phosphatase is synthesized by osteoblasts; serum levels are raised in the growing child and in bone diseases in which bone turnover is increased (Fig. 10.34).
- *Osteocalcin* is produced by osteoblasts. Serum levels are often elevated in high-turnover bone disease and are reduced by glucocorticoids.
- *Type I collagen propeptides* are by-products of collagen synthesis. Carboxyterminal propeptide of collagen I (P1CP) and the aminoterminal propeptide (P1NP) can both be measured in serum.

Markers of bone resorption

- *Pyridinoline or deoxypyridinoline cross-links of collagen* are produced by collagen degradation, and excreted in urine. Deoxypyridinoline is bone-specific, and both are more sensitive than urinary hydroxyproline.
- *N-terminal and C-terminal cross-linked telopeptides* also reflect bone resorption and may alter more rapidly in

response to disease or treatment. They can be assessed in urine or serum.

Diagnostic imaging

Plain radiographs identify fracture, tumours and infections. Features characteristic of specific metabolic bone diseases may be seen (see separate sections).

Radionuclide scans. Technetium-99m-labelled methylene bisphosphonate uptake is predominantly dependent on blood flow and osteoblastic activity, detecting increased bone activity in cases of fracture, infection, metastases or in metabolic bone disease with greater sensitivity than X-rays.

Magnetic resonance imaging allows detailed assessment of subchondral and other bone areas. Variations in technique (Tl, T2, STIR (which suppresses the high signal from fat in bone marrow)) offer specific diagnostic or prognostic information, for example in suspected avascular necrosis.

Bone density measurements (see p. 596)

Bone biopsy

A core of bone is removed (from cortex to cortex of the iliac crest) with a trephine, and the non-decalcified specimen is examined for indices of bone turnover and remodelling. A fluorochrome (usually oral tetracycline), given for 2 days on two occasions 10 days apart before the biopsy, enables measurement of actively forming surfaces of bone. In clinical practice, bone biopsy is most useful in the diagnosis of osteomalacia and renal osteodystrophy.

OSTEOPOROSIS

Definition and incidence

Osteoporosis is defined as 'a disease characterized by low bone mass and micro-architectural deterioration of bone tissue, leading to enhanced bone fragility and an increase in fracture risk'. Bone is normally mineralized but is deficient in quantity, quality and structural integrity (Fig. 10.35).

The World Health Organization (WHO) defines osteoporosis as a bone density more than 2.5 standard deviations (SDs) below the young adult mean value (T-score < -2.5). Values between 1 and 2.5 SDs below the young adult mean are termed 'osteopenia'.

As the risk of fracture increases exponentially with age, changing population demographics will increase the burden of disease (currently costing almost £1.75 billion annually in the UK). The remaining lifetime risk of hip fracture for a white woman at age 50 is around 15%, 5% for men, with equal risks around 11-13% for Colles' or vertebral fractures. Of those surviving to 80 years of age, 30% of women and 15% of men will suffer a hip fracture. Caucasian and Asian races are particularly at risk.

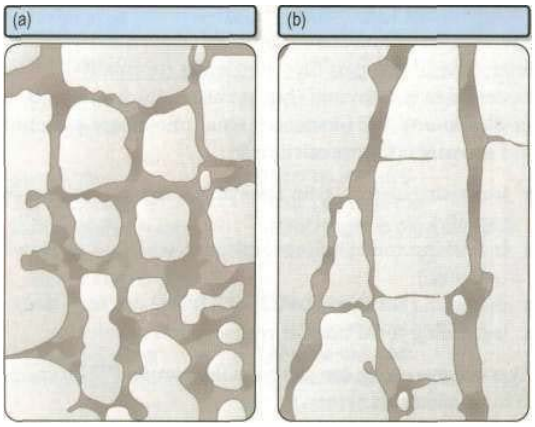

Fig. 10.35 **The microarchitecture of (a) normal and (b) osteoporotic bone.** There is thinning and a loss of trabecular plates in (b).

Pathogenesis

The changes in bone mass with age are shown in Figure 10.36. Peak bone mass is attained between 20-30 years of age. From around the age of 40 years, age-related bone loss occurs in both men and women and persists thereafter throughout life. In women there is an acceleration of bone loss around the time of the menopause which probably lasts between 5 and 10 years.

Oestrogen deficiency is a major factor in the pathogenesis of postmenopausal osteoporosis and also in osteoporosis in men. In the elderly, vitamin D insufficiency and consequent secondary hyperparathyroidism are pathogenetic factors.

Bone mass therefore depends on the peak mass attained and on the rate of loss later in life. Genetic factors are the single most significant influence on peak bone mass but multiple genes are involved, including the collagen type IA1, vitamin D receptor and oestrogen receptor genes. Nutritional factors, sex hormone status and physical activity also affect the peak mass attained.

Risk factors associated with increased bone loss may be considered as endogenous or exogenous.

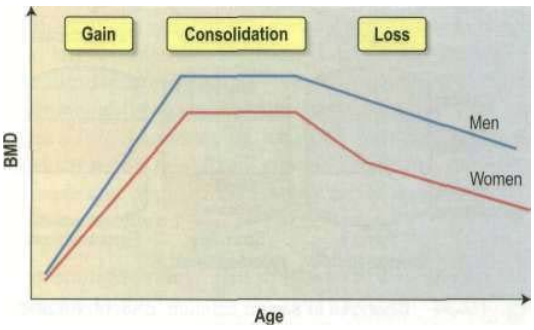

Fig. 10.36 **Schematic representation of lifetime changes in bone mineral density (BMD).**

- Endogenous factors include ethnicity, female gender, advancing age, family history of fracture.
- Exogenous factors include hypogonadism (male or female), glucocorticoid treatment, low body mass index, previous fracture, smoking, immobilization, and excess alcohol. Vitamin D insufficiency is particularly relevant in the elderly

Hyperparathyroidism, hyperthyroidism, coeliac disease, inflammatory bowel or joint diseases, chronic liver or renal disease increase the risk of osteoporosis. Recently raised serum homocysteine levels have been shown to be predictive for hip fractures in older people.

Falls contribute significantly to fracture risk, particularly in the elderly. Environment (e.g. poor lighting, uneven floor surface), neuromuscular and cardiovascular disease and commonly prescribed drugs (diuretics, sedatives, anxiolytics) are often overlooked causes of falls in the elderly. Some of these risk factors exert their effect through bone mineral density (BMD) whilst others are independent (Table 10.22).

Not all causes of osteoporosis affect bone remodelling and architecture in the same way. An early consequence of oestrogen deficiency (possibly transient) is reduced osteoclast apoptosis. Increased numbers of basic multicellular units (BMUs) appear, with increased resorption depth exceeding the synthetic capacity of osteoblasts, causing a loss of resistance to fracture not entirely reflected by measured BMD. Hyperparathyroidism and hyperthyroidism are also associated with increased turnover. In older individuals, reduced formation is more significant than increased resorption. Glucocorticoid-induced osteoporosis is initially associated with a high turnover state, though chronic glucocorticoid use is associated with reduced bone formation and low turnover.

Table 10.22 **Risk factors for osteoporosis**

BMD-dependent	BMD-independent
Female sex	Increasing age Previous fragility fracture Low body mass index Smoking Glucocorticoid therapy High bone turnover Increased risk of falling
Caucasian/Asian

Chronic renal disease	
Chronic hepatic disease	
Malabsorption Inflammatory bowel disease	
Rheumatoid arthritis	
Mastocytosis	
Multiple myeloma	
Osteogenesis imperfecta	

Clinical features

Fracture is the only cause of symptoms in osteoporosis. Sudden onset of severe pain in the spine, localized at the affected level and often radiating around to the front, suggests vertebral crush fracture. However, only about one in three vertebral fractures is symptomatic. Pain from mechanical derangement, increasing kyphosis, height loss and abdominal protuberance follow crushed vertebrae. Colles' fractures typically follow a fall on an outstretched arm. Fractures of the neck of the femur usually occur in older individuals falling on their side or back. Other causes of low-trauma fractures must not be overlooked, including metastatic disease and myeloma.

Investigations

If fracture suspected

Plain radiographs usually show a fracture and may reveal previous asymptomatic vertebral deformities (Fig. 10.37). Where plain films are normal, fractures (especially of pelvis) may be detected by bone scintigraphy.

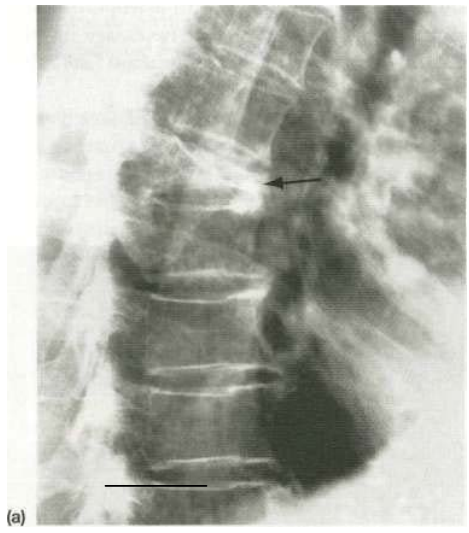

Fig. 10.37 **(a) Lateral X-ray of the thoracic spine showing a compression fracture (arrowed), (b) Types of vertebral deformity in osteoporosis.**

Bone density

m *Conventional radiographs* are relatively insensitive for detecting osteopenia.

- *Dual energy X-ray absorptiometry* (DXA) measures areal bone density (mineral per surface area rather than a true volumetric density), usually of the lumbar spine and proximal femur. It is precise, accurate, uses low doses of radiation and is the gold standard in osteoporosis diagnosis (Fig. 10.38). Because of osteophytes, spinal deformity and vertebral fractures, spinal values should be interpreted with caution in the elderly. Indications for DXA scanning are listed in Table 10.23.
- *Quantitative CT scanning* allows true volumetric assessment, and distinction between trabecular and cortical bone. However, it is more expensive, requires higher radiation than other techniques, and to date offers no clinical advantage.
- *Quantitative ultrasound* of the calcaneum. This does not require ionizing radiation and is cheaper than other methods. It has been shown to predict fracture risk in men and women.

Associated disease and risk factors

Investigations to exclude other diseases or identify contributory factors associated with osteoporosis should be performed and are particularly necessary in men, in whom secondary causes are more common (Table 10.22).

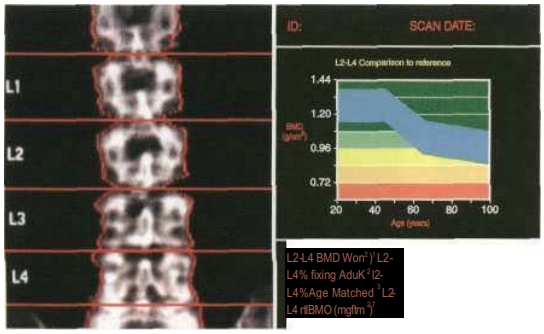

Fig. 10.38 **Dual energy X-ray absorptiometry of the lumbar spine.** The AP image of the lumbar spine is shown on the left and on the right, the patient's value is expressed in relation to the reference range.

Diseases associated with osteoporosis (Table 10.22)

Selection of individuals for treatment: risk assessment

At present, population screening for osteoporosis is not recommended and a case-finding strategy is used to select individuals for bone density measurement, based on risk factors. In general, a BMD T score below -2.5 is used as a starting point for decisions about intervention; however, other independent risk factors for fracture should also be taken into account (see Fig. 10.39 and Table 10.22). Algorithms using this approach are currently being developed to assess fracture probability over a time period of 5-10 years, which provides a more appropriate interventional threshold.

Prevention and treatment (Box 10.13)

New vertebral fractures may require bed rest for 1-2 weeks with strong analgesia (e.g. meptazinol) and transcutaneous electrical nerve stimulation (TENS) may be helpful. Muscle relaxants (e.g. diazepam 2 mg three times daily), subcutaneous calcitonin (50-100 IU daily) or a single intravenous infusion of pamidronate (60-90 mg) are useful for pain relief, and physiotherapy helps restore confident mobilization. Non-spinal fractures should be treated by conventional orthopaedic means.

Predisposing lifestyle factors should be addressed, and those at significant risk can be identified for DXA.

- *Diet* should include 700-1000 mg of calcium daily (ideally 1500 mg postmenopausally) and 400-800 IU of vitamin D in individuals not receiving adequate exposure to sunlight.

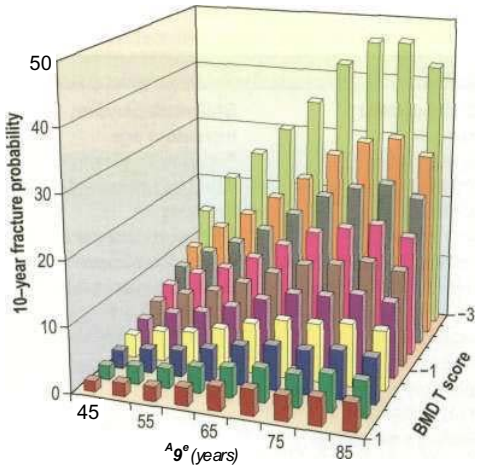

Fig. 10.39 **A graph illustrating the combined effects of age (x-axis) and reduced bone mass (expressed as T scores on the z-axis) on the 10-year probability of fracture (y-axis) in a population of women.** Reduced bone mass osteopenia, T scores between -1 and -2.5. Osteoporotic bone (T scores less than -2.5) is shown in pale green. Note that the risk of fracture may be greater in an older woman with osteopenia than in a young woman with osteoporosis. Data from Kanis JA (2002) Diagnosis of osteoporosis and assessment of fracture risk. *Lancet* **359:** 1929-1936.

Box 10.13 **Management of osteoporosis**

In all individuals
Assess risk factors
If present, proceed to DXA (may not be necessary in all patients with fragility fractures) » Exclude secondary causes in patients with osteoporosis

In patients with previous fragility fracture and those aged over 65 years with BMD T score < -2.5 measured by DXA
Offer lifestyle advice (e.g. exercise, diet, smoking cessation)
A Offer treatment:
First-line option alendronate or risedronate
Also - raloxifene in women with vertebral osteoporosis - teriparatide in women with very severe osteoporosis, or if intolerant to other therapies
Give calcium and vitamin D supplements where appropriate

In younger patients with BMD T score < -2.5 (measured by DXA, hip ± spine)
Assess need for treatment based on age and other independent risk factors : Offer lifestyle advice ■ Offer treatment as above, if appropriate

In frail older individuals
Offer lifestyle advice
Fall risk assessment and advice where appropriate
Give calcium and vitamin D supplements
Hip protectors for individuals in nursing homes

See also Royal College of Physicians' Guidelines (in list for further reading) ■

Box 10.14 **Medication to reduce risk of fractures**

Efficacy against vertebral, non-vertebral and hip fractures:
Bisphosphonates (alendronate, risedronate)
Strontium ranelate
Established efficacy against vertebral fractures:
Raloxifene
Established efficacy against non-vertebral and hip fractures:
Combined calcium and vitamin D Established efficacy against vertebral and non-vertebral fractures: Teriparatide
Conflicting evidence for efficacy:
Calcitonin Calcitriol

- *Exercise.* Thirty minutes of weight-bearing exercise three times a week may increase BMD, though this has not been a universal finding in all studies. Gentle exercise in the elderly may reduce the risk of falls and improve the protective responses to falling.
- *Smoking cessation.* Smoking is associated with lower BMD and increased fracture risk. Alcohol abuse should be avoided.
- *Reduce falls.* Physiotherapy and assessment of home safety may be required. Hip protectors for elderly patients in residential care may reduce fracture risk.

Pharmacological intervention

Most interventions used act by inhibiting bone resorption (anti-resorptives) although teriparatide stimulates bone formation and strontium ranelate (a new drug) does both. In clinical trials all interventions have been assessed against a background of calcium and vitamin D repletion, and in clinical practice supplements should therefore be given if there is any evidence or risk of deficiency.

The evidence base for anti-fracture efficacy of interventions varies. Adequately powered randomized controlled trials, with fracture as end-point, exist for alendronate, risedronate, raloxifene, hormone replacement therapy, teriparatide (recombinant human PTH pepride 1-34) and combined calcium/vitamin D (the latter in frail older individuals only). Some interventions have been shown to reduce fracture at vertebral and non-vertebral sites, including the hip, whereas others have not been demonstrated to be effective at all sites (Box 10.14). Since a fracture at one site increases the risk of subsequent fracture at any site, treatments with efficacy at all major fracture sites (particularly spine and hip) are preferable. Hence the bisphosphonates or strontium ranelate are generally regarded as the first-line options in the majority of women with osteoporosis.

- *Bisphosphonates,* synthetic analogues of bone pyrophosphate (Fig. 10.40) adhere to hydroxyapatite and inhibit osteoclasts. *Alendronate* and *risedronate* increase bone mass at the hip and spine, and reduce the incidence of fractures at vertebral, hip and other sites, particularly in women who have already sustained a vertebral fracture. These can be given as daily (10 mg and 5 mg respectively) or once-weekly doses; (70 mg and 35 mg respectively) are preferred by the vast majority of patients. Etidronate is given cyclically, alternating 2 weeks of the drug with 76 days of calcium supplement. It has been shown to reduce vertebral fractures and, in observational studies, a

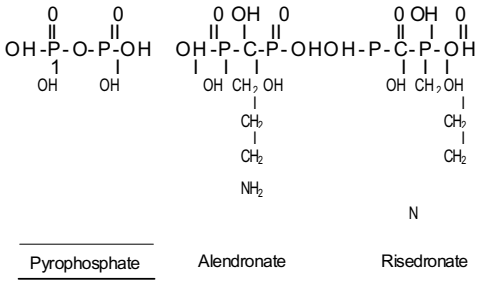

Fig. 10.40 **The chemical structures of the aminophosphonates alendronate and risedronate are compared with the structure of pyrophosphate.**

reduction in non-vertebral fractures has also been shown. The optimal duration of bisphosphonate therapy is unknown; prolonged suppression of bone turnover may have adverse effects, and it is currently advised to reassess treatment after 5-10 years. Nitrogen-containing bisphosphonates (e.g. alendronate, risedronate) may cause upper gastrointestinal side-effects, and adherence to a strict dosing regimen is necessary. The tablets should be taken in the fasting state with a large drink of water, while the patient is standing or sitting upright. The patient should subsequently remain upright and avoid food and drink for at least 30 minutes. Bisphosphonates should be used with caution in patients with renal impairment.

- *Raloxifene* is a selective oestrogen-receptor modulator (SERM). It has no stimulatory effect on the endometrium but activates oestrogen receptors in bone. It prevents BMD loss at the spine and hip in postmenopausal women, though fracture rates were only reduced in the spine. It also reduces the incidence of oestrogen-receptor-positive breast carcinoma in women treated for up to 4 years. Leg cramps and flushing may occur and the risk of thromboembolic complications is also increased to a degree similar to that seen with HRT. It is given as a daily oral dose (60 mg).
- *Recombinant human parathyroid hormone peptide 1-34 (teriparatide)* is an anabolic agent that stimulates bone formation. It has been shown to reduce vertebral and non-vertebral fractures in postmenopausal women with established osteoporosis, although data on hip fracture are not available. It is given by daily sub cutaneous injection in a dose of 20 ug. Its use is mainly indicated in very severe cases of osteoporosis or in women who are intolerant of or fail to respond to other therapies. Teriparatide causes only mild transient hypercalcaemia and routine monitoring is not required. Nausea and headache may occur.
- *Strontium ranelate* is a new dual action bone agent that has anti-resorptive and anabolic effects. It reduces the risk of vertebral and non-vertebral fractures, including hip fractures in post-menopausal women with osteo porosis. The dose is 2 g daily (granules are dissolved in water at night). Nausea, diarrhoea and headache are infrequent side effects and there is a small increase in the risk of venous thromboembolic disease.
- *Combination therapy of calcium with vitamin D* has been shown to reduce non-vertebral fractures, including hip fractures, in elderly women living in residential care The recommended dose is 800 IU of vitamin D and 1 g calcium daily.

Strategies used less commonly

These include:

- *Hormone replacement therapy* (HRT) prevents bone loss and reduces vertebral and non-vertebral fractures. However, because of adverse effects on breast cancer and cardiovascular disease risk it is now not used except in perimenopausal women with osteoporosis who also have menopausal symptoms and in women who are intolerant of other therapies (for a suggested maximum of 5 years).
- *Combination therapies,* either with two anti-resorptive agents or an anti-resorptive and an anabolic agent often produce larger increases in BMD than monotherapy but have not been shown to result in greater fracture reduction than with monotherapy.
- *Calcitriol* ($1,25\text{-}(OH)_2D_3$) may reduce vertebral fracture rate, although the data are inconsistent. Hypercalcaemia and hypercalciuria may occur and monitoring is necessary.
- *Calcitonin.* Nasal or subcutaneous calcitonin may be used; vertebral fracture rates may be reduced, although this has not been a universal finding.

Glucocorticoid-induced osteoporosis

Individuals requiring oral glucocorticoid therapy for 3 months or more (at any dose) should be assessed for coexisting risk factors (age, previous fracture, hormone status). Primary prevention is recommended in men and women aged over 65 years and in individuals who have sustained a fragility fracture aged 40 years or more. DXA results guide treatment for other patients. Bisphosphonates (etidronate, alendronate and risedronate) are the only approved agents for this indication. Calcium and vitamin D supplementation should also be given.

Osteoporosis in men

Alendronate (10 mg daily) has been shown to increase BMD and to reduce vertebral fractures in men with osteoporosis and is approved for this indication. In men with osteoporosis who have clinical and biochemical evidence of hypogonadism, testosterone replacement can be used.

PAGET'S DISEASE

Osteitis deformans or Paget's disease is a focal disorder of bone remodelling. The initial event of excessive resorption is followed by a compensatory increase in new bone formation, increased local bone blood flow and fibrous tissue in adjacent bone marrow. Ultimately, formation exceeds resorption but the new bone is structurally abnormal.

Epidemiological studies are difficult because most patients are asymptomatic. Most often seen in Europe and particularly in northern England, it affects men and women (2 : 3) over age 40 years. Incidence approximately doubles per decade thereafter, with up to 10% radiologically affected by the age of 90. A positive family history is noted in about 14%.

Aetiology and pathogenesis

A number of genes have been implicated in Paget's disease, including sequestersome p62, nuclear factor kappa B (NFkB), osteoprotegerin and *bell.* Intracellular inclusions in the osteoclasts in a pagetic lesion are believed to be paramyxovirus nucleocapsid (e.g. canine distemper virus, measles or respiratory syncytial virus). However, similar microfilaments are seen in other bone disorders, and theories of a viral aetiology in Paget's remain contentious. Altered expression of *c-fos* (an oncogene) is one suggested mechanism linking viral infection with the pathogenic changes in osteoclasts, which are more numerous, and contain an increased number of nuclei (up to 100). Increased osteoclastic bone resorption is followed by formation of woven bone; which is softer and may lead to deformity and increased fracture risk. Unaffected bone remains normal throughout life (i.e. Paget's disease does not spread, but can become symptomatic at previously silent sites).

Clinical features (Fig. 10.41)

Most (60-80%) patients with radiologically identified Paget's disease are asymptomatic. Diagnosis often follows the finding of an asymptomatic elevation of serum alkaline phosphatase, or a plain X-ray performed for other indications. The disease may involve one bone (monostotic, in 15%) or many (polyostotic). The most common sites in order of frequency are pelvis, lumbar spine, femur, thoracic spine, sacrum, skull, tibia. Symptoms can include:

- bone pain, most often in the spine or the pelvis
- joint pain when an involved bone is close to a joint, leading to cartilage damage and osteoarthritis
- deformities, in particular bowed tibia and skull changes
- complications from:
  (a) nerve compression (deafness from VHIth cranial nerve involvement; also cranial nerves II, V, VII may be involved; spinal stenosis, hydrocephalus)
  (b) increased bone blood flow (myocardial hyper trophy and high-output cardiac failure)
  (c) pathological fractures
- osteogenic sarcoma in pagetic bone (fewer than 1% of cases, but a 30-fold increased risk compared with non-pagetic patients).

Investigations

- **X-ray** features vary from predominantly lytic lesions (osteoporosis circumscripta in the skull is characteristic), **through** a mixed phase, to a mainly sclerotic phase of bone expansion, thickening of trabeculae and loss of distinction between cortex and trabeculae (de-differentiation).
- **Bone scans** show the extent of skeletal involvement, but are unable to distinguish between Paget's disease and sclerotic metastatic carcinoma (especially breast and prostate).
- **Increased serum alkaline phosphatase** with normal serum calcium and phosphate, reflects increased bone turnover. Levels may be normal with limited or monostotic Paget's. Levels are reduced with treatment and are a marker of relapse. Mild hypercalcaemia follows immobilization only when there is very extensive disease. Urinary hydroxyproline excretion is also increased and, together with serum alkaline phosphatase levels, may be used as a marker of disease activity.

Treatment

Bisphosphonates are the mainstay of treatment. New bone formed after treatment is lamellar, not woven (reflecting normalization of bone turnover rather than a direct effect on osteoblasts). In addition to treating symptomatic patients (the minority), studies to date indicate that treatment of asymptomatic lesions is appropriate if there is a significant risk of potential complications, e.g. fracture in weight-bearing long bones or the spine, nerve entrapment or deafness with skull involvement, and treatment before orthopaedic procedures in involved bone (to reduce vascularity).

Intravenous bisphosphonates

Intravenous pamidronate is highly efficacious. Regimens vary widely but up to 360 mg is given in divided doses over 6 weeks and then repeated as required after 6 months or longer. Pamidronate can be associated with a first-dose reaction characterized by 'flu-like' symptoms including a transient pyrexia over 24^8 hours.

Oral bisphosphonates

Tiludronate is indicated for the treatment of Paget's disease in a dose of 400 mg daily for 12 weeks, repeated as necessary after 6 weeks or longer. Ibandronate, 30 mg daily for 2 months, repeated if necessary after at least 2 months, is also approved for this indication. Risedronate,

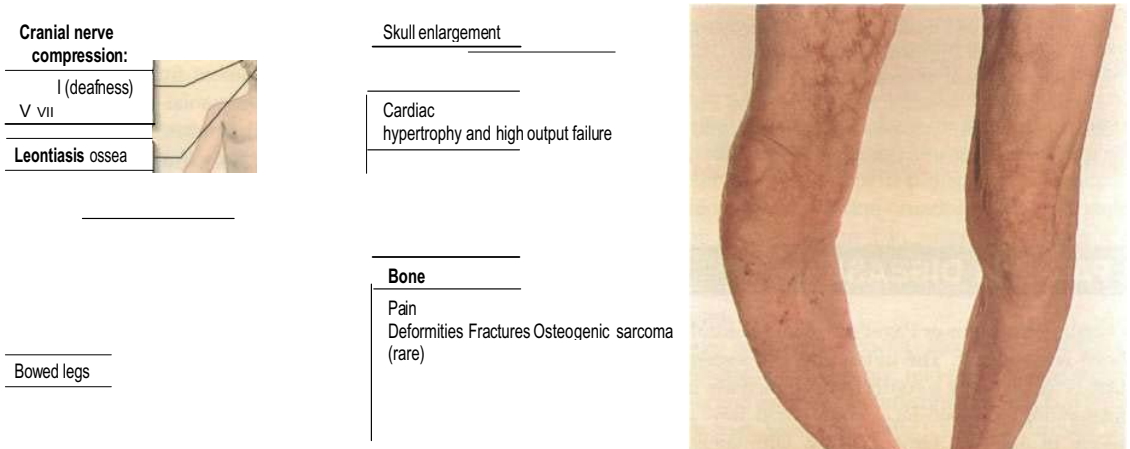

Fig. 10.41 **Paget's disease, (a) Clinical features, (b) Picture of the legs showing bowing of the tibia, caused by increased bone growth. Note the erythema ab igne on the medial aspect of the thigh, (c) X-ray appearance of the pelvis, showing osteoiytic and osteosclerotic lesions.**

30 mg/day for 2 months, repeated as necessary after at least 2 months, may also be used. Etidronate is also approved but is less often used because of its lower potency.

Treatment is monitored by regular measurement of serum alkaline phosphatase levels ± urinary hydroxyproline excretion.

Surgery

Joint replacement or osteotomy is sometimes necessary to correct deformity or pain due to (secondary) degenerative joint disease. Intra-articular injection of lidocaine can be useful to differentiate joint or bone disease. Neurosurgery may be required where there is spinal disease. Osteosarcoma usually requires amputation, though wide excision and limb-salvage can be successful at distal sites.

RICKETS AND OSTEOMALACIA

Rickets (in children) and osteomalacia (in adults) result from inadequate mineralization of bone matrix (osteoid). They are usually caused by a defect in vitamin D availability or metabolism.

Pathology

In children, the growth plate is elongated with distortion of the arrangement of chondrocytes. Calcification is delayed and vascularization impaired. In adults, osteomalacia is characterized by increased osteoid width (> 15 urn) and increased mineralization lag time.

Double tetracycline labelling shows lack of uptake of tetracycline in osteoid seams. Changes of secondary hyperparathyroidism are often present, except in hypophosphataemic osteomalacia.

Aetiology (Table 10.24)

Vitamin D deficiency is usually due to inadequate sunlight

Table 10.24 Causes of rickets and osteomalacia

Vitamin D deficiency
Inadequate synthesis in skin
Low dietary intake
Malabsorption:
Coeliac disease
Intestinal resection
Chronic cholestasis, e.g. primary biliary cirrhosis
Renal disease
Chronic renal failure Bone
disease due to dialysis
Tubular disorders, e.g. renal tubular acidosis, Fanconi's syndrome
Miscellaneous
Vitamin-D-dependent rickets types I and II
Dent's disease (X-linked hypophosphataemia - vitamin-D-resistant rickets) Tumour-induced
hypophosphataemic rickets and osteomalacia

exposure and/or dietary insufficiency (Fig. 10.33). Asian women and elderly individuals, especially those who are housebound, are particularly at risk. Anticonvulsant therapy (especially phenytoin and phenobarbital) affects vitamin D metabolism and predisposes to vitamin D deficiency. Malabsorption of vitamin D occurs in some gastrointestinal diseases, particularly coeliac disease and small intestinal Crohn's disease.

Chronic renal failure results in reduced la-hydroxylation of 25-$(OH)D_3$. Mutations in the $P450_{cl}$ a gene (chromosome 12) cause la-hydroxylase deficiency, also known as *vitamin D-dependent rickets type I,* an autosomal recessive disease (see p. 711). In *type II vitamin D-dependent rickets* there is a defect in the intracellular 1,25-$(OH)_2D_3$ receptor. X-linked hypophosphataemic rickets, resulting in lower-limb deformities and stunted growth rate in affected males, is caused by mutations in the *PHEX* gene (see p. 711). In the Fanconi syndrome and in renal tubular acidosis, osteomalacia can develop, mainly because of the continuous phosphaturia.

Hypophosphataemic osteomalacia has been associated with mesenchymal tumours which are believed to produce humoral factors ('phosphatonins') including fibroblast growth factor 23 (FGF23), which increases phosphate excretion. Treatment of the tumour results in remineralization.

Clinical features

Adult osteomalacia may produce vague symptoms of bone or muscle pain and tenderness. Pathological fractures may occur. Occasionally a marked proximal myopathy leads to a characteristic 'waddling' gait. Deformity is uncommon. In modern practice many cases are detected biochemically in high-risk patients, especially those with gastrointestinal disease or surgery, before clear symptoms are present. Occasionally, tetany or other hypocalcaemic features may occur.

At birth, neonatal rickets may present as craniotabes (thin deformed skull). In the first few years of life there may be widened epiphyses at the wrists and beading at the costochondral junctions, producing the 'rickety rosary', or a groove in the rib cage (Harrison's sulcus). In older children, lower limb deformities are seen. A myopathy may also occur. Hypocalcaemic tetany may occur in severe cases.

Investigations

- **Increased serum alkaline phosphatase,** indicating increased osteoblast activity, is the most common abnormality (note: alkaline phosphatase is elevated during skeletal growth).
- **Plasma calcium** is usually normal, in association with secondary hyperparathyroidism and a raised PTH., **but** may be low in severe cases.
- **Serum phosphate** may be low, owing to increased PTH-dependent phosphaturia, though this is variable.
- **Serum 25-hydroxyvitamin D_3** is usually low (exceptions being vitamin-D-resistant rickets).
- **X-rays** are often normal in adults, but may show defective mineralization, especially in the pelvis, long bones and ribs, with 'Looser's zones' - linear areas of low density surrounded by sclerotic borders.
- **Iliac crest biopsy** with double tetracycline labelling (see above) is occasionally necessary if biochemical tests are equivocal. . . ■ ■

Treatment

Treatment should be directed towards correction of the cause where possible, with increase in vitamin D intake and sunlight exposure.

Multiple formulations of vitamin D and its metabolites are available. When deficiency is nutritional, 'replacement' doses of the native vitamin are needed (400-800IU daily). Higher 'pharmacological' doses, sometimes administered parenterally, may be needed in some patients with gastrectomy, malabsorption or liver disease, although many respond to more conventional doses. Treatment with calcitriol or alfacalcidol is indicated where there is defective la-hydroxylation, e.g. chronic renal disease, vitamin D resistance and hypophosphataemic rickets and osteomalacia.

SKELETAL DYSPLASIAS

These include a large group of heterogeneous disorders of bone and connective tissue.

Collagen defects

Collagen is responsible for many of **the structural, tensile** and load-bearing properties in the various tissues where

it is found. The structure of collagen is discussed on page 530. Twenty-eight dispersed genes encode for more than 16 different types of collagen:

- The fibrillar collagens, e.g. types I, II, III, V and XI, are encoded by *COL1A1-2, COL2A1, COL3, COL5, COL11.* Mutations of these genes produce osteogenesis imperfecta and Ehlers-Danlos syndrome.
- Basement membrane collagen, type IV, is encoded by *COL4A1-5.* Mutations lead to Alport's disease (see p. 631).
- Fibril-associated collagens with interrupted triple helices (FACIT), e.g. types IX, XII and XIV, are encoded by *COL9, COL12.*
- Filament producing collagen type VI is encoded by *COL6A1, 2,* 3.
- Network-forming collagens types VIII and X are encoded by *COL8A1, COL10A1.*

m Anchoring fibril collagen, e.g. type VII, is encoded by *COL7A1.* Mutations of this gene produce epidermolysis bullosa (p. 1348).

Ehlers-Danlos syndrome

This is a heterogeneous group of disorders of collagen. Ten different types have been recognized with varying degrees of skin fragility, skin hyperextensibility and joint hypermobility. Types I, II and III are inherited in an autosomal dominant fashion; the biochemical basis is unknown. No abnormalities in *COL1A1, COL1A2* and *COL2A1* genes have been found.

Type IV is also autosomal dominant and involves arteries, the bowel and uterus, as well as the skin. Mutations in *COL3A1* gene produce abnormalities in structure, synthesis or secretion of type III collagen.

Type VI is a recessively inherited disorder and results from a mutation in the gene that encodes lysyl hydroxylase.

Type VII is an autosomal dominant disorder where there is a defect in the conversion of procollagen to collagen; *COL1A1* and *COL1A2* mutations delete the JV-proteinase cleavage sites.

Other forms of Ehlers-Danlos are very rare and their defects have not been elucidated. The clinical features are described on page 1356.

Osteogenesis imperfecta (fragilitas ossium, brittle bone syndrome)

This is a heterogeneous group of mainly autosomally dominant inherited disorders. In the majority there are mutations in the genes encoding the chains in type I collagen, i.e. *COL1A1, COL1A2.* There are four main types with very variable clinical pictures ranging from death in the perinatal period (type II), severe bone deformity (type III), to a normal lifespan (types I and IV). Recently three separate clinical subtypes have been identified (V, VI and VII).

The major clinical feature is very fragile and brittle bones but other collagen-containing tissues are also involved, such as tendons, the skin and the eyes. Osteogenesis imperfecta tarda (type I) has mild bony deformities, blue sclerae, defective dentine, early-onset deafness, hypermobility of joints, and heart valve disorders. More severe forms present with multiple fractures and gross deformities. Treatment is with bisphosphonates, which enhances bone cortical thickness. Prognosis is variable, depending on the severity of the disease.

Osteochondrodysplasia

There are over 150 variants, some, but not all, due to mutations in the *COL2A1* gene that encodes type II collagen. Many types have not been clearly identified. All show abnormalities of the vitreous humour of the eye and abnormalities of articular cartilage, both of which have abundant type II collagen.

Miscellaneous defects

Osteopetrosis (marble bone disease)

This condition may be inherited in either an autosomal dominant or an autosomal recessive manner; the recessive type is severe and the dominant type is mild. In addition, another recessive form associated with renal tubular acidosis is due to carbonic anhydrase II deficiency.

In the severe form, bone density is increased throughout the skeleton but bones tend to fracture easily. Involvement of the bone marrow leads to a leucoerythroblastic anaemia. There is mental retardation and early death.

In the mild form there may be only X-ray changes, but fractures and infection can occur. The acid phosphate level is raised.

Marfan's syndrome

This is described on page 1356.

Fibroblast growth factor receptor defect

Achondroplasia ('dwarfism') is diagnosed in the first years of life. The disease is inherited in an autosomal dominant manner and is caused by a defect in the fibroblast growth factor receptor-3 gene. The trunk is of normal length but the limbs are very short and broad. The vault of the skull is enlarged, the face is small and the nose bridge is flat. Intelligence is normal.

Renaldisease

FUNCTIONAL ANATOMY

The kidneys are paired organs, 11-14 cm in length in adults, 5-6 cm in width and 3^ cm in depth. The kidneys lie retroperitoneally on either side of the vertebral column at the level of T12 to L3. The renal parenchyma comprises an outer cortex and an inner medulla. The functional unit of the kidney is the nephron of which each contains approximately one million. *Each nephron* is made up of a glomerulus, proximal tubule, loop of Henle, distal tubule and collecting duct. The renal capsule and ureters are innervated via T10-12 and LI nerve roots, and renal pain is felt over the corresponding dermatomes.

Arterial blood is supplied to the kidneys via the renal arteries, which branch off the abdominal aorta, and venous blood is conveyed to the inferior vena cava via the renal veins. Approximately 25% of humans possess dual or multiple renal arteries on one or both sides. The left renal vein is longer than the right and for this reason the left kidney, where possible, is usually chosen for live donor transplant nephrectomy.

The *renal artery* undergoes a series of divisions within the kidney (Fig. 11.1) forming successively the *intcrlobar arteries,* which run radially to the corticomedullary junction, *arcuate arteries,* which run circumferentially along the corticomedullary junction, and *interlobular arteries* which run radially through the renal cortex towards the surface of the kidney. *Afferent glomerular arterioles* arise from the interlobular arteries to supply the glomerular capillary bed, which drains into *efferent glomerular arterioles.* Efferent arterioles from the outer cortical glomeruli drain into a peritubular capillary network within the renal cortex and thence into increasingly large and more proximal branches of the renal vein. By contrast, blood from the juxtamedullary glomeruli passes via the vasa recta in the medulla and then turns back towards the area of the cortex from which the vasa recta originated. *Vasa recta* possess fenestrated walls, which facilitates movement of diffusible substances. The collecting ducts merge in the inner medulla to form the ducts of Bellini, which empty at the apices of the papillae into the calyces. The calyces, in common with the renal pelvis, ureter and bladder are lined with transitional cell epithelium.

The *glomerulus* comprises four main cell types: (1) endothelial cells which are fenestrated with 500-1000 A pores; (2) visceral epithelial cells (podocytes) which support the delicate glomerular basement membrane by means of an extensive trabecular network (foot processes); (3) parietal epithelial cells which cover the Bowman's capsule; (4) mesangial cells (see Fig. 11.11). Mesangial cells are believed to be related to macrophages of the reticuloendothelial

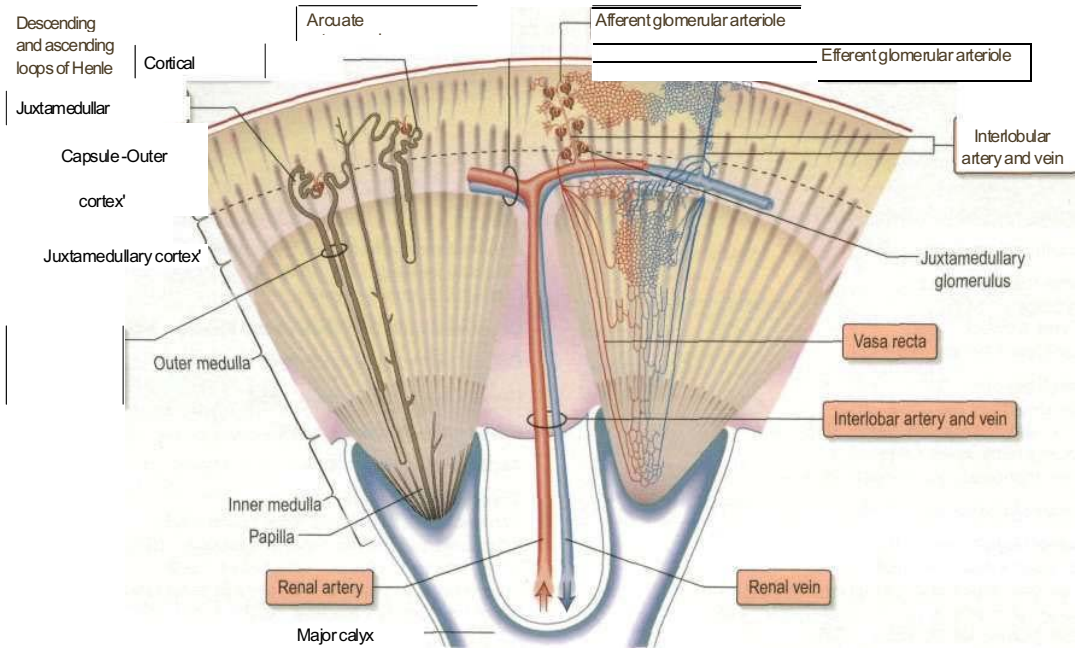

***Fig. 11.1* Functional anatomy of the kidney, (a)** The nephrons. (b) Arterial and venous supply. After Williams PL (ed) (1995) *Gray's Anatomy,* 38th edn. Edinburgh: Churchill Livingstone, with permission from Elsevier.

system and have a phagocytic function and contractile capabilities that can control blood flow and filtration surface area along the glomerular capillaries in response to a host of mediators. They also secrete the mesangial matrix, which provides skeletal framework for the entire glomerular capillaries. The glomerular capillary basement membrane lies between the endothelial and the visceral epithelial cells. The latter put out multiple long foot processes which interdigitate with those of adjacent epithelial cells. Together the endothelial cells, basement membrane and epithelial cells form the filtration barrier or sieve.

The *renal tubules* are lined by epithelial cells, which are cuboidal except in the thin limb of the loop of Henle where they are flat. Proximal tubular cells differ from other cells of the system as they have a luminal brush border. The cortical portion of the collecting ducts contains two cell types with different functions, namely principal cells and intercalated cells (see p. 694). Fibroblast-like cells in the renal cortical interstitium have been identified and shown to produce erythropoietin in response to hypoxia (p. 611).

The *juxtaglomerular apparatus* comprises the macula densa, the extraglomerular mesangium and the terminal portion of the afferent glomerular arteriole (which contains renin-producing granular cells) together with the proximal portion of the efferent arteriole. The macula densa is a plaque of cells containing large, tightly packed cell nuclei (hence the name macula densa) within the thick ascending limb of the loop of Henle. This anatomical arrangement is such as to allow changes in the renal tubule to influence behaviour of the adjacent glomerulus (tubulo-glomerular feedback).

RENAL FUNCTION

PHYSIOLOGY

A conventional diagrammatic representation of the nephron is shown in Figure 11.2a and a physiological version in Figure 11.2b.

An essential feature of renal function is that a large volume of blood - 25% of cardiac output or approximately 1300 mL per minute - passes through the two million glomeruli.

A hydrostatic pressure gradient of approximately 10 mmHg (a capillary pressure of 45 mmHg minus 10 mmHg of pressure within Bowman's space and 25 mmHg of plasma oncotic pressure) provides the driving force for ultrafiltration of virtually protein-free and fat-free fluid across the glomerular capillary wall into Bowman's space and so into the renal tubule (Fig. 11.3).

The *ultrafiltration rate* (glomerular filtration rate; GFR) varies with age and sex but is approximately 120-130 mL/min per 1.73 m^2 surface area in adults. This means that, each day, ultrafiltration of 170-180 L of water and unbound small-molecular-weight constituents of blood occurs. If these large volumes of ultrafiltrate were excreted unchanged as urine, it would be necessary to ingest huge amounts of water and electrolytes to stay in balance. This is avoided by the selective reabsorption of water, essential electrolytes and other blood constituents, such as glucose and ammo acids, from the filtrate in transit along the nephron. Thus, 60-80% of filtered water and sodium are reabsorbed in the proximal tubule along with virtually all the potassium, bicarbonate, glucose and

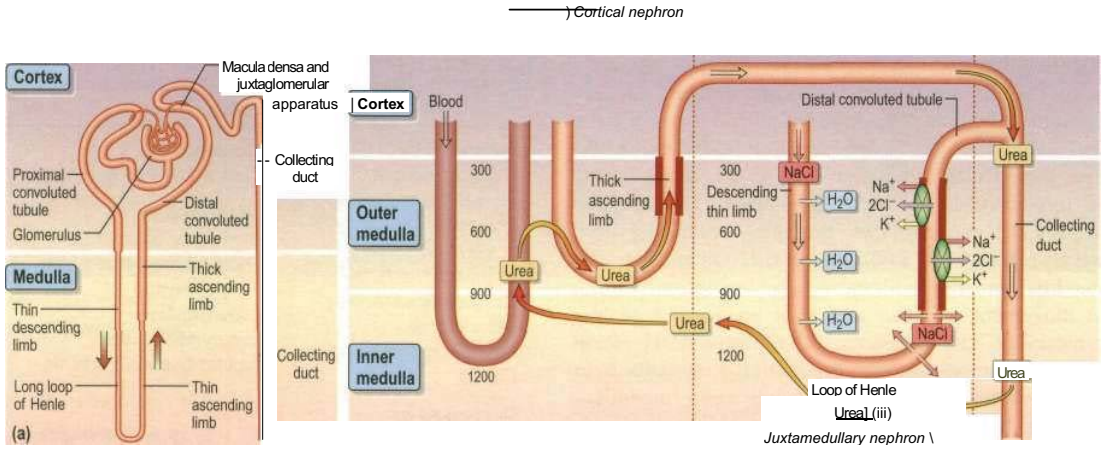

Fig. 11.2 (a) Principal parts of the nephron. The point where the distal tubule is in close proximity to its own glomerulus is called the juxtaglomerular apparatus. This contains the macula densa. (b) Diagrammatic representation of the counter-current system.
(i) Vasa recta: these vessels descend from the cortex into the medulla and then turn back towards the cortex, *(ii) Cortical nephron:* these have short descending limbs extending into the outer medulla, *(iii) Juxtamedullary nephron:* the descending limb dips deeply into the hypertonic inner medulla. Numbers indicate approximate osmolalities.

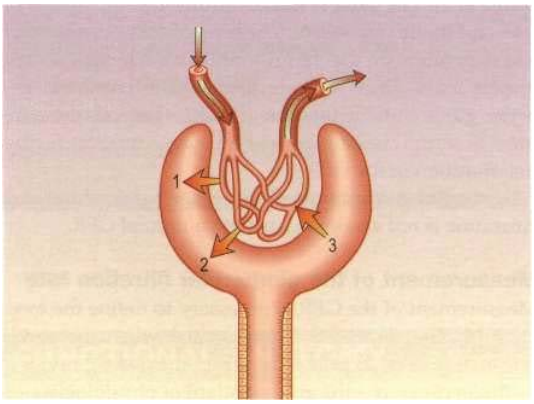

Fig. 11.3 Pressures controlling glomerular filtration. 1, capillary hydrostatic pressure (45 mmHg); 2, hydrostatic pressure in Bowman's space (10 mmHg); 3, plasma protein oncotic pressure (25 mmHg). Arrows (1, 2, 3) indicate the direction of a pressure gradient.

amino acids (Fig. 11.2b). Additional water and sodium chloride are reabsorbed more distally, and fine tuning of salt and water balance is achieved in the distal tubules and collecting ducts under the influence of aldosterone and antidiuretic hormone (ADH). The final urine volume is thus 1-2 L daily. Calcium, phosphate and magnesium are also selectively reabsorbed in proportion to the need to maintain a normal electrolyte composition of body fluids.

The urinary excretion of some compounds is more complicated. For example, potassium is freely filtered at the glomerulus, almost completely reabsorbed in the proximal tubule, and secreted in the distal tubule and collecting ducts. A clinical consequence of this is that the ability to eliminate unwanted potassium is less dependent on GFR than is the elimination of urea or creatinine. Other compounds filtered and reabsorbed or secreted to a variable extent include urate and many organic acids, including many drugs or their metabolic breakdown products. The more tubular secretion of a compound that occurs, the less dependent elimination is on the GFR; penicillin and cefradine are examples of compounds secreted by the tubules.

Urine concentration and the countercurrent system

Urine is concentrated by a complex interaction between the loops of Henle, the medullary interstitium, medullary blood vessels (vasa recta) and the collecting ducts (see p. 691). The proposed mechanism of urine concentration is termed 'the countercurrent mechanism'. The countercurrent hypothesis states that: 'a small difference in osmotic concentration at any point between fluid flowing in opposite directions in two parallel tubes connected in a hairpin manner is multiplied many times along the length of the tubes'. Tubular fluid moves from the renal cortex towards the papillary tip of the medulla via the proximal straight tubule and the thin descending limb of the loop of Henle, which is permeable to water and impermeable to sodium. The tubule then loops back towards the cortex so that the direction of the fluid movement is reversed in the ascending limb, which is impermeable to water but permeable to sodium. This results in a large osmolar concentration difference between the corticomedullary junction and the hairpin loop at the tip of the papilla, and hence countercurrent multiplication. There is an analogy with heat exchangers. Since the urine that emerges from the proximal tubule is iso-osmotic, the first nephron segment actually involved in urinary concentration is the descending limb of Henle's loop. There are two types of descending limbs (Fig. 11.2b). The short loops originate in superficial and midcortical glomeruli, which turn in the outer medulla. The long loops, which originate in the deep cortical and

juxtamedullary glomeruli, penetrate the outer medulla up to the tip of the papilla. Approximately 15% of nephrons have long loops and the remaining 85% have short loops. Both the ascending limb in the outer and inner medulla and the first part of the distal tubule are impermeable to water and urea. Through the $Na^+/K^+/2Cl$ cotransporter, the thick ascending limb actively transports sodium chloride, increasing the interstitial tonicity, resulting in tubular dilution with no net movement of water and urea on account of low permeability. The hypotonic fluid under ADH action undergoes osmotic equilibration with the interstitium in the late distal and the cortical and outer medullary collecting duct, resulting in water removal. Urea concentration in the tubular fluid rises on account of low urea permeability. At the inner medullary collecting duct, which is highly permeable to urea and water, especially in response to ADH, the urea enters the interstitium down its concentration gradient, preserving interstitial hypertonicity and generating high urea concentration in the interstitium.

The hypertonic interstitium causes abstraction of water from the descending limb of the loop of Henle, which is relatively impermeable to NaCl and urea, making the tubular fluid hypertonic with high NaCl concentration as it arrives at the bend of the loop of Henle. Urea plays a key role in the generation of medullary interstitial hypertonicity. The urea that is reabsorbed into the inner medullary stripe from the terminal inner medullary collecting duct is carried out of this region by ascending vasa recta, which deposits urea into the adjacent descending limb of both short and long loops of Henle, thus recycling the urea to the inner medullary collecting tubule. This process is facilitated by the close anatomical relationship that the hairpin loop of Henle and the vasa recta share.

Acid-base balance

Tubular function is also critical to the control of acid-base balance. Thus, filtered bicarbonate is largely reabsorbed and hydrogen ions are excreted mainly buffered by phosphate (see p. 713).

Glomerular filtration rate (GFR)

In health, the GFR remains remarkably constant owing to intrarenal regulatory mechanisms. In disease, with a reduction in intrarenal blood flow, damage to or loss of glomeruli, or obstruction to the free flow of ultrafiltrate along the tubule, the GFR will fall and the ability to eliminate waste material and to regulate the volume and composition of body fluid will decline. This will be manifest as a rise in the plasma urea or creatinine and in a reduction in measured GFR.

The concentration of urea or creatinine in plasma represents the dynamic equilibrium between production and elimination. In healthy subjects there is an enormous reserve of renal excretory function, and serum urea and creatinine do not rise above the normal range until there is a reduction of 50-60% in the GFR. Thereafter, the level of urea depends both on the GFR and its production rate (Table 11.1). The latter is heavily influenced by protein intake and tissue catabolism. The level of creatinine is much less dependent on diet but is more related to age, sex and muscle mass. Once it is elevated, serum creatinine is a better guide to GFR than urea and, in general, measurement of serum creatinine is a good way to monitor further deterioration in the GFR.

It must be re-emphasized that a normal serum urea or creatinine is not synonymous with a normal GFR.

Table 11.1 **Factors influencing serum urea levels**

Production	Elimination
Increased by	**Increased by**
High-protein diet Increased catabolism	Elevated GFR, e.g. pregnancy
Surgery	**Decreased by**
Infection	Glomerular disease Reduced renal blood flow
Trauma	Hypotension
Corticosteroid therapy	Dehydration Urinary obstruction Tubulointerstitial nephritis
Tetracyclines Gastrointestinal bleeding Cancer	
Decreased by	
Low-protein diet Reduced catabolism, e.g. old age	
Liver failure	

GFR, glomerular filtration rate

Measurement of the glomerular filtration rate

Measurement of the GFR is necessary to define the exact level of renal function. It is essential when the serum (plasma) urea or creatinine is within the normal range.

Inulin clearance - the gold standard of physiologists - is not practical or necessary in clinical practice. The most widely used measurement is the creatinine clearance (Fig. 11.4).

Creatinine clearance is dependent on the fact that daily production of creatinine (principally from muscle cells) is remarkably constant and little affected by protein intake. Serum creatinine and urinary output thus vary very little throughout the day. This permits the use of 24-hour urine collections, which reduce collection errors, and the measurement of a single serum creatinine value during the 24 hours.

Creatinine excretion is, however, by both glomerular filtration and tubular secretion, although at normal serum levels the latter is relatively small. As most laboratory methods for measurement of serum creatinine give slight overestimates, the calculation of clearance fortuitously gives a value close to that of inulin.

With progressive renal failure, creatinine clearance may overestimate GFR but, in clinical practice, this is seldom significant. Certain drugs - for example cimetidine, trimethoprim, spironolactone and amiloride - reduce tubular secretion of creatinine, leading to a rise in serum creatinine and a fall in measured clearance.

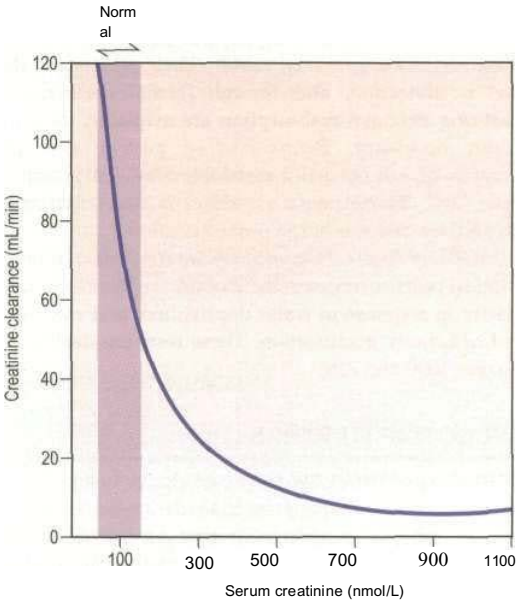

Fig. 11.4 **Creatinine clearance versus serum creatinine.** Note that the serum creatinine does not rise above the normal range until there is a reduction of 50-60% in the glomerular filtration rate (creatinine clearance).

Given these observations, creatinine clearance, nevertheless, is a reasonably accurate measure of GFR in those situations in which it is most required - normal or near normal renal function. Urine is collected over 24 hours for measurement of urinary creatinine. A plasma level of creatinine is measured sometime during the 24-hour period. Creatinine clearance is obtained from the formula:

$$UxV/P$$

where U = urine concentration of creatinine; V = rate or urine flow in mL/min; P = plasma concentration of creatinine. Normal ranges: men 90-140 mL/min; women 80-125 mL/min.

Where urine collections are difficult (e.g. with ileal conduits) or deemed inaccurate, the GFR may be measured by the single injection of compounds such as [^{51}Cr]EDTA (ethylenediaminetetraacetic acid), [^{99m}Tc]DTPA (diethylenetriaminepentaacetic acid) or [^{125}I]iothalamate, their excretion being primarily by glomerular filtration. Following intravenous injection of the compound, three blood samples are obtained at 2, 3 and 4 hours (or rather longer intervals if the patient is oedematous or if renal failure is suspected). The GFR may then be calculated from the slope of the exponential fall in blood level of the compound. Increasingly, iohexol (a low-osmolality, non-ionic contrast medium) is being used, particularly in study settings. It is non-radioactive and can be measured reliably by a routine biochemical HPLC (high-pressure liquid chromatography) technique. Iohexol clearance correlates with radioisotopic techniques and can be assessed from finger-prick blood samples.

Cystatin C is an endogenous cysteine protease inhibitor. It is a low-molecular-weight protein filtered freely by the glomerulus and is produced at a constant rate. It is not secreted by tubules and therefore correlates with GFR. The cystatin C level is unaffected by gender, and correction for surface area is not needed. Studies suggest that cystatin C levels correlate better with radioisotope estimation of GFR than do creatinine levels and are more sensitive to mild renal impairment, particularly when the creatinine level is still normal. However, there is a lack of prospective studies and the plasma normal range can be affected by malignancy and steroid therapy.

Calculated GFR. Measurement of true GFR is cumbersome, time consuming and may be inaccurate if 24-hour urine collections are incomplete. Therefore, several formulae have been developed that allow a prediction of creatinine clearance or GFR from serum creatinine and demographics. The Cockroft-Gault formula is used most frequently and takes into account the patient's age, gender, weight and plasma creatinine (Box 11.1). Recently, a new prediction equation has been developed based on the data derived from the Modification of Diet in Renal Disease (MDRD) study in patients with chronic renal failure (Box 11.1). This equation is based on, age, sex, serum urea, creatinine and albumin. In addition, unlike Cockroft-Gault it also considers racial background of the patient, which makes it more reliable in ethnically diverse

Box 11.1 **Calculation of creatinine clearance**

Cockroft-Gault equation *Men*

$$\text{Creatinine clearance} = \frac{1.23 \times (140 - \text{Age}) \times (\text{Weight in kg})}{\text{Serum creatinine (umol/L)}}$$

Women

Use the same equation but multiply by 1.04 instead of 1.23.

Modification of diet in renal disease (MDRD)

GFR = 170 x (S creatinine (mg/dL)-$^{0.999}$) x (Age-$^{0.176}$) x S urea mg/dL$^{-0.170}$) x (S albumin g/dL$^{+0.318}$) (x 0.762 if female: x 1.180 if black)

S = serum.

To convert creatinine values in umol/L to mg/dL multiply by 0.0113.

To convert serum urea in mmol/L to mL/dL multiply by 2.8.

See http://www.nephron.com for MDRD calculator.

National Kidney Foundation - clinical practice guidelines formula

$$\left(\frac{\text{q} \quad \text{\-i.i54} = \text{\^{}j}}{S_{Cr}} \quad \text{x Age}^{*0.203}\right.$$

S_{Cr} = serum creatinine (umol/L)

For woman - multiply by 0.742. If black African - multiply by 1.212.

groups of individuals. It is very popular in large population-based epidemiological studies where weight of the patient is usually not available. A clinical practice guideline formula produced by the National Kidney Foundation is also shown in Box 11.1.

TUBULAR FUNCTION

The major function of the tubule is the selective reabsorption or excretion of water and various cations and anions to keep the volume and electrolyte composition of body fluid normal (see Ch. 12).

The active reabsorption from the glomerular filtrate of compounds such as glucose and amino acids also takes place. Within the normal range of blood concentrations these substances are completely reabsorbed by the proximal tubule. However, if blood levels are elevated above the normal range, the amount filtered (filtered load = GFR x plasma concentration) may exceed the maximal absorptive capacity of the tubule and the compound 'spills over' into the urine. Examples of this occur with hyperglycaemia in diabetes mellitus or elevated plasma phenylalanine in phenylketonuria.

Conversely, inherited or acquired defects in tubular function may lead to incomplete absorption of a normal filtered load, with loss of the compound in the urine (a lowered 'renal threshold'). This is seen in renal glycosuria, in which there is a genetically determined defect in tubular reabsorption of glucose. It is diagnosed by demonstrating glycosuria in the presence of normal blood glucose levels. Inherited or acquired defects in the tubular reabsorption of amino acids, phosphate, sodium, potassium and calcium also occur, either singly or in combination. Examples include cystinuria and the Fanconi syndrome (see p. 1144 and Ch. 12). Tubular defects in the reabsorption of water result in nephrogenic diabetes insipidus (p. 1091). Under normal circumstances, antidiuretic hormone induces an increase in the permeability of water in the collecting ducts by attachment to receptors with subsequent activation of adenyl cyclase. This then activates a protein kinase, which induces preformed cytoplasmic vesicles containing water channels (termed 'aquaporins') to move to and insert into the tubular luminal membrane. This allows water entry into tubular cells down a favourable osmotic gradient. Water then crosses the basolateral membrane and enters the bloodstream. When the effect of ADH wears off, water channels return to the cell cytoplasm (Fig. 12.5).

Investigation of tubular function in clinical practice

Various tubular mechanisms could theoretically be investigated, but, in clinical practice, tests of tubular function are required less often than glomerular function. *Twenty-four-hour sodium output* may be helpful in determining whether a patient is complying with a low-salt diet and in the management of salt-losing nephropathy. *Tests of proximal tubular function* may be required in the diagnosis of Fanconi's syndrome or isolated proximal tubular defects (e.g. urate clearance). Bicarbonate, glucose, phosphate and amino acid are all reabsorbed in the proximal tubule. Their presence in the urine is abnormal, and though formal methods of measuring maximal reabsorption are available, they are seldom necessary. *Retinal-binding protein* and *fS2-microglobulin* are normally reabsorbed by the proximal tubule, and their urinary excretion is non-specifically increased by diseases of the proximal tubule.

Two tests of distal tubular function are commonly applied in clinical practice: measurement of urinary concentrating capacity in response to water deprivation, and measure ment of urinary acidification. These tests are dealt with on pages 1090 and 718.

ENDOCRINE FUNCTION

Renin-angiotensin system (see also p. 1096) The juxtaglomerular apparatus is made up of specialized arteriolar smooth muscle cells that are sited on the afferent glomerular arteriole as it enters the glomerulus. These cells synthesize prorenin, which is cleaved into the active proteolytic enzyme renin. Active renin is then stored in and released from secretary granules. Prorenin is also released in the circulation and comprises 50-90% of circulating renin, but its physiological role remains unclear as it cannot be converted into active renin in the systemic circulation. Renin converts angiotensinogen in blood to angiotensin I. Angiotensin-converting enzyme (ACE), which is located in the lung, luminal border of endothelial cells, glomeruli and other organs, converts angiotensin I (decapeptide) to angiotensin II (octapeptide). Renin release is controlled by:

- pressure changes in the afferent arteriole
- sympathetic tone
- chloride and osmotic concentration in the distal tubule via the macula densa (Fig. 11.2a)
- local prostaglandin and nitric oxide release.

Angiotensin II has two major systemic effects: systemic vasoconstriction and sodium and water retention. Both of these actions will tend to reverse the hypovolaemia or hypotension that is usually responsible for the stimulation of renin release. Angiotensin II promotes renal NaCl and water absorption by direct stimulation of Na^+ reabsorption in the early proximal tubule and by increased adrenal aldosterone secretion which enhances Na^+ transport in the collecting duct. In addition to influencing systemic haemodynamics, angiotensin II also regulates GFR. Although it constricts both afferent and efferent arterioles, vasoconstriction of efferent arterioles is three times greater than that of afferent, resulting in increase of glomerular capillary pressure and maintenance of GFR. In addition, angiotensin II constricts mesangial cells, reducing the filtration surface area, and sensitizes the afferent arteriole to the constricting signal of tubuloglomerular feedback (see p. 606). The net result is that angiotensin II has opposing effects on the regulation of GFR: (a) an increase in glomerular pressure and consequent rise in GFR; (b) reduction in renal blood

flow and mesangial cell contraction, reducing filtration. In renal artery stenosis with resultant low perfusion pressure, angiotensin II maintains GFR. However, in cardiac failure and hypertension, GFR may be reduced by angiotensin II.

Erythropoietin (see also p. 422)
Erythropoietin is the major stimulus for erythropoiesis. It is a glycoprotein produced principally by fibroblast-like cells in the renal interstitium. Under hypoxic conditions both the alpha and beta subunits of hypoxia inducible factor 1 (HIF-1) are expressed, leading to subsequent erythropoietin gene transcription via the combined effects of hepatic nuclear factor 4 (HNF-4), p300, and HIF-1-alpha and -beta. Erythropoietin, once formed, binds to its receptors on erythroid precursor cells. Under normal oxygen conditions, only the HIF-1-beta subunit is expressed. The alpha subunit undergoes proline hydroxylation in the presence of iron and oxygen by prolyl hydoxylase. The hydroxylated HIF-1-alpha subunit binds to von Hippel-Lindau protein and a ubiquitin ligase complex is activated. This leads to ubiquitination and subsequent degradation of HIF-1-alpha via proteosomes so that no erythropoietin is transcribed.

Loss of renal substance, with decreased erythropoietin production, results in a normochromic, normocytic anaemia. Conversely, erythropoietin secretion may be increased, with resultant polycythaemia, in patients with polycystic renal disease, benign renal cysts or renal cell carcinoma. Recombinant human erythropoietin has been biosynthesized and is available for clinical use, particularly in patients with renal failure (see p. 673).

Vitamin D metabolism (see also p. 592) Naturally occurring vitamin D (cholecalciferol) requires hydroxylation in the liver at position 25 and again by a 1a-hydroxylase enzyme (mitochondrial cytochrome P450) mainly in the distal convoluted tubule, the cortical and inner medullary part of the collecting ducts and the papillary epithelia of the kidney to produce the powerfully metabolically active 1,25-dihydroxycholecalciferol ($1,25\text{-}(OH)_2D_3$). The 1a-hydroxylase activity is increased by high plasma levels of parathyroid hormone (PTH), low phosphate and low $1,25\text{-}(OH)_2D_3$. 1,25-Dihydroxycholecalciferol and 25-hydroxycholecalciferol are degraded in part by being hydroxylated at position 24 by 24-hydroxylase. The activity of this enzyme is reduced by PTH and increased by $1,25\text{-}(OH)_2D_3$ (which therefore promotes its own inactivation).

Reduced 1a-hydroxylase activity in diseased kidneys results in relative deficiency of $1,25\text{-}(OH)_2D_3$. As a result, gastrointestinal calcium and to a lesser extent phosphate absorption is reduced and bone mineralization impaired. Receptors for $1,25\text{-}(OH)_2D_3$ exist in the parathyroid glands, and reduced occupancy of the receptors by the vitamin alters the set-point for release of PTH in response to a given decrement in plasma calcium concentration. Gut calcium malabsorption, which induces a tendency to hypocalcaemia, and relative lack of $1,25\text{-}(OH)_2D_3$, contribute therefore to the hyperparathyroidism seen regularly in patients with renal impairment, even of modest degree.

Autocrine function

Endothelins
The endothelins ET-1, ET-2 and ET-3 are a family of similar potent vasoactive peptides that also influence cell proliferation and epithelial solute transport. They do not circulate but act locally. ETs are produced by most types of cells in the kidney. The vascular actions are mediated by two receptors, with ET_A (specific for ET-1) mediating vasoconstriction and ET_B (responsive to all ETs) causing vasodilatation. Endothelins inhibit sodium and water absorption by suppressing Na^+/K^+-ATPase and Na^+/H^+ antiporter activity in the proximal tubule and antagonizing the action of ADH and aldosterone in the collecting duct. Tubular transport actions are mediated by ET_B. Endothelins, through vasoconstriction by ET_A and salt and water retention via ET_B receptors, cause hypertension. Endothelins, mainly through ET_A receptors, can also alter cell proliferation and matrix accumulation by increasing tissue inhibitor of metalloproteinase, cytokines, fibronectin and collagen. These peptides also stimulate the proliferation of a variety of renal cell types.

Prostaglandins
Prostaglandins are unsaturated, oxygenated fatty acids, derived from the enzymatic metabolism of arachidonic acid, mainly by constitutively expressed cyclo-oxygenase-1 (COX-1) or inducible COX-2 (see Fig. 14.32). COX-1 is highly expressed in the collecting duct, while COX-2 expression is restricted to the macula densa. Both COX isoforms convert arachidonic acid to the same product, the bioactive but unstable prostanoid precursor, prostaglandin H_2 (PGH_2). PGH_2 is converted to:

- PGE_2 (formed by PDE_2 synthase in the collecting duct, responsible for natriuretic and diuretic effects)
- PGD_2 (undetermined significance, produced in proximal tubule)
- prostacyclin (PGI_2) (mainly synthesized in the interstitial and vascular compartment)
- thromboxane A_2 (vasoconstrictor, mainly synthesized in glomerulus).

They all act through G-coupled transmembrane receptors. Prostaglandins maintain renal blood flow and glomerular filtration rate in the face of reductions induced by vasoconstrictor stimuli such as angiotensin II, catecholamines and a-adrenergic stimulation. In the presence of renal underperfusion, inhibition of prostaglandin synthesis by non-steroidal anti-inflammatory drugs results in a further reduction in GFR, which is sometimes sufficiently severe as to cause acute renal failure. Renal prostaglandins also have a natriuretic renal tubular effect and antagonize the action of antidiuretic hormone. Renal prostaglandins do not regulate salt and water excretion in normal subjects, but in some circumstances, such as chronic renal failure, prostaglandin-induced vasodilatation is involved in maintaining renal

blood flow. Patients with chronic renal failure are thus vulnerable to further deterioration in renal function on exposure to non-steroidal anti-inflammatory drugs, as are elderly patients in many of whom renal function is compromised by renal vascular disease and/or the effects of ageing upon the kidney. Moreover, in conditions such as volume depletion, which are associated with high renin release (facilitated by prostaglandins), inhibition of prostaglandin synthesis may lead to hyperkalaemia due to hyporeninaemic hypoaldosteronism (since angiotensin II is the main stimulus for aldosterone).

Urodilatin: renal natriuretic peptide

(see also p. 1096)

A 32-amino-acid atrial natriuretic-like peptide (ANP-like peptide), putatively synthesized by connecting and collecting ducts in the kidney, has been isolated from human urine. Its natriuretic potency equals or exceeds that of atrial ANP by increasing cGMP production in the collecting duct. It is postulated that cardiac ANP is primarily a regulator of the cardiovascular system through its vascular effects and that renal natriuretic peptide participates in the intrarenal regulation of sodium and chloride transport.

Nitric oxide and the kidney

Nitric oxide (Fig. 15.10), a molecular gas, is formed by the action of three isoforms of nitric oxide synthase (NOS). All three enzymes, neuronal (nNOS or NOS1), inducible (iNOS or NOS2) and endothelial (eNOS or NOS3), which are cytochrome P450-like proteins, facilitate the addition of the guanidine nitrogen of the amino acid arginine to molecular oxygen, producing nitric oxide and water. In general nNOS and eNOS are constitutively active, producing low levels of nitric oxide dependent upon intracellular calcium elevation. In contrast, the transcriptional regulation of iNOS can be markedly induced, particularly by inflammatory cytokines, resulting in extremely large amounts of nitric oxide. The most recognized cellular target of nitric oxide is soluble guanylate cyclase. The stimulation of this enzyme enhances the synthesis of cyclic GMP from GTP. All three isoforms, are expressed in the kidney with eNOS in the vascular compartment, nNOS mainly in the macula densa and inner medullary collecting duct and iNOS in several tubule segments. Nitric oxide mediates the following physiological actions in the kidney:

- regulation of renal haemodynamics
- natriuresis by inhibiting Na^+/K^+-ATPase and Na^+/H^+ antiporter and antagonizing ADH
- modulation of tubuloglomerular feedback so that the composition of tubular fluid delivered to the macula densa changes the filtration rate of the associated glomerulus.

Protein and polypeptide metabolism

The kidney is a major site for the catabolism of many small-molecular-weight proteins and polypeptides, including many hormones such as insulin, PTH and calcitonin by endocytosis carried out by megalin-cubilin complex in the brush border of proximal tubular cells. In renal failure the metabolic clearance of these substances is reduced and their half-life is prolonged. This accounts, for example, for the reduced insulin requirements of diabetic patients as their renal function declines.

INVESTIGATIONS

EXAMINATION OF THE URINE

Appearance

This is of little value in the differential diagnosis of renal disease except in the diagnosis of haematuria. Overt 'bloody' urine is usually unmistakable but should be checked using dipsticks (Stix testing). Very concentrated urine may also appear dark or smoky. Other causes of discoloration of urine include cholestatic jaundice, haemoglobinuria, drugs such as rifampicin, use of fluorescein or methylthioninium chloride (methylene blue), and ingestion of beetroot. Discoloration of urine after standing for some time occurs in porphyria, alkaptonuria and in patients ingesting the drug L-dopa.

Volume

In **health, the** volume of urine passed is primarily determined by diet and fluid intake. In temperate climates it lies within the range 800-2500 mL per 24 hours. The minimum amount passed to stay in fluid balance is determined by the amount of solute - mainly urea and electrolytes - being excreted and the maximum concentrating power of the kidneys. On a normal diet, some 800 mOsm of solute are passed daily. Since the maximum urine concentration is approximately 1200 mOsm/kg, the minimum volume of urine obligated by excretion of 800 mOsm of solute would thus be approximately 650 mL. A diet rich in carbohydrate and fat and low in protein and salt results in a lower solute excretion and as little as 300 mL of urine per day may be required. Conversely, a high-salt, high-protein intake obligates a larger urine flow and, via the thirst mechanism, a higher fluid intake. The appropriateness of a given daily urine output must therefore be related to factors such as diet, body size and fluid intake.

In diseases such as chronic renal failure or diabetes insipidus, impairment of concentrating ability requires increased volumes of urine to be passed, given the same daily solute output. An increased solute output, such as in glycosuria or increased protein catabolism following

surgery or associated with sepsis, also demands increased urine volumes.

The maximum urine output depends on the ability to produce dilute urine. Intakes of 10 or even 20 L daily can be tolerated by normal humans but, given a daily solute output of 800 mOsm, require the ability to dilute to 80 and 40 mOsm/kg, respectively. Where diluting ability is impaired such as inappropriate secretion of ADH, the ability to excrete large volumes of ingested water is also impaired.

Oliguria

Oliguria, usually defined as the excretion of less than 300 mL of urine per day, may be 'physiological', as in patients with hypotension and hypovolaemia, where urine is maximally concentrated in an attempt to conserve water. More often, it is due to intrinsic renal disease or obstructive nephropathy (see p. 654).

Anuria (no urine) suggests urinary tract obstruction until proved otherwise; bladder outflow obstruction must always be considered first.

Polyuria

Polyuria is a persistent, large increase in urine output, usually associated with nocturia. It must be distinguished from frequency of micturition with the passage of small volumes of urine. Documentation of fluid intake and output may be necessary. Polyuria is the result of an excessive (hysterical) intake of water, an increased excretion of solute (as in hyperglycaemia and glycosuria), or a defective renal concentrating ability or failure of production of ADH.

Specific gravity and osmolality

Urine specific gravity is a measure of the weight of dissolved particles in urine, whereas urine osmolality reflects the number of such particles. Usually the relationship between the two is close. An exception exists when a relatively small number of relatively large particles are present in urine, such as in multiple myeloma. Measurement of urine specific gravity or osmolality is required only in limited circumstances, such as the differential diagnosis of oliguric renal failure or the investigation of polyuria or inappropriate ADH secretion. Specific gravity is usually fixed at 1.010 in chronic failure or acute tubular necrosis as compared to prerenal acute renal failure where specific gravity is very high close to 1.025.

Urinary pH

Measurement of urinary pH is unnecessary except in the investigation and treatment of renal tubular acidosis (see p. 716).

Chemical (Stix) testing

Routine Stix testing of urine for blood, protein and sugar is obligatory in all patients suspected of having renal disease.

Blood

Haematuria may be overt, with bloody urine, or microscopic and found only on chemical testing. Currently used Stix tests for blood are very sensitive, being positive if two or more red cells are visible under the high-power field of a light microscope. Indeed, the test is too sensitive, sometimes giving positive results in normal individuals. A further disadvantage is that Stix testing cannot distinguish between blood and free haemoglobin. A positive Stix test must always be followed by microscopy of fresh urine to confirm the presence of red cells and so exclude the relatively rare conditions of haemoglobinuria or myoglobinuria. In females with a positive Stix test result for blood, it is essential to enquire whether the patient is menstruating. Bleeding may come from any site within the urinary tract (Fig. 11.5):

- *Overt bleeding from the urethra* is suggested when blood is seen at the start of voiding and then the urine becomes clear.
- *Blood diffusely present* throughout the urine comes from the bladder or above.
- *Blood only at the end of micturition* suggests bleeding from the prostate or bladder base.

Careful urine microscopy is mandatory as the presence of red-cell casts is diagnostic of bleeding from the kidney itself, most often due to glomerulonephritis. In the absence of red-cell casts, further investigations, such as urine cytology, renal imaging and cystoscopy, are required to define the site of bleeding. Renal biopsy may be required (see p. 618).

Protein

Proteinuria is one of the most common signs of renal disease. Detection is primarily by Stix testing. Most

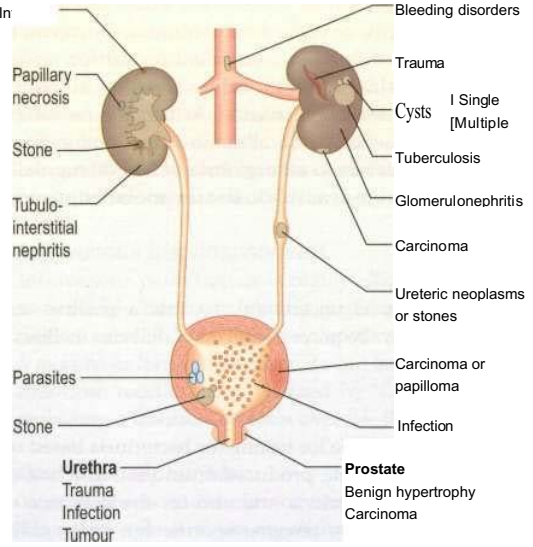

Fig. 11.5 Sites and causes of bleeding from the urinary tract.

reagent strips can detect a concentration of 100-200 mg/L or more in urine. They react primarily with albumin and are relatively insensitive to globulin and Bence Jones proteins.

If proteinuria is confirmed on repeated Stix testing, protein excretion in 24-hour urine collections should be measured (but see below). Healthy adults excrete up to 30 mg daily of albumin. Pyrexia, exercise and adoption of the upright posture all increase urinary protein output. Proteinuria, while occasionally benign, always requires further investigation. In some glomerular disease the protein leak is selective (e.g. minimal change) and urine electrophoresis can demonstrate the relative leaks, e.g. IgA or albumin.

Postural proteinuria. This term is used to refer to proteinuria present on dipstick testing which becomes undetectable after a period of hours lying flat. Typically, a negative dipstick result is obtained on the first urine passed on rising in the morning, whereas subsequent specimens give a positive result. This is regarded even for insurance purposes as a benign condition.

Microalbuminuria

The term microalbuminuria is an unfortunate one since the albumin referred to is of normal molecular size and weight. Normal individuals excrete less than 20 |ig of albumin per minute (30 mg in 24 hours). Dipsticks, however, detect albumin only in a concentration above 200 mg/L (300 mg per 24 hours if urine volume is normal). An increase in albumin excretion between these two levels - so-called microalbuminuria - is now known to be an early indicator of diabetic glomerular disease. It is widely used as a predictor of the development of nephropathy in diabetics and may be extended to other conditions.

Timed 24-hour urinary excretion rates provide the most precise measure of microalbuminuria. However, in clinical practice it is more convenient to test for microalbuminuria using random urine samples in which albumin concentration is related to urinary creatinine concentration. Generally an albumin : creatinine ratio of 2.5 to 20 corresponds to albuminuria of 30-300 mg daily respectively. Kits are available to test for microalbuminuria.

Glucose

Renal glycosuria is uncommon, so that a positive test for glucose always requires exclusion of diabetes mellitus.

Bacteriuria

Dipsticks are available for testing for bacteriuria based on the detection of nitrite produced from the reduction of urinary nitrate by bacteria and also for the detection of leucocyte esterase, an enzyme specific for neutrophils. Although each test on its own has limitations, a positive reaction with both tests has a high predictive value for urinary tract infection (p. 640).

Microscopy

Urine microscopy should be carried out in all patients suspected of having renal disease. Care must be taken to obtain a 'clean' sample of mid-stream urine. The presence of numerous skin squames suggests a contaminated, poorly collected sample that cannot be properly interpreted.

If a clean sample of urine cannot be obtained, supra-pubic aspiration is required in suspected urinary tract infections, particularly in children.

White cells

The presence of 10 or more white blood cells (WBCs) per cubic millimetre in fresh unspun mid-stream urine samples is abnormal and indicates an inflammatory reaction within the urinary tract. Most commonly it is due to urinary tract infection (UTI), but it may also be found in sterile urine in patients during antibiotic treatment of urinary infection or within 14 days of treatment. Sterile pyuria also occurs in patients with stones, tubulointerstitial nephritis, papillary necrosis, tuberculosis, and interstitial cystitis.

Red cells

The presence of one or more red cells per cubic millimetre in unspun urine samples results in a positive Stix test *for* blood and is abnormal. It is claimed that red cells of glomerular origin can be identified by their dysmorphic appearance, especially on phase-contrast microscopy, but the method is subject to observer error and has not gained wide acceptance. . . ; . - ■ ■ . : ,

Casts (see Fig. 11.6) - "-
These cylindrical bodies, which are moulded ('cast') in the shape of the distal tubular lumen, may be hyaline, granular or cellular. Hyaline casts and fine granular casts represent precipitated protein and may be seen in normal urine, particularly after exercise. More coarsely granular casts occur with pathological proteinuria in glomerular and tubular disease. Red-cell casts - even one - always indicate renal disease. If red cells degenerate, a rusty coloured 'haemoglobin' granular cast is seen. White *cell* casts may be seen in acute pyelonephritis. They may be confused with the tubular cell caste \.V\a\. occvtf\t\ p&V\erte with acute tubular necrosis.

Bacteria

The demonstration of bacteria on Gram staining of the centrifuged deposit of a clean-catch mid-stream urine sample is highly suggestive of urinary infection and can be of value in the immediate differential diagnosis of UTI. If accompanied by pyuria it may be accepted as evidence of UTI in the ill and febrile patient and treatment should be initiated.

Urine for quantitative culture (see p. 640) must always be obtained prior to starting antibiotic treatment in order to confirm the diagnosis and to allow definition of bacterial antibiotic sensitivities.

Stix testing for blood or protein is of no value in the diagnosis of UTI, as both may be absent from the urine of many patients with bacteriuria.

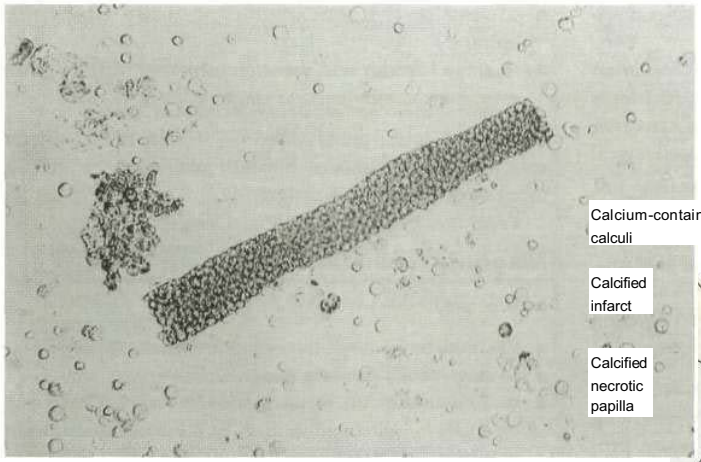

Fig. 11.6 Red-cell cast. Note aggregation of red cells as a 'cast' of the tubule.

BLOOD AND QUANTITATIVE TESTS

The use of serum urea, creatinine and GFR as measures of renal function is discussed on page 608. Other quantitative tests of disturbed renal function are described under the relevant disorders.

IMAGING TECHNIQUES

Plain X-ray

A plain radiograph of the abdomen is always taken prior to urography. Its main value is to identify renal calcification or radiodense calculi in the kidney, renal pelvis, line of the ureters or bladder (Fig. 11.7).

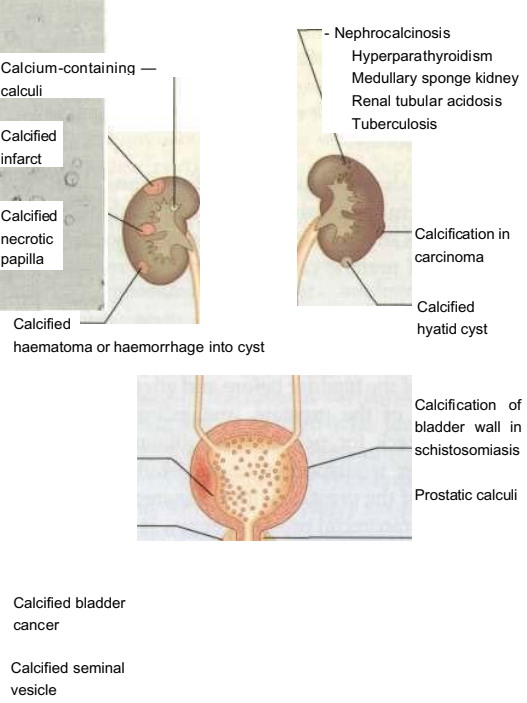

Fig. 11.7 Calcification in the renal tract. Calculi can occur at any site.

Excretion urography

Excretion urography, also known as intravenous urography (IVU) or intravenous pyelography (IVP), still plays a role in renal diagnosis, especially in patients with haematuria and stone disease, but has in part been replaced by ultrasonography and CT scanning. An organic iodine-containing contrast medium is given intravenously. A small proportion of patients will have an 'allergic' reaction to contrast medium. With low-osmolality contrast media the risk is relatively low (e.g. 1% develop bronchospasm or urticaria, less than 0.003% develop more severe complications such as cardiac arrhythmias and convulsions and the mortality is of the order 1 in 200 000). Patients who have had a previous contrast medium reaction, who have asthma or a history of allergy requiring medical treatment should receive steroid prophylaxis before contrast medium (e.g. prednisolone 30 mg 12 hours and 2 hours before contrast medium). Contrast media do not cause renal damage in normovolaemic patients with normal renal function, but may be nephrotoxic in patients with impaired renal function, especially when this results from diabetic nephropathy or multiple myeloma. The IVU series should be inspected for renal size and position (kidneys span over three lumbar vertebrae and the left is higher than the right). Any distortion of the smooth renal outline, calyceal dilatation (e.g. due to obstruction), filling defects in renal pelves (e.g. stones, tumour), ureteric obstruction and displacement (e.g. retroperitoneal fibrosis) should be noted. The bladder should be examined both pre- and postmicturition for abnormalities of contour and residual volume.

Ultrasonography

Ultrasonography of the kidneys and bladder has the advantage over X-ray techniques of avoiding ionizing radiation and intravascular contrast medium. In renal diagnosis it is the method of choice for:

- renal measurement and for renal biopsy or other interventional procedures
- checking for pelvicalyceal dilatation as an indication of renal obstruction when chronic renal obstruction is suspected; in suspected acute ureteric obstruction either intravenous urography or unenhanced spiral CT are the methods of choice
- characterizing renal masses as cystic or solid
- diagnosing polycystic kidney disease
- detecting intrarenal and/or perinephric fluid (e.g. pus, blood)
- demonstrating renal arterial perfusion or detecting renal vein thrombosis using Doppler technique.

Doppler ultrasonography is based on the principle that, when incident sound waves are reflected from a moving structure, their frequency is shifted by an amount proportional to the velocity of the reflector (e.g. an RBC); this shift can be quantified and displayed as a spectral Doppler scan or colour overlay (colour Doppler).

Ultrasonography of the distended bladder is used to measure bladder wall thickness and to check for bladder tumours and stones. A scan obtained after voiding allows bladder emptying to be assessed.

The disadvantages of using ultrasonography to assess the urinary tract are:

- It does not show detailed pelvicalyceal anatomy.
- It does not fully visualize the normal adult ureter.
- It may miss small renal calculi and does not detect the majority of ureteric calculi. CT may be required (see below).
- It is operator-dependent.

In patients with suspected benign prostatic hypertrophy, examination of the bladder before and after voiding, with measurement of the prostate, and examination of the kidneys to check for pelvicalyceal dilatation suffice. If prostate cancer is suspected, more detailed ultrasound examination of the prostate with a transrectal transducer, usually with transrectal prostate biopsy, is necessary.

Computed tomography (CT)

Computed tomography is used mainly as a second-line imaging method in the urinary tract, but increasingly as a first-line investigation in cases of suspected ureteric colic. Spiral CT has both improved image resolution and allows reconstruction of the imaging data in a variety of planes. CT is used:

- to characterize renal masses which are indeterminate at ultrasonography
- to stage renal tumours
- to detect 'lucent' calculi; low-density calculi which are lucent on plain films (e.g. uric acid stones) are well seen on CT
- to evaluate the retroperitoneum for tumours, retroperitoneal fibrosis (periaortitis) and other causes of ureteric obstruction
- to assess severe renal trauma
- to visualize the renal arteries and veins by helical or spiral CT
- to stage bladder and prostate tumours; MRI is, however, increasingly used to stage prostate cancer.

The use of spiral unenhanced CT in suspected ureteric colic permits diagnosis of causes of pain other than calculi more readily than does urography.

Magnetic resonance imaging (MRI)

MRI is used:

- to characterize renal masses as an alternative to CT
- to stage renal, prostate and bladder cancer
- to demonstrate the renal arteries by *magnetic resonance angiography* with gadolinium as contrast medium. In experienced hands its sensitivity and specificity approaches renal angiography.

Magnetic resonance urography is preferred over IVU in patients with chronic urolithiasis or intrinsic or extrinsic ureteric tumour, and in paediatric uroradiology. It is analogous to IVU. Gadolinium is used as contrast medium, which is regarded as less nephrotoxic than iodine-containing agents used in IVU.

Antegrade pyelography (Fig. n.8)

Antegrade pyelography involves percutaneous puncture of a pelvicalyceal system with a needle and the injection of contrast medium to outline the pelvicalyceal system and ureter to the level of obstruction. It is used when ultrasonography has shown a dilated pelvicalyceal system in a patient with suspected obstruction. Antegrade pyelography is the preliminary to percutaneous placing of a drainage catheter or ureteric stent in the obstructed pelvicalyceal system (percutaneous nephrostomy).

Retrograde pyelography

Following cystoscopy, preferably under screening control, a catheter is either impacted in the ureteral orifice or passed a short distance up the ureter, and contrast medium is injected. Retrograde pyelography is mainly used to investigate lesions of the ureter and to define the lower level of ureteral obstruction shown on excretion urography or ultrasound plus antegrade studies. It is invasive, commonly requires a general anaesthetic, and may result in the introduction of infection.

Micturating cystourethrography (MCU)

This involves catheterization and the instillation of contrast medium into the bladder. The catheter is then removed and the patient screened during voiding to check for vesicoureteric reflux and to study the urethra and bladder emptying. It is used primarily in children with recurrent infection (see p. 639).

MCU is not an appropriate investigation in adults because vesicoureteric reflux and urinary tract infection

Fig. 11.8 Antegrade pyelography via percutaneous catheter (small arrow) of obstructed system. Percutaneous drainage catheter (large arrow) has been inserted.

cause renal scarring and calyceal distortion in early life, but reflux tends to disappear by the time adulthood is reached. If reflux is detected in an adult with normal renal anatomy, it is thought not to induce kidney damage later. The absence of reflux in an adult does not therefore exclude the diagnosis of reflux nephropathy. Therefore, whatever the finding on micturating cystourethrography, management is not altered.

The presence or absence of vesicoureteric reflux may also be investigated by scintigraphy (see below).

Aortography or renal arteriography

Conventional or digital subtraction angiography (DSA) is used. The latter allows the use of smaller doses of contrast medium which can be injected via a central venous catheter (venous DSA) or via a fine transfemoral arterial catheter (arterial DSA). Angiography is mainly used to define extrarenal or intrarenal arterial disease. Arteriography is still the 'gold standard' method of renal artery imaging but magnetic resonance angiography and spiral CT angiography are being used increasingly (Fig. 11.9). Complications include cholesterol embolizations (p. 648) and contrast-induced kidney damage.

Venography is only used occasionally to exclude renal vein thrombosis. In most instances this can be done less invasively with Doppler ultrasonography, CT or MRI.

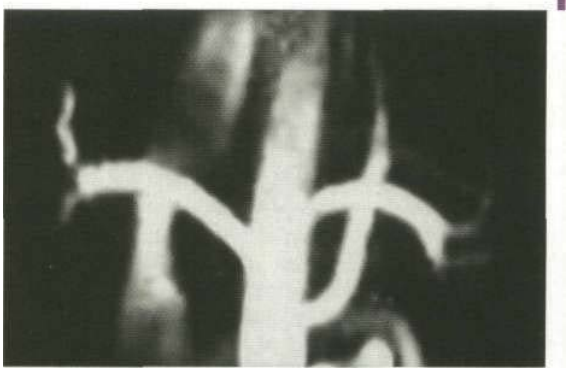

Fig. 11.9 Magnetic resonance angiogram of normal renal arteries.

Renal scintigraphy

Renal scintigraphy using a gamma camera is divided into:

- dynamic studies in which the function of the kidney is examined serially over a period of time, most often using a radiopharmaceutical excreted by glomerular filtration
- static studies involving imaging of tracer that is taken up and retained by the renal tubule.

Dynamic scintigraphy

The radiopharmaceutical technetium-labelled diethylenetriaminepentaacetic acid, [^{99m}Tc]DTPA is excreted by glomerular filtration. ^{123}I-labelled ortho-iodohippuric acid (Hippuran) is both filtered and secreted by the tubules and mercaptoacetyltriglycine (MAG3) labelled with technetium (^{99m}Tc) is excreted by renal tubular secretion. Following venous injection of a bolus of tracer, emissions from the kidney can be recorded by gamma camera. This information allows examination of blood perfusion of the kidney, uptake of tracer as a result of glomerular filtration, transit of tracer through the kidney, and the outflow of tracer-containing urine from the collecting system.

Renal blood flow

Dynamic studies can be used to investigate patients in whom renal artery stenosis is suspected as a cause for hypertension and in patients with severe oliguria (post-traumatic, post-aortic surgery, or after a kidney transplant) to establish whether, and to what extent, there is renal perfusion. In patients with unilateral renal artery stenosis there is, typically, a slowed and reduced uptake of tracer with delay in reaching a peak. Studies carried out before and after administration of an ACE inhibitor may demonstrate a fall in uptake that is suggestive of functional arterial stenosis. Both false-positive and false-negative results occur, particularly in patients with renal impairment, and renal arteriography remains the 'gold standard' in the diagnosis of main renal artery stenosis. In patients with total renal artery occlusion, no kidney uptake of tracers is observed.

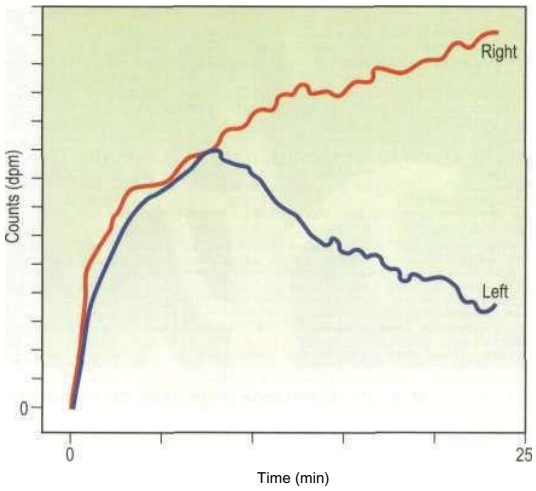

***Fig. 11.10* Dynamic scintigram.** Note the progressive rise of the right kidney curve to a plateau (in contrast to the normal left kidney curve) owing to urinary tract obstruction on the right side.

Static scintigraphy

This is usually performed using [^{99m}Tc]DMSA (dimercaptosuccinic acid), which is taken up by tubular cells. Uptake is proportional to renal function. :

Relative renal function

Function is normally evenly divided between the kidneys, with a range of 45-55%. Static studies are particularly useful in unilateral renal disease, where the relative uptake of the two kidneys can be calculated.

Kidney visualization

Normal kidneys show a uniform uptake with a smooth renal outline. Scars can be identified as photon-deficient 'bites'. Static scintigraphy is of considerable value in identifying ectopic kidneys or 'pseudotumours' of the kidneys (i.e. normally functioning renal tissue abnormally placed within the kidney).

Localization of infection

The use of citrate labelled with gallium-67 or isotopically labelled leucocytes that are taken up by inflammatory tissue may be of value in defining localized infection, such as renal abscesses or infection within a renal cyst.

Investigation of obstruction

Renal scintigraphy provides functional evidence of obstruction. After injection usually of (^{99m}Tc)MAG3 a rise in resistance to flow in the pelvis or ureter prolongs the parenchymal transit of tracer and there is usually a delay in emptying the pelvis. On whole-kidney renograms, the time-activity curve fails to fall after an initial peak, or continues to rise (Fig. 11.10).

When the possibility of obstruction is suspected, a dynamic renal scintigram is performed with diuresis. Furosemide (frusemide) (0.5 mg/kg, adult dose 40 mg) is given intravenously about 18-20 minutes into the study. Time-activity curves show an immediate fall after the injection of furosemide in the normal and in the absence of obstruction. In the presence of obstruction, the retention of activity in the pelvis persists, the activity-time curve fails to fall or falls to a lesser extent than the previous rate of rise of the activity-time curve.

A decision as to whether conservative surgery or nephrectomy should be carried out in unilateral obstruction is facilitated by renographic assessment of the contribution of each kidney.

Bladder emptying

At the end of dynamic studies, bladder emptying may be investigated and any postmicturition residual urine measured. Vesicoureteric reflux may be observed, although the sensitivity for detection of this is low. Increased sensitivity can be obtained by direct isotope cystography when a dilute isotope solution is instilled into the bladder by catheter.

Glomerular filtration rate

This is discussed on page 608.

TRANSCUTANEOUS RENAL BIOPSY

(Practicalbox11.1)

The renal biopsy is carried out under ultrasound control in specialized centres and requires interpretation by an experienced pathologist. The pathologist should provide information that helps clinical management. Renal biopsy is helpful in the investigation of the nephritic and nephrotic syndromes, acute and chronic renal failure, haematuria after urological investigations and renal graft dysfunction. Native renal biopsy material must be

Practical Box 11.1
Transcutaneous renal biopsy

Before biopsy

1. A coagulation screen is performed. It must be normal.
2. The serum is grouped and saved for crossmatching.
3. The patient is given a full explanation of what is involved and consent obtained.

During biopsy

1. The patient lies prone with a hard pillow under the abdomen.
2. The kidney is localized by ultrasound.
3. Local anaesthetic is injected along the biopsy track.
4. The patient holds a breath when the biopsy is performed.

After biopsy

1. A pressure dressing is applied to the biopsy site and the patient rests in bed for 24 hours.
2. The fluid intake is maximized to prevent clot colic.
3. The pulse and blood pressure are checked regularly.
4. The patient is advised to avoid heavy lifting or gardening for 2 weeks.

Table 11.2 Complications of transcutaneous renal biopsy

Macroscopic haematuria - about 20%
Pain in the flank, sometimes referred t o shoulder tip
Perirenal haematoma
Arteriovenous aneurysm formation - about 20%, almost always of no clinical significance Profuse haematuria demanding blood transfusion - 1-3% Profuse haematuria demanding occlusion of bleeding vessel at angiography or nephrectomy - approximately 1 in 400
Introduction of infection The mortality rate is about 0.1 %

examined by conventional histochemical staining, by electron microscopy, and by immunoperoxidase or immunofluorescence. Techniques like in situ hybridization and polymerase chain reaction analysis are also widely used in renal biopsy specimens.

The complications of transcutaneous renal biopsy are shown in Table 11.2.

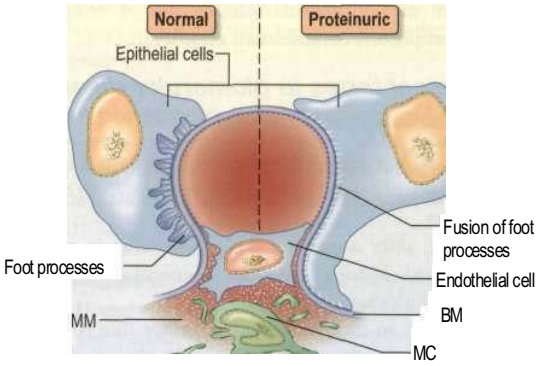

***Fig. 11.11* Diagram showing a normal (left) and proteinuric (right) glomerulus.** A capillary loop showing normal glomerular morphology on the left with an epithelial cell with pseudopodia (foot processes). In the proteinuric diagram (right) there is fusion of the foot processes characteristic of many diseases. BM, basement membrane; MC, mesangial cell; MM, mesangial matrix. After Marsh FP (1985) *Postgraduate Nephrology.* Butterworth Heinemann.

GLOMERULAR DISEASES

A glomerulus consists of a collection of capillaries which come from the afferent arteriole and are confined within the urinary space (Bowman's capsule); this is continuous with the proximal tubule. The capillaries are partially attached to mesangium, a continuation of the arteriolar wall consisting of mesangial cells and the matrix. The free wall of glomerular capillaries (across which filtration takes place) consists of basement membrane covered by visceral epithelial cells with individual foot processes and lined by endothelial cells (Fig. 11.11). The normal thickness of the basement membrane equals about 250-300 nm. The spaces between foot processes, with diameters of 20-60 nm, are called filtration pores. It is believed they are the pores by which filtered fluid reaches the urinary space. The endothelial cells on the luminal aspect of the basement membrane are fenestrated (diameter 70-100 nm). The basement membrane is arranged in three zones - lamina rara externa, lamina rara densa and lamina rara interna - and is composed of type IV collagen and negatively charged proteoglycans (heparan sulphate).

Glomerular disease includes glomerulonephritis, i.e. inflammation of the glomeruli and glomerulopathies when there is no evidence of inflammation. There is an overlap between these terms.

GLOMERULOPATHIES

Glomerulopathies are the third most common cause of end-stage renal disease (after diabetes and hypertension) in Europe and the USA, accounting for some 10-15% of such patients.

Glomerulopathy (GN) is a general term for a group of disorders in which:

- there is primarily an immunologically mediated injury to glomeruli, although renal interstitial damage is a regular accompaniment
- kidneys are involved symmetrically
- secondary mechanisms of glomerular injury come into play following an initial immune insult such as fibrin deposition, platelet aggregation, neutrophil infiltration and free radical-induced damage.
- renal lesion may be part of a generalized disease (e.g. systemic lupus erythematosus, SLE).

Pathogenesis

GN is considered to be an immunologically mediated disorder with involvement of cellular immunity (T lymphocytes, macrophages/ dendritic cells), humoral immunity (antibodies, immune complexes, complement), and other inflammatory mediators (including cytokines, chemokines and the coagulation cascade). The immune response can be directed against known target antigens, particularly when GN complicates infections, neoplasia or drugs. More frequently the underlying antigenic target is unknown. Primary GN may occur in genetically susceptible individuals following an environmental insult. The genetic susceptibility is usually determined by major histocompatibilty complex (HLA) genes (e.g. HLA-A1, B8, DR2, DR3). The environmental factors may be drugs (e.g. hydralazine), chemicals (e.g. gold, silica, hydrocarbons) or infectious agents. The known predisposing factors are discussed in more detail below. The physical evidence of immune reactions is indicated by the presence of circulating autoantibodies and/or abnormalities in serum

complement and glomerular deposition of antibodies, immune complexes, complement and fibrin.

Pathological terms in glomerular disease

The most commonly used terms are:

- *Focal:* some but not all the glomeruli contain the lesion
- *Diffuse* (global): most of the glomeruli (> 75%) contain the lesion
- *Segmental:* only a part of the glomerulus is affected (most focal lesions are also segmental, e.g. focal segmental glomerulosclerosis)
- *Proliferative:* an increase in cell number due to hyperplasia of one or more of the resident glomerular cells with or without inflammation
- *Membrane alterations:* capillary wall thickening due to deposition of immune deposits or alterations in base ment membrane
- *Crescent formation:* epithelial cell proliferation with mononuclear cell infiltration in Bowman's space.

Classification of glomerulopathies

There is no complete correlation between the histopathological types of GN and the clinical features of disease. Glomerular diseases have been classified in numerous ways. Here they are organized and discussed as they relate to four major glomerular syndromes:

- *Nephrotic syndrome* - massive proteinuria (> 3.5 g/day), hypoalbuminaemia, oedema, lipiduria and hyperlipidaemia.
- *Acute glomerulonephritis (acute nephritic syndrome)* - abrupt onset of glomerular haematuria (RBC casts or dysmorphic RBC), non-nephrotic range proteinuria, oedema, hypertension and transient renal impairment.
- *Rapidly progressive glomerulonephritis* - features of acute nephritis, focal necrosis with or without crescents and rapidly progressive renal failure over weeks.
- *Asymptomatic haematuria, proteinuria or both.*

Certain types of GN, particularly those that are a part of a systemic disease, can present as more than one syndrome, e.g. lupus nephritis, cryoglobulinaemia, and Henoch-Schonlein purpura, but more typically they are associated with the nephrotic syndrome and will be discussed below. Investigation of glomerular diseases are shown in Table 11.3.

Table 11.3 **Investigation of glomerular diseases**

Investigations	Positive findings
Urine microscopy	Red cells, red-cell casts
Urinary protein	Nephrotic or sub-nephrotic range proteinuria
Serum urea	May be elevated
Serum creatinine	May be elevated
Culture (throat swab, discharge from ear, swab from inflamed skin)	Nephritogenic organism (not always)
Antistreptolysin-0 titre	Elevated in post-streptococcal nephritis
C3 and C4 levels	May be reduced
Antinuclear antibody	Present in significant titre in systemic lupus erythematosus
ANCA	Positive in vasculitis
Anti-GBM	Positive in Goodpasture's syndrome
Cryoglobulins	Increased in cryoglobulinaemia
Creatinine clearance	Normal or reduced
Chest X-ray	Cardiomegaly, pulmonary oedema (not always)
Renal imaging	Usually normal
Renal biopsy	Any glomerulopathy

NEPHROTIC SYNDROME

Pathophysiology

Hypoalbuminaemia.

Urinary protein loss of the order 3.5 g daily or more in an adult is required to cause hypoalbuminaemia. In children, proportionately less proteinuria results in hypoalbuminaemia. The normal dietary protein intake in the UK is of the order 70 g daily and the normal liver can synthesize albumin at a rate of 10-12 g daily. How then does a urinary protein loss of the order of 3.5 g daily result in hypoalbuminaemia? This can be partly explained by increased catabolism of reabsorbed albumin in the proximal tubules during the nephrotic syndrome even though actual albumin synthesis rate is increased. However, in addition, dietary intake of protein increases albuminuria, so that the plasma albumin concentration tends to decrease during consumption of a high-protein diet. If the increase in urinary albumin excretion that follows dietary augmentation is prevented by administration of ACE inhibitors (ACEI), a high-protein diet causes an increase in plasma albumin concentration in the nephrotic syndrome. Therefore, to maximize serum albumin concentration in nephrotic patients, a reduction in urinary albumin excretion with an ACEI is always necessary.

Proteinuria. The mechanism of the proteinuria is complex. It occurs partly because structural damage to the glomerular basement membrane leads to an increase in the size and number of pores, allowing passage of more and larger molecules. Electrical charge is also involved in glomerular permeability. Fixed negatively charged components are present in the glomerular capillary wall, which repel negatively charged protein molecules. Reduction of this fixed charge occurs in glomerular disease and appears to be a key factor in the genesis of heavy proteinuria.

Hyperlipidaemia. The characteristic disorder is an increase in the low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and/or intermediate-density lipoprotein (IDL) fractions, but no change or decrease in HDL. This results in an increase in the LDL/HDL

cholesterol ratio. Hyperlipidaemia is the consequence of increased synthesis of lipoproteins (such as apolipoprotein B, C-III, Lp(a) lipoprotein), as a direct consequence of a low plasma albumin. There is also a reduced clearance of the principal triglycerides bearing lipoprotein (chylomicrons and VLDL) in direct response to albuminuria.

Oedema in hypoalbuminaemia. See Chapter 12 (p. 696).

Management

General measures

- Initial treatment should be with dietary sodium restriction and a thiazide diuretic (e.g. bendroflumethiazide). Unresponsive patients require furosemide 40-120 mg daily with the addition of amiloride (5 mg daily), but the serum potassium concentration should be monitored carefully. Nephrotic patients may malabsorb diuretics (as well as other drugs) owing to gut mucosal oedema. Resistance to oral diuretic treatment may demand parenteral administration for a time. Patients are sometimes hypovolaemic, and moderate oedema may have to be accepted in order to avoid postural hypotension.
- A high-protein diet (approximately 80-90 g protein daily) increases proteinuria and can be harmful in the long term. Normal protein intake is advisable.

  Infusion of albumin produces only a transient effect. It is normally only employed in diuretic-resistant patients and those with oliguria and uraemia in the absence of severe glomerular damage, e.g. in minimal-change nephropathy. Albumin infusion is combined with diuretic therapy. Diuresis, when once initiated in this way, often continues with diuretic treatment alone.
- Hypercoagulable states predispose to venous thrombosis. The hypercoagulable state is due to loss of clotting factors (e.g. antithrombin) in the urine and an increase in hepatic production of fibrinogen. Prolonged bed rest should therefore be avoided as thromboembolism is very common in the nephrotic syndrome. In the absence of any contraindication, long-term prophylactic anticoagulation is desirable. Once renal vein thrombosis has occurred, permanent anticoagulation is required.
- Sepsis is a major cause of death in nephrotic patients. The increased susceptibility to infection is partly due to loss of immunoglobulin in the urine. Pneumococcal infections are particularly common and pneumococcal vaccine should be given. Early detection and aggressive treatment of infections, rather than long-term antibiotic prophylaxis, is the best approach.
- Lipid abnormalities are responsible for an increase in the risk of myocardial infarction or peripheral vascular disease in patients with proteinuria. Treatment of hypercholesterolaemia is best with an HMG-CoA reductase inhibitor, with fibrates if necessary (p. 1141).
- ACE inhibitors and/or angiotensin II receptor antagonists (AURA) are increasingly used for their antiproteinuric properties in all types of GN. These groups of drugs reduce proteinuria by lowering glomerular capillary filtration pressure; the blood pressure and renal function should be monitored regularly.

Table 11.4 Glomerulopathies associated with the nephrotic syndrome

Nephrotic syndrome with 'bland' urine sediments
Primary glomerular disease Minimal-change glomerular lesion Congenital nephrotic syndrome Focal segmental glomerular sclerosis Membranous nephropathy
Secondary glomerular disease Amyloidosis Diabetic nephropathy
Nephrotic syndrome with 'active' urine sediments (mixed nephrotic/nephritic)
Primary glomerular disease Mesangiocapillary glomerulonephritis Mesangial proliferative glomerulonephritis
Secondary glomerular disease Systemic lupus erythematosus Cryoglobulinaemic disease Henoch-Schonlein syndrome Idiopathic fibrillary glomerulopathy Immunotactoid glomerulopathy

Specific measures

The aim is to reverse the abnormal urinary protein leak. These are discussed in detail below.

Table 11.4 shows the glomerular lesions commonly associated with the nephrotic syndrome. These are divided into diseases with or without RBC casts (bland or active urine sediments). Each of these entities may occur as a primary renal lesion or as a secondary component of a systemic disease.

Nephrotic syndrome with 'bland' urine sediments

Minimal-change glomerular lesion (minimal-change nephropathy)

In this condition the glomeruli appear normal on light microscopy (Fig. 11.12). The only abnormality seen on electron microscopy is fusion of the foot processes of epithelial cells (podocytes) (Fig. 11.11). This is a non-specific finding and is seen in many conditions associated with proteinuria. Neither immune complexes nor anti-GBM antibody can be demonstrated by immunofluorescence. However, the immunological pathogenesis of this condition is suggested by three factors:

- its response to steroids and immunosuppressive drugs
- its occurrence in Hodgkin's lymphoma, with remission following successful treatment
- patients with the condition and their family members have a high incidence of asthma and eczema; remission of the nephrotic syndrome following desensitization or antigen avoidance has been described.

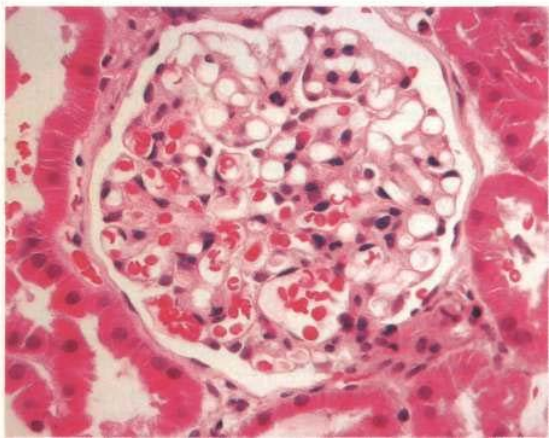

Fig. 11.12 Normal glomerulus on light microscopy in minimal change disease.

A suggested explanation for the proteinuria is the production by T lymphocytes of a factor that increases glomerular permeability to protein.

Clinical features

Minimal-change nephropathy is most common in children, particularly males, accounting for the large majority of cases of nephrotic syndrome (proteinuria is usually highly selective) in childhood. Oedema is present and in children this may be facial. The condition accounts for 20-25% of cases of adult nephrotic syndrome. It is often regarded as a condition that does not lead to chronic renal failure (but see focal sclerosis below).

Management

High-dose corticosteroid therapy with prednisolone 60 mg/m^2 daily (up to a maximum of 80 mg/day) for a maximum of 4-6 weeks followed by 40 mg/m^2 every other day for a further 4-6 weeks corrects the urinary protein leak in more than 95% of children. Response rates in adults are significantly lower and response may occur only after many months (12 weeks with daily steroid therapy and 12 weeks of maintenance with alternate-day therapy). Spontaneous remission also occurs and steroid therapy should, in general, be withheld if urinary protein loss is insufficient to cause hypoalbuminaemia or oedema.

In children, one-third subsequently do not relapse, but further courses of corticosteroids are indicated in the remainder. One-third of these patients relapse regularly on steroid withdrawal, and remission is once more induced with steroid therapy; a course of cyclophosphamide 1.5-2.0 mg/kg daily is given for 8-12 weeks with concomitant prednisolone 7.5-15 mg/day. This increases the likelihood of long-term remission. Steroid unresponsive patients may also respond to cyclophosphamide. No more than two courses of cyclophosphamide should be prescribed in children because of the risk of side-effects, which include azoospermia.

In both children and adults, if remission lasts for 4 years after steroid therapy, further relapse is very rare.

An alternative to cyclophosphamide is ciclosporin 3-5 mg/kg/day, which is effective but must be continued long term to prevent relapse on stopping treatment. Excretory function and ciclosporin blood levels (recommended trough levels 80-150 ng/mL) must be monitored carefully, as ciclosporin is potentially nephrotoxic. In corticosteroid-dependent children, the anthelminthic agent levamisole 2.5 mg/kg to a maximum of 150 mg on alternate days is useful in maintenance of remission but its mode of action is unexplained. Most of the controlled studies have been conducted in the paediatric age group, making recommendations on treatment in adults difficult.

Congenital nephrotic syndrome

Congenital nephrotic syndrome (Finnish type) is an autosomal recessively inherited disorder due to mutations in the gene coding for a transmembrane protein, nephrin, that occurs with a frequency of 1 per 8200 live births in Finland. Nephrin was the first slit-diaphragm protein identified. Its loss of function results in massive proteinuria shortly after birth; these patients usually have an enlarged placenta. This disorder can be diagnosed in utero; increased alpha-fetoprotein in amniotic fluid is a common feature. The microscopic features of the kidney are varied. Some glomeruli are small and infantile, whereas others are enlarged, more mature and have diffuse mesangial hypercellularity. Because of the massive proteinuria, some tubules develop microcysts and are dilated. On electron microscopy, complete effacement of the foot processes of visceral epithelial cells is observed. This condition is characterized by relentless progression to end-stage renal failure. Other inherited nephrotic syndromes involve mutations in other genes that encode podocyte proteins such as podocin, alpha-actinin-4 and Wilms' tumour suppressor gene.

Focal segmental glomerulosclerosis (FSGS)

This is a disease of unknown aetiology. It usually presents as massive proteinuria (usually non-selective), haematuria, hypertension and renal impairment. Patients with nephrotic syndrome are often resistant to steroid therapy. All age groups are affected. It usually recurs in transplanted kidneys, sometimes within days of transplantation, particularly in patients with aggressive native renal disease.

Aetiology

It is generally believed that a circulating permeability factor (with serine protease activity) causes the increased protein leak because plasma from patients increases membrane permeability in isolated glomeruli. Kidneys transplanted into murine models of FSGS develop the lesion, but kidneys from FSGS-prone mice transplanted to a normal strain are protected. Removal of this factor by plasmapheresis results in transient amelioration of proteinuria. Upregulation of CD80 in podocytes has a

major role in the co-stimulatory immune response pathway. Anti-CD80 antibodies, used in renal transplantation, are likely to be used in FSGS in the future.

Pathology

This glomerulopathy is defined primarily by its appearance on light microscopy. Segmental glomerulosclerosis is seen, which later progresses to global sclerosis. The deep glomeruli at the corticomedullary junction are affected first. These may be missed on transcutaneous biopsy, leading to a mistaken diagnosis of a minimal-change glomerular lesion. A pathogenetic link may exist between minimal-change nephropathy and focal glomerulosclerosis, as a proportion of cases classified as having the former condition develop progressive renal impairment. Immunofluorescence may show deposits of C3 and IgM in affected portions of the glomerulus. The other glomeruli are usually enlarged but may be of normal size. In some patients mesangial hypercellularity is a feature. Focal tubular atrophy and interstitial fibrosis are invariably present. Electron microscopic findings mirror light microscopic features with capillary obliteration by hyaline deposits (mesangial matrix and basement membrane material) and lipids. The other glomeruli exhibit primarily foot process effacement, occasionally in patchy distribution.

Two histological variants of FSGS exist. In *classic FSGS* (Fig. 11.13a) the involved glomeruli show sclerotic segments in any location of the glomerulus. The *glomerular tip lesion* is characterized by segmental sclerosis at an early evolution, at the tubular pole of all the affected glomeruli (tip FSGS) (Fig. 11.13b). Capillaries contain foam cells, and overlying visceral epithelial cells are enlarged and adherent to the most proximal portion of proximal tubules. These patients have a more favourable response to steroids and run a more benign course. In the other variant, known as *collapsing FSGS* (Fig. 11.13c) the visceral cells are usually enlarged and coarsely vacuolated with wrinkled and collapsed capillary walls. These features indicate a severe lesion, with a corresponding progressive clinical course of the disease. Collapsing FSGS is commonly seen in young blacks with human immunodeficiency virus (HIV) infection or disease and is known as HIV-associated nephropathy (HIVAN) (see p. 134).

Similar glomerular changes are seen as a secondary phenomenon when the number of functioning nephrons is reduced for any reasons (e.g. nephrectomy, hypertension, gross obesity, ischaemia, sickle nephropathy, reflux nephropathy, heroin abuse, chronic allograft nephropathy, IgA nephropathy and scarring following renal vasculitis), leading to the hypothesis that FSGS results from overloading (glomerular hyperfiltration) of the remaining nephrons.

Treatment

Prednisolone 0.5-2 mg/kg/day is used in most patients and continued for 6 months before declaring the patient resistant to therapy; this is common. The use of ciclosporin at doses to maintain serum trough levels at

Fig. 11.13 **Focal segmental glomerulosclerosis (FSGS).**

150-300 ng/mL may be effective in reducing or stopping urinary protein excretion. Relapse after reducing or stopping ciclosporin is very common. Long-term use may be required to maintain remission. Cyclophosphamide, chlorambucil or azathioprine is used for second-line therapy in adults. In FSGS patients with mesangial hypercellularity and tip lesion, use of cyclophosphamide 1-1.5 mg/kg/day with 60 mg of prednisolone for 3-6 months followed by prednisolone and azathioprine as maintenance therapy has found some success. About 50% of patients progress to end-stage renal failure within 10 years of diagnosis, particularly those who are resistant to therapy.

Membranous glomerulopathy

This condition occurs mainly in adults, predominantly in males. Patients present with asymptomatic proteinuria or frank nephrotic syndrome. Microscopic haematuria, hypertension and/or renal impairment may accompany the nephrotic syndrome. Like all nephritides, hypertension and the degree of renal impairment are poor prognostic signs. The clinical evolution of membranous GN over time has shown that almost half of patients undergo spontaneous or therapy-related remission. However, eventually about 40% develop chronic renal failure, usually in association with persistent nephrotic range proteinuria. Younger patients, females and those with asymptomatic proteinuria of modest degree at the time of presentation do best.

Aetiopathogenesis

An identical glomerular histological picture is seen in the primary or idiopathic form (which comprises 75% of the cases) and also when membranous GN is secondary to drugs (e.g. penicillamine, gold, NSAIDs, probenecid, mercury, captopril), autoimmune disease (e.g. SLE, thyroiditis), infectious disease (e.g. hepatitis B, hepatitis C, schistosomiasis, *Plasmodium malariae),* neoplasia (e.g. carcinoma of lung, colon, stomach, breast and lymphoma) and other causes (e.g. sarcoidosis, kidney transplantation, sickle cell disease). The changes seen by light and electron microscopy mirror one another quite well and represent morphological progression that is dependent on the duration of the disease. At all stages, immunofluorescence shows the presence of uniform granular capillary wall deposits of IgG and complement C3. In the early stage the deposits are small and can be missed on light microscopy. Electron microscopy reveals small electron-dense deposits in the subepithelial aspects of the capillary walls. In the intermediate stage the deposits are encircled by basement membrane, which gives an appearance of spikes of basement membrane perpendicular to the basement membrane on silver staining. Late in the disease the deposits are completely surrounded by basement membrane and are undergoing resorption, which appears as uniform thickening of the capillary basement membrane on light microscopy (Fig. 11.14a, b and c).

(c)

condition can be induced in susceptible rats by immunization with renal autoantigens such as the brush border component of proximal tubular cells, megalin (gp330). However, the target autoantigen is unknown in humans, as megalin is absent from human podocytes. Several neutral endopeptidases located in the brush border and glomeruli are potential target autoantigens. Immune complexes are formed in situ after reacting with autoantibodies directed against these renal autoantigens.

Treatment

Oral high-dose corticosteroids are ineffective in producing either a sustained remission of nephrotic syndrome or preserving renal function in patients with membranous GN. The use of azathioprine is not associated with any significant benefits. The alkylating agents, cyclophosphamide and chlorambucil, are both effective in the management of membranous GN. Because of growing concern about long-term toxicity, these drugs should be reserved for patients who exhibit clinical features, such as severe or prolonged nephrosis (i.e. proteinuria > 6 g/day for > 6 months), renal insufficiency and hypertension, that predict a high likelihood of progression to end-stage renal failure. Chlorambucil (0.2 mg/kg/day in months 2, 4 and 6 alternating with oral prednisolone 0.4 mg/kg/day in months 1, 3 and 5) and cyclophosphamide (1.5-2.5 mg/kg/day for 6-12 months with 1 mg/kg/day of oral prednisolone on alternate days for the first 2 months) are equally effective. Ciclosporin and mycophenolate with oral steroids may become the agents of choice for membranous GN. As membranous GN is caused by circulating autoantibodies, anti-B lymphocyte therapy would seem more logical than broad-spectrum immunosuppressive agents, which are more effective against T lymphocytes. Anti-CD20 antibodies (rituximab, which ablates B lymphocytes), has been shown to improve renal function, reduce proteinuria and increase the serum albumin; no significant adverse affects have been shown in the short term.

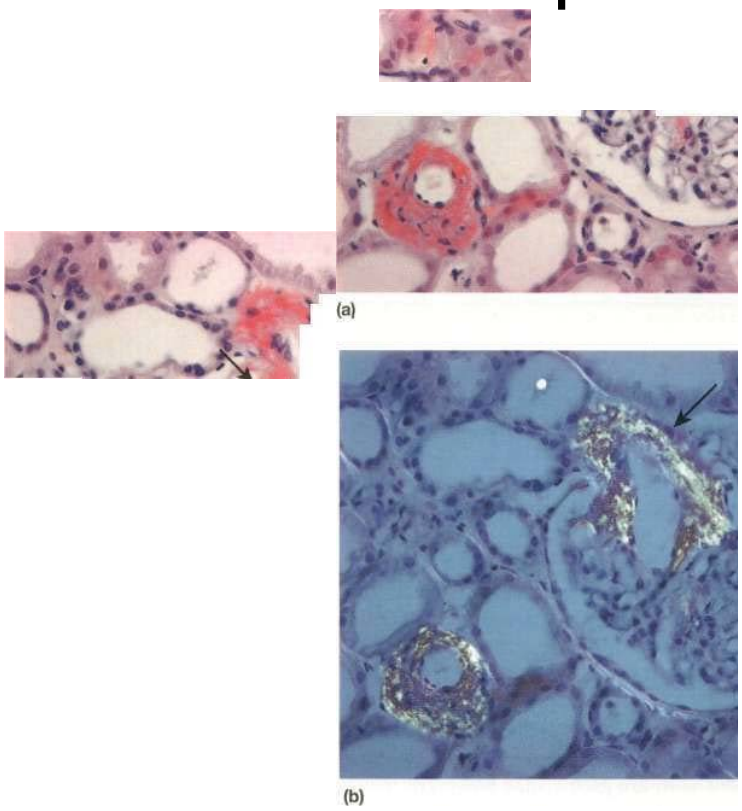

***Fig. 11.15* Amyloid, (a)** Light microscopy of eosinophilic amyloid deposits (arrow), (b) Congo red stain under polarized light showing apple green refringence.

Amyloidosis (p. ru7)

Amyloidosis is an acquired or inherited disorder of protein folding, in which normally soluble proteins or fragments are deposited extracellularly as abnormal insoluble fibrils.

Pathology

On light microscopy, eosinophilic deposits are seen in the mesangium, capillary loops and arteriolar walls. Staining with Congo red renders these deposits pink and they show green birefringence under polarized light (Fig. 11.15). Immunofluorescence is unhelpful, but on electron microscopy the characteristic fibrils of amyloid can be seen. Amyloid consisting of immunoglobulin light chains (AL amyloid) can be identified by immunohistochemistry in only 40% of the cases as compared to almost 100% of patients with protein found in secondary amyloid (amyloid protein A, A A amyloid).

Diagnosis and treatment (see p. 1148)

The *diagnosis* can often be made clinically when features of amyloidosis are present elsewhere. On imaging, the kidneys are often large. Scintigraphy with radiolabelled serum amyloid P (SAP), a technique for quantitatively imaging amyloid deposits in vivo, is desirable because of its ability to detect the rate of regression or progression of amyloidsis over a period of time (p. 1148). Renal biopsy is necessary in all suspected cases of renal involvement.

Treatment of the underlying cause should be undertaken. Renoprotective measures should be started (p. 672). The success of dialysis and kidney transplantation is dependent upon the extent of amyloid deposition in extrarenal sites, especially the heart.

Diabetic nephropathy

Diabetic renal disease is the leading cause of end-stage renal failure in the western world. Type 1 and type 2

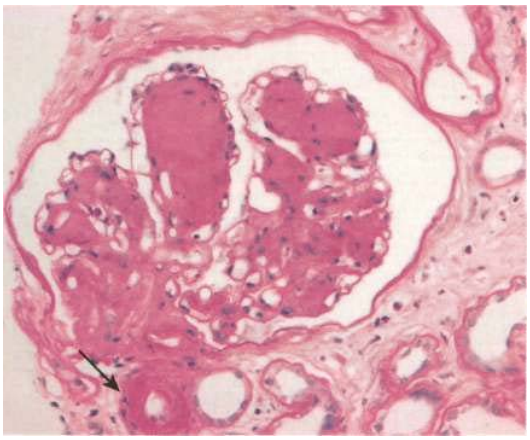

Fig. 11.16 Diabetes mellitus. Advanced diabetic glomerulopathy and arteriolar sclerosis (arrow).

diabetic patients (see p. 1126) have equivalent rates of proteinuria, azotaemia, and ultimately end-stage renal failure. Both types of diabetes show strong similarities in their rate of renal functional deterioration, and onset of co-morbid complications.

Pathology

The kidneys enlarge initially and there is glomerular hyperfiltration (GFR > 150 mL/min). The major early histological lesions seen are glomerular basement membrane thickening and mesangial expansion. Later, glomerulosclerosis develops with nodules (Kimmelstiel-Wilson lesion) and hyaline deposits in the glomerular arterioles (see Fig. 11.16). These later changes are associated with heavy proteinuria. The lesions seen in type 1 are also seen in type 2. The pathophysiology is discussed on page 1126.

Treatment

The timing of renoprotection therapy in diabetes is a subject of current investigation. Lifestyle changes (cessation of smoking and increase in exercise), hypertension, poor metabolic regulation, and hyperlidaemia should be addressed in every diabetic. Microalbuminuria is a reason to start treatment with ACE inhibitors or an angiotensin II receptor antagonist (AURA) in either type of diabetes, regardless of blood pressure elevation. Like other kidney diseases, however, nearly the entire course of renal injury in diabetes is clinically silent. Medical intervention during this silent phase (Box 11.3) is renoprotective, as judged by slowed loss of glomerular filtration. Despite intensified metabolic control and antihypertension treatment in diabetic patients, a substantial number still go on to develop end-stage renal failure.

Nephrotic syndrome with 'active' urine sediments (mixed nephrotic/nephritic)

Mesangiocapillary (membranoproliferative) glomerulonephritis (MCGN)

This uncommon lesion has three subtypes with similar clinical presentations: the nephrotic syndrome, haematuria, hypertension and renal impairment. They also have similar microscopic findings although the pathogenesis may be different. Electron microscopy defines:

- Type 1 MCGN. There is mesangial cell proliferation, with mainly subendothelial immune deposition and apparent splitting of the capillary basement membrane, giving a 'tram-line' effect. It can be associated with persistently reduced plasma levels of C3 and normal levels of C4 due to activation of the complement cascade by the classical pathway. It may be idiopathic or may occur with chronic infection (abscesses, infective endocarditis, infected ventriculoperitoneal shunt) or cryoglobulinaemia secondary to hepatitis C infections (Fig. 11.17a).
- Type 2 MCGN. There is mesangial cell proliferation with electron-dense, linear intramembranous deposits that usually stain for C3 only (Fig. 11.17b). This type may be idiopathic or be associated with partial lipodystrophy (loss of subcutaneous fat on face and upper trunk). MCGN affects young adults. These patients have low C3 levels like in type 1 but this is due to the activation of the alternative pathway of the complement cascade; they also have autoantibodies to C3 convertase enzyme.
- Type 3 MCGN has features of both types 1 and 2. Complement activation appears to be via the final common pathway of the cascade.

Most patients eventually go on to develop renal failure over several years. Type 2 MCGN recurs in virtually 100% of renal transplant patients but recurrence is less common in type 1 (25%). However, recurrence does not interfere with long-term graft function.

Management

For all age groups, for idiopathic MCGN with normal renal function, non-nephrotic range proteinuria, no specific therapy is required. Close follow-up every four months, with specific attention to blood pressure control is recommended.

In children with the nephritic syndrome and/or impaired renal function, a trial of steroids is warranted (alternate-day prednisolone 40 mg/m^2 for a period of 6-12 months). If no benefit is seen, this treatment is discontinued. Regular follow-up with control of blood pressure, use of agents to reduce proteinuria and correction of lipid abnormalities is necessary.

In adults with the nephritic syndrome and/or renal impairment, aspirin (325 mg) or dipyridamole (75-100 mg) or a combination of the two, should be given for 6-12 months. Again if no benefits are seen, the treatment should be stopped. Treatment to slow the rate of progression of renal failure is instituted (p. 672).

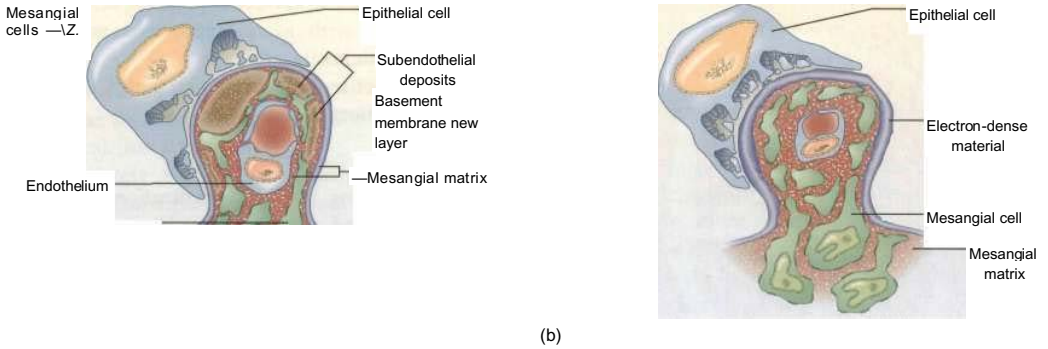

Fig. 11.17 **Mesangiocapillary glomerulonephritis (MCGN). (a) Type I MCGN** showing expanded mesangial matrix and mesangial cells, thickened capillary wall, large subendothelial deposits and formation of a new layer of basement membrane (tram-line effect), **(b) Type II MCGN.** This shows a variable glomerular appearance, very electron-dense material has replaced the Bowman's capsule and tubular basement membrane and part of the capillary. There is some proliferation of mesangial cells. (After Marsh FP (1985) *Postgraduate Nephrology.* Butterworth Heinemann.)

Mesangial proliferative GN (IgM nephropathy, C1q nephropathy)

In addition to minimal-change disease, there are two other disorders that usually present with heavy proteinuria with only minor changes on light microscopy.

IgM nephropathy is characterized by increased mesangial cellularity in most of the glomeruli, associated with granular immune deposits (IgM and complement) in the mesangial regions. Patients present with episodic or persistent haematuria with the nephrotic syndrome. Unlike minimal-change disease, the prognosis is not uniformly good, as steroid response is only 50% compared to 90% in minimal-change disease. Between 10% and 30% develop progressive renal insufficiency with signs of secondary FSGS on repeat biopsy. A trial of cyclophosamide with prednisolone is used with persistent nephrotic syndrome, particularly with a rising plasma creatinine concentration.

C1q nephropathy is very similar to IgM nephropathy in presenting features and microscopic appearance with the exception of Clq deposits in the mesangium. Sometimes it is misdiagnosed as lupus nephritis, particularly in patients with negative serology (so-called seronegative lupus.) The distinguishing features are intense Clq staining and absence of tubuloreticular inclusions (attributable to high circulating alpha-interferon) on electron microscopy. Only some patients are steroid dependent. Progression to renal failure is, as in most glomerular diseases, most likely to occur in patients with heavy proteinuria and renal insufficiency.

Systemic lupus erythematosus (lupus glomerulonephritis) (see also p. 575)

Overt renal disease occurs in at least one-third of SLE patients and, of these, 25% reach end-stage renal failure within 10 years. Histologically almost all patients will have changes which are classified by the World Health Organization (modified with added clinical manifestations) as:

- Type I - Mesangial immune deposits (normal glomeruli on light microscopy). Asymptomatic.
- Type II - Mesangial immune deposits with mesangial cell hypercellularity and matrix expansion. Clinically there is mild renal disease.
- Type III - Focal proliferative glomerulonephritis (involving < 50% of the total number of glomeruli on renal biopsy) with subdivisions for active or sclerotic lesions. Haematuria and proteinuria are seen in almost all.
- Type IV - Diffuse proliferative glomerulonephritis (involving > 50% of total number of glomeruli on renal biopsy) either with segmental (class IV-S) or global (class IV-G) involvement, and also with subdivisions for active or sclerotic lesions (Fig. 11.18). Clinically, as in type III, but the nephrotic syndrome, hypertension and renal insufficiency are often seen.
- Type V - Membranous GN. Heavy proteinuria is seen, with signs of the nephrotic syndrome, haematuria and hypertension.
- Type VI - Advanced sclerosing lesions (> 90% glomeruli are sclerosed). Progressive renal failure is seen.

Serial renal biopsies show that in approximately 25% of patients, histological appearances alter from one histological classification to another during the interbiopsy interval. The prognosis is better in patients with types I, II and V. Immune deposits in the glomeruli and mesangium are characteristic of SLE and stain positive for IgG, IgM, IgA and the complement components C3, Clq and C4 on immunofluorescence. ■

Pathophysiology

SLE is now known to be an autoantigen-driven, T-cell-dependent and B-cell-mediated autoimmune disease (p. 574). Lupus nephritis typically has circulating auto-

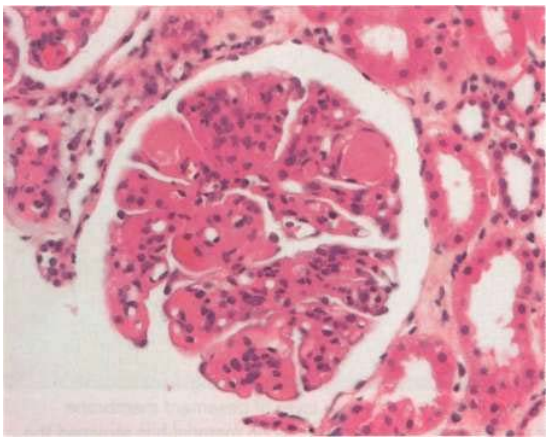

Fig. 11.18 Lupus nephritis type IV - a diffuse proliferative nephritis. There is proliferation of endothelial and mesangial cells.

antibodies to cellular antigens (particularly anti-dsDNA, anti-Ro) and complement activation which leads to reduced levels of C3, C4, and particularly Clq. Clq is the first component of the classical pathway of the complement cascade (see p. 201) and is involved in the activation of complement and clearance of self-antigens generated during apoptosis. Anti-Clq antibodies may help in distinguishing a renal from a non-renal relapse. However, not all autoantibodies are pathogenic to the kidney. These nephritogenic antibodies have specific physicochemical characteristics and correlate well with the pattern of renal injury. DNA was thought to be the inciting autoantigen, but now nucleosomes (structures comprising DNA and histone, generated during apoptosis) are the most likely autoantigen. Nucleosome-specific T cells, antinucleosome antibodies and nephritogenic immune complexes are generated. Positively charged histone components of the nucleosome bind to the negatively charged heparan sulphate (within the glomerular basement membrane) inciting an inflammatory reaction and resulting in mesangial cell proliferation, mesangial matrix expansion and inflammatory leucocytes. Other pathogenic mechanisms include infarction of glomerular segments, thrombotic microangiopathy, vasculitis and glomerular sclerosis.

The extraglomerular features of lupus nephritis include tubulointerstitial nephritis (75% of patients), renal vein thrombosis and renal artery stenosis. Thrombotic manifestations are associated with autoantibodies to phospholipids (anticardiolipin or lupus anticoagulant).

Management

Initial treatment depends on the clinical presentation but hypertension and oedema should be treated. A definite histopathofogical diagnosis is required. Type I requires no treatment. Type II usually runs a benign course but some are treated with steroids.

There have been a number of clinical trials with immunosuppressive agents in types III, IV and V. At present, steroids and cyclophosphamide are usually used for induction, with azathioprine and mycophenolate mofetil for maintenance therapy.

B cell depletion with rituximab (anti-CD20) has been shown to be effective in a small study.

Prognosis

Treatment leading to the normalization of proteinuria, hypertension and renal dysfunction indicates a good prognosis. Glomerulosclerosis (type VI) usually predicts end-stage renal disease (p. 665).

Cryoglobulinaemic renal disease

Cryoglobulins (CG) are immunoglobulins and complement components, which precipitate reversibly in the cold. Three types are recognized:

In *type I,* the cryoprecipitable immunoglobulin is a single monoclonal type, as is found in multiple myeloma and lymphoproliferative disorders.

Types II and *III* cryoglobulinaemias are mixed types. In each, a polyclonal IgG antigen is bound to an antiglobulin. In type II, the antiglobulin component, which is usually of the IgM or IgA class with rheumatoid factor activity, is monoclonal, while in type III it is polyclonal. Type II CGs account for 40-60% cases, whilst 40-50% of all CG cases are of type III.

Glomerular disease is more common in type 11 than in type III cryoglobulinaemia. In approximately 30% of these 'mixed' cryoglobulinaemias, no underlying or associated disease is found (essential cryoglobulinaemia). Recognized associations include viral infections (hepatitis B and C, HIV, cytomegalovirus, Epstein-Barr infection), fungal and spirochaetal infections, malaria and infective endocarditis and autoimmune diseases (SLE, rheumatoid arthritis and Sjogren's syndrome). Glomerular pathological changes resemble MCGN (Fig. 11.17).

Presentation is usually in the fourth or fifth decades of life, and women are more frequently affected than men. Systemic features include purpura, arthralgia, leg ulcers, Raynaud's phenomenon, evidence of systemic vasculitis, a polyneuropathy, and hepatic involvement. The glomerular disease presents typically as asymptomatic proteinuria, microscopic haematuria or both, but presentation with an acute nephritic and nephrotic syndrome (commonest presentation) or features of renal impairment also occurs.

Serological investigation reveals a reduction in concentration of early complement components with an elevation of later components, detection of CGs, monoclonal gammopathy, rheumatoid factor, autoantibodies and antiviral antibodies or mRNA of hepatitis C, depending on the associated disorder.

Spontaneous remission occurs in about one-third of cases and approximately one-third pursue an indolent course. Corticosteroid and/or immunosuppressive therapy with cyclophosphamide may be of benefit, but evaluation of treatment is difficult owing to the rarity of the disease and the occurrence of spontaneous remissions. Intensive plasma exchange or cryofiltration has been used in selected cases. Interferon reduces

the viraemia in hepatitis C but does not influence the cryoglobulinaemia.

Henoch-Schonlein syndrome

This clinical syndrome comprises a characteristic skin rash, abdominal colic, joint pain and glomerulonephritis. Approximately 30-70% have clinical evidence of renal disease with haematuria and/ or proteinuria. The renal disease is usually mild but the nephrotic syndrome and acute renal failure can occur. The renal lesion is a focal segmental proliferative glomerulonephritis, sometimes with mesangial hypercellularity. In the more severe cases, epithelial crescents may be present. Immunoglobulin deposition, mainly of IgA, is seen in the glomerular mesangium, similar to IgA nephropathy. There is no treatment of proven benefit. Treatment is usually supportive but with crescentic GN aggressive immunosuppression has been tried with variable outcome.

Idiopathic fibrillary glomerulopathy

In this rare condition, characteristic microfibrillary structures are seen in the mesangium and glomerular capillary wall on electron microscopy that are clearly different from those seen in amyloidosis; the fibrils are larger than those in amyloidosis (20-30 versus 10 ran diameter) and do not stain with Congo red. The median age at presentation is approximately 45 years (range 10-80 years). Patients present with proteinuria, mostly in the nephrotic range (60%), and microscopic haematuria (70%), hypertension and renal impairment (50%) that may progress rapidly: 40-50% of patients develop end-stage renal failure within 2-6 years.

No treatment is known to be of benefit, although isolated instances of an apparent response to corticosteroid and immunosuppressive therapy have been reported.

Immunotactoid glomerulopathy

In this disorder, microtubules which are much larger (30-40 nm diameter) than the fibrils in fibrillary glomerulopathy are seen on electron microscopy. The majority of patients have circulating paraprotein or monoclonal immunoglobulin deposition is seen in the glomeruli on immunofluorescence microscopy. A lymphoproliferative disease is the underlying cause in over 50% of cases. The clinical presentation and course are similar to fibrillary glomerulopathy, although therapy can be effective in patients with lymphoproliferative disease and/or paraproteinaemia. Complete or partial remission of the nephrotic syndrome can be achieved by various chemotherapeutic agents in over 80% of patients.

ACUTE GLOMERULONEPHRITIS (ACUTE NEPHRITIC SYNDROME) (Table 11 5)

This comprises:

- haematuria (macroscopic or microscopic) - red-cell casts are typically seen on urine microscopy

Table 11.5 **Diseases commonly associated with the acute nephritic syndrome**

Post-streptococcal glomerulonephritis
Non-streptococcal post-infectious glomerulonephritis, e.g. *Staphylococcus,* pneumococcus, *Legionella,* syphilis, mumps, varicella, hepatitis B and C, echovirus, Epstein-Barr virus, toxoplasmosis, malaria, schistosomiasis, trichinosis
Infective endocarditis
Shunt nephritis
Visceral abscess
Systemic lupus erythematosus (see p. 575)
Henoch-Schonlein syndrome (see p. 587)
Cryoglobulinaemia (see p. 628)

- proteinuria
- hypertension
- oedema (periorbital, leg or sacral)
- temporarily oliguria and uraemia.

The histological pattern is characterized by cellular proliferation (mesangial and endothelial) and inflammatory cell infiltration (neutrophils, macrophages).

Post-streptococcal glomerulonephritis (PSGN)

The patient, usually a child, suffers a streptococcal infection 1-3 weeks before the onset of the acute nephritic syndrome. Streptococcal throat infection, otitis media or cellulitis may all be responsible. The infecting organism is a Lancefield group A (3-haemolytic streptococcus of a nephritogenic type. The latent interval between the infection and development of symptoms and signs of renal involvement reflects the time taken for immune complex formation and deposition and glomerular injury to occur. PSGN is now rare in developed countries. Renal biopsy shows diffuse, florid, acute inflammation in the glomerulus (without necrosis but occasionally cellular crescents), with neutrophils and deposition of immunoglobulin (IgG) and complement (Fig. 11.19a, b). Ultrastructural findings are those of electron-dense deposits, characteristically but not solely in the subepithelial aspects of the capillary walls. Endothelial cells often are swollen. Similar biopsy findings may be seen in *non-streptococcal post-infectious glomerulonephritis* - shown in Table 11.5.

Management

The acute phase should be treated with antihypertensives, diuretics, salt restriction and dialysis as necessary. If recovery is slow, corticosteroids may be helpful. The prognosis is usually good in children. A small number of adults develop hypertension and/or renal impairment later in life. Therefore in older patients, an annual blood pressure check, and an estimation of serum creatinine, is a reasonable precaution, even after apparent complete recovery. Evidence in support of long-term penicillin prophylaxis after the development of glomerulonephritis is lacking. In non-streptococcal post-infectious glomerulonephritis, prognosis is equally good if the underlying infection is eradicated.

(b) Light microscopy showing acute inflammation of the glomerulus with neutrophils.

Glomerulonephritis with infective endocarditis

GN occurs rarely in patients with infective endocarditis (usually i.v. drug abusers). It usually manifests itself as acute nephritic syndrome. A similar presentation is in patients with infected ventriculoperitoneal shunt *(shunt nephritis)*. Microscopic appearances resemble post-infectious GN, but lesions are usually focal and segmental. Crescentic GN with acute renal failure has been described, particularly with *Staphylococcus aureus* infection. Appropriate antibiotic therapy or surgical eradication of infection in fulminant cases (embolic infarct of the kidney) usually results in a return of normal renal function.

Glomerulonephritis associated with visceral abscesses (mainly pulmonary)

Clinical and microscopic features are indistinguishable from post-infectious GN, but usually complement levels are normal and immune deposits are absent on biopsy. Antibiotic therapy and surgical drainage of the abscess results in complete recovery of renal function in approximately 50% of patients.

Asymptomatic urinary abnormalities

A variety of renal lesions may present as either isolated proteinuria or haematuria, alone or with proteinuria. *Isolated proteinuria* without haematuria in asymptomatic patients is usually an incidental finding. It is usually in the sub-nephrotic range without an active urine sediment and there is normal renal function. Over 50% of these patients have postural proteinuria. The outcome of isolated proteinuria (postural or non-postural) is excellent in the majority of patients, with a gradual decline in proteinuria. Occasionally, it may be an early sign of a serious glomerular lesion such as membranous GN, IgA nephropathy, FSGS, diabetic nephropathy or amyloidosis. Moreover, mild proteinuria may accompany a febrile illness, congestive heart failure or infectious diseases with no clinical renal significance.

Haematuria with or without sub-nephrotic range proteinuria in an asymptomatic patient may lead to early discovery of potentially serious glomerular disease such as SLE, Henoch-Schonlein purpura, post-infectious GN or idiopathic hypercalciuria in children. Asymptomatic haematuria is also the primary presenting manifestation of a number of specific glomerular diseases discussed below.

IgA nephropathy (Fig. 11.20a, b)

This disease has replaced post-streptococcal glomerulonephritis as the commonest form of glomerulonephritis world-wide. There is a focal and segmental proliferative glomerulonephritis with mesangial deposits of polymeric IgA^ In some cases IgG, IgM and C3 may also be seen in the glomerular mesangium. The disease may be a result of an exaggerated bone marrow and tonsillar IgAj immune response to viral or other antigens and is associated with an abnormality in O-linked galactosylation in the hinge region of the IgAj molecule. Quantitative and structural changes of IgAj play a key role in the development of disease due to functional abnormalities of two IgA receptors: CD89 expressed on blood myeloid cells and the transferring receptor (CD71) on mesangial cells. Abnormal IgAj induces the release of soluble CD89, which is responsible for the formation of circulating IgA complexes. These complexes may then be trapped by CD71, which is overexpressed on mesangial cells in IgA nephropathy patients, allowing IgA complex formation in the mesangium. Up to 50% of patients exhibit elevated serum IgA (polyclonal) concentration. Superimposed crescent formation is frequent, particularly following macroscopic haematuria due to upper respiratory tract infection. Several diseases may be associated with IgA deposits, including Henoch-Schonlein purpura, chronic liver disease, malignancies (especially carcinoma of bronchus), seronegative spondyloarthrides, coeliac disease, mycosis fungoides and psoriasis.

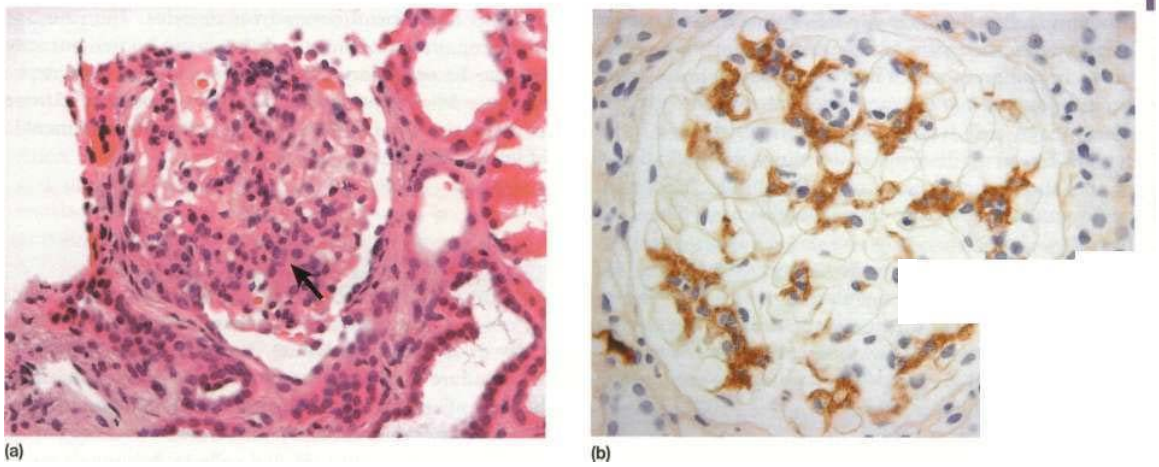

Fig. 11.20 **IgA nephropathy. (a)** Light microscopy. Showing mesangial cell proliferation (arrow) and increased matrix, (b) IgA deposits on immunoperoxidase staining.

Clinical presentation

IgA nephropathy tends to occur in children and young males. They present with asymptomatic microscopic haematuria or recurrent macroscopic haematuria sometimes following an upper respiratory or gastrointestinal viral infection. Proteinuria occurs and 5% can be nephrotic. The prognosis is usually good, especially in those with normal blood pressure, normal renal function and absence of proteinuria at presentation. Surprisingly, recurrent macroscopic haematuria is a good prognostic sign, although this may be due to 'lead-time bias' (p. 488), as patients with overt haematuria come to medical attention at an earlier stage of their illness. The risk of eventual development of end-stage renal failure is about 25% in those with proteinuria of more than 1 g per day, elevated serum creatinine, hypertension, ACE gene polymorphism (DD isoform) and tubulointerstitial fibrosis on renal biopsy.

Management

Patients with proteinuria over 1-3 g/day, mild glomerular changes only and preserved renal function should be treated with steroids. Steroids reduce proteinuria and stabilize renal function. The combination of cyclophosphamide, dipyridamole and warfarin should not be used, nor should ciclosporin. In patients with progressive disease (creatinine clearance less than 70 mL/min), fish oil or prednisolone with cyclophosphamide for 3 months followed by maintenance with prednisolone and azathioprine may be tried. A tonsillectomy can reduce proteinuria and haematuria in those patients with recurrent tonsillitis. All patients, with or without hypertension and proteinuria, should receive a combination of ACE inhibitor and angiotensin II receptor antagonist rather than each agent alone because reduction of proteinuria and preservation of renal function are better with combination therapy despite similar blood pressure control. Mesangial IgA deposits are commonly found in the allografts of transplanted patients but loss of graft function as a result is uncommon.

Alport's syndrome

Alport's syndrome is a rare condition characterized by an hereditary nephritis with haematuria, proteinuria (less than 1-2 g/day) progressive renal failure and high-frequency nerve deafness. Approximately 15% of cases may have ocular abnormalities such as bilateral anterior lenticonus and macular and perimacular retinal flecks. In about 85% of patients with Alport's syndrome there is X-linked inheritance of a mutation in the *COLIVcS* gene encoding the COLIV06 collagen chain. In female carriers, penetrance is variable and depends on the type of mutation or degree of mosaicism following hybridization of the X chromosome. Patients with autosomal recessive or dominant modes of inheritance have also been described with mutations in *COLIVa3* or *COLIVa4* genes. In families with stromal cell tumours there is an additional mutation in the *COLIVa6* gene.

Mutations present in Alport's syndrome that produce post-translational defects in oc3, a4 and c6 chains result in incorrect assembly or folding of monomers; such defective monomers are rapidly degraded. These mutations arrest the normal developmental switch and cause the persistence of embryonic ocl,al and oc2 networks in glomerular basement membrane. The ccl,al and a2 network is more susceptible to endoproteolysis and oxidative stress than the a3, a4 and oc5 network. Over time, patients with Alport's syndrome probably become more sensitive to selective basement membrane proteolysis, which may explain why their glomerular membranes thicken unevenly, split and ultimately deteriorate.

The primary glomerular filtration barrier of the glomerular capillary consists of the basement membrane and the outer slit diaphragm formed between adjacent podocytes. Loss of slit function causes massive proteinuria (congenital nephrotic syndrome, p. 622) but deterioration of glomerular basement produces only mild

proteinuria. Proteinuria in Alport's syndrome is the result of glomerular sclerosis, rather than primary loss of slit pores. In pedigrees with a history of renal failure, disease progresses from concomitant interstitial fibrosis, macrophage and lymphocyte infiltration secondary to tubular basement disruption and trans-differentiation of epithelial mesenchymal cells to fibroblasts. This fibrogenic response destroys renal architecture. The renal histology characteristically shows split basement membrane. In some patients with Alport's syndrome and carriers, thin basement membrane, as seen in benign familial haematuria, is the only abnormality detected on histology. For this reason, the boundary between Alport's and benign familial haematuria has become increasingly vague.

Management

The disease is progressive and accounts for some 5% of cases of end-stage renal failure in childhood or adolescence. Patients with early renal failure can be treated with ACE inhibitors to attenuate proteinuria and slow the rate of progression. Anti-GBM antibody does not adhere normally to the glomerular basement membrane of affected individuals but development of crescentic glomerulonephritis in the transplanted kidney due to anti-GBM alloantibody is a well-recognized complication.

Thin glomerular basement membrane disease

The condition is inherited as an autosomal dominant and typically presents with persistent microscopic glomerular haematuria (RBC casts or dysmorphic RBCs). The diagnosis is made by renal biopsy, which shows thinning of the glomerular capillary basement membrane on electron microscopy. The condition was underdiagnosed and is much commoner than previously believed. The prognosis for renal function is usually very good but some patients develop renal insufficiency over decades. The cause of renal impairment in this condition is not known but may be due to secondary FSGS or concomitant IgA nephropathy. Misdiagnosis occurs with Alport's syndrome which shares similar histological features. No treatment is of known benefit.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS (RPGN)

RPGN is a syndrome with glomerular haematuria (RBC casts or dysmorphic RBCs), rapidly developing acute renal failure over weeks to months and focal glomerular necrosis (Fig. 11.21) with or without glomerular crescent development on renal biopsy. The 'crescent' is an aggregate of macrophages and epithelial cells in Bowman's space (Fig. 11.21). RPGN can develop with immune deposits (anti-GBM or immune complex type) or without immune deposits (pauci-immune). It can also develop as an idiopathic primary glomerular disease or can be superimposed on other glomerular diseases, primary or secondary. The classification used here is based on the immunofluorescence information obtained from renal histology (Table 11.6).

Anti-GBM glomerulonephritis (Fig. 11.22a) Anti-GBM glomerulonephritis, characterized by linear capillary loop staining with IgG and C3 and extensive crescent formation, accounts for 15-20% of all cases of RPGN, although overall it accounts for less than 5% of all forms of glomerulonephritis. This condition is rare, with an incidence of 1 per 2 million in the general population. About two-thirds of these patients have Goodpasture's syndrome with associated lung haemorrhage (p. 940). The remainder have a renal restricted anti-GBM RPGN, which is seen in people above 50 years and affects both genders equally.

(a) (b)

F/g. *11.22*Immunofluorescence. (a) Showing antiglomerular basement membrane antibody (anti-GBM) deposition in a linear pattern typical of Goodpasture's syndrome, (b) Showing immune complex deposition in a diffuse granular pattern.

Anti-GBM antibodies (detected by ELISA) are present in serum and are directed against the non-collagenous (NCI) component of a3 (IV) collagen of basement membrane. This target antigen must be present as a component of the native a3, cc4, a5 (IV) network of selected basement membrane in order for pulmonary and renal disease to develop. Consequently, there are no known cases of anti-GBM glomerulonephritis in patients with Alport's syndrome (p. 631). Anti-GBM RPGN is restricted by the major histocompatibilty complex; HLA-DRB1*15O1 and HLA-DRB1*15O2 alleles increase susceptibility, whereas HLA-DR7 and HLA-DR1 are protective. The thymus expresses a3 (IV) NCI peptides that can eliminate autoreactive $CD4^+$ helper T cells, but a few such cells escape deletion and are kept in check by circulating regulatory cells. Breakdown of this peripheral tolerance (the mechanism of which is unknown) results in these autoreactive $CD4^+$ cells producing anti-GBM antibodies. These antibodies are very specific as shown by the fact that antibodies against al,al and <x2 NCI domains do not cause RPGN. Since the a3 (IV) NCI epitope is hidden within the a3, a4 and a5 (IV) promoter, it is presumed that an environmental factor, such as exposure to hydrocarbons or tobacco smoke, is required in order to reveal cryptic epitopes to the immune system.

The mechanism of renal injury is complex. When anti-GBM antibody binds basement membrane it activates complement and proteases and results in disruption of the filtration barrier and Bowman's capsule, causing proteinuria and the formation of crescents. Crescent formation is facilitated by interleukin-12 and gamma-interferon which are produced by resident and infiltrating inflammatory cells.

ANCA-associated systemic vasculitides

Management

This is based on counteracting the factors involved in the pathogenesis. Thus plasma exchange is used to remove circulating antibodies, steroids to suppress inflammation from antibody already deposited in the tissue and cyclophosphamide to suppress further antibody synthesis. The prognosis is directly related to the extent of glomerular damage (measured by percentage of crescents, serum creatinine and need for dialysis) at the initiation of treatment. When oliguria occurs or serum creatinine rises above 600-700 uxnol/L, renal failure is usually irreversible. Once the active disease is treated, this condition, unlike other autoimmune diseases, does not follow a remitting/relapsing course. Furthermore, if left untreated, autoantibodies diminish spontaneously within 3 years and autoreactive T cells cannot be detected in the convalescent patients. This is suggestive of re-establishment of peripheral tolerance which coincides with re-emergence of regulatory $CD25^+$ cells in the peripheral blood; these play a key role in inhibiting the autoimmune response. The emergence and persistence of these regulatory cells may underlie the 'single hit' nature of this condition.

ANCA-positive vasculitides (see also p. 584)

Inflammation and necrosis of the blood vessel wall occurs in many primary vasculitic disorders. Wegener's granulomatosis, microscopic polyangiitis and Churg-Strauss syndrome are described as small vessel vasculitides and

Fig. 11.23 Vasculitic rash.

are commonly associated with antineutrophil cytoplasm antibodies (ANCA). These diseases share common pathology with focal necrotizing lesions, which affect many different vessels and organs; in the lungs, a capillaritis may cause lung haemorrhage; within the glomerulus of the kidney, crescentic GN and/or focal necrotizing lesions may cause acute renal failure (Fig. 11.21a, b); in the dermis, a purpuric rash (Fig. 11.23) or vasculitic ulceration. Wegener's and Churg-Strauss syndrome may have additional granulomatous lesions.

Autoantibodies directed against constituents of the cytoplasm of normal human granulocytes and monocytes are useful in the understanding of the above disorders. Two forms of antineutrophil cytoplasmic antibodies (ANCA) can be demonstrated; proteinase-3 (PR3)-ANCA and myeloperoxidase (MPO)-ANCA. Binding of PR3-ANCA to neutrophils in indirect immunofluorescence assays produces a granular cytoplasmic stain - hence the use of the old term 'cytoplasmic (c)-ANCA'. MPO-ANCA produces a perinuclear stain - hence the old term 'perinuclear (p)-ANCA'. If ELISA and indirect immunofluorescence techniques are combined, diagnostic specificity is 99%.

PR3-ANCA positivity is found in the large majority of patients with active Wegener's granulomatosis and in up to 50% of patients with microscopic polyangiitis. Anti-MPO positivity is present in the majority of patients with idiopathic crescentic glomerulonephritis and in a variable number of cases of microscopic polyangiitis. Churg-Strauss syndrome may have either anti-MPO- or anti-PR3-ANCA. Testing for antineutrophil cytoplasmic antibodies should be accompanied by appropriate tests of autoantibodies directed against DNA and the glomerular basement membrane antigen. The simultaneous occurrence of ANCA and anti-GMB antibody is well documented; such patients tend to follow the natural history of Goodpasture's disease. Variations in the ANCA titres have been used in the assessment of disease activity. Several drugs (e.g. propylthiouracil, hydralazine, minocycline, penicillamine) may induce vasculitides associated with ANCA. Most patients reported with drug-induced ANCA-associated vasculitis have MPO-ANCA, often in very high titres. In addition to MPO-ANCA, most also have antibodies to elastase or to lactoferrin. A relatively small number have PR3-ANCA. Many cases of drug-induced ANCA-associated vasculitis present with constitutional symptoms, arthralgias/arthritis, and cutaneous vasculitis. However, the full range of clinical features associated with ANCA, including crescentic GN and lung haemorrhage, can also occur.

It remains unclear how and why autoimmunity with formation of ANCA antibodies occurs. However, a recent study, using material from patients with anti-PR3 suggests that such patients also have autoantibodies to a peptide translated from the antisense DNA strand of PR-3 (complementary PR-3; cPR-3) or to a mimetic of this peptide. This suggests that autoimmunity can be initiated through an immune response against a peptide that is antisense or complementary to the autoantigen, which then induces anti-idiotypic antibodies (autoantibodies) that cross-react with the autoantigen.

There is some evidence to suggest that ANCA are pathogenic and not just markers of disease; for example, development of drug-induced ANCA and associated vasculitic lesions in humans. Studies in MPO knockout mice further highlight the pathogenic significance of ANCA.

ANCA do not act alone. There may be multiple factors that contribute to the initiation of an ANCA autoimmune response and the induction of injury by ANCA, such as genetic predisposition (aj-antitrypsin deficiency; Pi-Z allele) and environmental factors (e.g. silica exposure, viral infection, *Staph. aureus* infection) can result in high local or systemic pro-inflammatory cytokines such as tumour necrosis factor (TNF).

Treatment

The sooner treatment is instituted the more chance there is of recovery of renal function. Corticosteroids and cyclophosphamide are of benefit: high-dose oral prednisolone (maximum 80 mg/day reducing over time to 15 mg/day by 3 months) and cyclophosphamide (2 mg/kg/day, adjusted for age, renal function and prevailing WBC count). Intravenous pulse, rather than daily oral, cyclophosphamide is associated with an equivalent response with better side-effect profile but is associated with higher relapse rate. The best indicators of prognosis are pulmonary haemorrhage and severity of renal failure at presentation. Patients who present with fulminant disease need intensification of immunosuppression with adjuvant plasma exchanges (7 x 3-4 L over 14 days) or intravenous pulse methyl prednisolone (1 g/day for 3 consecutive days). In a recent randomized control study of patients with severe renal failure at presentation (creatinine > 500 umol/day) plasma exchange appeared to have better outcome than pulse methyl prednisolone.

Once remission has been achieved, azathioprine should be substituted for cyclophosphamide. In cases of intolerance to azathioprine or cyclophosphamide, mycophenolate has been tried with some success. Colonization of the upper respiratory tract with *Staph. aureus* increases the risk of relapse, and treatment with

sulphamethoxazole/trimethoprim reduces the relapse rate. Relapse after complete cessation of immunosuppressive therapy has been observed relatively frequently, and therefore long-term, albeit relatively low-dose, immunosuppression is necessary. Long-term follow-up of patients is mandatory. Intravenous immunoglobulin (ATG directed against activated T lymphocytes causes lymphopenia) and anti-TNF therapy show promise in the treatment of severe and drug-resistant cases.

OTHER GLOMERULAR DISORDERS HIV-associated nephropathy (HIVAN) (P 134)

A number of renal lesions have been described in association with HIV infection. These include glomerulonephritis of various histological types and the haemolytic uraemic syndrome. The most common (80-90%) histological abnormality is a focal glomerulosclerosis (FGS).

HIV-associated FGS

A characteristic 'collapsed' appearance of glomeruli is often seen on light microscopy similar to that seen in other causes of focal segmental glomerulosclerosis (see Fig. 11.13c). In HIVAN many visceral epithelial cells (podocytes) are enlarged, hyperplastic, coarsely vacuolated, contain protein absorption droplets and overlie capillaries with varying degrees of wrinkling and collapse of the walls. It is associated with loss of podocyte-specific markers such as Wilms' tumour factor and synaptopodin. There is now clear evidence that HIV-1 infects podocytes of patients with HIVAN. HIVAN has striking predilection; over 90% of patients are black. Clinically HIVAN presents with proteinuria in the nephrotic range, oedema and a 'bland' urine. Hypertension is unusual. If untreated, patients go on to renal failure which can be rapid in progression.

IgA may be an integral feature of HIV-1 infection, as is IgA nephropathy. In this setting, HIV antigen may be a part of the glomerular immune complexes and circulating immune complexes.

Highly active antiretroviral therapy (HAART) may result in stabilization of renal function and prevention of progression to end-stage renal failure (efficacy 23%) and HIV-associated mortality in patients with end-stage renal failure. A cyclin-dependent kinase inhibitor, roscovitine, has been successfully used in the treatment of experimental HIVAN.

Fabry's disease

This is the result of deficiency of the enzyme alpha-galactosidase with accumulation of sphingolipids in many cells. In the kidney, accumulations of sphingolipids especially affects podocytes, which on light microscopy appear enlarged and vacuolated. Ultrastructurally, these inclusion bodies appear as zebra or myeloid bodies representing sphingolipids. These structures can also be found in endothelial, mesangial, and arterial and arteriolar smooth muscle cells. The most common renal manifestation is proteinuria and progressive renal failure.

Treatment (p. 1147).

Sickle nephropathy

Sickle disease or trait is complicated relatively commonly by papillary sclerosis or necrosis, nephrogenic diabetes insipidus and incomplete renal tubular acidosis. Glomerular lesions are rare and can sometimes be traced to hepatitis B or C infection acquired through repeated blood transfusions. Occasionally, proteinuria or nephrotic syndrome with progressive renal insufficiency is seen without prior infection. The rare glomerular lesion is that of membranous GN or mesioproliferative GN with IgG deposits. No form of effective therapy is known.

Glomerulopathy associated with pre-eclampsia

The glomerular lesion of pre-eclampsia is characterized by marked endothelial swelling and obliteration of capillary lumina. Fibrinogen-fibrin deposits may be found in the mesangium. The renal lesion may not be reversible as 30% of patients have changes for 6 months or longer. Patients who have had pre-eclampsia are more likely to develop hypertension in subsequent pregnancies. Severe proteinuria may occur during the course of pre-eclampsia and from time to time produce features of nephrotic syndrome. Ordinarily, proteinuria disappears after delivery.

In severe cases, associated with cortical necrosis, there may be microangiopathic haemolytic anaemia. Vascular endothelial growth factor (VEGF) and placental growth factor (PLGF) play a key role in the development of the placenta. Relative deficiency of either factor can theoretically cause implantation abnormalities normally seen in pre-eclampsia. A soluble fms-like tyrosine kinase (sFltl) receptor, which is an antagonist of PLGF and specifically of VEGF, is upregulated in the placenta of patients with pre-eclampsia. Excessive free radical generation in the placenta of pre-eclamptic patients is due to upregulation of NADPH oxidase activity caused by generation of an angiotensin II receptor agonist antibody.

RENAL INVOLVEMENT IN OTHER DISEASES

Polyarteritis nodosa (PAN) (see also p. 583)

Classical PAN is a multisystem disorder. Aneurysmal dilatation of medium-sized arteries may be seen on renal arteriography. The condition is more common in men and in the elderly and, typically, the patient is ANCA-negative. Hypertension, polyneuropathy, and features indicating ischaemic infarction of various organs including the kidney are presenting features. It may be associated with drug abuse and hepatitis B infection. This form

of polyangiitis is associated with slowly progressive renal failure, often accompanied by severe hypertension. Rapidly progressive renal failure is rare. Treatment with immunosuppression is less effective than it is for microscopic polyangiitis.

Haemolytic uraemic syndrome (HUS)

HUS is characterized by intravascular haemolysis with red cell fragmentation (microangiopathic haemolysis), thrombocytopenia and acute renal failure due to thrombosis in small arteries and arteriole (Fig. 11.24). These features are also seen in disseminated intravascular coagulation, but coagulation tests are typically normal in HUS. The syndrome often follows a febrile illness, particularly gastroenteritis (also known as diarrhoea-associated HUS - D+HUS) often associated with *Escherichia coli,* notably strain O157. This strain of *E. coli* produces verocytotoxin (shiga toxin), which has an A unit and five B units. The A unit is pathogenic by inhibiting protein synthesis and initiating endothelial damage. The role of B units is to facilitate the entry of the A unit into the endothelial cells by binding to a receptor (Gb3) on the endothelial cell. The toxins are transported to endothelial cells from the gut on neutrophils. Most patients with D+HUS recover renal function, but supportive care including maintenance of fluid and electrolyte balance, antihypertensive medication, nutritional support and dialysis is commonly required. Plasmapheresis is not beneficial but is usually tried as last resort. About 5% die during the acute episode, 5% develop chronic renal failure and 30% exhibit evidence of long-term damage with persistent proteinuria. Antibiotic and antimotility agents for the diarrhoea increase the risk of the HUS and its complications.

Recurrent episodes of HUS have been described in the same individual, and familial forms of the disease (with both recessive and dominant inheritance) exist. It is suggested that the non-diarrhoeal-induced form of HUS (D-HUS) may be a complement-driven illness related to deficiency of complement factor H. Factor H is a soluble protein produced by the liver, which regulates the activity of the alternative complement activation pathway; in particular, it protects host cell surfaces from complement-mediated damage. In some families with D-HUS, a mutation has been traced to another complement regulatory protein known as membrane cofactor protein (MCP). This protein is highly expressed in the kidney and normally prevents glomerular C3 activation. A loss of function mutation in MCP may result in unopposed complement activation and development of HUS. Treatment is often very difficult because of severe hypertension and the possibility of frequent recurrences. The course of the disease is often indolent and progressive. *Post-renal transplant* recurrences are frequent. Plasmapheresis or plasma infusion, although unproven, is still recommended. Liver transplantation is potentially the only curative treatment.

Sporadic cases of D-HUS can be associated with pregnancy, SLE, scleroderma, malignant hypertension, metastatic cancer, HIV infection and various drugs including oral contraceptives, ciclosporin, tacrolimus, chemotherapeutic agents (e.g. cisplatin, mitomycin C, bleomycin) and heparin. Treatment is supportive with removal of the offending agent or specific treatment of the underlying cause. There is no evidence in favour of plasma infusion or plasmapheresis in these sporadic cases but it is tried, usually as last resort.

Pneumococcus-associated HUS: This rare complication of *Streptococcus pneumoniae* infection was previously associated with a high morbidity and mortality. This organism produces an enzyme (possibly neuroaminidase) which can expose an antigen (Thomsen antigen) present on RBCs, platelets and glomeruli. Antibodies to the Thomsen antigen result in an antigen-antibody reaction and can lead to HUS and anaemia. The improved outcome is due to increasing awareness of this complication, judicious use of blood products (washed blood products) and avoiding plasma infusion or plasmapheresis.

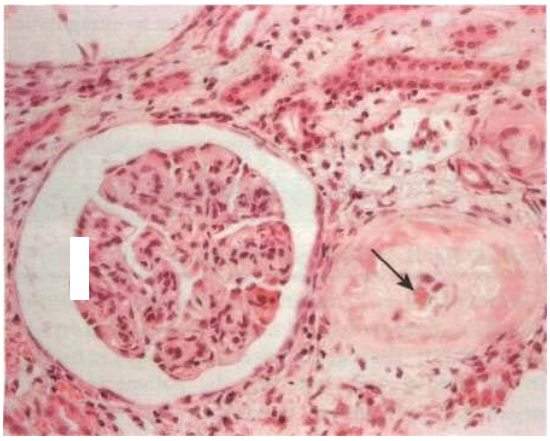

Fig. 11.24 Typical haemolytic uraemic syndrome (HUS) renal lesion - light microscopy. Arrow shows microthrombi.

Thrombotic thrombocytopenic purpura (TTP) (p. 471)

TTP is characterized by microangiopathic haemolysis, renal failure and evidence of neurological disturbance. Young adults are most commonly affected.

Antiphospholipid syndrome (APS) (p. 577)

The central feature of APS is recurrent thrombosis (both venous and arterial) and fetal loss in the presence of antiphosphoiipid antibodies. Such antibodies may be primary or secondary to infections (HIV, hepatitis C) or autoimmune disease (SLE). There are many types of antibodies but one, which binds to (3_2-glycoprotein, changes the endothelial cell profile to being procoagulant and proinflammatory: 50% have renal involvement with proteinuria. Thrombotic microangiopathy is a rare but

well-recognized presentation. In some cases a lupus nephritis-like (usually membranous GN) lesion is seen. The only proven treatment for APS is warfarin with an INR of 3-4. Use of steroids or plasmapheresis is reserved for patients with APS and life-threatening renal involvement with thrombotic microangiopathy. Treatment is variably successful (30-70%).

Multiple myeloma

Acute renal failure is relatively common in myeloma, occurring in 20-30% of affected individuals at the time of diagnosis, and is mainly due to the nephrotoxic effects of the abnormal immunoglobulins. The following types of renal lesions are associated with myeloma.

1. Light chain cast nephropathy - intratubular deposition of light chains, particularly kappa chains facilitated by Tamm-Horsfall glycoprotein, which characteristically appear on renal histology as fractured casts with giant cell reaction (Fig. 11.25).
2. AL amyloidosis - deposition of amyloid fibrils of light chains (Congo red positive)
3. Light chain deposition disease - nodular glomerulosclerosis with granular deposits of usually lambda light chains (Congo red negative)
4. Plasma cell infiltration - often incidental finding at autopsy
5. Fanconi's syndrome - tubular toxicity due to light chains
6. Hypercalcaemic nephropathy - bone resorption causing hypercalcaemia
7. Hyperuricaemic nephropathy - tumour lysis causing tubular crystallization of uric acid.
8. Radiocontrast nephropathy - interaction between light chains and radiocontrast.

Acute renal failure due to cast nephropathy is usually irreversible. Treatment of underlying myeloma is indicated (p. 518).

URINARY TRACT INFECTION

Urinary tract infection (UTI) is common in women, in whom it usually occurs in an anatomically normal urinary tract. Conversely, it is uncommon in men and children, and the urinary tract is often abnormal and requires investigation. The incidence of UTI is 50 000 per million persons per year and accounts for 1-2% of patients in primary care. Recurrent infection causes considerable morbidity; if complicated, it can cause severe renal disease including end-stage renal failure. It is also a common source of life-threatening Gram-negative septicaemia.

Aetiology and pathogenesis

Infection is most often due to bacteria from the patient's own bowel flora (Table 11.7). Transfer to the urinary tract may be via the bloodstream, the lymphatics or by direct extension (e.g. from a vesicocolic fistula), but is most often via the ascending transurethral route (Fig. 11.26).

Symptomatic infection is related to the virulence of the organisms, which competes with the innate host defence system, However, inflammation and injury are determined by the host response and not by the bacterium.

Virulence. Ability to adhere to epithelial cells determines the degree of virulence of the organism. For *E. coli,* these factors include flagellae (for motility), aerobactin (for iron acquisition in the iron-poor environment of the urinary tract), haemolysin (for pore forming) and above all, the presence of adhesins on the bacterial fimbriae and on the cell surface. There are two types of E. *coli:* those with *type 1 fimbriae* (with adhesin known as FimH) associated with cystitis; and those with *type P fimbriae* (with adhesin known as PapG) commonly responsible for pyelonephritis. Bacterial adhesins are necessary for attachment of bacteria to the mucous membranes of the perineum and urothelium. There are several molecular forms of adhesins. The most studied is the PapG adhesin, which is located on the tip of P fimbriae. This lectin (one of the P blood group antigens) structure recognizes binding sites consisting of oligosaccharide sequences present on the mucosal surface.

Innate host defence. The following hosts defence mechanisms are necessary to prevent UTI:

Table 11.7 Organisms causing urinary tract infection in domiciliary practice

Organism	Approximate frequency (%)
Escherichia coli and other 'coliforms'	68+
Proteus mirabilis	12
*Klebsiella aerogenes**	4
*Enterococcus faecalis**	6
Staphylococcus saprophyticus or *epidermidis*^	10

* More common in hospital practice
[f] More common in young women (20-30%)

- *Neutrophils* - adhesins activate receptors, e.g. Toll 4, on the mucosal surface, resulting in IL-8 production and expression of its receptor CXCR1 on neutrophil surfaces. Activation of neutrophils is essential for bacterial killing. Defective IL-8 production or reduced expression of CXCR1 results in impaired function of neutrophils predisposing an individual to severe UTI.
- *Urine osmolcdity and pH* - urinary osmolality > 800 mOsm/kg and low or high pH reduce bacterial survival.
- *Complement* - complement activation with IgA pro duction by uroepithelium (acquired immunity) also plays a major role in defence against UTI.
- *Commensal organisms* - such as lactobacilli, coryne-bacteria, streptococci and bacteroides are part of the normal host defence. Eradication of these commensal organisms by spermicidal jelly or disruption by certain antibiotics results in overgrowth of *E. coli.*
- *Urine flow* - urine flow and normal micturition wash out bacteria. Urine stasis promotes UTI.
- *Uroepithelium* - mannosylated proteins such as Tamm-Horsfall proteins (THP), which are present in the mucus and glycocalyx covering uroepithelium, have antibacterial properties. These proteins interfere with bacterial binding to uroepithelium. Disruption of this uroepithelium by trauma (e.g. sexual intercourse or catheterization) predisposes to UTI. Cranberry juice (blueberry juice) contains a large-molecular-weight factor (proanthrocyanidins) that prevents binding of *E. coli* to the uroepithelium (see p. 641).
- *Blood group antigens* - women who are non-secretors of ABH blood group antigens are three to four times more likely to have recurrent UTIs.

Natural history

UTI is commonly an isolated, rather than a repeated, event (Fig. 11.27).

Complicated versus uncomplicated infection

(Fig. 11.28)

It is necessary to distinguish between UTI occurring in patients with functionally normal urinary tracts and in those with abnormal tracts.

Functionally normal urinary tracts (with normal renal imaging). Here, persistent or recurrent infection seldom results in serious kidney damage (uncomplicated UTI).

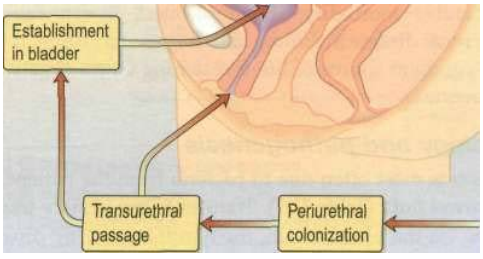

Fig. 11.26 **Ascending infection of the urinary tract.**

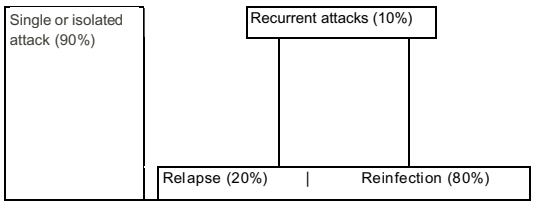

Fig. 11.27 **The natural history of urinary tract infection.**

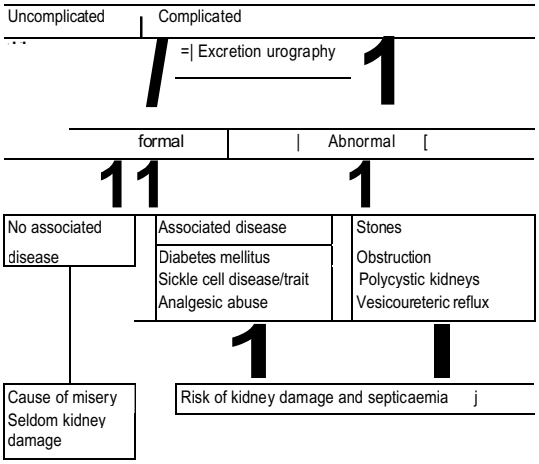

Fig. 11.28 Complicated versus uncomplicated urinary tract infection.

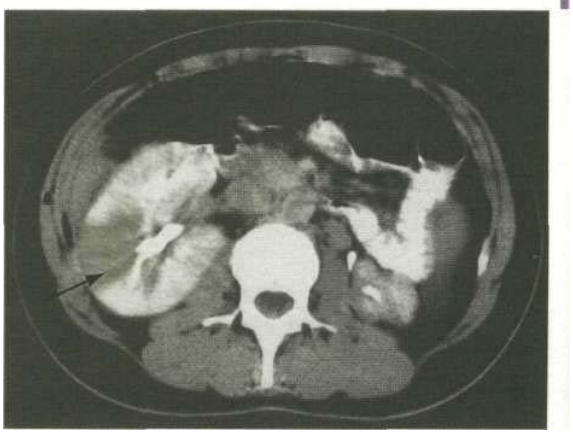

Fig. 11.29 CT scan showing a wedge-shaped area of renal cortical loss (arrow) following acute pyelonephritis.

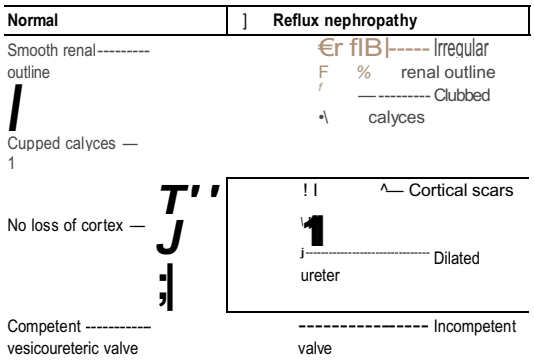

Fig. 11.30 Findings in reflux nephropathy compared with normal.

Abnormal urinary tracts. Tracts with stones, or associated diseases such as diabetes mellitus which themselves cause kidney damage, may be made worse with infection (complicated UTI). UTI, particularly with *Proteus*, may predispose to stone formation. The combination of infection and obstruction results in severe, sometimes rapid, kidney damage (obstructive pyonephrosis) and is a major cause of Gram-negative septicaemia.

Acute pyelonephritis

The combination of fever, loin pain with tenderness and significant bacteriuria usually implies infection of the kidney (acute pyelonephritis). Small renal cortical abscesses and streaks of pus in the renal medulla are often present. Histologically there is focal infiltration by polymorphonuclear leucocytes and many polymorphs in tubular lumina.

Although, with antibiotics, significant permanent kidney damage in adults with normal urinary tracts is rare, CT scanning can show wedge-shaped areas of inflammation in the renal cortex (Fig. 11.29) and hence damage to renal function.

Reflux nephropathy

This was called chronic pyelonephritis or atrophic pyelonephritis, and it results from a combination of:

- vesicoureteric reflux, and
- infection acquired in infancy or early childhood.

Normally the vesicoureteric junction acts as a one-way valve (Fig. 11.30), urine entering the bladder from above; the ureter is shut off during bladder contraction, thus preventing reflux of urine. In some infants and children - possibly even in utero - this valve mechanism is incompetent, bladder voiding being associated with variable reflux of a jet of urine up the ureter. A secondary consequence is incomplete bladder emptying, as refluxed urine returns to the bladder after voiding. This latter event predisposes to infection, and the reflux of infected urine leads to kidney damage.

Typically there is papillary damage, tubulointerstitial nephritis and cortical scarring in areas adjacent to 'clubbed calyces'.

Diagnosis is based on CT scan of the kidneys, which shows irregular renal outlines, clubbed calyces and a variable reduction in renal size. The condition may be unilateral or bilateral and affect all or part of the kidney.

Reflux usually ceases around puberty with growth of the bladder base. Damage already done persists and progressive renal fibrosis and further loss of function occur in severe cases even though there is no further infection.

Reflux nephropathy cannot occur in the absence of reflux and therefore does not begin in adult life. Consequently, adult females with bacteriuria and a normal urogram can be reassured that kidney damage will not develop.

Chronic reflux nephropathy acquired in infancy predisposes to hypertension in later life and, if severe, is a relatively common cause of end-stage renal failure in childhood or adult life. Meticulous early detection and control of infection, with or without ureteral reimplantation to create a competent valve, can prevent further scarring and allow normal growth of the kidneys. No proof exists, however, that reimplantation surgery confers long-term benefit.

Reinfection versus relapsing infection

When UTI is recurrent it is necessary to distinguish between relapse and reinfection.

Relapse is diagnosed by recurrence of bacteriuria with the same organism within 7 days of completion of antibacterial treatment and implies failure to eradicate infection (Fig. 11.31) usually in conditions such as stones, scarred kidneys, polycystic disease or bacterial prostatitis.

Reinfection is when bacteriuria is absent after treatment for at least 14 days, usually longer, followed by recurrence of infection with the same or different organisms. This is not due to failure to eradicate infection, but is the result of reinvasion of a susceptible tract with new organisms. Approximately 80% of recurrent infections are due to reinfection.

Symptoms and signs of UTI

The most typical symptoms of UTI are:

- frequency of micturition by day and night
- painful voiding (dysuria)
- suprapubic pain and tenderness
- haematuria
- smelly urine.

These symptoms relate to bladder and urethral inflammation, commonly called 'cystitis', and suggest lower urinary tract infection. Loin pain and tenderness, with fever and systemic upset, suggest extension of the infection to the pelvis and kidney, known as pyelitis or pyelonephritis. However, localization of the site of infection on the basis of symptoms alone is unreliable.

UTI may also be present with minimal or no symptoms or may be associated with atypical symptoms such as abdominal pain, fever or haematuria in the absence of frequency or dysuria.

In small children, who cannot complain of dysuria, symptoms are often 'atypical'. The possibility of UTI must always be considered in the fretful, febrile sick child who fails to thrive.

Diagnosis

This is based on quantitative culture of a clean-catch midstream specimen of urine and the presence or absence of pyuria. The criteria for the diagnosis of UTI, particularly in symptomatic women, are shown in Table 11.8. A diagnosis based on rigid adherence to a bacterial count of at least 10^5 organisms per millilitre of urine in symptomatic women is incorrect. Diagnosis of 'low count bacteriuria' ($>10^2$ organisms) demands additionally the presence of pyuria.

Dipstick tests can be used to detect nitrites in urine. Most Gram-negative organisms reduce nitrates to nitrites and produce a red colour in the reagent square. False-negative results are common. Dipsticks that detect significant pyuria depend on the release of esterases from leucocytes. Dipstick tests positive for both nitrite and leucocyte esterase are highly predictive of acute infection (sensitivity of 75% and specificity of 82%).

Abactehuric frequency or dysuria ('urethral syndrome')

Causes of truly abacteriuric frequency/dysuria include postcoital bladder trauma, vaginitis, atrophic vaginitis or urethritis in the elderly, and interstitial cystitis (Hunner's ulcer). In symptomatic young women with 'sterile pyuria', *Chlamydia* infection and tuberculosis must be excluded.

Interstitial cystitis is an uncommon but distressing complaint, most often affecting women over the age of 40 years. It presents with frequency, dysuria and often severe suprapubic pain. Urine cultures are sterile. Cysto-

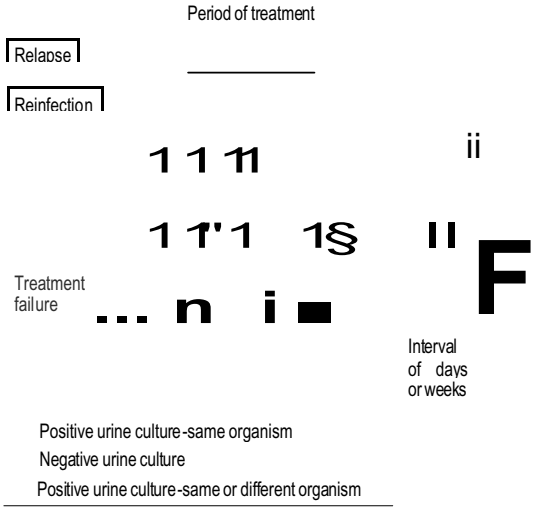

Fig. 11.31 **A comparison of reinfection, relapse and treatment failure in urinary tract infection.**

Table 11.8 **Criteria for diagnosis of bacteriuria**

Symptomatic young women
> 10^2 coliform organisms/mL urine plus pyuria (> 10 WCC/mm^3)

OR

> 10^5 any pathogenic organism/mL urine

OR

any growth of pathogenic organisms in urine by suprapubic aspiration

Symptomatic men
> 10^3 pathogenic organisms/mL urine

Asymptomatic patients
> 10^5 pathogenic organisms/mL urine on two occasions

scopy shows typical inflammatory changes with ulceration of the bladder base. It is commonly thought to be an autoimmune disorder. Various treatments are advocated with variable success. These include oral prednisolone therapy, bladder instillation of sodium cromoglicate or dimethyl sulphoxide and bladder stretching under anaesthesia.

Predominant frequency and passage of small volumes of urine ('irritable bladder') is possibly consequent on previous UTI or conditioned by psychosexual factors. Such patients must be distinguished from those with frequency due to polyuria. Repeated courses of antibiotics in patients with genuine abacteriuric frequency or dysuria are quite inappropriate and detract from identifying the true nature of the problem.

Special investigations

Uncomplicated UTI usually does not require radiological evaluation unless it is recurrent or affecting males and children or there are unusually severe symptoms. Patients with predisposing conditions such as diabetes mellitus or immunocompromised states may also benefit from early imaging. If pyonephrosis is suspected, early imaging and possible drainage is warranted. Intravenous urography and ultrasound are used in the assessment of these patients, allowing the detection of calculi, obstruction, and incomplete emptying, but only in the adult. CT is a more sensitive modality for diagnosis and follow-up of complicated renal tract infection. Contrast-enhanced CT allows different phases of excretion to be studied and can define the extent of disease and identify significant complications or obstruction. Nuclear medicine has a limited role in the evaluation of UTI in adults. Its main role is in the assessment of renal function, often prior to surgery. MRI is particularly useful in those with iodinated contrast allergies, offering an ionizing radiation-free alternative in the diagnosis of both medical and surgical diseases of the kidney.

Treatment

Single isolated attack

Pretreatment urine culture is desirable but not mandatory. In primary care, a positive dipstick test for nitrite and leucocyte esterase is sufficient. Treatment is over 3-5 days with amoxicillin (250 mg three times daily), nitrofurantoin (50 mg three times daily), trimethoprim (200 mg twice daily) or an oral cephalosporin. The treatment regimen is modified in light of the result of urine culture and sensitivity testing, and/or the clinical response. For resistant organisms the alternative drugs are co-amoxiclav or ciprofloxacin.

A high (2 L daily) fluid intake should be encouraged during treatment and for some subsequent weeks. Urinalysis, microscopy and culture should be repeated 5 days after treatment. 'Single-shot' treatment with 3 g of amoxicillin or 1.92 g of co-trimoxazole can be used for patients with bladder symptoms of less than 36 hours' duration who have no previous history of UTI.

If the patient is acutely ill with high fever, loin pain and tenderness (acute pyelonephritis), a broad-spectrum antibiotic is given intravenously, such as aztreonam, cefuroxime, ciprofloxacin or gentamicin (2-5 mg/kg daily in divided doses) switching to a further 7 days' treatment with oral therapy as symptoms improve. Intravenous fluids may be required to achieve a good urine output.

In patients presenting for the first time with high fever, loin pain and tenderness, urgent renal ultrasound examination is required to exclude an obstructed pyonephrosis. If this is present it should be drained by percutaneous nephrostomy (p. 616).

Recurrent infection ■■■■;■■

Pretreatment and post-treatment urine cultures are mandatory to confirm the diagnosis and identify whether recurrent infection is due to relapse or reinfection.

In *relapse,* a search should be made for a cause (e.g. stones or scarred kidneys), and this should be eradicated if possible, for example by the removal of stones. Intense or prolonged treatment - intravenous or intramuscular aminoglycoside for 7 days or oral antibiotics for 4-6 weeks - is required. If this fails, long-term antibiotics are required.

Reinfection implies that the patient has a predisposition to periurethral colonization or poor bladder defence mechanisms. Contraceptive practice should be reviewed and the use of a diaphragm and spermicidal jelly discouraged. Atrophic vaginitis should be identified in postmenopausal women, who should be treated (see below). All patients must undertake prophylactic measures:

- a 2 L daily fluid intake
- voiding at 2- to 3-hour intervals with double micturition if reflux is present
- voiding before bedtime and after intercourse
- avoidance of spermicidal jellies and bubble baths and other chemicals in bathwater
- avoidance of constipation, which may impair bladder emptying.

Evidence of impaired bladder emptying on excretion urography/ultrasound requires urological assessment. If UTI continues to recur, treatment for 6-12 months with low-dose prophylaxis (trimethoprim 100 mg, co-trimoxazole 480 mg, cefalexin 125 mg at night, or macrocrystalline nitrofurantoin) is required; it should be taken last thing at night when urine flow is low. An alternative for infrequent attacks is immediate self-treatment with a conventional antibiotic for 3-5 days. When infection is clearly related to coitus, a single dose of macrocrystalline nitrofurantoin following intercourse may reduce the total drug usage for prophylaxis. Intravaginal oestrogen therapy has been shown to produce a reduction in the number of episodes of UTI in postmenopausal women. Cranberry juice is said to reduce the risk of symptoms and reinfection by 12-20% but studies are limited.

Urinary infections in the presence of an indwelling catheter

Colonization of the bladder by a urinary pathogen is common after a urinary catheter has been present for more than a few days, partly due to organisms forming biofilms. So long as the bladder catheter is in situ, antibiotic treatment is likely to be ineffective and will encourage the development of resistant organisms. Treatment with antibiotics is indicated only if the patient has symptoms or evidence of infection, and should be accompanied by replacement of the catheter. Prevention of infection with sterile insertion and closed drainage systems plays a major role. Catheters should not be used unnecessarily. Bladder stones may form in patients with long-term indwelling catheters, further complicating the situation.

Infection by *Candida* is a frequent complication of prolonged bladder catheterization. Treatment should be reserved for patients with evidence of invasive infection or those who are immunosuppressed, and should consist of removal or replacement of the catheter and in severe infections intravesical amphotericin.

Bacteriuria in pregnancy

The urine of pregnant women must always be cultured as 2-6% have asymptomatic bacteriuria. Whilst asymptomatic bacteriuria in the non-pregnant female seldom leads to acute pyelonephritis and often does not require treatment, acute pyelonephritis frequently occurs in pregnancy under these circumstances. Failure to treat may thus result in severe symptomatic pyelonephritis later in pregnancy, with the possibility of premature labour. Asymptomatic bacteriuria, in the presence of previous renal disease, may predispose to pre-eclamptic toxaemia, anaemia of pregnancy, and small or premature babies. Therefore bacteriuria must always be treated and be shown to be eradicated. Reinfection may require prophylactic therapy. Tetracycline, trimethoprim, sulphonamides and 4-quinolones must be avoided in pregnancy. Amoxicillin and ampicillin, nitrofurantoin and oral cephalosporins may safely be used in pregnancy.

Bacterial prostatitis

Bacterial prostatitis is a relapsing infection which is difficult to treat. It presents as perineal pain, recurrent epididymo-orchitis and prostatic tenderness, with pus in expressed prostatic secretion. Treatment is for 4-6 weeks with drugs that penetrate into the prostate, such as trimethoprim or ciprofloxacin. Long-term low-dose treatment may be required. Prostadynia (prostatic pain in the absence of active infection) may be a very persistent sequel to bacterial prostatitis. Amitriptyline and carbamazepine may alleviate the symptoms.

Renal carbuncle

Renal carbuncle is an abscess in the renal cortex caused by a blood-borne *Staphylococcus,* usually from a boil or carbuncle of the skin. It presents with a high swinging fever, loin pain and tenderness, and fullness in the loin. The urine shows no abnormality as the abscess does not communicate with the renal pelvis, more often extending into the perirenal tissue. Staphylococcal septicaemia is common. Diagnosis is by ultrasound or CT scanning. Treatment involves antibacterial therapy with flucloxacillin and surgical drainage.

Tuberculosis of the urinary tract

Tuberculous infection is on the increase world-wide, partly due to the reservoir of infection in susceptible HIV-infected individuals and by the emergence of drug-resistant strains. Tuberculosis of the urinary tract presents with frequency, dysuria or haematuria. In the UK it is mainly seen in the Asian immigrant population. Cortical lesions result from haematogenous spread in the primary phase of infection. Most heal, but in some, infection persists and spreads to the papillae, with the formation of cavitating lesions and the discharge of mycobacteria into the urine. Infection of the ureters and bladder commonly follows, with the potential for the development of ureteral stricture and a contracted bladder. Rarely, cold abscesses may form in the loin. In males the disease may present with testicular or epididymal discomfort and thickening.

Diagnosis depends on constant awareness, especially in patients with sterile pyuria. Excretion urography may show cavitating lesions in the renal papillary areas, commonly with calcification. There, may also be evidence of ureteral obstruction with hydronephrosis. Diagnosis of active infection depends on culture of mycobacteria from early-morning urine samples. The urogram may be normal in diffuse interstitial renal tuberculosis when diagnosis is made by renal biopsy. Some patients present with small unobstructed kidneys, when the diagnosis is easy to miss.

Treatment. The treatment is as for pulmonary tuberculosis (see p. 932). Renal ultrasonography or excretion urography should be carried out 2-3 months after initiation of treatment as ureteric strictures may first develop in the healing phase.

Xanthogranulomatous pyelonephritis

This is an uncommon chronic interstitial infection of the kidney, most often due to *Proteus,* in which there is fever, weight loss, loin pain and a palpable enlarged kidney. It is usually unilateral and associated with staghorn calculi. CT scanning shows up intrarenal abscesses as lucent areas within the kidney. Nephrectomy is the treatment of choice; antibacterial treatment rarely, if ever, eradicates the infection.

Malakoplakia

This is a rare condition in which plaques of abnormal inflammatory tissue grow within the urinary tract in the

presence of urinary infection. The histological appearances are characteristic. It is thought that the condition is caused by an acquired inability of macrophages to kill phagocytosed bacteria. Muscarinic agonists and ascorbic acid may improve macrophage function; ciprofloxacin penetrates the macrophage well and is the antibiotic of choice. Prolonged treatment is often needed.

TUBULOINTERSTITIAL NEPHRITIS (TIN)

Diseases of the kidney primarily affect the glomeruli, vasculature, or the remainder of the renal parenchyma that consists of the tubules and interstitium. Although the tubules and the interstitium are distinct functional entities, they are intimately related. Injury involving one of them invariably results in damage to the other.

Acute tubulointerstitial nephritis (TIN)

In approximately 70% of the cases, acute TIN is due to a hypersensitivity reaction to drugs (Table 11.9), most commonly drugs of the penicillin family and non-steroidal anti-inflammatory drugs (NSAIDs). Fifteen per cent are infection related, 8% are idiopathic and 5% are cases of tubulointerstitial nephritis with uveitis (TINU) syndrome.

Drug induced acute TIN. Patients present with fever, arthralgia, skin rashes and acute oliguric or non-oliguric renal failure. Many have eosinophilia and eosinophiluria. Renal histology shows an intense interstitial cellular infiltrate, often including eosinophils, with variable tubular necrosis. Rarely, NSAIDs can cause a glomerular minimal-change lesion in addition to TIN and present as the nephrotic syndrome. *Treatment* involves withdrawal of offending drugs. High-dose steroid therapy (prednisolone 60 mg daily) is commonly given but its efficacy has not been proven. Patients may require dialysis for management of the acute renal failure. Most patients make a good recovery in kidney function, but some may be left with significant interstitial fibrosis and a persistent high serum creatinine.

Table 11.9 **Common causes of acute tubulointerstitial nephritis**

Drugs (70%)	
Penicillins	Rifampicin
Sulphonamides	Diuretics:
Non-steroidal anti-inflammatory drugs	furosemide
	thiazides
Phenindione	Cimetidine
Allopurinol	Phenytoin
Cephalosporins	
Infection (15%)	
Viruses, e.g. hantavirus	
Bacteria, e.g. streptococci	
Idiopathic (8%)	
Tubulointerstitial nephritis with uveitis (TINU) (5%)	
Systemic inflammatory disorders, e.g. systemic lupus erythematosus (SLE)	

Infection causing acute TIN. Acute pyelonephritis leads to inflammation of the tubules, producing a neutrophilic cellular infiltrate. TIN can complicate systemic infections with viruses (hantavirus, Epstein-Barr virus, HIV, measles, adenovirus), bacteria *(Legionella, Leptospira,* streptococci, *Mycoplasma, Brucella, Chlamydia)* and others *(Leishmania, Toxoplasma).* Hantavirus causes haemorrhagic fever with TIN and can be fatal. Epstein-Barr virus DNA has been found in renal biopsy tissue of cases of idiopathic TIN; if confirmed, this could potentially become a relatively common cause of acute TIN. In immunocompromised patients such as post-renal transplantation, CMV, polyoma, and herpes simplex virus can cause acute TIN in the renal graft. *Treatment* involves eradication of infection by appropriate antibiotics or antiviral agents.

Acute TIN as part of multisystem inflammatory diseases. Several non-infectious inflammatory disorders such as Sjogren's syndrome, SLE and Wegener's granulomatosis can cause acute or chronic TIN rather than glomerulonephritis. SjSgren's syndrome may additionally present as renal tubular acidosis. Sarcoidosis presents as granulomatous TIN in up to 20% of patients. Associated hypercalcaemia causes acute renal failure. These heterogeneous conditions with TIN generally respond to steroids.

TINU syndrome. In this syndrome, uveitis generally coincides with acute TIN. It is common in childhood, but has been reported in adulthood. Among adults it is more common in females, but its cause remains unknown. Patients present with weight loss, anaemia and raised ESR. A prolonged course of steroids leads to improvement in both renal function and uveitis.

Chronic tubulointerstitial nephritis

The major causes of chronic tubulointerstitial nephritis are given in Table 11.10. In many cases no cause is found. Chronic TIN changes evolve in progressive primary glomerular or vascular disease of the kidney, where its severity is a better predictor of long-term renal survival than the primary site of insult.

The patient usually either presents with polyuria and nocturia, or is found to have proteinuria or uraemia. Proteinuria is usually slight (less than 1 g daily). Papillary necrosis with ischaemic damage to the papillae occurs in

Causes of chronic tubulointerstitial nephritis *Table 11.10*

Common	Uncommon
Reflux nephropathy	Alport's syndrome Balkan nephropathy and herbal nephropathy
Non-steroidal anti-inflammatory drugs	Irradiation
Diabetes mellitus	Sjogren's syndrome
Sickle cell disease or trait	Hyperuricaemic nephropathy
Cadmium or lead intoxication	

a number of tubulointerstitial nephritides, for example in analgesic abuse, diabetes mellitus, sickle cell disease or trait. The papillae can separate and be passed in the urine. Microscopic or overt haematuria or sterile pyuria also occurs, and occasionally a sloughed papilla may cause ureteric colic or produce acute ureteric obstruction. The radiological appearances must be distinguished from those of reflux nephropathy (Fig. 11.32).

Tubular damage to the medullary area of the kidney leads to defects in urine concentration and sodium conservation with polyuria and salt wasting. Fibrosis progressing into the cortex leads to loss of excretory function and uraemia.

Analgesic nephropathy

The chronic consumption of large amounts of analgesics (especially those containing phenacetin) and NSAIDs leads to chronic tubulointerstitial nephritis and papillary necrosis. Analgesic nephropathy is twice as common in women as in men and presents typically in middle-age. Patients are often depressed or neurotic. Presentation may be with anaemia, chronic renal failure, UTIs, haematuria, or urinary tract obstruction (owing to sloughing of a renal papilla). Salt and water-wasting renal disease may occur. Chronic analgesic abuse also predisposes to the development of uroepithelial tumours.

The consumption of the above analgesics should be discouraged. If necessary, dihydrocodeine or paracetamol is a reasonable alternative. This may result in the arrest of the disease and even in improvement in function. UTI, hypertension (if present) and saline depletion will require appropriate management. The development of flank pain or an unexpectedly rapid deterioration in renal function should prompt ultrasonography to screen for urinary tract obstruction due to a sloughed papilla.

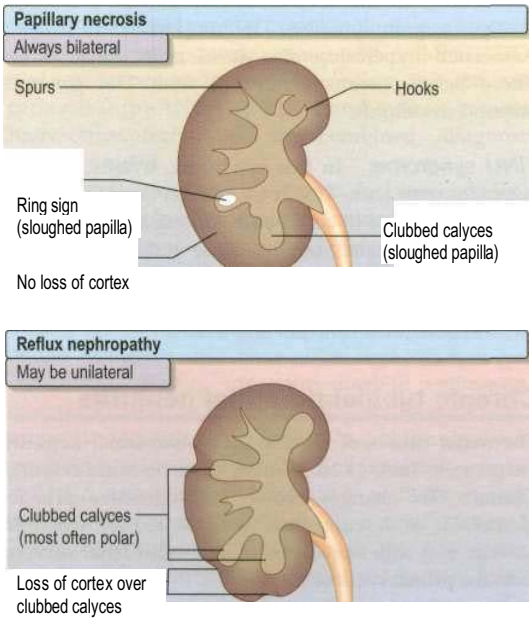

Fig. 11.32 **A comparison of radiological appearances of papillary necrosis and reflux nephropathy.**

Balkan nephropathy

This is a chronic TIN endemic in areas along the tributaries of the River Danube. Inhabitants of the low-lying plains, which are subjected to frequent flooding and where the water supply comes from shallow wells, are affected, whereas the disease does not occur in hillside villages where surface water provides the water supply. Its cause is unknown. The disease is insidious in onset, with mild proteinuria progressing to renal failure in 3 months to 10 years. Patients exhibit a high incidence of uroepithelial tumours. There is no treatment.

Chinese herb nephropathy

Chinese herbal medicines have been increasingly used in the West, e.g. for slimming, and have caused a nephropathy. The renal histology is similar to Balkan nephropathy but the clinical course is very aggressive. The causal agent has been identified as aristolochic acid produced as a result of fungal contamination of the herbal medicine. It is characterized by relentless progression to end-stage renal failure. There is a high incidence of uroepithelial tumours.

Other forms of chronic tubulointerstitial nephritis

These are rare (see Table 11.10). Diagnosis of all forms depends on a history of drug ingestion or industrial exposure to nephrotoxins. In patients with unexplained renal impairment with normal-sized kidneys, renal biopsy must always be undertaken to exclude a treatable tubulointerstitial nephritis such as granulomatous TIN due to renal sarcoidosis, which may be the first presentation of sarcoidosis (see p. 935). Renal sarcoidosis generally responds rapidly to steroids.

Hyperuricaemic nephropathy (see p. 570)

Acute hyperuricaemic nephropathy is a well-recognized cause of acute renal failure in patients with marked hyperuricaemia that is usually due to lymphoproliferative or myeloproliferative disorders. It may

occur prior to treatment but most often follows commencement of treatment, when there is rapid lysis of malignant cells, release of large amounts of nucleoprotein and increased uric acid production. Renal failure is due to intrarenal and extrarenal obstruction caused by deposition of uric acid crystals in the collecting ducts, pelvis and ureters. The condition is manifest as oliguria or anuria with increasing uraemia. There may be flank pain or colic. Plasma urate levels are above 0.75 mmol/L and may be as high as 4.5 mmol/L. Diagnosis is based on the hyperuricaemia and the clinical setting. Ultrasound may demonstrate extrarenal obstruction due to stones, but a negative scan does not exclude this where there is coexistent intrarenal obstruction.

Allopurinol 100-200 mg three times daily for 5 days is given prior to and throughout treatment with radiotherapy or cytotoxic drugs. A high rate of urine flow must be maintained by oral or parenteral fluid and the urine kept alkaline by the administration of sodium bicarbonate 600 mg four times daily and acetazolamide 250 mg three times daily, since uric acid is more soluble in an alkaline than in an acid medium. Rasburicase (p. 492) is occasionally used. In severely oliguric or anuric patients, dialysis is required to lower the plasma urate.

There is no convincing evidence for *chronic hyperuricaemia nephropathy*.

HYPERTENSION AND THE KIDNEY

Hypertension can be the cause or the result of renal disease. It is often difficult to differentiate between the two on clinical grounds. Routine tests as described on page 860 should be performed on all hypertensive patients, but renal imaging is usually unnecessary. A guide to how patients should be fully investigated is given on page 1095.

The mechanisms responsible for the normal regulation of arterial blood pressure and the development of essential primary hypertension are unclear (p. 858). One basic concept is that the long-term regulation of arterial pressure is closely linked to the ability of the kidneys to excrete sufficient salt to maintain normal sodium balance, extracellular fluid volume, and normal blood volume at normotensive arterial pressures. Several studies point to the kidney as involved in the genesis of essential primary hypertension. Cross-transplantation experiments suggest that hypertension travels with the kidney, in that hypertension will develop in a normotensive recipient of a kidney genetically programmed for hypertension. Likewise patients with end-stage renal failure due to hypertension become normotensive after receiving a renal allograft from normotensive donors, provided the new kidney works.

One of many renal factors involved in the genesis of hypertension is the total number of nephrons in the kidney. There is now circumstantial as well direct evidence to suggest that patients with hypertension and normal renal function have a significantly reduced number of nephrons in each kidney alongside enlargement of the remaining glomeruli due to glomerular hyperfiltration. Moreover, certain races (blacks, Hispanics) with predilection for hypertension have increased glomerular volume, a surrogate marker for a reduced number of nephrons.

Whether the reduced number of nephrons is caused by genetic or environmental factors is unclear. Changes in the intrauterine environment may lead to retarded renal growth before birth, low birthweight and hypertension during adult life. In humans, an association has been found between low birthweight and reduced renal volume, possibly indicating reduced numbers of nephrons.

ESSENTIAL HYPERTENSION

Pathophysiology

In benign essential hypertension, arteriosclerosis of major renal arteries and changes in the intrarenal vasculature (nephrosclerosis) occur as follows:

- In small vessels and arterioles, intimal thickening with reduplication of the internal elastic lamina occurs and the vessel wall becomes hyalinized.
- In large vessels, concentric reduplication of the internal elastic lamina and endothelial proliferation produce an 'onion skin' appearance.
- Reduction in size of both kidneys may occur; this may be asymmetrical if one major renal artery is more affected than the other.
- The proportion of sclerotic glomeruli is increased compared with age-matched controls.

Deterioration in excretory function accompanies these changes, but severe renal failure is unusual in whites (1 in 10 000). In black Africans, by contrast, hypertension much more often results in the development of renal failure with a fourfold higher incidence of end-stage renal failure in blacks compared to whites. This racial difference in incidence of hypertensive renal disease may be due to overestimation of diagnosis on clinical grounds, poor compliance with medication, higher incidence of hypertension, which is usually a salt-sensitive type, and reduced number of nephrons.

In accelerated, or malignant-phase hypertension:

- Arteriolar fibrinoid necrosis occurs, probably as a result of plasma entering the media of the vessel through splits in the intima. It is prominent in afferent glomerular arterioles.
- Fibrin deposition within small vessels is often associated with thrombocytopenia and red-cell fragmentation

seen in the peripheral blood film (microangiopathic haemolytic anaemia).

Microscopic haematuria, proteinuria, usually of modest degree (1-3 g daily), and progressive uraemia occur. If untreated, fewer than 10% of patients survive 2 years.

Management

The management of benign essential and malignant hypertension is described on page 861.

If treatment is begun before renal impairment has occurred, the prognosis for renal function is good. Stabilization or improvement in renal function with healing of intrarenal arteriolar lesions and resolution of microangiopathic haemolysis occur with effective treatment of malignant-phase hypertension. Lifelong follow-up of the patient is mandatory. In blacks with hypertensive nephrosclerosis and renal impairment, a blood pressure target of < 140/85 mmHg should be achieved. ACE inhibitors appear to be more effective than beta-blockers, and, if possible, calcium-channel blockers of the dihydropyridine group (e.g. amlodipine) should be avoided.

RENAL HYPERTENSION

Hypertension commonly complicates bilateral renal disease such as chronic glomerulonephritis, bilateral reflux nephropathy (chronic atrophic pyelonephritis of childhood), polycystic disease and analgesic nephropathy. Two main mechanisms are responsible:

- activation of the renin-angiotensin-aldosterone system
- retention of salt and water owing to impairment in excretory function, leading to an increase in blood volume and hence blood pressure.

The second of these assumes greater significance as renal function deteriorates.

Hypertension occurs earlier, is more common and tends to be more severe in patients with renal cortical disorders, such as glomerulonephritis, than in those with disorders affecting primarily the renal interstitium, such as reflux or analgesic nephropathy.

Management is described on page 861. Meticulous control of the blood pressure is necessary to prevent further deterioration of renal function secondary to vascular changes produced by the hypertension itself. There is good evidence that ACE-inhibitor drug treatment confers an additional renoprotective effect for a given degree of blood pressure control than other hypotensive drugs.

Renovascular disease

Narrowing of the renal arteries (renal artery stenosis) usually is caused by one of two pathological entities: fibromuscular disease or atherosclerotic renovascular disease (ARVD). The epidemiology and the natural history of these two conditions differ and they are considered separately.

Mechanism of hypertension

Renal ischaemia results in a reduction in the pressure in afferent glomerular arterioles. This leads to an increase in the production and release of renin from the juxtaglomerular apparatus (see p. 606) with a consequent increase in angiotensin II, a very potent vasoconstrictor. Angiotensin II also causes hypertension by upregulating NADPH oxidase enzyme with excessive superoxide generation. Superoxide chelates nitric oxide (a potent vasodilator) resulting in reduced vasodilator activity and also hypertension.

Physiological changes in renal artery stenosis

In renal artery stenosis, renal perfusion pressure is reduced and nephron transit time is prolonged on the side of the stenosis; salt and water reabsorption is therefore increased. As a result, urine from the ischaemic kidney is more concentrated and has a lower sodium concentration than urine from the contralateral kidney. Inulin, creatinine and p-aminohippuric acid (PAH) clearances are decreased on the ischaemic side.

Fibromuscular disease of the renal arteries

Fibromuscular disease accounts for 20-40% of renal vascular disease and encompasses four distinct types: (1) medial fibroplasia (65-85%); (2) perimedial fibroplasia (10-15%); (3) intimal fibroplasia (5-10%); and (4) medial hyperplasia (5%). Medial fibroplasia usually follows a benign course and never follows a progressive course after the age of 40 years. The other two types of fibroplasia follow a progressive course and may lead to total occlusion. Medial hyperplasia is a distinct but rare entity, which accounts for only 1% of renovascular disease. It commonly affects young females, who exhibit elevated blood pressures but with well-preserved renal function. Angiography reveals a characteristic string of beads appearance. Angioplasty (occasionally stent insertion) is usually successful in improving or even curing hypertension in affected individuals, and overall prognosis is very good.

Atherosclerotic renovascular disease (ARVD)

This is a common cause of hypertension and chronic renal failure due ischaemic nephropathy. Its incidence increases with age, rising from 5% under 60 years to 16% in those over 60 years old. In most patients the atherosclerotic lesion is ostial (within 1 cm of the origin of the renal artery) and usually associated with symptomatic atherosclerotic vascular disease elsewhere. Patients with peripheral vascular disease (39%), coronary artery disease (10-29%), congestive cardiac failure (34%) and aortic aneurysm (38%) are at high risk of developing significant renal artery stenosis.

Many patients are asymptomatic and are discovered incidentally during investigation for other conditions. Aortography experience from the USA shows 11% of asymptomatic patients have significant unilateral stenosis and 4% have bilateral disease. The renal consequences of ARVD are functional, such as hypertension (present in 50%), sodium retention (ankle and flash

pulmonary oedema), proteinuria (usually sub-nephrotic range) and decreased GFR. The morphological features of the affected kidneys include vascular sclerosis, tubular atrophy, interstitial fibrosis with inflammatory cellular infiltrate, atubular glomeruli, cholesterol emboli, and secondary FSGS changes. Baseline renal function is related to the extent of renal parenchymal injury rather than to the degree of stenosis, as is the response (improvement in hypertension and renal function) to revascularization.

Renovascular disease is easy to miss and should be considered in patients with hypertension and/ or chronic renal failure. Other clues to the diagnosis include: abdominal audible bruits, as well as over carotid arteries suggestive of generalized arterial disease; ultrasonography showing > 1.5 cm renal asymmetry; recurrent flash pulmonary oedema without cardiopulmonary disease; progressive chronic renal failure in patients with evidence of generalized atherosclerosis.

Screening for renovascular disease

Radionuclide studies (see p. 617). These can demonstrate decreased renal perfusion on the affected side. In unilateral renal artery stenosis, a disproportionate fall in uptake of isotope on the affected side following administration of captopril or aspirin is suggestive of the presence of significant renal artery stenosis. A completely normal result renders the diagnosis unlikely.

Doppler ultrasound. This method is very sensitive but highly operator-dependent and time-consuming. It generates data about intrarenal vascular resistance, which can be valuable in predicting the success of revascularization procedures. A resistive index of > 80 is a predictor of poor response following intervention.

Magnetic resonance angiography. MRA can be used to visualize the renal arteries and there is a good - though not perfect — correlation between MRA findings and those of renal arteriography.

Helical ('spiral') CT scanning. This permits non-invasive imaging of the renal arteries. It is much less expensive than MRI but does expose the patient to ionizing radiation and to contrast injection and is less reliable than MRI.

Renal arteriography (see p. 617) remains the 'gold standard' investigation in the diagnosis of renal arterial disease.

Treatment

The aim of treatment is to correct hypertension and improve renal perfusion and excretory function. Renal artery stenosis can progress to occlusion, particularly in patients with stenosis > 75% as shown by serial angiography, necessitating revascularization in ARVD. The options in renal artery stenosis include transluminal angioplasry to dilate the stenotic region, insertion of stents across the stenosis (sometimes the only endoscopic option when the stenosis occurs close to the origin of the renal artery from the aorta, rendering angioplasty technically difficult or impossible), reconstructive vascular surgery and nephrectomy. Revascularization is indicated in vessels with stenosis > 75% and recurrent flash pulmonary oedema, drug resistant severe hypertension, ARVD affecting solitary functioning kidney, patients with cardiac failure needing ACE inhibitors, unexplained progressive renal failure and dialysis-dependent renal failure. With good selection of patients, hypertension is cured or improved by intervention in more than 50%. Occasional dramatic improvements in renal function ensue but results are generally disappointing. All patients with ARVD should be treated with a combination of aspirin, statins and optimal control of blood pressure as prophylaxis against progression of atherosclerosis.

Mortality is high because of other associated co-morbidities, and ARVD patients have generalized endothelial dysfunction. ARVD patients with end-stage renal failure have higher rates than those with good renal function. Five-year survival is only 18% in patients with end-stage renal failure due to ARVD.

Systemic sclerosis (see also p. 577)

Interlobular renal arteries are affected with intimal thickening, and fibrinoid changes occur in afferent glomerular arterioles similar to renal changes in malignant hypertension. Glomerular changes are non-specific. The pathogenesis is unknown and neither steroid nor immunosuppressive therapy is of value. Serum ANCA is not present. Treatment with ACE-inhibitor drugs is of immense benefit, reducing proteinuria and often halting or even partially reversing decline in renal function. 'Scleroderma renal crisis' is a term applied to rapid loss of renal function owing to rapid progression of renal microvascular disease in this condition. Early ACE inhibitor treatment may be of benefit, as may continuous intravenous infusion of prostacyclin.

OTHER VASCULAR DISORDERS OF THE KIDNEY

Renal artery occlusion

This occurs from thrombosis in situ usually in a severely damaged atherosclerotic vessel or more commonly from embolization. Both lead to renal infarction, resulting in a wide spectrum of clinical manifestations depending on the size of the artery involved. Occlusion of a small branch artery may produce no effect, but occlusion of larger vessels results in dull flank pain and varying degrees of renal failure.

Embolization may occur from the heart (e.g. in atrial fibrillation). Intra-arterial thrombolytic therapy has been tried with mixed results.

Cholesterol embolization

Showers of cholesterol-rich atheromatous material from ulcerated plaques may reach the kidney from the aorta and/or renal arteries, particularly after catheterization of the abdominal aorta or attempts at renal artery angioplasty. Anticoagulants and thrombolytic agents may also precipitate cholesterol embolization. Renal failure from cholesterol emboli may be acute or slowly progressive. Clinical features include fever, eosinophilia, back and abdominal pain, and evidence of embolization elsewhere, for example to the retina or digits. The diagnosis can be confirmed by renal biopsy. No treatment is of proven benefit.

Renal vein thrombosis

This is usually of insidious onset, occurring in the nephrotic syndrome, with a renal cell carcinoma, and in conditions associated with an increased risk of venous thrombosis (e.g. antithrombin deficiency or the presence of anticardiolipin antibodies). Anticoagulation is indicated.

CALCULI AND NEPHROCALCINOSIS

Renal and vesical calculi

In the UK, approximately 2% of people have a urinary tract stone at any given time. Prevalence of stone disease is much higher in the Middle East. Most stones occur in the upper urinary tract; the incidence of bladder stones has declined in the UK, but in some developing countries they are still common.

Most stones are composed of calcium oxalate and phosphate; these are more common in men (Table 11.11). Mixed infective stones, which account for about 15% of all calculi, are twice as common in women as in men. The overall male to female ratio of stone disease is 2 :1.

Stone disease is frequently a recurrent problem. More than 50% of patients with a history of nephrolithiasis will develop a recurrence within 10 years. The risk of recurrence increases if a metabolic or other abnormality predisposing to stone formation is present and is not modified by treatment.

Table 11.11 **Type and frequency of renal stones in the UK**

Type of renal stone	Approximate frequency (%)
Calcium oxalate usually with calcium phosphate	65
Calcium phosphate alone	15
Magnesium ammonium phosphate (struvite)	10-15
Uric acid	3-5
Cystine	1-2

Aetiology

Inhibitors of crystal formation are present in normal urine preventing the formation of stones, as the concentrations of stone-forming substances exceed their maximum solubility in water. Many stone-formers have no detectable metabolic defect, although microscopy of warm, freshly passed urine reveals both more and larger calcium oxalate crystals than are found in normal subjects. Factors predisposing to stone formation in these so-called 'idiopathic stone-formers' are:

- chemical composition of urine that favours stone crystallization
- production of a concentrated urine as a consequence of dehydration associated with life in a hot climate or work in a hot environment
- impairment of inhibitors that prevent crystallization in normal urine. Postulated inhibitors include inorganic magnesium, pyrophosphate and citrate. Organic inhibitors include glycosaminoglycans and nephrocalcin (an acidic protein of tubular origin). Tamm-Horsfall protein may have a dual role in both inhibiting and promoting stone formation.

Recognized causes of stone formation are listed in Table 11.12.

Hypercalcaemia

If the GFR is normal, hypercalcaemia almost invariably leads to hypercalciuria. The common causes of hypercalcaemia leading to stone formation are:

- primary hyperparathyroidism
- vitamin D ingestion
- sarcoidosis.

Table 11.12 **Causes of urinary tract stone formation**

Dehydration	Infection
Hypercalcaemia	Cystinuria
Hypercalciuria	Renal tubular acidosis
Hyperoxaluria	Primary renal disease (polycystic kidneys, medullary sponge kidneys)
Hyperuricaemia and hyperuricosurea	Drugs

Of these, primary hyperparathyroidism (see p. 901) is the most common cause of stones.

Hypercalciuria

This is by far the most common metabolic abnormality detected in calcium stone-formers.

Approximately 8% of men excrete in excess of 7.5 mmol of calcium in 24 hours. Calcium stone formation is more common in this group, but as the majority of even these individuals do not form stones the definition of 'pathological' hypercalciuria is arbitrary. A reasonable definition is 24-hour calcium excretion of more than 7.5 mmol in male stone-formers and more than 6.25 mmol in female stone-formers.

The kidney is the major site for plasma calcium regulation. Approximately 90% of the ionized calcium filtered by the kidney is reabsorbed. Renal tubular reabsorption is controlled largely by parathyroid hormone (PTH).

Approximately 65% of the filtered calcium is absorbed in the proximal convoluted tubule, 20% by the thick ascending limb of the loop of Henle, and 15% by the distal convoluted tubule and collecting ducts.

Causes of hypercalciuria are:

- hypercalcaemia
- an excessive dietary intake of calcium
- excessive resorption of calcium from the skeleton, such as occurs with prolonged immobilization or weightlessness
- idiopathic hypercalciuria.

Idiopathic hypercalciuria is a common risk factor for the formation of stones, and uncontrolled hypercalciuria is a cause of recurrences. The majority of patients with idiopathic hypercalciuria have increased absorption of calcium from the gut. Moreover, studies have shown that animal protein and salt also have a considerable influence on calcium excretion.

Hyperoxaluria

There are two inborn errors of glyoxalate metabolism that cause increased endogenous oxalate biosynthesis, and are inherited in an autosomal recessive manner. In both types, calcium oxalate stone formation occurs.

The prognosis is poor owing to widespread calcium oxalate crystal deposition in the kidneys. Renal failure typically develops in the late teens or early twenties. Successful liver transplantation has been shown to cure the metabolic defect.

Much more common causes of mild hyperoxaluria are:

- excess ingestion of foodstuffs high in oxalate, such as spinach, rhubarb and tea
- dietary calcium restriction, with compensatory increased absorption of oxalate
- gastrointestinal disease (e.g. Crohn's), usually with an intestinal resection, associated with increased absorption of oxalate from the colon.
- Dehydration secondary to fluid loss from the gut also plays a part in stone formation.

Hyperuricaemia and hyperuricosuria

Uric acid stones account for 3—5% of all stones in the UK, but in Israel the proportion is as high as 40%. Uric acid is the end-point of purine metabolism. Hyperuricaemia (see p. 569) can occur as a primary defect in idiopathic gout, and as a secondary consequence of increased cell turnover, for example in myeloproliferative disorders. Increased uric acid excretion occurs in these conditions, and stones will develop in some patients. Some uric acid stone-formers have hyperuricosuria (> 4 mmol per 24 hours on a low-purine diet) without hyperuricaemia.

Dehydration alone may also cause uric acid stones to form. Patients with ileostomies are at particular risk both from dehydration and from the fact that loss of bicarbonate from gastrointestinal secretions results in the production of an acid urine (uric acid is more soluble in an alkaline than in an acid medium).

Some patients with calcium stones also have hyperuricaemia and/or hyperuricosuria; it is believed the calcium salts precipitate upon an initial nidus of uric acid in such patients.

Urinary tract infection

Mixed infective stones are composed of magnesium ammonium phosphate together with variable amounts of calcium. Such struvite stones are often large, forming a cast of the collecting system (staghorn calculus). These stones are usually due to UTI with organisms such as *Proteus mirabilis* that hydrolyse urea, with formation of the strong base ammonium hydroxide. The availability of ammonium ions and the alkalinity of the urine favour stone formation. An increased production of mucoprotein from infection also creates an organic matrix on which stone formation can occur.

Cystinuria (see also p. 1146)

Cystinuria results in the formation of cystine stones. About 1-2% of all stones are composed of cystine.

Primary renal diseases

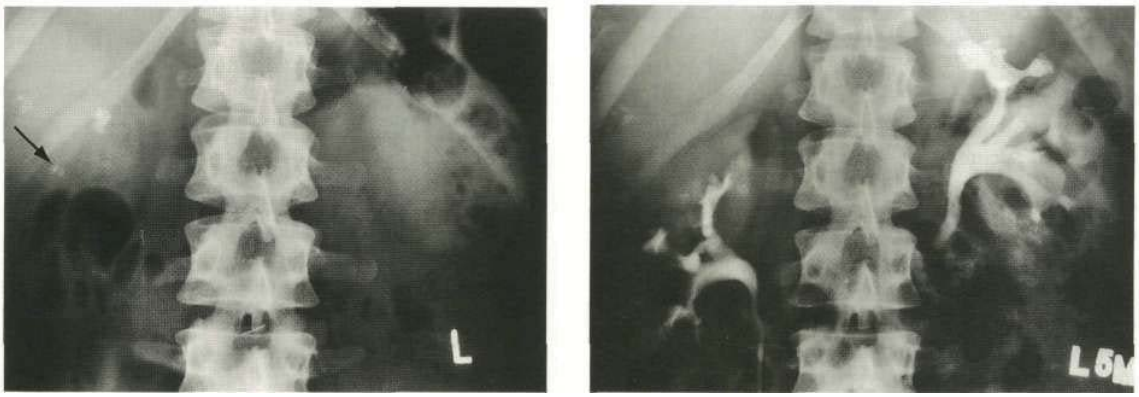
There is a high prevalence of stone disease in patients with polycystic renal disease (see p. 681).

Medullary sponge kidney is also associated with stones. There is dilatation of the collecting ducts with associated stasis and calcification (Fig. 11.33). Approximately 20% of these patients have hypercalciuria and a similar proportion have a renal tubular acidification defect.

Renal tubular acidoses, both inherited and acquired, are associated with nephrocalcinosis and stone formation, owing, in part, to the production of a persistently alkaline urine and reduced urinary citrate excretion.

Drugs

Some drugs promote calcium stone formation (e.g. loop diuretics, antacids, glucocorticoids, theophylline, vitamins D and C, acetazolamide); some promote uric acid stones (e.g. thiazides, salicylates,); and some precipitate into stones (e.g. indinavir, triamterene).



(a) (b)

Fig. 11.33 **Medullary sponge kidney, (a)** Plain film showing 'spotty' calcification in the renal areas (arrow), (b) After injection of contrast, the calcification is shown to be small calculi in the papillary zones.

Aetiology of bladder stones

Bladder stones are endemic in some developing countries. The cause of this is unknown but dietary factors probably play a role. Bladder stones may be the result of:

- bladder outflow obstruction (e.g. urethral stricture, neuropathic bladder, prostatic obstruction)
- the presence of a foreign body (e.g. catheters, non-absorbable sutures).

Significant bacteriuria is usually found in patients with bladder stones. Some stones found in the bladder have been passed down from the upper urinary tract.

Pathology

Stones may be single or multiple and vary enormously in size from minute, sand-like particles to staghorn calculi or large stone concretions in the bladder. They may be located within the renal parenchyma or within the collecting system. Pressure necrosis from a large calculus may cause direct damage to the renal parenchyma, and stones regularly cause obstruction, leading to hydronephrosis. They may ulcerate through the wall of the collecting system, including the ureter. A combination of obstruction and infection accelerates damage to the kidney.

Clinical features

Most people with urinary tract calculi are asymptomatic. Pain is the most common symptom and may be sharp or dull, constant, intermittent or colicky (Table 11.13).

When urinary tract obstruction is present, measures that increase urine volume, such as copious fluid intake or diuretics, including alcohol, make the pain worse.

Table 11.13 **Clinical features of urinary tract stones**

Asymptomatic
Pain: renal colic
Haematuria
Urinary tract infection
Urinary tract obstruction

Physical exertion may cause mobile calculi to move, precipitating pain and, occasionally, haematuria. Ureteric colic occurs when a stone enters the ureter and either obstructs it or causes spasm during its passage down the ureter. This is one of the most severe pains known. Radiation from the flank to the iliac fossa and testis or labium in the distribution of the first lumbar nerve root is common. Pallor, sweating and vomiting often occur and the patient is restless, tending to assume a variety of positions in an unsuccessful attempt to obtain relief from the pain. Haematuria often occurs. Untreated, the pain of ureteric colic typically subsides after a few hours.

When urinary tract obstruction and infection are present, the features of acute pyelonephritis or of a Gram-negative septicaemia may dominate the clinical picture.

Vesical calculi associated with bladder bacteriuria may present with frequency, dysuria and haematuria; severe introital or perineal pain may occur if trigonitis is present. A calculus at the bladder neck or an obstruction in the urethra may cause bladder outflow obstruction, resulting in anuria and painful bladder distension.

A history of possible aetiological factors should be obtained, including:

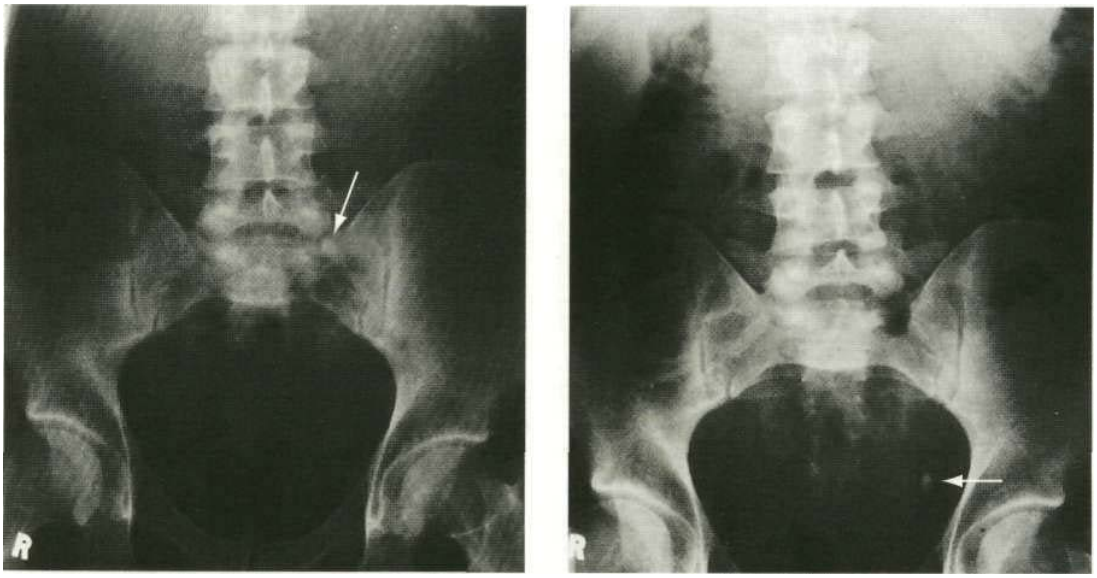
- occupation and residence in hot countries likely to be associated with dehydration
- a history of vitamin D consumption
- gouty arthritis.

Calcified papillae may mimic ordinary calculi, so that causes of papillary necrosis such as analgesic abuse should be considered.

Physical examination should include a search for corneal or conjunctival calcification, gouty tophi and arthritis and features of sarcoidosis.

Investigations

These should include a mid-stream specimen of urine for culture and measurement of serum urea, electrolyte, creatinine and calcium levels.



(a) (b)

Fig. 11.34 **X-rays showing calculus, (a)** The calculus (arrow) is overlying bone on the left (easily missed), (b) The same patient 1 week later: the calculus has descended and is easily seen in the pelvis of the left side (arrow).

Plain abdominal X-ray and excretion urography are still used widely for diagnosis, although unenhanced helical (spiral) CT is the best diagnostic test available. Ureteric stones can be missed by ultrasound.

Pure uric acid stones are radiolucent. Mixed infective stones in which organic matrix predominates are barely radiopaque. Calcium-containing and cystine stones are radiopaque. Calculi overlying bone are easily missed (Fig. 11.34). Staghorn calculi may be missed if the plain abdominal X-ray carried out before contrast injection during urography is not inspected (Fig. 11.35). Uric acid stones may present as a filling defect after injection of contrast medium (Fig. 11.36). Such stones are readily seen on CT scanning (Fig. 11.37).

Excretion urography is carried out during the episode of pain; a normal urogram excludes the diagnosis of pain due to calculous disease. The urographic appearances in a patient with acute left ureteric obstruction are shown in Figure 11.38. The urine of the patient should be passed through a sieve to trap any calculi for chemical analysis.

Fig. 11.35 Staghorn calculus. X-ray appearances before and after contrast on the right side are identical owing to a staghorn calculus in a non-functioning right kidney. A plain film may be confused with those taken after contrast injection.

Management

Adequate analgesia should be given. An NSAID, e.g. diclofenac 75 mg by i.v. infusion, compares favourably with pethidine and does not cause nausea. Stones less than 0.5 cm diameter usually pass spontaneously. Stones greater than 1 cm diameter usually require urological or radiological intervention. Extracorporeal shock wave lithotripsy (ESWL) will fragment most stones, which then pass spontaneously. Ureteroscopy with a Yag laser can be

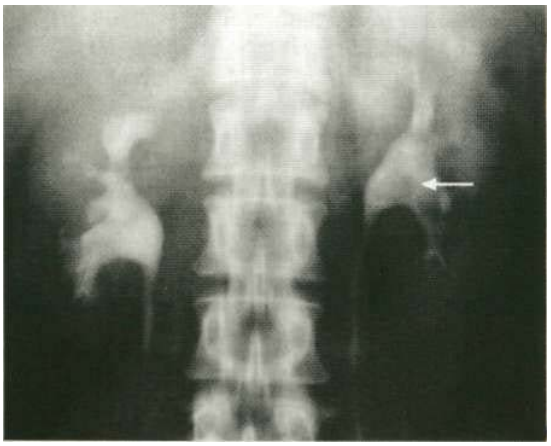


Fig. 11.36 Excretion urogram, showing a lucent filling **defect (uric acid stone; arrow) in the left renal pelvis.** The differential diagnosis includes a sloughed papilla and a transitional cell tumour.

Fig. 11.37 **CT scan, showing a uric acid stone,** which appears as a bright lesion in the left kidney (arrow).

used for larger stones. Percutaneous nephrolithotomy is also used. Open surgery is rarely needed.

Investigating the cause of stone formation

In an elderly patient who has had a single episode with one stone, only limited investigation is required. Younger patients and those with recurrent stone formation require detailed investigation.

- **Renal imaging** is necessary to define the presence of a primary renal disease predisposing to stone formation.
- **Significant bacteriuria** may indicate mixed infective stone formation, but relapsing bacteriuria may be a consequence of stone formation rather than the original cause.
- **Chemical analysis** of any stone passed may be of great value and all that is required in the diagnosis of cystinuria or uric acid stone formation.
- **Serum calcium concentration** should be estimated and corrected for serum albumin concentration (see p. 593). Hypercalcaemia, if present, should be investigated further (see p. 1093).
- **Serum urate concentration** is often, but not invariably, elevated in uric acid stone-formers.
- **A screening test for cystinuria** should be carried out by adding sodium nitroprusside to a random unacidified urine sample; a purple colour indicates that cystinuria may be present. Urine chromatography is required to define the diagnosis precisely.
- **Urinary calcium, oxalate and uric acid output** should be measured in two consecutive carefully collected 24-hour urine samples. After withdrawing aliquots for estimation of uric acid, it is necessary to add acid to the urine in order to prevent crystallization of calcium salts upon the walls of the collection vessel, which would give falsely low results for urinary calcium and oxalate.
- **Plasma bicarbonate** is low in renal tubular acidosis. The finding of a urine pH that does not fall below 5.5 in the face of metabolic acidosis is diagnostic of this condition (see p. 716).

Prophylaxis

The age of the patient and the severity of the problem affect both the need for and the type of prophylaxis.

Idiopathic stone-formers

Where no metabolic abnormality is present, the mainstay of prevention is maintenance of a high intake of fluid throughout the day and night. The aim should be to ensure a daily urine volume of 2-2.5 L, which requires a fluid intake in excess of this, substantially so in the case of those who live in hot countries or work in a hot environment.

Idiopathic hypercalciuria

Severe dietary calcium restriction is inappropriate (see p. 649). Patients should be encouraged to consume a normal-calcium (30 mmol/day) diet. Dietary calcium restriction results in hyperabsorption of oxalate, and so foods containing large amounts of oxalate should also be limited. A high fluid intake should be advised as for

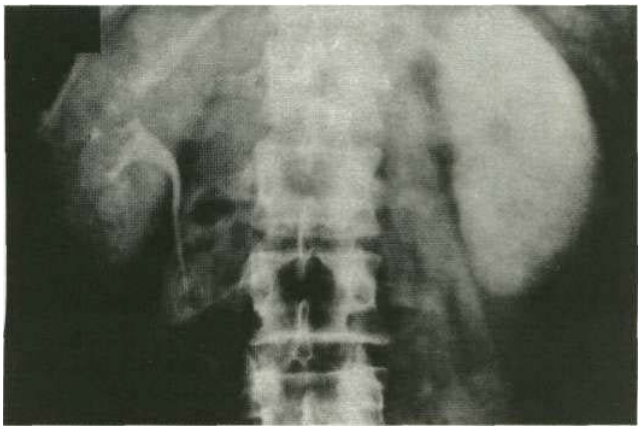

***Fig. 11.38* X-ray, showing acute left ureteric obstruction.** Note the increased density of the nephrogram and the absence of a pyelogram on the left side 15 minutes after contrast injection. From Cox TM, Firth D, Benz J et al (eds) (2003) *Oxford Textbook of Medicine,* 3rd edn, by permission of Oxford University Press.

idiopathic stone-formers. Patients who live in a hard-water area may benefit from drinking softened water.

If hypercalciuria persists and stone formation continues, a thiazide is used (e.g. bendroflumethiazide 2.5 or 5 mg each morning). Thiazides reduce urinary calcium excretion by a direct effect on the renal tubule. They may precipitate diabetes mellitus or gout and worsen hypercholesterolaemia. Reduction of animal proteins to 50 g/day and sodium intake to 50 mmol/day is also advisable, as a randomized controlled trial has found that a diet restricted in animal protein and salt but with normal calcium was more effective in the prevention of calcium and particularly oxalate stones than a diet restricted in calcium.

Mixed infective stones

Recurrent stones should be prevented by maintenance of a high fluid intake and meticulous control of bacteriuria. This will require long-term follow-up and often the use of long-term low-dose prophylactic antibacterial agents.

Uric acid stones

Dietary measures are probably of little value and are difficult to implement. Effective prevention can be achieved by the long-term use of allopurinol to maintain the serum urate and urinary uric acid excretion in the normal range. A high fluid intake should also be maintained. Uric acid is more soluble at alkaline pH, and long-term sodium bicarbonate supplementation to maintain an alkaline urine is an alternative approach in those few patients unable to take allopurinol. However, alkalinization of the urine facilitates precipitation of calcium oxalate and phosphate.

Cystine stones

These can be prevented and indeed will dissolve slowly with a high fluid intake. Five litres of water is drunk each 24 hours, and the patient must wake twice during the night to ingest 500 mL or more of water. Many patients cannot tolerate this regimen. An alternative, though potentially more troublesome, option is the long-term use of the chelating agent penicillamine; this causes cystine to be converted to the more soluble penicillamine-cysteine complex. Side-effects include drug rashes, blood dyscrasias and immune complex-mediated glomerulonephritis. However, it is especially effective in promoting dissolution of cystine stones already present.

Mild hyperoxaluria with calcium oxalate stones

A high fluid intake and dietary oxalate restriction are required. Dietary advice as in hypercalciuria is also advisable.

Nephrocalcinosis

The term 'nephrocalcinosis' means diffuse renal parenchymal calcification that is detectable radiologically (Fig. 11.39). The condition is typically painless. Hypertension and renal impairment commonly occur. The main causes of nephrocalcinosis are listed in Table 11.14.

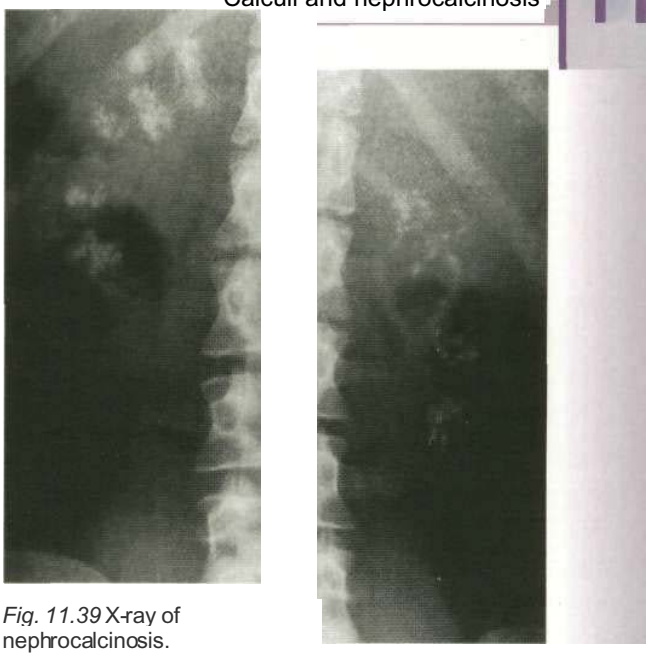

Fig. 11.39 X-ray of nephrocalcinosis.

Table 11.14 Causes of nephrocalcinosis

Mainly cortical (rare)
Renal cortical necrosis (tram-line calcification)
Mainly medullary
Hypercalcaemia (primary hyperparathyroidism, hypervitaminosis D, sarcoidosis) Renal tubular acidosis (inherited and acquired)
Primary hyperoxaluria Medullary sponge kidney Tuberculosis

Dystrophic calcification occurs following renal cortical necrosis. In hypercalcaemia and hyperoxaluria, deposition of calcium oxalate results from the high concentration of calcium and oxalate within the kidney.

In renal tubular acidosis (see p. 716) failure of urinary acidification and a reduction in urinary citrate excretion both favour calcium phosphate and oxalate precipitation, since precipitation occurs more readily in an alkaline medium and the calcium-chelating action of urinary citrate is reduced.

Treatment and prevention of nephrocalcinosis consist of treatment of the cause.

URINARY TRACT OBSTRUCTION

The urinary tract may be obstructed at any point between the kidney and the urethral meatus. This results in dilatation of the tract above the obstruction. Dilatation of the renal pelvis is known as hydronephrosis.

Aetiology

Obstructing lesions may lie within the lumen, or in the wall of the urinary tract, or outside the wall, causing obstruction by external pressure. The major causes of obstruction are shown in Table 11.15. Overall, the frequency is the same in men and women. However, in the elderly, urinary tract obstruction is more common in men owing to the frequency of bladder outflow obstruction.

Pathophysiology

Obstruction with continuing urine formation results in:

- progressive rise in intraluminal pressure
- dilatation proximal to the site of obstruction
- compression and thinning of the renal parenchyma, eventually reducing it to a thin rim and resulting in a decrease in the size of the kidney.

Acute obstruction is followed by transient renal arterial vasodilatation succeeded by vasoconstriction, probably mediated mainly by angiotensin II and thromboxane A_2. Ischaemic interstitial damage mediated by free oxygen radicals and inflammatory cytokines compounds the damage induced by compression of the renal substance.

***Table 11.15* Causes of urinary tract obstruction**

Within the lumen
Calculus Blood clot Sloughed papilla (diabetes; analgesia abuse; sickle cell disease or trait)
Tumour of renal pelvis or ureter
Bladder tumour

Within the wall
Pelviureteric neuromuscular dysfunction (congenital, 10% bilateral)
Ureteric stricture (tuberculosis, especially after treatment; calculus; after surgery)

Pelviureteric compression (bands; aberrant vessels)
Tumours (e.g. retroperitoneal tumour or glands; carcinoma of colon; tumours in pelvis, e.g. carcinoma of cervix)
Diverticulitis Aortic aneurysm
Retroperitoneal fibrosis (periaortitis)
Accidental ligation of ureter
Retrocaval ureter (right-sided obstruction) Prostatic obstruction Phimosis

Clinical features

Symptoms of upper tract obstruction

Loin pain occurs which can be dull or sharp, constant or intermittent. It may be provoked by measures that increase urine volume and hence distension of the collecting system, such as a high fluid intake or diuretics, including alcohol. Complete anuria is strongly suggestive of complete bilateral obstruction or complete obstruction of a single kidney.

Conversely, polyuria may occur in partial obstruction owing to impairment of renal tubular concentrating capacity. Intermittent anuria and polyuria indicates intermittent complete obstruction.

Infection complicating the obstruction may give rise to malaise, fever and septicaemia.

Symptoms of bladder outflow obstruction

Symptoms may be minimal. Hesitancy, narrowing and diminished force of the urinary stream, terminal dribbling and a sense of incomplete bladder emptying are typical features. The frequent passage of small volumes of urine occurs if a large volume of residual urine remains in the bladder after urination. Incontinence of such small volumes of urine is known as 'overflow incontinence' or 'retention with overflow'.

Infection commonly occurs, causing increased frequency, urgency, urge incontinence, dysuria and the passage of cloudy smelly urine. It may precipitate acute retention.

Signs

Loin tenderness may be present. An enlarged hydronephrotic kidney is often palpable. In acute or chronic retention the enlarged bladder can be felt or percussed. Examination of the genitalia, rectum and vagina is essential, since prostatic obstruction and pelvic malignancy are common causes of urinary tract obstruction. However, the apparent size of the prostate on digital examination is a poor guide to the presence of prostatic obstruction.

Investigations

Routine blood and biochemical investigations may be abnormal; for example, there may be a raised serum urea or creatinine, hyperkalaemia, anaemia of chronic disease or blood in the urine. Nevertheless, the diagnosis of obstruction cannot be made on these tests alone and further investigations must be performed.

Ultrasonography (see **p.** 615)

This is a reliable means of ruling out upper urinary tract dilatation. Ultrasound cannot distinguish a baggy, low-pressure unobstructed system from a tense, high-pressure obstructed one, so that false-positive scans are seen. However, in the hands of an experienced observer, a normal

scan does rule out urinary tract obstruction, except in very rare circumstances such as, for example, encasement of the kidney by fibrous or malignant tissue.

Radionuclide studies (see p. 617)
These have no place in the initial investigation of acute obstruction. Their main role is in possible long-standing obstruction to differentiate true obstructive nephropathy from retention of tracer in a baggy, low-pressure, unobstructed pelvicalyceal system.

Excretion urography

A plain film is necessary to detect calcification. However, calculi overlying bone are easily missed.

In recent unilateral obstruction, the affected kidney is enlarged and smooth in outline. The nephrogram is delayed owing to a reduction in the GFR. The calyces and pelvis fill with contrast medium later than on the normal side.

In time, the nephrogram on the affected side becomes denser than normal, owing to the prolonged nephron transit time, which allows greater than normal concentration of contrast medium within the tubules. Later, the site of obstruction may be seen, with dilatation of the system proximal to the level of the block (Fig. 11.40).

A full-length film should be taken after an attempt at bladder emptying by the patient. Complete emptying indicates either that no obstruction to bladder outflow exists or that intravesical pressure can be raised sufficiently to overcome it. Apparent bladder outflow impairment may be the result of nervousness or embarrassment on the part of the patient, or failure to carry out the X-ray before the bladder has refilled with contrast medium from above, or it may be due to an atonic but non-obstructed bladder. Vesicoureteric reflux can result in contrast medium returning to the bladder from above, giving the appearance of a partially full bladder. - ■;

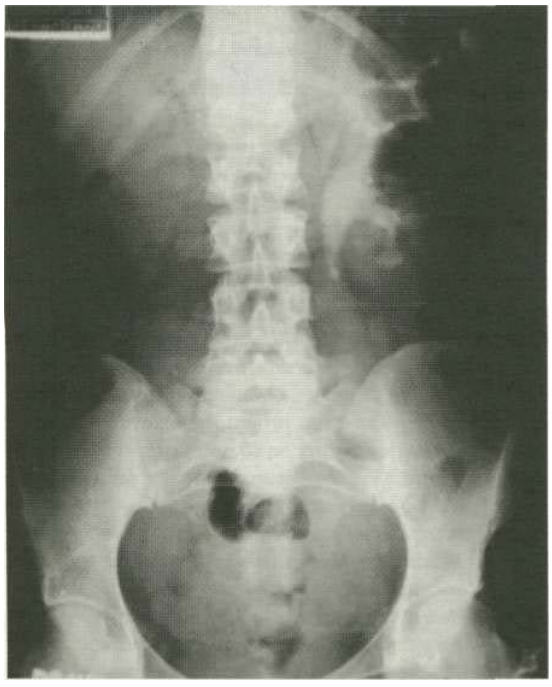

Fig. 11.40 **X-ray taken 24 hours after injection of contrast, showing a delayed nephrogram and pyelogram on the left side and dilatation of the system to the level of the block.** By this time contrast medium has disappeared from the normal right side.

Helical (spiral) CT scanning

This is used to outline in detail the cause of the obstruction.

Antegrade pyelography and ureterography

(see p. 616)
This defines the site and cause of obstruction. It can be combined with drainage of the collecting system by percutaneous needle nephrostomy.

Retrograde ureterography (see p. 616) This is indicated if antegrade examination cannot be carried out or if there is the possibility of dealing with ureteric obstruction from below at the time of examination. The technique carries the risk of introducing infection into an obstructed urinary tract.

In obstruction due to neuromuscular dysfunction at the pelviureteric junction or retroperitoneal fibrosis, the collecting system may fill normally from below.

Cystoscopy, urethroscopy and urethrography

Obstructing lesions within the bladder and urethra can be seen directly by endoscopic examination.

Urethrography involves introducing contrast medium into the bladder by catheterization or suprapubic bladder puncture, and taking X-ray films during voiding to show obstructing lesions in the urethra. It is of particular value in the diagnosis of urethral valves and strictures.

Treatment

Aims

Treatment involves:

- relieving the obstruction
- treating the underlying cause
- preventing and treating infection.

The ultimate aim of treatment is to relieve symptoms and to preserve renal function.

Temporary external drainage of urine by nephrostomy may be valuable, as this allows time for further investigation when the site and nature of the obstructing lesion are uncertain, doubt exists as to the viability of the obstructed kidney, or when immediate definitive surgery would be hazardous.

Recent, complete upper urinary tract obstruction demands urgent relief to preserve kidney function, particularly if infection is present.

In contrast, with partial urinary tract obstruction, particularly if spontaneous relief is expected — such as by passage of a calculus - there is no immediate urgency.

Surgical management

This depends on the cause of the obstruction and local expertise. Dialysis may be required in the ill patient prior to surgery.

Diuresis usually follows relief of obstruction at any site in the urinary tract. Massive diuresis may occur following relief of bilateral obstruction owing to previous sodium and water overload and the osmotic effect of retained solutes combined with a defective renal tubular reabsorptive capacity (as in the diuretic phase of recovering acute tubular necrosis). This diuresis is associated with increased blood volume and high levels of atrial natriuretic peptide (ANP). Defective renal tubular reabsorptive capacity cannot be the sole mechanism of severe diuresis since this phenomenon is not observed following relief of unilateral obstruction. The diuresis is usually self-limiting, but a minority of patients will develop severe sodium, water and potassium depletion requiring appropriate intravenous replacement. In milder cases, oral salt and potassium supplements together with a high water intake are sufficient.

Specific causes of obstruction

Calculi

These are discussed on page 617.

Pelviureteric junction obstruction (Fig. 11.41)

This results from a functional disturbance in peristalsis of the collecting system in the absence of mechanical obstruction. Surgical attempts at correction of the obstruction by open or percutaneous pyeloplasty are indicated in patients with recurrent loin pain and those in whom serial excretion urography, or measurements of GFR indicate progressive kidney damage. Nephrectomy to remove the risk of developing pyonephrosis and septicaemia is indicated if long-standing obstruction has destroyed kidney function.

Obstructive megaureter

This childhood condition may become evident only in adult life. It results from the presence of a region of defective peristalsis at the lower end of the ureter adjacent to the ureterovesical junction. The condition is more common in males. It presents with UTI, flank pain or haematuria. The diagnosis is made on excretion urography or, if necessary, ascending ureterography.

Excision of the abnormal portion of ureter with reimplantation into the bladder is always indicated in children, and in adults when the condition is associated with evidence of progressive deterioration in renal function, bacteriuria that cannot be controlled by medical means, or recurrent stone formation.

Retroperitoneal fibrosis (chronic periaortitis)

In this condition the ureters become embedded in dense retroperitoneal fibrous tissue with resultant unilateral or bilateral obstruction. The condition may extend from the level of the second lumbar vertebra to the pelvic brim. The incidence of the condition in men is three times that in women. An autoallergic response to leakage of material, probably ceroid, derived from atheromatous plaques is considered to be the underlying cause of the condition. Recognized associations are with abdominal aortic aneurysm and prolonged exposure to the drug methysergide and ergot-derived dopamine receptor agonists, e.g. cabergoline, and asbestos. The differential diagnosis includes retroperitoneal lymphoma or cancer.

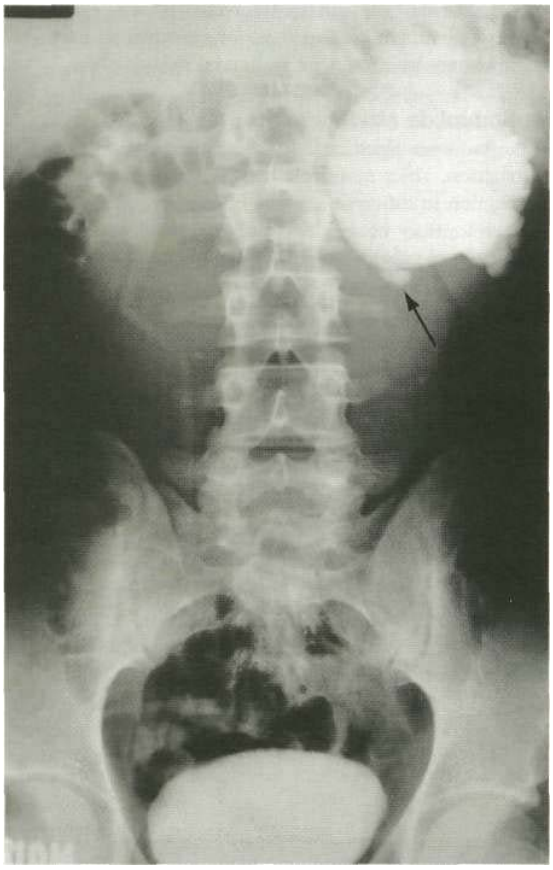

Fig. 11.41 X-ray, showing left pelviureteric junction obstruction (arrow).

Malaise, back pain, normochromic anaemia, uraemia and a raised erythrocyte sedimentation rate (ESR) are typical features. Excretion urography shows bilateral or unilateral ureteric obstruction commencing at the level of the pelvic brim. A periaortic mass may be seen on a CT scan (Fig. 11.42).

Obstruction is relieved surgically by ureterolysis. Biopsy should be performed to determine whether there is an underlying lymphoma or carcinoma. Corticosteroids are of benefit, and in bilateral obstruction in frail patients it may be best to free only one ureter and to rely upon steroid therapy to induce regression of fibrous tissue on the contralateral side, since bilateral ureterolysis is a major operation. In some patients, surgery alone or steroid therapy alone may suffice, but in the majority both surgery and subsequent corticosteroid therapy appear to be necessary. An alternative approach is placement of a

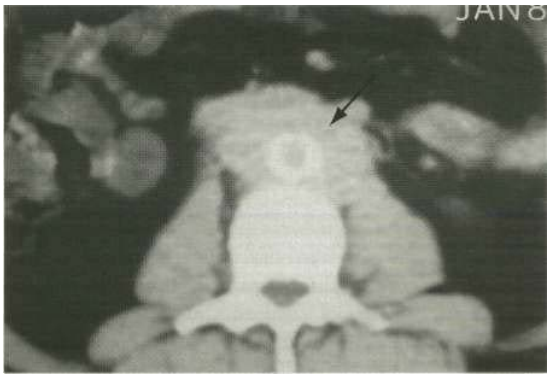

Fig. 11.42 Retroperitoneal fibrosis (periaortitis). Note the large mass surrounding the abdominal aorta on this CT scan (arrow).

ureteric stent or stents and corticosteroid therapy. A disadvantage is that an adequate biopsy of the mass - readily obtainable on open operation - is not easily obtained, and regular (usually 6-monthly) changes of the stent or stents is required if the periaortic mass does not regress.

Response to treatment and disease activity are assessed by serial measurements of ESR and GFR supplemented by isotopic and imaging techniques including CT scanning. Relapse after withdrawal of steroid therapy may occur and treatment may need to be continued for years. Mycophenolate or tamoxifen are also effective. Long-term follow-up is mandatory.

Benign prostatic hypertrophy

Benign prostatic hypertrophy is a common cause of urinary tract obstruction. It is described on page 685.

Prognosis of urinary tract obstruction

The prognosis depends upon the cause and the stage at which obstruction is relieved. In obstruction, four factors influence the rate at which kidney damage occurs, its extent and the degree and rapidity of recovery of renal function after relief of obstruction. These are:

- whether obstruction is partial or complete
- the duration of obstruction
- whether or not infection occurs
- the site of obstruction.

Complete obstruction for several weeks will lead to irreversible or only partially reversible kidney damage. If the duration of complete obstruction is several months, total irreversible destruction of the affected kidney will result. Partial obstruction carries a better prognosis, depending upon its severity. Bacterial infection coincident with obstruction rapidly increases kidney damage. Obstruction at or below the bladder neck may induce hypertrophy and trabeculation of the bladder without a rise in pressure within the upper urinary tract, in which case the kidneys are protected from the effects of back-pressure.

DRUGS AND THE KIDNEY

Drug-induced impairment of renal function

Prerenal

Impaired perfusion of the kidneys can result from drugs that cause:

- hypovolaemia - for example:
  (a) potent loop diuretics such as furosemide, especially in elderly patients
  (b) renal salt and water loss, such as from hypercalcaemia induced by vitamin D therapy (since hypercalcaemia adversely affects renal tubular salt and water conservation)
- decrease in cardiac output, which impairs renal perfusion (e.g. beta-blockers)
- decreased renal blood flow (e.g. ACE inhibitors particularly in the presence of renovascular disease).

Renal

Several mechanisms of drug-induced renal damage exist and may coexist.

- *Acute tubular necrosis produced by direct nephrotoxicity.* Examples include prolonged or excessive treatment with aminoglycosides (e.g. gentamicin, streptomycin), amphotericin B, heavy metals or carbon tetrachloride. The combination of aminoglycosides with furosemide is particularly nephrotoxic.
- *Acute tubulointerstitial nephritis* (see p. 643) with interstitial oedema and inflammatory cell infiltration. This cell-mediated hypersensitivity nephritis occurs with many drugs, including penicillins, sulphonamides and NSAIDs.
- *Chronic tubulointerstitial nephritis* due to drugs. See page 643.
- *Immune complex-mediated glomerulonephritis.* Examples include penicillamine.

Postrenal

Retroperitoneal fibrosis with urinary tract obstruction may result from the use of drugs (p. 656).

Use of drugs in patients with impaired renal function (Box n.2)

Many aspects of drug handling are altered in patients with renal impairment.

Absorption

This may be unpredictable in uraemia as nausea and vomiting are frequently present.

***Box 11.2* Safe prescribing in renal disease**

Safe prescribing in renal failure demands knowledge of the clinical pharmacology of the drug and its metabolites in normal individuals and in uraemia. The clinician should ask the following questions when prescribing:

1 Is treatment mandatory? Unless it is, it should be withheld.
2 Can the drug reach its site of action? For example, there is little point in prescribing the urinary antiseptic, nitrofurantoin, in renal failure since bacteriostatic concentrations will not be attained in the urine.
3 Is the drug's metabolism altered in uraemia?
4 Will accumulation of the drug or metabolites occur? Even if accumulation is a potential problem owing to the drug or its metabolites being excreted by the kidneys, it is not necessarily an indication to change the drug given. The size of the loading dose will depend upon the size of the patient and is unrelated to renal function.

Avoidance of toxic levels of drug in blood and tissues subsequently requires the administration of normal doses of the drug at longer time intervals than usual or smaller doses at the usual time intervals.

5 Is the drug toxic?
6 Are the effective concentrations of the drug in biological tissues similar to the toxic concentrations? Should blood levels of the drug be measured?
7 Will the drug worsen the uraemic state by means other than nephrotoxicity, e.g. steroids tetracycline?
8 Is the drug a sodium or potassium salt? These are potentially hazardous in uraemia.

Not surprisingly, adverse drug reactions are more than twice as common in renal failure as in normal individuals. Elderly patients, in whom unsuspected renal impairment is common, are particularly at risk. Careful attention to the above and careful titration of the dose of drugs employed should reduce the problem.

The dose may be titrated by:

observation of its clinical effect, e.g. hypotensive agents
early detection of toxic effects
measurement of drug levels in the blood, e.g. gentamicin levels.

Metabolism

Oxidative metabolism of drugs by the liver may be altered in uraemia. This is rarely of clinical significance.

The rate of drug metabolism by the kidney is reduced as a result of two factors:

- *Reduced drug catabolism.* Insulin, for example, is in part catabolized by the normal kidney. In renal disease, insulin catabolism is reduced. The insulin require ments of diabetics decline as renal function deterio rates, for this reason.
- *Reduced conversion of a precursor to a more active metabolite,* such as the conversion of 25-hydroxycholecalciferol to the more active 1,25-$(OH)_2D_3$. The la-hydroxylase enzyme responsible for this conversion is located in the kidney. In renal disease, production of the enzyme declines and deficiency of 1,25-$(OH)_2D_3$ results.

Protein binding

Reduced protein binding of a drug potentiates its activity and increases the potential for toxic side-effects. Measurement of the total plasma concentration of such a drug can give misleading results. For example, the serum concentration of phenytoin required to produce an antiepileptic effect is much higher in normal individuals than in those with renal failure, since in the latter proportionately more drug is present in the free form.

Some patients with renal disease are hypoproteinaemic and reduced drug-binding to protein results. This is not the sole mechanism of reduced drug-binding in such patients. For example, hydrogen ions, which are retained in renal failure, bind to receptors for acidic drugs such as sulphonamides, penicillin and salicylates, thus enhancing their potential for causing toxicity.

Volume of distribution

Salt and water overload or depletion may occur in patients with renal disease. This affects the concentration of drug obtained from a given dose.

End-organ sensitivity

The renal response to drug treatment may be reduced in renal disease. For example, mild thiazide diuretics have little diuretic effect in patients with severe renal impairment.

Renal elimination

The major problem in the use of drugs in renal failure concerns the reduced elimination of many drugs normally excreted by the kidneys.

Water-soluble drugs such as gentamicin that are poorly absorbed from the gut, typically given by injection and are not metabolized by the liver, give rise to far more problems than lipid-soluble drugs such as propranolol, which are well absorbed and principally metabolized by the liver. Metabolites of lipid-soluble drugs, however, may themselves be water-soluble and potentially toxic.

Drugs causing uraemia by effects upon protein anabolism and catabolism

Tetracyclines, with the exception of doxycycline, have a catabolic effect and as a result the concentration of nitrogenous waste products is increased. They may also cause impairment of GFR by a direct effect. Corticosteroids have a catabolic effect and so also increase the production of nitrogenous wastes. A patient with moderate impairment of renal function may therefore become severely uraemic if given tetracyclines or corticosteroid therapy.

Drugs and toxic agents causing specific renal tubular syndromes include mercury, lead, cadmium and vitamin D.

Problem patients

Particular problems are presented by patients in whom renal function is altering rapidly, such as those with recovering acute tubular necrosis. In addition, drugs may

be removed by dialysis and haemofiltration, which will affect the dosage required.

FURTHER READING

British Medical Association and Royal Pharmaceutical Society of Great Britain (2005) Renal impairment. In: British National Formulary, 50th edn. Bath: Bath Press.

ACUTE RENAL FAILURE (ARF)

The term 'renal failure' means failure of renal excretory function due to depression of the glomerular filtration rate. This is accompanied to a variable extent by failure of erythropoietin production (see p. 611), vitamin D hydroxylation (p. 611), regulation of acid-base balance (p. 714) and regulation of salt and water balance and blood pressure (p. 610).

Definition

Acute renal failure means abrupt deterioration in parenchymal renal function, which is usually, but not invariably, reversible over a period of days or weeks. In clinical practice, such deterioration in renal function is sufficiently severe to result in uraemia. Oliguria is usually, but not invariably, a feature. Acute renal failure may cause sudden, life-threatening biochemical disturbances and is a medical emergency. The distinction between acute and chronic renal failure may not be readily apparent in a patient presenting with uraemia. Patients with chronic renal impairment are not immune from the development of a superimposed acute-on-chronic renal failure under appropriate circumstances.

Epidemiology

The observed incidence and outcomes of ARF are highly dependent upon the populations studied and the definition of ARF employed. The incidence of hospital-acquired ARF has increased from 4.9% in the 1970s to 7% in the 1990s. However, the incidence of community-acquired ARF on admission to hospital is approximately 1% with ARF superimposed on chronic renal failure accounting for 50% of these patients. The incidence of severe ARF (creatinine > 500 u.mol/L) is about 130-140/million population and in patients with creatinine levels of up to 177 |imol/L or a 50% rise from baseline (less severe) it is about 200/million/year. Uncomplicated ARF can usually be managed outside the intensive care unit (ITU) setting and carries a good prognosis, with mortality rates less than 5-10%. In contrast, ARF complicating non-renal organ system failure (in the ITU setting) is associated with mortality rates of 50-70%, which have not changed for several decades. Moreover, sepsis-related ARF has a significantly worse prognosis than ARF in the absence of sepsis.

Classification

Renal failure results in reduced excretion of nitrogenous waste products of which urea is the most commonly measured. A raised serum urea concentration (uraemia) is classified as: (i) prerenal, (ii) renal or (iii) postrenal. More than one category may be present in an individual patient. Other causes of altered serum urea and creatinine concentration are shown in Table 11.16.

Table 11.16 **Causes of altered serum urea and creatinine concentration other than altered renal function**

	Decreased concentration	Increased concentration
Urea	Low protein intake Liver failure Sodium valproate treatment	Corticosteroid treatment Tetracycline treatment Gastrointestinal bleeding
Creatinine	Low muscle mass	High muscle mass Red meat ingestion Muscle damage (rhabdomyolysis) Decreased tubular secretion (e.g. cimetidine, trimethoprim therapy)

Prerenal uraemia

In prerenal uraemia, there is impaired perfusion of the kidneys with blood. This results either from hypovolaemia, hypotension, impaired cardiac pump efficiency or vascular disease limiting renal blood flow, or combinations of these factors. Usually the kidney is able to maintain glomerular filtration close to normal despite wide variations in renal perfusion pressure and volume status - so-called 'autoregulation'. Further depression of renal perfusion leads to a drop in glomerular filtration and development of prerenal uraemia. Drugs which impair renal autoregulation, such as ACE inhibitors and NSAIDs, increase the tendency to develop prerenal uraemia. All causes of prerenal uraemia may lead to established parenchymal kidney damage and the development of acute renal failure. By definition, excretory function in prerenal uraemia improves once normal renal perfusion has been restored.

A number of criteria have been proposed to differentiate between prerenal and intrinsic renal causes of uraemia (Table 11.17).

Table 11.17 **Criteria for distinction between prerenal and intrinsic causes of renal dysfunction**

	Prerenal	Intrinsic
Urine specific gravity	> 1.020	< 1.010
Urine osmolality (mOsm/kg)	> 500	< 350
Urine sodium (mmol/L)	< 20	> 40
FF - $\frac{U_{Na}}{P_{Na}} \div \frac{U_{Cr}}{P_{Cr}}$ x 100	<1%	>1%
	< i/o	> i/o

FE, fractional excretion; P, plasma; U, urine; Cr, creatinine; Na, sodium

Urine specific gravity and urine osmolality are easily obtained measures of concentrating ability but are unreliable in the presence of glycosuria or other osmotically active substances in the urine.

- *Urine sodium* is low if there is avid tubular reabsorption, but may be increased by diuretics or dopamine.
- *Fractional excretion of sodium (FE_{Na}),* the ratio of sodium clearance to creatinine clearance, increases the reliability of this index but may remain low in some 'intrinsic' renal diseases, including contrast nephropathy and myoglobinuria.

Laboratory tests, however, are no substitute for clinical assessment. A history of blood or fluid loss, sepsis potentially leading to vasodilatation, or of cardiac disease may be helpful. Hypotension (especially postural), a weak rapid pulse and a low jugular venous pressure will suggest that the uraemia is prerenal. In doubtful cases, measurement of central venous pressure is often invaluable, particularly with fluid challenge (see p. 969).

Management

If the prerenal uraemia is a result of hypovolaemia and hypotension, prompt replacement with appropriate fluid is essential to correct the problem and prevent development of ischaemic renal injury and acute renal failure (p. 974). Since prerenal and renal uraemia may coexist, and fluid challenge in the latter situation may lead to volume overload with pulmonary oedema, careful clinical monitoring is vital. Blood pressure should be checked regularly and signs of elevated jugular venous pressure and of pulmonary oedema sought frequently. Central venous pressure monitoring is usually advisable (see p. 968). If the problem relates to cardiac pump insufficiency or occlusion of the renal vasculature, appropriate measures - albeit often unsuccessful - need to be taken.

Postrenal uraemia

Here, uraemia results from obstruction of the urinary tract at any point from the calyces to the external urethral orifice. The causes and presentation of urinary tract obstruction are dealt with on page 654. Screening for urinary tract obstruction is by renal ultrasonography. Urinary tract obstruction may present in an acute fashion (if obstruction of a single functioning kidney by, for example, a calculus occurs) but typically is of insidious onset.

Acute uraemia due to renal parenchymal disease

Causes

This is most commonly due to acute renal tubular necrosis (Table 11.18). Other causes include disease affecting the intrarenal arteries and arterioles as well as glomerular capillaries, such as a vasculitis (p. 581), accelerated hypertension, cholesterol embolism, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura (TTP), pre-eclampsia and crescentic glomerulonephritis. Acute tubulointerstitial nephritis (p. 643) may also cause acute renal failure. This also occurs when renal tubules are acutely obstructed by crystals, for example following sulphonamide therapy in a dehydrated patient (sulphonamide crystalluria) or after rapid lysis of certain malignant tumours following chemotherapy (acute hyperuricaemic nephropathy). Acute bilateral suppurative pyelonephritis or pyelonephritis of a single kidney can cause acute uraemia.

***Table 11.18* Some causes of acute tubular necrosis**

Haemorrhage	Haemoglobinaemia (due to haemolysis, e.g. in falciparum malaria, 'blackwater fever') Hepatorenal syndrome Radiological contrast agents Drugs, e.g. aminoglycosides, NSAIDs, ACE inhibitors, platinum derivatives Abruptio placentae Pre-eclampsia and eclampsia
Burns	
Diarrhoea and vomiting, fluid loss from fistulae	
Pancreatitis	
Diuretics	
Myocardial infarction	
Congestive cardiac failure	
Endotoxic shock	
Snake bite	
Myoglobinaemia	

Acute tubular necrosis

Causes

Acute tubular necrosis (ATN) is common, particularly in hospital practice. It results most often from renal ischaemia but can also be caused by direct renal toxins including drugs such as the aminoglycosides, lithium and platinum derivatives (Table 11.18).

Kidneys appear to be particularly vulnerable to ischaemic injury when cholestatic jaundice is present, and more than one ischaemic factor appears to be present in some situations. For example, disseminated intravascular coagulation complicating Gram-negative septicaemia and complications of pregnancy such as placental rupture, pre-eclampsia and eclampsia, may result in occlusion or partial occlusion of intrarenal vessels, exacerbating the ischaemic insult resulting from hypotension associated with the underlying condition.

Myoglobinaemia and haemoglobinaemia consequent upon muscle injury (rhabdomyolysis) complicating trauma, pressure necrosis or heroin use predispose to ATN, perhaps in part owing to occlusion of renal tubules by myoglobin and haemoglobin casts. In liver failure, acute renal failure appears to result from rapidly reversible vasomotor abnormalities within the kidney. A kidney removed from a patient with hepatic cirrhosis and liver failure dying with oliguric renal failure may function normally immediately after transplantation into a normal individual. Efferent glomerular arteriolar dilatation resulting from ACE-inhibitor drug therapy, with consequent lowering of glomerular filtration pressure, may cause acute deterioration in excretory function if renal arterial disease is also present. The effect is compounded by concomitant use of non-steroidal anti-

inflammatory agents which reduce prostaglandin production, opposing this effect.

Pathogenesis

Factors postulated to be involved in the development of ATN include:

- *Intmrenal microvascular vasoconstriction:*
  (a) Vasoconstriction is increased in response to endothelin, adenosine, thromboxane A_2, leukotrienes and sympathetic nerve activity. However, endothelin antagonists failed to show any beneficial effect in the clinical setting.
  (b) Vasodilatation is reduced in response to: (i) nitric oxide, prostaglandins (PGE_2), acetylcholine and bradykinin; (ii) increased endothelial and vascular smooth muscle cell structural damage; (iii) increased leucocyte-endothelial adhesion, vascular congestion and obstruction, leucocyte activation and inflammation. After success in the prevention of ARF in animal models, anti-ICAM (intercellular adhesion molecule) in the clinical setting failed to live up to its initial promise.
- *Tubular cell injury.* Ischaemic injury results in rapid depletion of intracellular ATP stores resulting in cell death either by necrosis or apoptosis, due to the following: (i) entry of calcium into cells with an increase in cytosolic cell calcium concentration; (ii) induction by hypoxia of inducible nitric oxide synthases with increased production of nitric oxide causing cell death; (iii) increased production of intracellular proteases such as calpain, which cause proteolysis of cytoskeletal proteins and cell wall collapse; (iv) activation of phospholipase A_2 with increased production of free fatty acids, particularly arachidonic acid, due to its action on the lipid layer of cell membranes; (v) cell injury resulting from reperfusion with blood after initial ischaemia causing excessive free radical generation; (vi) tubular obstruction by desquamated viable or necrotic cells and casts; (vii) loss of cell polarity, i.e. integrins located on the basolateral side of the cell are trans located to the apical surface, which when combined with other desquamated cells forms casts, with tubular obstruction and back leak of tubular fluid.

Tubular cellular recovery. Tubular cells have the capacity to regenerate rapidly and to reform the disrupted tubular basement membrane, which explains the reversibility of ATN. Multiple growth factors, including insulin like growth factor 1, epidermal growth factor and hepatocyte growth factor and their receptors are upregulated during the regenerative process after injury. Clinical utility of growth factors in the treatment of ARF is unproven.

In established ATN renal blood flow is much reduced, particularly blood flow to the renal cortex. Ischaemic tubular damage contributes to a reduction in glomerular filtration by a number of interrelated mechanisms:

- *Glomerular contraction* reducing the surface area available for filtration, due to reflex afferent arteriolar spasm mediated by increased solute delivery to the macula densa. Increased solute delivery is due to impaired sodium absorption in the proximal tubular cells because of loss of cell polarity with mislocalization of the Na^+/K^+-ATPase and impaired tight junction integrity, resulting in decreased apical-to-basal transcellular sodium absorption.
- *'Back leak' of filtrate* in the proximal tubule owing to loss of function of the tubular cells.
- *Obstruction of the tubule* by debris shed from ischaemic tubular cells.

Course

The clinical course of acute renal failure associated with ATN is variable depending on the severity and duration of the renal insult. Oliguria is common in the early stages: non-oliguric renal failure is usually a result of a less severe renal insult. Recovery of renal function typically occurs after 7-21 days, although recovery is delayed by continuing sepsis. In the recovery phase, GFR may remain low while urine output increases, sometimes to many litres a day owing to defective tubular reabsorption of filtrate. The clinical course is variable and ATN may last for up to 6 weeks, even after a relatively short-lived initial insult. Eventually renal function usually returns almost to normal or to normal, although exceptions exist (e.g. in renal cortical necrosis - see below).

No treatment is, as yet, known which will reduce the duration of acute renal tubular necrosis once it has occurred. The use of intravenous mannitol, furosemide or 'renal-dose' dopamine is not supported by controlled trial evidence, and none of these treatments is without risk. The synthetic analogue of atrial natriuretic factor, anaritide, did not reduce the duration of or mortality from ATN. However, oliguric patients did appear to do better whilst non-oliguric ones did worse when treated with this agent in a large clinical trial. Moreover, use of exogenous IGF-1 failed to show any beneficial effect in clinical ARF.

Whether a state of 'incipient' ATN exists in some patients with prerenal uraemia, and whether ATN can be prevented by administration of mannitol, furosemide or dopamine, also remain uncertain. Many nephrologists will administer one or more of these agents if correction of prerenal factors does not initiate a diuresis, but proof of benefit is lacking.

Clinical and biochemical features

These are the features of the causal condition together with features of rapidly progressive uraemia. The rate at which serum urea and creatinine concentrations increase is dependent upon the rate of tissue breakdown in the individual patient. This is increased in the presence of trauma, sepsis and following surgery. *Hyperkalaemia* is common, particularly following trauma to muscle and in haemolytic states. *Metabolic acidosis* is usual unless hydrogen ion loss by vomiting or aspiration of gastric contents is a feature. *Hyponatraemia* may be present owing to water overload if patients have continued to drink in the face of oliguria, or if overenthusiastic fluid replacement with 5% dextrose has been carried out. *Pulmonary*

oedema owing to salt and water retention is not uncommon, particularly after inappropriate attempts to initiate a diuresis by infusion of normal 0.9% saline without adequate monitoring of the patient's volume status. *Hypocalcaemia* due to reduced renal production of 1,25-dihydroxycholecalciferol and *hyperphosphataemia* due to phosphate retention are common.

Symptoms of uraemia such as anorexia, nausea, vomiting and pruritus develop, followed by intellectual clouding, drowsiness, fits, coma and haemorrhagic episodes. Epistaxes and gastrointestinal haemorrhage are relatively common. Severe infection may have initiated the acute renal failure or have complicated it owing to the impaired immune defences of the uraemic patient or ill-considered management, such as the insertion and retention of an unnecessary bladder catheter with complicating urinary tract infection and bacteraemia.

Investigation of the uraemic emergency

Investigations are aimed at defining whether the patient has acute or chronic uraemia, whether uraemia results from prerenal, renal or postrenal factors, and establishing the cause.

Acute or chronic uraemia?

The distinction between acute and chronic uraemia depends in part on the history, duration of symptoms and previous urinalysis or measurements of renal function.

A rapid rate of change of serum urea and creatinine with time suggests an acute process. A normochromic, normocytic anaemia suggests chronic disease, but anaemia may complicate many of the diseases that cause acute renal failure, owing to a combination of haemolysis, haemorrhage and deficient erythropoietin production.

Ultrasound assessment of renal echogenicity and size is helpful. Small kidneys of increased echogenicity are diagnostic of a chronic process, although the reverse is not true; the kidney may remain normal in size in diabetes and amyloidosis, for instance.

Evidence of renal osteodystrophy (for example, digital subperiosteal erosions due to hyperparathyroid bone disease) is indicative of chronic disease.

Measurement of carbamylated haemoglobin (a product of non-enzymatic reaction between urea and haemoglobin, cf. glycosylated haemoglobin) is not widely employed.

Prerenal, renal or postrenal uraemia?

Bladder outflow obstruction is ruled out by insertion of a urethral catheter or flushing of an existing catheter, which should then be removed unless a large volume of urine is obtained. Absence of upper tract dilatation on renal ultrasonography will, with very rare exceptions, rule out urinary tract obstruction.

The distinction between prerenal and renal uraemia may be difficult (see p. 659). Assessment of the patient's volume status is essential and central venous pressure measurement may be extremely helpful. If volume status is low, appropriate corrective measures are indicated. If no diuresis ensues, acute intrinsic renal failure is present. Use of low-dose dopamine, mannitol or furosemide (frusemide) is unhelpful and they should not be given.

Other investigations

These include urinalysis, urine microscopy, particularly for red cells and red-cell casts (indicative of glomerulonephritis), and urine culture. Blood tests include measurement of serum urea, electrolytes, creatinine, calcium, phosphate, albumin, alkaline phosphatase and urate concentrations, as well as full blood count and examination of the peripheral blood film where necessary. Coagulation studies, blood cultures and measurements of nephrotoxic drug blood levels should be carried out. Urine should be tested for free haemoglobin and myoglobin, where appropriate.

Management

The aim of management of acute renal tubular necrosis is to keep the patient alive until spontaneous recovery of renal function occurs. Ideally patients should be managed by a nephrologist or intensivist with access to facilities for blood purification and fluid removal (see p. 663). Early specialist referral is advisable. Poor initial management and late referral result in the arrival in the specialist centre of a patient who is severely uraemic, acidotic and hyperkalaemic, with pulmonary oedema following over-enthusiastic intravenous fluid administration and with a Gram-negative septicaemia complicating the presence of an unnecessary indwelling bladder catheter.

General measures

Good nursing and physiotherapy are vital. Regular oral toilet, chest physiotherapy and consistent documentation of fluid intake and output, and where possible measurement of daily bodyweight to assess fluid balance changes, all have a role. The patient should be confined to bed only if essential.

Emergency measures

Hyperkalaemia

This is a life-threatening complication owing to the risk of cardiac dysrhythmias, particularly ventricular fibrillation. Treatment is outlined in Emergency box 12.1. Correction of acidosis with intravenous sodium bicarbonate will also reduce serum potassium concentration, but administration of sodium may be inappropriate if the patient is salt and water overloaded. Rapid correction of acidosis in a hypocalcaemic patient may also trigger tetany, since hydrogen ions displace calcium from albumin-binding sites, thus increasing the physiologically active calcium concentration in blood. Ion exchange resins are used to prevent subsequent hyperkalaemia rather than to deal with the acute emergency. In many patients, hyperkalaemia will be controlled only by dialysis or haemofiltration.

Pulmonary oedema

Unless a diuresis can be induced with intravenous furosemide (frusemide), dialysis or haemofiltration will be required.

Sepsis

Infections, when detected, should be treated promptly, bearing in mind the need to avoid nephrotoxic drugs and to use drugs with appropriate monitoring and drug levels (e.g. gentamicin, vancomycin). Prophylactic antibiotics or barrier nursing is not recommended in all cases.

Use *of drugs*

Great care must be exercised in the use of drugs (see p.657).

Fluid and electrolyte balance

Twice-daily clinical assessment is needed. In general, once the patient is euvolaemic, daily fluid intake should equal urine output plus losses from fistulae and from vomiting, plus an allowance of 500 mL daily for insensible loss. Febrile patients will require an additional allowance. Sodium and potassium intake should be minimized. If abnormal losses of fluid occur, for example in diarrhoea, additional fluid and electrolytes will be required. The development of signs of salt and water overload (peripheral oedema, basal crackles, elevation of jugular venous pressure) or of hypovolaemia should prompt reappraisal of fluid intake. Large changes in daily weight reflecting change in fluid balance status should also prompt a reappraisal of the situation.

Diet

With rare exceptions, sodium and potassium restriction are appropriate. The place of dietary protein restriction is controversial. If it is hoped to avoid dialysis or haemofiltration, protein intake is sometimes restricted to approximately 40 g daily. This poses the risk of a negative nitrogen balance despite attempts to reduce endogenous protein catabolism by maintenance of a high energy intake in the form of carbohydrate and fat. Patients treated by blood purification techniques are more appropriately managed by providing 70 g protein daily or more. Hypercatabolic patients will require an even higher nitrogen intake to prevent negative nitrogen balance.

Routes of intake are, in preferred order, enteral by mouth, enteral by nasogastric tube, and parenteral. The last of these is, however, only necessary if vomiting or bowel dysfunction render the enteral route inappropriate.

Vitamin supplements are usually supplied. Vitamin D analogue therapy and pharmacological doses of erythropoietin are not employed routinely.

Dialysis and haemofiltration

The main indications for blood purification and/or excess **fluid** removal by these techniques are:

- symptoms of uraemia
- complications of uraemia, such as pericarditis
- severe biochemical derangement in the absence of symptoms (especially if a rising trend is observed in an oliguric patient and in hypercatabolic patients)
- hyperkalaemia not controlled by conservative measures
- pulmonary oedema
- severe acidosis
- for removal of drugs causing the acute renal failure, e.g. gentamicin, lithium, severe aspirin overdose.

The main options are peritoneal dialysis, intermittent haemodialysis (HD) combined with ultrafiltration, if necessary, intermittent haemofiltration, continuous arteriovenous or venovenous haemofiltration, and haemodiafiltration. For reasons that are incompletely understood, adverse cardiovascular effects are much less during haemofiltration than during haemodialysis. Continuous treatments are superior to intermittent ones in this respect.

Continuous renal replacement treatments (CRRT)

Blood flow is achieved either by using the patient's own blood pressure to generate arterial blood flow through a filter or by the use of a blood pump to draw blood from the lumen of a dual-lumen catheter placed in the jugular, subclavian or femoral vein.

Continuous arteriovenous or venovenous haemofiltration ***(CAVH, CWH)*** refers to the continuous removal of ultrafiltrate from the patient, usually at rates of up to 1000 mL/h, combined with simultaneous infusion of replacement solution. For instance, in a fluid-overloaded patient one might remove filtrate at 1000 mL/h and replace at a rate of 900 mL/h, achieving a net fluid removal of 100 mL/h.

Continuous haemodiafiltration (CAVHDF, CWHDF) is a combination of haemofiltration and haemodialysis, involving both the net removal of ultrafiltrate from the blood and its replacement with a replacement solution, together with the countercurrent passage of dialysate (which may be identical to the replacement solution). Both the ultrafiltrate and the spent dialysate appear as 'waste'.

Comparisons of dialysis modalities

Peritoneal dialysis (PD) is used infrequently in the management of ARF, with decreasing utilization over the past 5-10 years. Drawbacks to the use of PD in ARF are: (i) low efficiency in fluid and solute removal compared to CRRT or intermittent HD; (ii) ARF complicating intra-abdominal pathology is unsuitable for PD; (iii) increasing intra-abdominal pressure can compromise lung function; (iv) use of dialysis fluids with a high dextrose content may produce hyperglycaemia and other metabolic derangements. Data suggest that PD is significantly less effective than CRRT in the management of ARF and should be reserved for situations where other modalities of therapy are not available.

A meta-analysis of 13 studies comparing intermittent HD to CRRT in ARF failed to demonstrate any difference in mortality between the two modalities. There are thus insufficient data to favour either HD or CRRT as a superior mode of therapy in ARF. However, there is consensus that in haemodynamically unstable patients, CRRT is better tolerated.

Membrane biocompatibility

The concept of membrane 'biocompatibility' relates to the activation of cellular (neutrophils, platelets) and humoral (complement system and coagulation cascade) components upon contact between blood and dialysis membranes. As a general rule, unsubstituted cellulosic membranes (cuprophan) are the least biocompatible, with biocompatibility improving with substitution of free hydroxyl groups by tertiary amino groups (hemophan), acetate (cellulose acetate, diacetate, triacetate) or the use of synthetic polymers (e.g. polysulphone, polyamide, polyacrilonitrile and polymethylmethacrylate).

In a recent meta-analysis, synthetic membranes appeared to confer a significant survival advantage over unsubstituted cellulose (cuprophan)-based membranes but no benefit on recovery of renal function was observed.

Acute renal failure in the intensive care unit

In the UK, increasing numbers of patients with acute renal failure are managed in the setting of an intensive care unit. Many such patients have multiorgan failure, sepsis or both, with associated cardiovascular instability. Continuous methods of blood purification and control of fluid balance, such as venovenous haemofiltration, are preferable to intermittent haemodialysis or peritoneal dialysis in such patients. Advantages include:

- much less disturbance of cardiovascular stability
- the ability to generate as much 'space' for fluid administration as is required, which can be adjusted flexibly to the needs of the patient (many patients require large volumes of fluid to be administered for nutritional and other reasons)
- the removal of potentially harmful substances such as inflammatory cytokines via the more porous membrane employed in haemofiltration.

Acute respiratory distress syndrome (ARDS) is not uncommon in patients with multiorgan failure, including acute renal failure, requiring intensive therapy. In such patients the wish to remove as much fluid from the patient as possible to reduce pulmonary congestion must be balanced against the need of organs, including the kidneys, for an adequate blood flow, if recovery is to

Management of the recovery phase

Usually, after 1-3 weeks, renal function improves, as evidenced by an increase in urine volume and improvement in serum biochemistry. Dialysis or haemofiltration, if they have been required, can be discontinued. A careful watch on clinical state, salt and water balance, and serum chemistry is required at this stage, particularly if a major diuretic phase develops owing to recovery of glomerular filtration at a time when renal tubular reabsorptive capacity for sodium, potassium and water remains impaired. Intravenous fluid replacement is sometimes required together with supplements of sodium chloride and potassium. Typically, the diuretic phase lasts for only a few days.

Acute cortical necrosis

Renal hypoperfusion results in diversion of blood flow from the cortex to the medulla, with a drop in GFR. Medullary ischaemic damage is largely reversible owing to the capacity of the tubular cells for regeneration. In contrast, glomerular ischaemic injury does not heal with regeneration but with scarring - glomerulosclerosis. Prolonged cortical ischaemia may lead to irreversible loss of renal function termed 'cortical necrosis'. This may be patchy or complete. Any cause of acute tubular necrosis, if sufficiently severe or prolonged, may lead to cortical necrosis. This outcome is particularly common if acute renal failure has been accompanied by derangements of the vascular endothelial system or coagulation system, such as occurs in haemolytic uraemic syndrome and complications of pregnancy.

Contrast nephropathy

In patients with impaired renal function, iodinated radiological contrast media may be nephrotoxic, possibly by causing renal vasoconstriction and by a direct toxic effect upon renal tubules. The effect is dose-dependent and therefore more commonly seen in procedures that require large amounts of contrast media, such as angiography with or without angioplasty. In many patients the effect is mild, transient, fully reversible and of no clinical significance. The risk and severity of contrast nephropathy is amplified by the presence of hypovolaemia and renal impairment, especially if due to diabetic nephropathy. Diabetes per se is not a risk factor.

Prevention involves minimization as far as possible of the dose of contrast employed and use of a low-osmolality contrast medium. Pre-hydration with intravenous saline is of proven benefit. A popular regimen involves infusion of 1 L of saline during the 12 hours before and 12 hours after contrast exposure. Care must be taken to avoid volume overload in susceptible patients.

N-acetylcysteine (NAC; a potent antioxidant) given 48 hours prior to radiological intervention may be of benefit in preventing worsening of pre-existing renal impairment following intravenous contrast, but the effect on morbidity and mortality is unknown. Routine use of dopamine, theophylline (adenosine antagonist) and prophylactic haemodialysis (removing contrast agent from circulation) are of no benefit. In patients with advanced CRF who are undergoing coronary angiography, periprocedural haemofiltration given in an ITU setting appears to be effective in preventing the deterioration of renal function due to contrast agent-induced nephropathy and is associated with improved in-hospital and long-term outcomes.

When deterioration in renal function occurs after intra-arterial injection of contrast (for example, after

coronary angiography) it may be difficult to differentiate the effects of contrast-induced damage from those of atheromatous embolization (see p. 648). The latter carries a worse prognosis.

Hepatorenal syndrome (HRS)

The renal failure observed in HRS results from profound renal vasoconstriction with histologically normal kidneys (p. 384). Although many of the features of HRS resemble prerenal ARF, the defining feature is a lack of improvement in renal function with volume expansion. Renal recovery is usually observed after restoration of hepatic function after successful liver transplantation.

CHRONIC RENAL FAILURE (CRF)

Chronic renal failure implies long-standing, and usually progressive, impairment in renal function. In many instances, no effective means are available to reverse the primary disease process. Exceptions include correction of urinary tract obstruction, immunosuppressive therapy for systemic vasculitis and Goodpasture's syndrome, treatment of accelerated hypertension, and correction of critical narrowing of renal arteries causing renal impairment. The rate of deterioration in renal function can, however, be slowed (see p. 672). A list of causes of CRF is given in Table 11.19.

Wide geographical variations in the incidence of disorders causing CRF exist. The most common cause of glomerulonephritis in sub-Saharan Africa is malaria. Schistosomiasis is a common cause of renal failure due to urinary tract obstruction in parts of the Middle East, including southern Iraq. The incidence of end-stage renal failure varies between racial groups, as does the relative importance of different causes of chronic renal failure. End-stage renal failure is three to four times as common in black Africans in the UK and USA as it is in whites, and hypertensive nephropathy is a much more frequent cause of end-stage renal failure in this group. The prevalence of diabetes mellitus and hence of diabetic nephropathy is higher in some Asian groups than in whites. The age is of relevance; CRF due to atherosclerotic renal vascular disease is much more common in the elderly than in the young.

***Table 11.19* Causes of chronic renal failure**

Congenital and inherited disease
- Polycystic kidney disease (adult and infantile forms)
- Medullary cystic disease
- Tuberose sclerosis
- Oxalosis
- Cystinosis
- Congenital obstructive uropathy

Glomerular disease
- *Primary* glomerulonephritides including focal glomerulosclerosis
- *Secondary* glomerular disease (systemic lupus, polyangiitis, Wegener's granulomatosis, amyloidosis, diabetic glomerulosclerosis, accelerated hypertension, haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, systemic sclerosis, sickle cell disease)

Vascular disease
- Hypertensive nephrosclerosis (common in black Africans)
- Reno-vascular disease Small and medium-sized vessel vasculitis

Tubulointerstitial disease
- Tubulointerstitial nephritis - idiopathic, due to drugs (especially nephrotoxic analgesics), immunologically mediated
- Reflux nephropathy
- Tuberculosis
- Schistosomiasis
- Nephrocalcinosis
- Multiple myeloma (myeloma kidney)
- Balkan nephropathy
- Renal papillary necrosis (diabetes, sickle cell disease and trait, analgesic nephropathy)
- Chinese herb nephropathy

Urinary tract obstruction
- Calculus disease
- Prostatic disease
- Pelvic tumours
- Retroperitoneal fibrosis
- Schistosomiasis

Clinical approach to the patient with CRF or any other form of renal disease

History

Particular attention should be paid to:

- *duration of symptoms*
- *m drug ingestion,* including non-steroidal anti-inflammatory agents, analgesic and other medications, and unorthodox treatments such as herbal remedies
- *previous medical and surgical history,* e.g. previous chemotherapy, multisystem diseases such as SLE
- *previous occasions* on which urinalysis or measurement of urea and creatinine might have been performed, e.g. pre-employment or insurance medical examinations, new patient checks
- *family history* of renal disease.

Symptoms

The early stages of renal failure are often completely asymptomatic, despite the accumulation of numerous metabolites. Serum urea and creatinine concentrations are measured in renal failure since methods for their determination are available and a rough correlation exists

between urea and creatinine concentrations and symptoms. These substances are, however, in themselves not particularly toxic. The nature of the metabolites that are involved in the genesis of symptoms is unclear. Such metabolites must be products of protein catabolism (since dietary protein restriction may reverse symptoms associated with renal failure) and many of them must be of relatively small molecular size (since haemodialysis employing membranes which allow through only relatively small molecules improves symptoms). Little else is known with certainty.

Symptoms are common when the serum urea concentration exceeds 40 mmol/L, but many patients develop uraemic symptoms at lower levels of serum urea. Symptoms include:

- malaise, loss of energy
- loss of appetite
- insomnia
- nocturia and polyuria due to impaired concentrating ability
- itching
- nausea, vomiting and diarrhoea
- paraesthesiae due to polyneuropathy
- 'restless legs' syndrome (overwhelming need to frequently alter position of lower limbs) (p. 1287)
- bone pain due to metabolic bone disease
- paraesthesiae and tetany due to hypocalcaemia
- symptoms due to salt and water retention - peripheral or pulmonary oedema
- symptoms due to anaemia (see p. 424)
- amenorrhoea in women; erectile dysfunction in men.

In more advanced uraemia (serum urea > 50-60 mmol/L), these symptoms become more severe, and CNS symptoms are common:

- mental slowing, clouding of consciousness, and seizures
- myoclonic twitching.

Severe depression of glomerular filtration can result in oliguria. This can occur with either acute renal failure or in the terminal stages of chronic renal failure. However, even if the GFR is profoundly depressed, failure of tubular reabsorption may lead to very high urine volumes; the urine output is therefore not a useful guide to renal function.

Examination

There are few physical signs of uraemia per se. Findings include:

- *short stature* - in patients who have had chronic renal failure in childhood
- *pallor* - due to anaemia
- *increased photosensitive pigmentation* - which may make the patient look misleadingly healthy
- *brown discoloration of the nails*
- *scratch marks* due to uraemic pruritus
- signs *of fluid overload* (p. 695)
- *pericardial friction rub*
- *flow murmurs* - mitral regurgitation due to mitral annular calcification; aortic and pulmonary regurgitant murmurs due to volume overload
- *glove and stocking peripheral sensory loss* (rare).

The kidneys themselves are usually impalpable unless grossly enlarged as a result of polycystic disease, obstruction or rumour. Rectal and vaginal examination may disclose evidence of an underlying cause of renal failure, particularly urinary obstruction, and should always be performed.

In addition to these findings, there may be physical signs of any underlying disease which may have caused the renal failure, for instance:

- cutaneous vasculitic lesions in systemic vasculitides
- retinopathy in diabetes
- evidence of peripheral vascular disease
- evidence of spina bifida or other causes of neurogenic bladder.

An assessment of the central venous pressure, skin turgor, blood pressure both lying and standing and peripheral circulation should also be made. The major symptoms and signs of chronic renal failure are shown in Figure 11.43.

Investigations

The following investigations are common for all renal patients. This includes patients with glomerular or non-

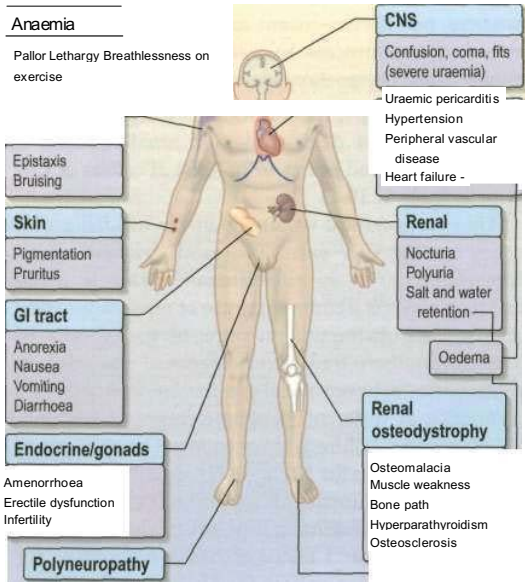

Fig. 11.43 Symptoms and signs of chronic renal failure. Oedema may be due to a combination of primary renal salt and water retention and heart failure.

glomerular disease, renal involvement in systemic diseases, ARF and CRF, as renal symptoms and signs are non-specific.

Urinalysis

- *Haematuria* may indicate glomerulonephritis, but other sources must be excluded. Haematuria should not be assumed to be due to the presence of an indwelling catheter.
- *Proteinuria,* if heavy, is strongly suggestive of glomerular disease. Urinary infection may also cause proteinuria.
- *Glycosuria* with normal blood glucose is common in CRF.

Urine microscopy (see p. 614)

- *White cells* in the urine usually indicate active bacterial urinary infection, but this is an uncommon cause of renal failure; sterile pyuria suggests papillary necrosis or renal tuberculosis.
- *Eosinophiluria* is strongly suggestive of allergic tubulointerstitial nephritis or cholesterol embolization.
- *Granular casts* are formed from abnormal cells within the tubular lumen, and indicate active renal disease.
- *Red-cell casts* are highly suggestive of glomerulonephritis.
- *Red cells in the urine* may be from anywhere between the glomerulus and the urethral meatus (Fig. 11.5).

Urine biochemistry

- *24-hour creatinine clearance* is useful in assessing the severity of renal failure.
- *Measurements of urinary electrolytes* are unhelpful in chronic renal failure. The use of urinary sodium concentration in the distinction between prerenal and intrinsic renal disease is discussed on page 659.
- *Urine osmolality* is a measure of concentrating ability. A low urine osmolality is normal in the presence of a high fluid intake but indicates renal disease when the kidney should be concentrating urine, such as in hypovolaemia or hypotension.
- *Urine electrophoresis and immunofixation* is necessary for the detection of light chains, which can be present without a detectable serum paraprotein.

Serum biochemistry

- *Urea and creatinine.*
- *Electrophoresis and immunofixation* should be performed for myeloma.
- *Extreme elevations of creatine kinase* and a disproportionate elevation in serum creatinine and potassium compared to urea suggest rhabdomyolysis.

Haematology

- *Eosinophilia* suggests vasculitis, allergic tubulointerstitial nephritis, or cholesterol embolism.
- *Markedly raised viscosity or ESR* suggests myeloma or vasculitis.
- *Fragmented red cells and/or thombocytopenia* suggests intravascular haemolysis due to accelerated hypertension, haemolytic uraemic syndrome or thrombotic thrombocytopenic purpura.
- Tests *for sickle cell disease* should be performed when relevant.

Immunology

- *Complement components* may be low in active renal disease due to SLE, mesangiocapillary glomerulonephritis, post-streptococcal glomerulonephritis, and cryoglobulinaemia.
- *Autoantibody screening* is useful in detection of SLE (p. 576), scleroderma (p. 579), Wegener's granulomatosis and microscopic polyangiitis (p. 938), and Goodpasture's syndrome (p. 632).
- *Cryoglobulins* should be sought in patients with unexplained glomerular disease, particularly mesangiocapillary glomerulonephritis.
- *Urine culture* should always be performed.
- *Early-morning urine samples* should be cultured if tuberculosis is possible.
- *Antibodies to streptococcal antigens* (ASOT, anti-DNase B) should be sought if post-streptococcal glomerulonephritis is possible.
- *Antibodies to hepatitis B and C* may point to polyarteritis or membranous nephropathy (hepatitis B) or to cryoglobulinaemic renal disease (hepatitis C).
- *Antibodies to HIV* raise the possibility of HIV-associated renal disease.
- *Malaria* is a major cause of glomerular disease in the tropics.

Radiological investigation

- *Ultrasound.* Every patient should undergo ultrasonography (for renal size and to exclude hydronephrosis), and plain abdominal radiography and CT (without contrast) to exclude low-density renal stones or nephrocalcinosis, which may be missed on ultrasound.
- *Intravenous urography* is seldom necessary in advanced renal disease.
- *CT* is also useful for the diagnosis of retroperitoneal fibrosis and some other causes of urinary obstruction, and may also demonstrate cortical scarring.
- *MRI.* Magnetic resonance angiography in renovascular disease.

Renal biopsy (see p. 618)

This should be performed in every patient with unexplained renal failure and normal-sized kidneys, unless there are strong contraindications. If rapidly progressive glomerulonephritis is possible, this investigation must be performed within 24 hours of presentation if at all possible, to guide immunosuppressive treatment.

COMPLICATIONS OF CHRONIC RENAL FAILURE

Anaemia

Several factors have been implicated:

- *erythropoietin deficiency* (the most significant)
- *bone marrow toxins* retained in renal failure

- *bone marrow fibrosis* secondary to hyperparathyroidism
- *haematinic deficiency* - iron, vitamin B_{12}, folate
- *increased red cell destruction*
- *abnormal red cell membranes* causing increased osmotic fragility
- *increased blood loss* - occult gastrointestinal bleeding, blood sampling, blood loss during haemodialysis or because of platelet dysfunction
- *ACE inhibitors* (may cause anaemia in chronic renal failure, probably by interfering with the control of endogenous erythropoietin release).

Red cell survival is reduced in renal failure. Increased red cell destruction may occur during haemodialysis owing to mechanical, oxidant and thermal damage.

Bone disease: renal osteodystrophy

The term 'renal osteodystrophy' embraces the various forms of bone disease that may develop alone or in combination in chronic renal failure - hyperparathyroid bone disease, osteomalacia, osteoporosis, osteosclerosis and adynamic bone disease (Fig. 11.44). Most patients with chronic renal failure are found, histologically to have mixed bone disease. Covert renal osteodystrophy is present in many patients with moderate renal impairment and in almost all of those with end-stage renal failure.

Pathogenesis of bone disease

Decreased renal production of the la-hydroxylase enzyme results in reduced conversion of 25-$(OH)_2D_3$ to the more metabolically active 1,25-$(OH)_2D_3$.

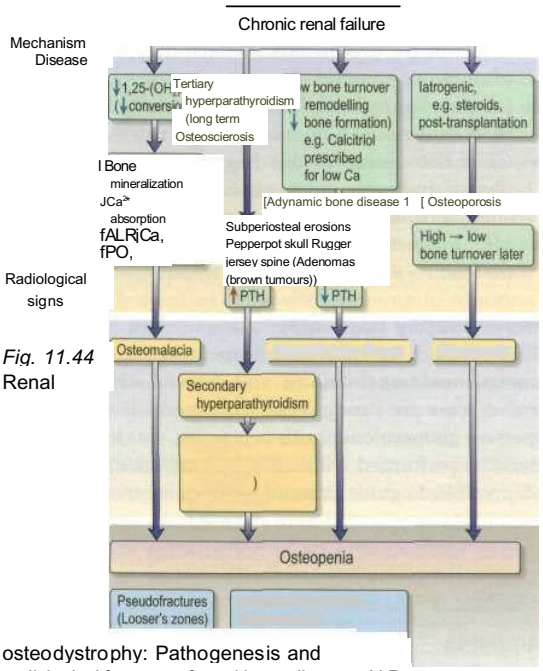

Fig. 11.44 Renal osteodystrophy: Pathogenesis and radiological features of renal bone disease. ALP, alkaline phosphatase.

- Reduced activation of vitamin D receptors in the para thyroid glands leads to increased release of parathyroid hormone.
- 1,25-Dihydroxycholecalciferol deficiency also results in gut calcium malabsorption.
- Phosphate retention owing to reduced excretion by the kidneys, also indirectly by lowering ionized calcium (and probably directly via a putative but unrecognized phosphate receptor), results in an increase in PTH synthesis and release.
- PTH promotes reabsorption of calcium from bone and increased proximal renal tubular reabsorption of calcium, and this opposes the tendency to develop hypocalcaemia induced by 1,25-$(OH)_2D_3$ deficiency and phosphate retention. This *'secondary' hyperpara thyroidism* leads to increased osteoclastic activity, cyst formation and bone marrow fibrosis (osteitis fibrosa cystica).

Radiologically, digital subperiosteal erosions and 'pepperpot skull' are seen. Long-standing secondary hyperparathyroidism ultimately leads to hyperplasia of the glands with *autonomous* or *'tertiary' hyperpara-thyroidism* in which hypercalcaemia is present. Serum alkaline phosphatase concentration is raised in both secondary and tertiary hyperparathyroidism. Long-standing parathyroid hormone excess is also thought to cause increased bone density (osteosclerosis) seen particularly in the spine where alternating bands of sclerotic and porotic bone give rise to a characteristic 'rugger jersey' appearance on X-ray.

1,25-$(OH)_2D_3$ deficiency and hypocalcaemia result in impaired mineralization of osteoid *{osteomalacia).* Such impaired mineralization also occurs when osteoblasts are inhibited by, for example, aluminium given as gut phosphorus binders, or accumulated in bone as a result of exposure to aluminium in source water used to make up dialysate for haemodialysis. In this situation, serum alkaline phosphatase concentration tends to be low or normal.

The condition of 'adynamic bone disease' in which both bone formation and resorption are depressed (in the absence of aluminium bone disease or overtreatment with vitamin D) is also seen. The pathogenesis of this condition is unclear and it is not known whether it leads to an increased risk of fractures or other complications. There may be hypercalcaemia; the serum alkaline phosphatase is normal, the PTH is low. X-rays and DEXA scan show osteopenia. No treatment is of proven benefit.

Osteoporosis is commonly found in CRF, often after transplantation and the use of corticosteroids. Monitoring is with yearly DEXA scan.

Management is discussed on page 596.

Skin disease

Pruritus (itching) is common in severe renal failure and is usually attributed in the main to retention of nitrogenous waste products of protein catabolism. Certainly, marked improvement often follows the institution of dialysis. Other causes of pruritus include:

- hypercalcaemia
- hyperphosphataemia
- elevated calcium x phosphate product
- hyperparathyroidism (even if calcium and phosphate levels are normal)
- iron deficiency.

In dialysis patients, inadequate dialysis is a cause of pruritus. Nevertheless, a significant number of dialysis patients who are well dialysed and in whom other causes of pruritus can be excluded suffer persistent itching. The cause is unknown and no effective treatment exists.

Many patients with renal failure suffer from dry skin for which simple aqueous creams are helpful. Eczematous lesions, particularly in relation to the region of an arteriovenous fistula, are relatively common. Chronic renal failure may also cause porphyria cutanea tarda (PCT), a blistering photosensitive skin rash. This results from a decrease in hepatic uroporphyrinogen decarboxylase combined with a decreased clearance of porphyrins in the urine or by dialysis. Pseudoporphyria a condition similar to PCT but without enzyme deficiency is also seen in CRF with increased frequency.

Gastrointestinal complications

These include:

- decreased gastric emptying and increased risk of reflux oesophagitis
- increased risk of peptic ulceration
- increased risk of acute pancreatitis
- constipation - particularly in patients on continuous ambulatory peritoneal dialysis (CAPD).

Elevations of *serum amylase* of up to three times normal may be found in chronic renal failure without any evidence of pancreatic disease, owing to retention of high-molecular-weight forms of amylase normally excreted in the urine.

Metabolic abnormalities

Gout. Urate retention is a common feature of chronic renal failure. Treatment of clinical gout is complicated by the nephrotoxic potential of NSAIDs. Colchicine is useful in treatment of the acute attack, and allopurinol should be introduced later under colchicine cover to prevent further attacks. The dose of allopurinol should be reduced in renal impairment.

Insulin. Insulin is catabolized by and to some extent excreted via the kidneys. For this reason, insulin requirements in diabetic patients decrease as renal failure progresses. By contrast, end-organ resistance to insulin is a feature of advanced renal impairment resulting in modestly impaired glucose tolerance when a standard glucose tolerance test is carried out. Insulin resistance may contribute to hypertension and lipid abnormalities.

Lipid metabolism abnormalities. These are common in renal failure, and include:

- impaired clearance of triglyceride-rich particles
- hypercholesterolaemia (particularly in advanced renal failure).

The situation is further complicated in end-stage renal disease, when regular heparinization (in haemodialysis), excessive glucose absorption (in CAPD) and immunosuppressive drugs (in transplantation) may all contribute to lipid abnormalities. Correction of lipid abnormalities by, for example, HMG-CoA reductase inhibitor therapy (statins) is used in renal failure patients, although without formal proof of benefit derived from prospective controlled trials.

Endocrine abnormalities

These include:

- hyperprolactinaemia, which may present with galactorrhoea in men as well as women
- increased luteinizing hormone (LH) levels in both sexes, and abnormal pulsatility of LH release
- decreased serum testosterone levels (only seldom below the normal level); sexual dysfunction and decreased spermatogenesis are common
- absence of normal cyclical changes in female sex hormones, resulting in oligomenorrhoea or amenorrhoea
- complex abnormalities of growth hormone secretion and action, resulting in impaired growth in uraemic children (pharmacological treatment with recombinant growth hormone and insulin-like growth factor is used)
- abnormal thyroid hormone levels, partly because of altered protein binding.

Measurement of thyroid-stimulating hormone (TSH) is the best way to assess thyroid function. True hypothyroidism occurs with increased frequency in renal failure. Posterior pituitary gland function is normal in renal failure.

Muscle dysfunction

Uraemia appears to interfere with muscle energy metabolism, but the mechanism is uncertain. Decreased physical fitness (cardiovascular deconditioning) also contributes.

Nervous system

Central nervous system

Severe uraemia causes an unusual combination of depressed cerebral function and decreased seizure threshold. However, convulsions in a uraemic patient are much more commonly due to other causes such as accelerated hypertension, thrombotic thrombocytopenic purpura, or drug accumulation. Asterixis, tremor and myoclonus are also features of severe uraemia.

Rapid correction of severe uraemia by haemodialysis leads to 'dialysis disequilibrium' owing to osmotic cerebral swelling. This can be avoided by correcting uraemia gradually by short, repeated haemodialysis treatments or by the use of peritoneal dialysis.

'Dialysis dementia' is a syndrome of progressive intellectual deterioration, speech disturbance, myoclonus

and fits, which is due to aluminium intoxication; it may be accompanied by aluminium bone disease and by microcytic anaemia. Low-grade aluminium exposure may also cause more subtle, subclinical deterioration in intellectual function. Prevention involves removal of aluminium from source water used to manufacture dialysis fluid, and restriction or avoidance of aluminium-containing gut-phosphorus binders. Treatment is with the chelating agent desferrioxamine.

Autonomic nervous system

Autonomic dysfunction is common in renal impairment. Findings include:

- increased circulating catecholamine levels associated with down-regulation of cc-receptors
- impaired baroreceptor sensitivity
- impaired efferent vagal function.

Overactivity of the sympathetic nervous system in chronic renal failure is believed to play a part in the genesis of hypertension in this condition. All of these abnormalities improve to some extent after institution of regular dialysis and resolve after successful renal transplantation.

Peripheral nervous system

Median nerve compression in the carpal tunnel is common, usually due to P_2-microglobulin-related amyloidosis. 'Restless legs' syndrome (p. 666) is common in uraemia. The syndrome is difficult to treat. Iron deficiency should be treated if present. Attention should be paid to adequacy of dialysis. Symptoms may improve with the correction of anaemia by erythropoietin. Clonazepam is sometimes useful. Renal transplantation cures the problem. A polyneuropathy occurs in patients who are inadequately dialysed.

Psychiatric problems are common. Patients can have anxiety, depression, phobias and psychoses.

Cardiovascular disease

Life expectancy remains severely reduced compared with the normal population owing to a greatly increased (16-fold) incidence of cardiovascular disease, particularly myocardial infarction, cardiac failure, sudden cardiac death and stroke.

Risk factors

Hypertension is a frequent complication of renal failure. Diabetes mellitus is the commonest cause of end-stage renal failure. Dyslipidaemia is universal in uraemic patients. Furthermore, smoking is as common as in the general population and male gender is over-represented in patients with CRF. Cardiac hypertrophy is common, as is systolic and diastolic dysfunction. Diastolic dysfunction is largely attributable to left ventricular hypertrophy and contributes to hypotension during fluid removal on haemodialysis. Systolic dysfunction may be due to:

- myocardial fibrosis
- abnormal myocyte function owing to uraemia
- calcium overload and hyperparathyroidism
- carnitine and selenium deficiency.

Left ventricular hypertrophy is a risk factor for early death in renal failure, as in the general population. Systolic dysfunction is also a marker for early death in renal failure.

Coronary artery calcification. Traditional risk factors (e.g. smoking, diabetes) can only in part explain the risk differential between the general population and the population of patients with chronic nephropathies. Coronary artery calcification is more common in patients with end-stage renal failure than in normal individuals and it is highly likely that this contributes significantly to cardiovascular mortality. Vascular calcification is frequent in all sizes of vessel in renal failure. In addition to the classical risk factors for atherosclerosis, a raised calcium x phosphate product causes medial calcification. Hyperparathyroidism may also contribute independently to the pathogenesis by increasing intracellular calcium. It is now believed that vascular calcification in uraemia is an active process whereby vascular smooth muscle cells acquire osteoblast-like characteristics, possibly in response to elevated phosphate or calcium x phosphate product. Recently, inflammation has emerged as a potent mediator of vascular calcification by inhibition of fetuin (a glycoprotein synthesized by liver, which is a potent inhibitor of vascular calcification). The impact of vascular calcification is the reduction of vascular compliance, which manifests by increased pulse pressure and pulse wave velocity, and increased afterload contributing further to left ventricular hypertrophy. In addition to myocardial abnormalities, vascular calcification with its associated biomechanical vessel wall alterations is a strong predictor of all-cause and cardiovascular morbidity and mortality in patients with CRF. Diffuse calcification of the myocardium is also common; the causes are similar.

Other cardiovascular risk factors. These include hyperhomocysteinaemia, *Chlamydia pneumoniae* infection, oxidative stress and elevated endogenous inhibitor of nitric oxide synthase and asymmetric dimethyl arginine (ADMA) levels. High ADMA levels in uraemia are in part caused by oxidative stress and can possibly explain the 52% increase in the risk of death and 34% increase in the risk of cardiovascular events in uraemic patients. The use of antioxidants, vitamin E or N-acetylcysteine has been associated with a significant reduction in all-cause and cardiovascular mortality.

Pericarditis

This is common and occurs in two clinical settings:

- Uraemic pericarditis is a feature of severe, pre-terminal uraemia or of underdialysis. Haemorrhagic pericardial effusion and atrial arrhythmias are often associated. There is a danger of pericardial tamponade, and anticoagulants should be used with caution. Pericarditis usually resolves with intensive dialysis.

- Dialysis pericarditis occurs as a result of an intercurrent illness or surgery in a patient receiving apparently adequate dialysis.

Malignancy

The incidence of malignancy is raised in patients with CRF and with dialysis. Malignant change can occur in multicystic kidney disease. Lymphomas, primary liver cancer and thyroid cancers also occur.

Management

Successful renal transplantation improves some, but not all, of the complications of CRF, therefore, attempts should be made to prevent these complications by careful monitoring with ECG, echocardiography, angiography (if necessary) and nuclear imaging. CT (electron beam tomography, spiral CT) and/or MRI are useful in the assessment of arterial calcification. Treatment is with the control of risk factors (p. 670) as well as the treatment of hypercalcaemia and hyperparathyroidism (p. 670).

PROGRESSION OF CHRONIC RENAL IMPAIRMENT

Once established, and whatever the initial cause, chronic renal impairment tends to progress inexorably to end-stage renal failure, although the rate of progression may depend upon the underlying nephropathy. Patients with chronic glomerular diseases tend to deteriorate more quickly than those with chronic tubulointerstitial nephropathies. Hypertension and heavy proteinuria are bad prognostic indicators in this context. A non-specific renal scarring process common to renal disorders of different aetiologies may be responsible for progression.

In 1982, the hypothesis of 'glomerular hyperfiltration' in response to nephron loss was postulated as a common pathway of progression of renal failure. A rise in intraglomerular capillary pressure and adaptive glomerular hypertrophy due to reduced arteriolar resistance and increased glomerular blood flow under conditions of reduced nephron mass have been postulated as causes of glomerular scarring and proteinuria. Since the afferent arteriolar tone decreases more than efferent arteriolar tone, intraglomerular pressure and the amount of filtrate formed by a single nephron rises. Angiotensin II produced locally modulates intraglomerular capillary pressure and GFR. Angiotensin II predominantly causes vasoconstriction of postglomerular arterioles, thereby increasing the glomerular hydraulic pressure and filtration fraction (Fig. 11.45). In addition, by its effect on mesangial cells and podocytes, it increases the pore sizes and impairs the size-selective function of basement membrane for macromolecules. Angiotensin II also modulates cell growth directly and indirectly by upregulating TGF-P, a potent fibrogenic cytokine, increases collagen synthesis and also causes epithelial cell transdifferentiation to myofibroblasts which contribute to excessive matrix formation. Furthermore, angiotensin II by upregulating plasminogen activator inhibitor-1 (PAI-1) inhibits matrix proteolysis by plasmin, resulting in accumulation of excessive matrix and scarring both in the glomeruli and interstitium.

Renal interstitial scarring is also a factor. The prognosis for renal function in chronic glomerular disorders is judged more accurately by interstitial histological appearances than by glomerular morphology. The cause of this progressive interstitial damage and fibrosis is mutifactorial. In addition to non-haemodynamic effects of angiotensin II, proteinuria per se by exposing tubular cells to albumin and its bound fatty acids and cytokines promotes secretion of pro-inflammatory mediators, which by promoting interstitial inflammatory cell infiltrate further augments fibrosis and progression of renal failure. Therapeutic manoeuvres aimed at inhibiting angiotensin II and reducing proteinuria mainly by ACEI and angiotensin-receptor antagonists have beneficial effects in slowing the rate of progression of renal failure in both diabetic and non-diabetic renal diseases in humans.

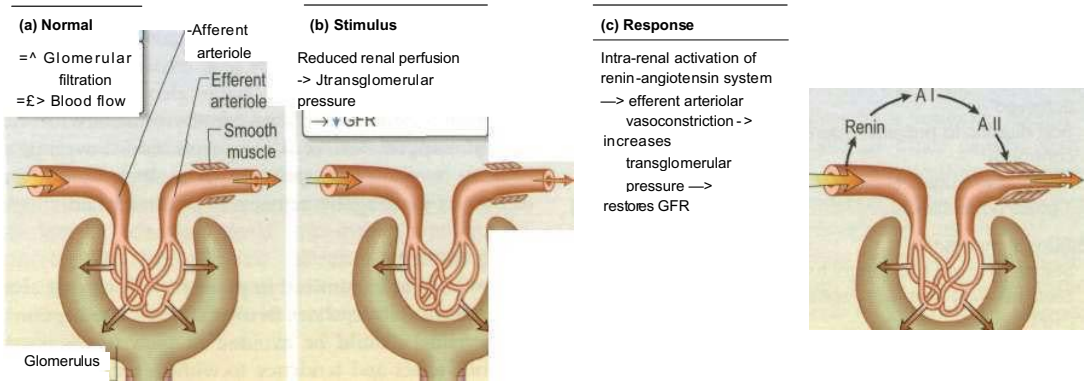

Fig. 11.45 Glomerular dynamics: Effect of the renin-angiotensin system. AI, angiotensin I; AII, angiotensin II.

MANAGEMENT OF CHRONIC RENAL FAILURE

The underlying cause of renal disease should be treated aggressively wherever possible.

Renoprotection

The multidrug approach to chronic nephropathies has been formalized in an international protocol (Box 11.3).

Correction of complications

Hyperkalaemia

Hyperkalaemia often responds to dietary restriction of potassium intake. Drugs which cause potassium retention (see p. 708) should be stopped. Occasionally it may be necessary to prescribe ion-exchange resins to remove potassium in the gastrointestinal tract. Emergency treatment of severe hyperkalaemia is described on page 709.

Acidosis

Correction of acidosis helps to correct hyperkalaemia in chronic renal failure, and may also decrease muscle catabolism. Sodium bicarbonate supplements are often effective (4.8 g (57 mmol) of Na^+ and HCCV daily), but may cause oedema and hypertension owing to extracellular fluid expansion. Calcium carbonate, also used as a calcium supplement and phosphate binder, has a beneficial effect on acidosis.

Calcium and phosphate control and suppression of PTH

Hypocalcaemia and hyperphosphataemia should be treated aggressively, preferably with regular (e.g. 3-monthly) measurements of serum PTH to assess how effectively hyperparathyroidism is being suppressed.

Box 11.3 **Renoprotection**

Goals of treatment

BP< 120/80

Proteinuria < 0.3 g/24 hours

Treatment

Patients with chronic renal failure and proteinuria > 1 g/24 hours:

- ACE inhibitor increasing to maximum dose
- Add angiotensin receptor antagonist if goals are not achieved*
- Add diuretic to prevent hyperkalaemia and help to control BP
- Add calcium-channel blocker (verapamil or diltiazem) if goals not achieved

Additional measures

- Statins to lower cholesterol to < 4.5 mmol/L
- Stop smoking (threefold higher rate of deterioration in CRF)
- Treat diabetes (HbA_{1c} < 7%)
- Normal protein diet (0.8-1 g/kg bodyweight)

"In type 2 diabetes start with angiotensin receptor antagonist

Suppression of PTH levels to below two or three times the upper limit of 'normal' carries a high risk of development of adynamic bone disease.

Dietary restriction of phosphate is seldom effective alone, because so many foods contain it. Oral calcium carbonate or acetate reduces absorption of dietary phosphate but is contraindicated where there is hypercalcaemia or hypercalciuria. Aluminium-containing gut phosphate binders are very effective but absorption of aluminium poses the risk of aluminium bone disease and development of cognitive impairment. Regular monitoring of plasma aluminium should be carried out, and signs of aluminium toxicity mandate chelation with desferrioxamine. The polymer sevelamar is also used as a gut phosphate binder. It reduces the calcium load and attenuates vascular calcification and also lowers cholesterol levels by 10%. Lanthanum carbonate is a new non-calcium, non-aluminium phosphate binder that is effective and has a good safety profile. It is currently undergoing approval in Europe and the USA for clinical use. An alternative to phosphate binders is nicotinamide, which blocks the intestinal sodium/inorganic phosphate (Na/Pi) cotransporter. Preliminary results are very promising in that it reduced phosphate levels and PTH levels in dialysis patients alongside improvement in the lipid profile. This approach may become a useful alternative for the suppression of hyperparathyroidism and reduction of phosphate levels without inducing hypercalcaemia.

Treatment with calcitriol or a vitamin D analogue such as alfacalcidol in early renal impairment has no deleterious effect upon renal function provided hypercalcaemia is avoided. New vitamin D metabolites (22-oxacalcitriol, paricalcitol, doxercalciferol) are less calcaemic. However, with the exception of paricalcitol (19-nor-1,25 dihydroxyvitamin D_2, which may have survival advantage), their usefulness over conventional but less expensive calcitriol or alphacalcidol remains to be established. Treatment with vitamin D analogues should be started only if serum PTH level is three times or more above the upper limit of normal, in order to prevent the development of adynamic bone disease (see p. 668). Vitamin D therapy has the disadvantage that it increases not only calcium but also phosphate absorption and may therefore exacerbate hyperphosphataemia and ectopic calcification including calciphylaxis (calcification of small vessels). Calcimimetic agents (e.g. cinacalcet - calcium-sensing receptor agonist) have also been tried in established secondary hyperparathyroidism with successful suppression of PTH levels and lowering of calcium x phosphate product. Long-term safety and efficacy of these agents remains to be established.

Drug therapy

This should be minimized in patients with chronic renal impairment. Tetracyclines (with the possible exception of doxycycline) should be avoided in view of their anti-anabolic effect and tendency to worsen uraemia. Drugs excreted by the kidneys, such as gentamicin, should be prescribed with caution and drug levels monitored if

feasible. Non-steroidal anti-inflammatory drugs should be avoided. Potassium-sparing agents, such as spironolactone and amiloride, pose particular dangers, as do artificial salt substitutes, all of which contain potassium.

Anaemia

The anaemia of erythropoietin (EPO) deficiency can be treated with synthetic (recombinant) human EPO (erythropoietin-alpha or -beta, or the longer-acting darbopoietin-alpha). Subcutaneous administration of erythropoietin-alpha is contraindicated (see below) in CRF and the intravenous route is used, initially 50 U/kg of epoietin-alpha over 1-5 min three times weekly. Blood pressure, haemoglobin concentration and reticulocyte count are measured every 2 weeks and the dose adjusted to maintain a target haemoglobin of 10-12 g/dL.

Failure to respond to 300 U/kg weekly, or a fall in haemoglobin after a satisfactory response, may be due to iron deficiency, bleeding, malignancy, infection or formation of anti-EPO neutralizing antibodies. The demand for iron by the bone marrow is enormous when erythropoietin is commenced. Patients on EPO therapy are regularly monitored for iron status and considered iron deficient if plasma ferritin is < 100 ug/L, hypochromic RBCs > 5%, transferin saturation < 20%. Intravenous (rather than oral) iron supplements optimize response to EPO treatment by repletion of iron stores.

Correction of anaemia with EPO improves quality of life, exercise tolerance, sexual and cognitive function in dialysis patients, and leads to regression of left ventricular hypertrophy. Avoidance of blood transfusion also lessens the chance of sensitization to HLA antigens, which may otherwise be a barrier to successful renal transplantation.

The disadvantages of erythropoietin therapy are that it is expensive and causes a rise in blood pressure in up to 30% of patients, particularly in the first 6 months. Peripheral resistance rises in all patients, owing to loss of hypoxic vasodilatation and to increased blood viscosity. A rare complication is encephalopathy with fits, transient cortical blindness and hypertension. Recently, several reports of anti-EPO antibody-mediated pure red cell aplasia in patients receiving subcutaneous EPO therapy (particularly EPO alpha) have been described. The exact cause is unknown but interventions such as using the intravenous route and changes in manufacture have reduced the number of cases by 80%. Other causes of anaemia should be looked for and treated appropriately

(see p. 423).

Male erectile dysfunction

Testosterone deficiency should be corrected. The oral phosphodiesterase inhibitors, e.g. sildenafil, tadalafil and vardenafil, are effective in end-stage renal failure and are the first line of therapy. The use of nitrates is a contraindication to this treatment. Other treatments are discussed on page 1055.

Fig. 11.46 Intravenous cannula in exactly the wrong place, in a right-handed patient with chronic renal impairment who will in future need a left (non-dominant arm) radiocephalic fistula.

EARLY REFERRAL OF PATIENTS WITH CHRONIC RENAL FAILURE

Patients with chronic renal impairment should be referred to a nephrologist with access to facilities for renal replacement therapy at an early stage since late referral has been shown to be associated with increased mortality and morbidity when such patients commence renal replacement therapy. Old age is no bar to referral in the reasonably fit elderly patient.

Patients need time to adjust to the demands of chronic renal failure and its treatment, and to absorb information. Veins required in the future for fashioning of an arteriovenous fistula should not be rendered useless by cannulation (Fig. 11.46).

If the patient opts for regular haemodialysis, fashioning of an arteriovenous fistula should be carried out well in advance of the need for dialysis, when serum creatinine is of the order 400-500 mmol/L in non-diabetics and at an even earlier stage in diabetics with poorer vasculature. Such fistulae require several weeks to mature and become usable for vascular access.

RENAL REPLACEMENT THERAPY

Approximately 100 white individuals per million population commence renal replacement therapy in the UK each year. The corresponding figure in black Africans and Asians in the UK is three to four times higher, largely owing to diabetic and hypertensive nephropathy. The aim of all renal replacement techniques is to mimic the excretory functions of the normal kidney, including excretion of nitrogenous wastes, maintenance of normal electrolyte concentrations, and maintenance of a normal extracellular volume.

Haemodialysis

Basic principles

In haemodialysis, blood from the patient is pumped through an array of semipermeable membranes (the

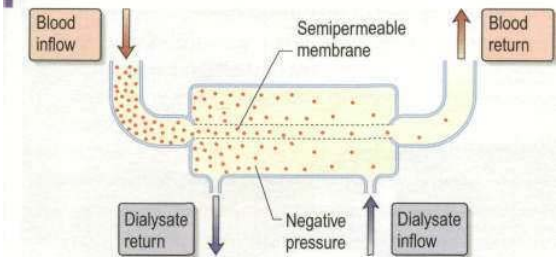

Fig. 11.47 **Changes across a semipermeable dialysis membrane.**

Table 11.20 **Range of concentrations (mmol/L) in routinely available final dialysates used for haemodialysis**

Sodium	130-145
Potassium	0.0-4.0
Calcium	1.0-1.6
Magnesium	0.25-0.85
Chloride	99-108
Bicarbonate	35-40
OR	
Acetate	35-40
Glucose	0-10

dialyser, often called an 'artificial kidney') which bring the blood into close contact with dialysate, flowing countercurrent to the blood. The plasma biochemistry changes towards that of the dialysate owing to diffusion of molecules down their concentration gradients (Fig. 11.47).

The dialysis machine comprises a series of blood pumps, with pressure monitors and bubble detectors and a proportionating unit, also with pressure monitors and blood leak detectors. Blood flow during dialysis is usually 200-300 mL per minute and the dialysate flow usually 500 mL per minute. The efficiency of dialysis in achieving biochemical change depends on blood and dialysate flow and the surface area of the dialysis membrane.

Dialysate is prepared by a proportionating unit, which mixes specially purified water with concentrate, resulting in fluid with the composition described in Table 11.20. Highly permeable synthetic membranes allow more rapid haemodialysis than with cellulose-based membranes (high-flux haemodialysis).

Access for haemodialysis

Adequate dialysis requires a blood flow of at least 200 mL per minute. The most reliable long-term way of achieving this is surgical construction of an arteriovenous fistula (Fig. 11.48a, b), using the radial or brachial artery and the cephalic vein. This results in distension of the vein and thickening ('arterialization') of its wall, so that after 6-8 weeks, large-bore needles may be inserted to take blood to and from the dialysis machine. In patients with poor-quality veins or arterial disease (e.g. diabetes mellitus) arteriovenous polytetrafluoroethylene (PTFE)

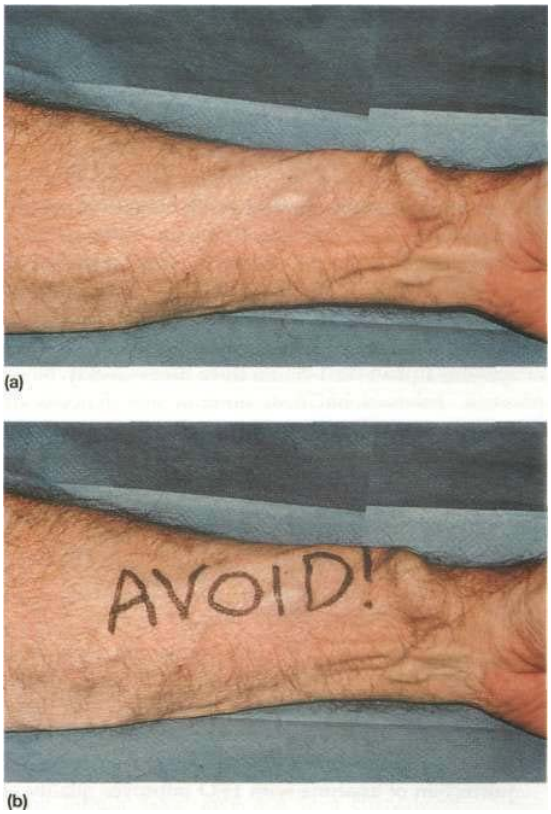

Fig. 11.48 **Arteriovenous (radiocephalic) fistula, (a)** In the left forearm, (b) One way of reminding the anaesthetic, nursing and surgical team about the presence of an existing arteriovenous fistula in a haemodialysis patient about to undergo surgery. In particular, the fistula should not be compressed during surgery to avoid thrombosis within it.

grafts are used for access. However, these grafts have a very high incidence of thrombosis and 2-year graft patency is only 50-60%. Dipyridamole or fish oils improve graft patency but warfarin, aspirin and clopidogrel do not and are associated with a high incidence of complications.

If dialysis is needed immediately, a large-bore double-lumen cannula may be inserted into a central vein — usually the subclavian, jugular or femoral. *Semipermanent dual-lumen venous catheters* can also be used, usually inserted via a skin tunnel to lessen the risk of infection. Nevertheless, local and systemic sepsis is high, with increased morbidity and mortality. Stenosis of the subclavian vein is also common, and the jugular route is preferred.

Dialysis prescription

Dialysis must be tailored to an individual patient to obtain optimal results.

Dry weight

This is the weight at which a patient is neither fluid overloaded nor depleted. Patients are weighed at the start

of each dialysis session and the transmembrane pressure adjusted to achieve fluid removal equal to the amount by which they exceed their dry weight.

The dialysate buffer

The dialysate buffer is usually acetate or bicarbonate. The sodium and calcium concentrations of the dialysate buffer are carefully monitored. A high dialysate sodium causes thirst and hypertension. A high dialysate calcium causes hypercalcaemia, whilst a low-calcium dialysate combined with poor compliance of medication with oral calcium carbonate and vitamin D may result in hyperparathyroidism.

Frequency and duration

Frequency and duration of dialysis are adjusted to achieve adequate removal of uraemic metabolites and to avoid excessive fluid overload between dialysis sessions. An adult of average size usually receives 4-5 hours' treatment three times a week. Twice-weekly dialysis is adequate only if the patient has considerable residual renal function.

Short-duration dialysis using very biocompatible high-flux membranes is commonly employed. Advantages include shorter duration of treatment and hence increased patient convenience. Disadvantages include higher cost of the membranes employed and, in all probability, higher prevalence of hypertension in such patients, requiring hypotensive medication. It should not be forgotten that normal kidneys work for 24 hours a day, 7 days a week, and that dialysis is a poor substitute for the natural state.

Adequate/optimal dialysis should be adjusted to individual patient's needs. All patients are anticoagulated (usually with heparin) during treatment as contact with foreign surfaces activates the clotting cascade. In the UK, a small number of patients manage self-supervised home haemodialysis.

Complications

Hypotension during dialysis is the major complication. Contributing factors include: an excessive removal of extracellular fluid, inadequate 'refilling' of the blood compartment from the interstitial compartment during fluid removal, abnormalities of venous tone, autonomic neuropathy, acetate intolerance (acetate acts as a vasodilator) and left ventricular hypertrophy.

Very rarely patients may develop anaphylactic reactions to ethylene oxide, which is used to sterilize most dialysers. Patients receiving ACE inhibitors are at risk of anaphylaxis if polyacrylonitrile dialysers are used.

Other potential, rare, complications include the hard-water syndrome (caused by failure to soften water resulting in a high calcium concentration prior to mixing with dialysate concentrate), haemolytic reactions and air embolism.

Adequacy of dialysis

Dialysis treatment is empirical since the size, number and nature of 'uraemic toxins' is unclear. The only true measure of adequacy is patient mortality and morbidity. Adequate nutrition of the patient as well as adequate dialysis is necessary to reduce morbidity and mortality.

Symptoms of underdialysis are non-specific and include insomnia, itching, fatigue despite adequate correction of anaemia, restless legs and a peripheral sensory neuropathy.

Adequacy of dialysis may be assessed by computerized calculation of urea kinetics, requiring measurement of the residual renal urea clearance, the rate of rise of urea concentration between dialysis sessions, and the reduction in urea concentration during dialysis. The dialysis dose is normally defined in terms of urea reduction ratio (URR) and/or equilibrated urea clearance, eKt/V (where K is the dialyser clearance, t is the duration of dialysis in minutes, and V is the urea distribution volume estimated as total body water). Kt/V of 1.0-1.2 and/or URR of 65% per dialysis session is the minimum threshold required for well-nourished dialysis patients dialysed three times per week. It is unclear whether a higher eKt/V is associated with a better outcome, although no additional benefits of high (1.53) compared to standard (1.16) eKt/V were seen over 5 years follow-up. It is likely that duration of haemodialysis session is a factor in itself in addition to the efficiency with which small molecules such as urea are cleared. The best haemodialysis outcome data are seen in renal units where long hours (8 hours per session) of dialysis are routinely practiced.

Haemodialysis is the most efficient way of achieving rapid biochemical improvement, for instance in the treatment of acute renal failure or severe hyperkalaemia. This advantage is offset by disadvantages such as haemodynamic instability, especially in acutely ill patients with multiorgan disease, and over-rapid correction of uraemia can lead to 'dialysis disequilibrium'. This is characterized by nausea and vomiting, restlessness, headache, hypertension, myoclonic jerking, and in severe instances seizures and coma owing to rapid changes in plasma osmolality leading to cerebral oedema.

These problems have led to the increasing adoption of gentler continuous methods for the treatment of acute renal failure (see below).

Haemofiltration

This involves removal of plasma water and its dissolved constituents (e.g. K^+, Na^+, urea, phosphate) by convective flow across a high-flux semipermeable membrane, and replacing it with a solution of the desired biochemical composition (Fig. 11.49). Lactate is used as buffer in the replacement solution because rapid infusion of acetate causes vasodilatation and bicarbonate may cause precipitation of calcium carbonate.

Haemofiltration can be used for both acute and chronic renal failure. High volumes need to be exchanged in order to achieve adequate small molecule removal; typically a 22 L exchange three times a week for maintenance treatment and 1 L per hour in acute renal failure. Financial costs of disposable items (such as filters and replacement fluid) are high and only a tiny minority of

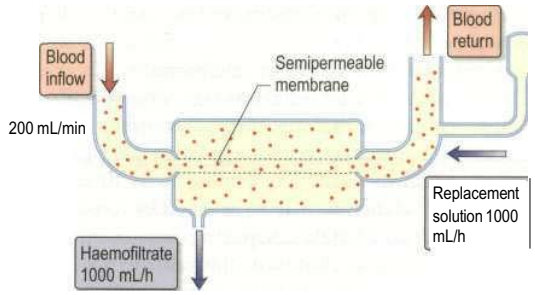

Fig. 11.49 **Principles of haemofiltration.**

Table 11.21 Range of concentrations (mmol/L) in routinely available CAPD dialysate*

Sodium	130-134
Potassium	0
Calcium	1.0-1.75
Magnesium	0.25-0.75
Chloride	95-104
Lactate	35-40
Glucose	77-236
Total osmolality	356-511 mOsm/kg

* Glucose content is often expressed as g/dL of anhydrous glucose (e.g. 1.36% = 77 mmol/L). An even more hypertonic dialysate (6.36%) is available for acute (intermittent) peritoneal dialysis

patients with end-stage renal failure are managed in this way. However, nursing costs are reduced when acute renal failure is managed in an intensive care unit setting since haemofiltration can be managed by ITU nursing staff rather than renal unit nurses.

Peritoneal dialysis

Peritoneal dialysis utilizes the peritoneal membrane as a semipermeable membrane, avoiding the need for extracorporeal circulation of blood. This is a very simple, low-technology treatment compared to haemodialysis. The principles are simple (Fig. 11.50).

- A tube is placed into the peritoneal cavity through the anterior abdominal wall.
- Dialysate is run into the peritoneal cavity, usually under gravity.
- Urea, creatinine, phosphate, and other uraemic toxins pass into the dialysate down their concentration gradients.
- Water (with solutes) is attracted into the peritoneal cavity by osmosis, depending on the osmolarity of the dialysate. This is determined by the glucose or polymer (icodextrin) content of the dialysate (Table 11.21).
- The fluid is changed regularly to repeat the process.

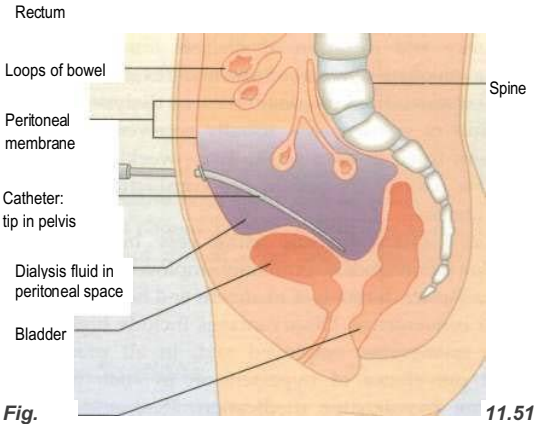

Fig. 11.51 **The siting of a Tenckhoff peritoneal dialysis catheter.**

Chronic peritoneal dialysis requires insertion of a soft catheter, with its tip in the pelvis, exiting the peritoneal cavity in the midline and lying in a skin tunnel with an exit site in the lateral abdominal wall (Fig. 11.51).

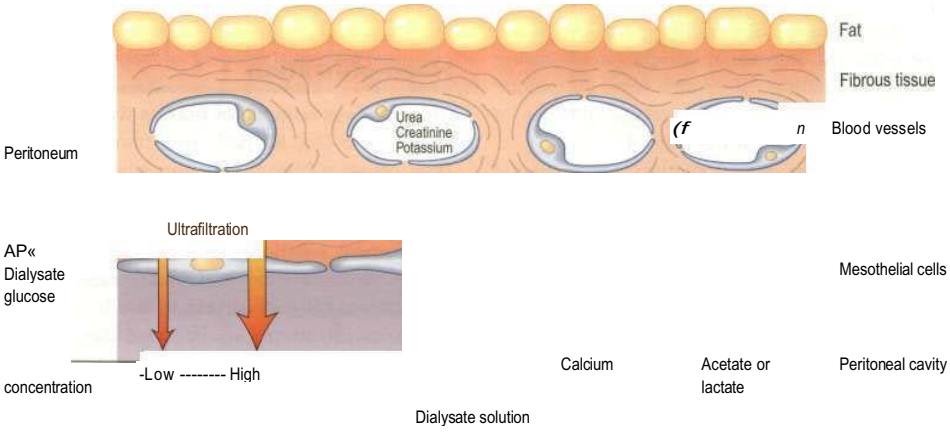

***Fig. 11.50* Principles of peritoneal dialysis.** Water is attracted into the peritoneal cavity depending on the osmolarity of the dialysate.

This form of dialysis can be adapted in several ways.

- **Continuous ambulatory peritoneal dialysis (CAPD).** Dialysate is present within the peritoneal cavity continuously, except when dialysate is being exchanged. Dialysate exchanges are performed three to five times a day, using a sterile no-touch technique to connect 1.5-3 L bags of dialysate to the peritoneal catheter; each exchange takes 20-40 minutes. This is the technique most often used for maintenance peritoneal dialysis in patients with end-stage renal failure.
- **Nightly intermittent peritoneal dialysis (NIPD).** An automated device is used to perform exchanges each night while the patient is asleep. Sometimes dialysate is left in the peritoneal cavity during the day in addition, to increase the time during which biochemical exchange is occurring.
- **Tidal dialysis.** A residual volume is left within the peritoneal cavity with continuous cycling of smaller volumes in and out.

Osmotic removal of excess plasma water and solutes is achieved using hypertonic dialysate, which exerts an osmotic 'drag'. Depending on the patient's fluid intake and residual urine output, it may be necessary to use one or more hypertonic dialysate bags daily to achieve fluid balance in CAPD. Fluid overload is a relatively common problem in CAPD, and is due to failure of transport across the peritoneal membrane.

Complications

Peritonitis

Bacterial peritonitis is the most common serious complication of CAPD and other forms of peritoneal dialysis. Clinical presentations include abdominal pain of varying severity (guarding and rebound tenderness are unusual), and a cloudy peritoneal effluent - without which, the diagnosis cannot be made. Microscopy reveals a neutrophil count of above 100 cells per mL. Nausea, vomiting, fever and paralytic ileus may be seen if peritonitis is severe. The incidence of CAPD-associated peritonitis has been much reduced (to about one episode every two patient years) by use of a Y-disconnect system in preference to previous methods.

CAPD peritonitis must be investigated with culture of peritoneal effluent. Empirical antibiotic treatment is started, with a spectrum which covers both Gram-negative and Gram-positive organisms. Antibiotics may be given by the oral, intravenous or intraperitoneal route; most centres rely on intraperitoneal antibiotics. Common causative organisms are listed in Table 11.22.

Staph. aureus peritonitis should lead to a search for nasal carriage of this organism, and *Staph. epidermidis* peritonitis may indicate contamination from the patient's (or helper's) skin. Relapsing *Staph. epidermidis* peritonitis with an organism with the same antibiotic sensitivity pattern on each occasion may indicate that the Tenckhoff catheter has become colonized: often this is difficult to eradicate without replacement of the catheter under antibiotic cover.

Table 11.22 Some causes of CAPD peritonitis*

	Approximate percentage of cases
Staphylococcus epidermidis	40-50
Escherichia coli, Pseudomonas and other Gram-negative organisms	25
Staphylococcus aureus	15
Mycobacterium tuberculosis	2
Candida and other fungal species	2

* In approximately 20%, no bacteria are found

Gram-negative peritonitis may complicate septicaemia from urinary or bowel infection. A mixed growth of Gram-negative and anaerobic organisms strongly suggests bowel perforation, and is an indication for laparotomy.

Fungal peritonitis often follows antibacterial treatment but may occur de novo. Clinical presentation is very variable. It is rare to be able to cure fungal peritonitis without catheter removal as well as antifungal treatment. Intraperitoneal amphotericin has been associated with the formation of peritoneal adhesions.

Infection around the catheter site

Infection where the catheter exits through the skin is relatively common. It should be treated aggressively (with systemic and/or local antibiotics) to prevent spread of the infection into the subcutaneous tunnel and the peritoneum. The most common causative organisms are staphylococci.

Other complications

CAPD is often associated with constipation, which in turn may impair flow of dialysate in and out of the pelvis. Occasionally dialysate may leak through a diaphragmatic defect into the thoracic cavity, causing a massive pleural 'effusion'. The glucose content of the effusion is usually diagnostic, or the diagnosis may be made by instillation of methylthioninium chloride (methylene blue) with dialysate and the demonstration of a blue colour on pleural tap. Dialysate may also leak into the scrotum down a patent processus vaginalis.

Failure of peritoneal membrane function is a predictable complication of long-term CAPD, resulting in worsening biochemical exchange and decreased ultrafiltration with hypertonic dialysate. It is thought that this problem may be accelerated by excessive reliance on hypertonic dialysate to remove fluid.

Sclerosing peritonitis is a potentially fatal complication of CAPD. The cause is often unclear, but recurrent peritonitis, and exposure of the peritoneum to unphysiological high glucose concentrations, is responsible in most cases. Progressive thickening of the peritoneal membrane occurs in association with adhesions and strictures, turning the small bowel into a mass of matted loops and causing repeated episodes of small bowel obstruction. CAPD should be abandoned. Improvement

may follow renal transplantation or treatment with prednisolone or azathioprine.

Contraindications

There are few absolute contraindications apart from unwillingness or inability on the patient's part to learn the technique.

Previous peritonitis causing peritoneal adhesions may make peritoneal dialysis impossible: but the extent of adhesions is difficult to predict, and it may be worth an attempted surgical placement of a dialysis catheter.

The presence of a stoma (colostomy, ileostomy, ileal urinary conduit) makes successful placement of a dialysis catheter extremely unlikely.

Active intra-abdominal sepsis, for instance due to diverticular abscesses, is an absolute contraindication to peritoneal dialysis although diverticular disease per se is not.

Abdominal hernias may often expand during CAPD as a result of increased intra-abdominal pressure, and should ideally be repaired before or at the time of CAPD catheter insertion.

Visual impairment may make it difficult for a patient to perform dialysate exchanges, but completely blind patients can be trained in the technique if adequately motivated.

Severe arthritis makes it difficult to perform the exchanges, but a large number of mechanical aids are available. Sterilization of connections by heat or ultraviolet light reduces the risk of peritonitis.

Recent studies suggest that end-stage renal failure patients with coronary artery disease or congestive heart failure have significantly higher morbidity and mortality on CAPD compared to HD. Moreover, elderly patients do worse on CAPD than younger patients. It is advisable to consider HD as the first-choice dialysis modality in these patients where it is possible.

Adequacy of peritoneal dialysis

No consensus yet exists on how the adequacy of peritoneal dialysis should be measured and the optimum degree of removal of urea and other waste products to be obtained in unit time. Urea kinetic modelling may be employed, as with haemodialysis. Based on observational studies, weekly *Kt/V* of 2.0 coupled with a creatinine clearance target of 60 L per week has been recommended. However, in a recent randomized prospective study (ADEMEX), standard daily exchanges of 8 L in total (creatinine clearance 40 L per week) compared to a creatinine clearance of 60 L per week yielded similar patient and technique survival. Peritoneal dialysis inadequacy becomes common when residual renal function declines to zero. With increasing time on treatment, adequacy may become impaired owing to alterations in the efficiency of the peritoneal membrane in transporting waste products, fluid and electrolytes.

Complications of long-term dialysis

Cardiovascular disease (see p. 670) and sepsis are the leading causes of death in long-term dialysis patients.

Causes of fatal sepsis include peritonitis complicating peritoneal dialysis and *Staph. aureus* infection (including endocarditis) complicating the use of indwelling access devices for haemodialysis.

Dialysis amyloidosis

This is the accumulation of amyloid protein (p. 1147) as a result of failure of clearance of β_2-microglobulin, a molecule of 11.8 kDa. This protein is the light chain of the class I HLA antigens and is normally freely filtered at the glomerulus but is not removed by cellulose-based haemodialysis membranes. The protein polymerizes, possibly after modification by non-enzymic glycosylation, to form amyloid deposits, which may cause median nerve compression in the carpal tunnel or a dialysis arthropathy - a clinical syndrome of pain and disabling stiffness in the shoulders, hips, hands, wrists and knees. β_2~microglobulin-related amyloid may be demonstrated in the synovium. Amyloid deposits can also cause pathological bone cysts and fractures, pseudotumours and gastrointestinal bleeding caused by amyloid deposition around submucosal blood vessels. The extent of amyloid deposition is best assessed by nuclear imaging, either using [^{99m}Tc]DMSA, or, more specifically, by the use of radiolabelled serum amyloid P component.

Rapid improvement after renal transplantation is probably due to steroid therapy as low-dose prednisolone alone can also cause an improvement. A change to a biocompatible synthetic membrane has also been reported to be of benefit: again, the mechanism for this improvement is not clear.

Transplantation

Successful renal transplantation offers the potential for almost complete rehabilitation in end-stage renal failure. This mode of renal replacement therapy has significant survival advantage compared to dialysis patients on transplant waiting lists. It allows freedom from dietary and fluid restriction; anaemia and infertility are corrected; and the need for parathyroidectomy is reduced. It is the treatment of choice for most patients with end-stage renal failure. The supply of donor organs (in the UK, 30/ million/ year) is greatly exceeded by demand (48/million/year), and donor organs are therefore scarce and a valuable resource that must be used optimally.

The technique involves the anastomosis of an explanted human kidney, usually either from a cadaveric donor or from a living close relative, on to the iliac vessels of the recipient (Fig. 11.52). The donor ureter is placed into the recipient's bladder. Unless the donor is genetically identical (i.e. an identical twin), immunosuppressive treatment is needed, for as long as the transplant remains in place, to prevent rejection. Refinements in patient selection and assessment of donor-recipient compatibility, improvements in surgical techniques and the development of more efficient immunosuppressive regimens have increased patient and graft survival. Eighty per cent of grafts now survive for 5-10 years in the best centres, and 50% for 10-30 years.

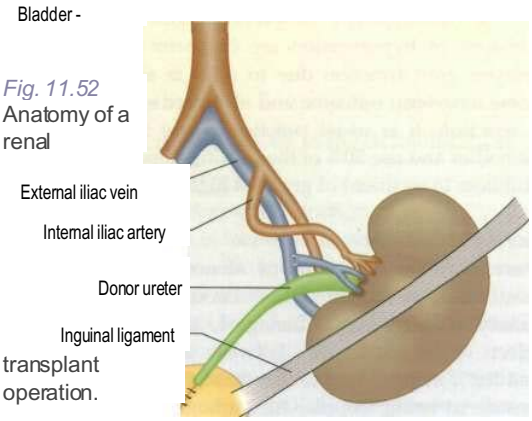

Fig. 11.52 Anatomy of a renal transplant operation.

Factors affecting success

ABO (blood group) compatibility between donor and recipient is required. However, in some centres, particularly in Japan where a cadaveric organ-donation programme is not well established, ABO-incompatible renal transplants are increasingly performed after desensitizing with immunoadsorption to remove pre-formed antibodies, splenectomy, anti-CD20 antibodies to remove B lymphocytes, and intravenous pooled immunoglobulins for immunomodulation or anti-idiotypic antibodies. In experienced hands, results are acceptable.

Matching donor and recipient for HLA type

Matching for HLA-DR antigens appears to have the most impact on graft survival. Studies have shown that matching at the HLA-B locus has only a minor effect on graft outcomes. Complete compatibility at A, B and DR offers the best chance of success, followed by a single HLA mismatch (i.e. antigen possessed by the donor and not possessed by the recipient). The effect of further degrees of mismatching upon graft survival in first transplants is of modest degree. Nationwide matching schemes for kidneys retrieved from cadaver donors are in existence. However, with availability of more efficient immunosuppressive agents, the value of HLA matching in the overall transplant outcome is, if any, only modest. Transplantation with completely mismatched kidneys, particularly when the donor is the patient's partner, is routinely practiced and results are as good as, if not better than, beneficially matched cadaveric kidneys.

Adequate immunosuppressive treatment

See below.

The donor kidney

Cadaveric donation

Most countries allow the removal of kidneys and other organs from patients who have suffered irretrievable brain damage ('brainstem death') while their hearts are still beating (see p. 989).

Living related donation

A close relative may volunteer as a potential donor. A sibling donor may be HLA identical or share one or no haplotypes with the potential recipient. In the UK, donor age must be 18 years or more.

Potential living related donors are subjected to an intensive preoperative evaluation, including clinical examination and measurement of renal function, tests for carriage of hepatitis B, C, HIV and cytomegalovirus, and detailed imaging of renal anatomy, to be sure that transplantation will be technically feasible.

Unrelated living donors may be accepted provided no inducement (financial or otherwise) is involved. Paid live non-related donor transplantation is illegal in the UK.

Immunosuppression for transplantation

Long-term drug treatment for the prevention of rejection is employed in all cases apart from living related donation from an identical twin. Some degree of immunological tolerance does develop, and the risk of rejection is highest in the first 3 months after transplantation. In the early months rejection episodes occur in less than 30% of cadaver kidney recipients. Most are reversible. A combination of immunosuppressive drugs is usually used.

Corticosteroids. Corticosteroids have a non-specific anti-inflammatory (inhibition of phospholipase A_2 and arachidonic acid cascade) and immunosuppressive action (inhibition of gamma-interferon-dependent adhesion molecules and thereby dendritic cell and T lymphocyte interaction). High-dose methylprednisolone is used as the primary treatment for acute rejection.

Azathioprine. Azathioprine prevents cell-mediated rejection by blocking purine synthesis and replication of lymphocytes. A recent study suggests that azathioprine and its metabolite 6-mercaptopurine can convert a CD28-dependent costimulatory Racl signal (proliferation and differentiation) upon dendritic cell and T-lymphocyte interaction into an apoptotic response by their ability to form 6-thio-GTP. 6-Thio-GTP competes with GTP for Racl, preventing its anti-apoptotic action. Adverse effects include suppression of red cell and platelet production, an increased incidence of infections (particularly viral), and hepatotoxicity. It also interacts with allopurinol, which increases levels of the active metabolites of azathioprine (6-mercaptopurinol), resulting in toxicity.

Mycophenolate mofetil is metabolized to mycophenolic acid and blocks inosine monophosphate dehydrogenase (IMPD) an enzyme in the de-novo synthetic pathway of purine synthesis. It may be more specific for lymphocytes because unlike in other cells an alternative purine synthetic salvage pathway is absent from lymphocytes. It is more potent than azathioprine, as trials have shown a reduction in rejection episodes. Gastrointestinal symptoms such as nausea, vomiting and diarrhoea are more than with azathioprine but the drug can be used with allopurinol.

Ciclosporin (CSA). Ciclosporin, a calcineurin inhibitor, prevents the activation of T lymphocytes in response to new antigens and is highly effective in preventing rejection, while leaving the functioning of the rest of the immune system largely intact. Intracellularly, CSA forms complexes with cyclophilin (isomerase) and inhibits calmodulin-calcineurin-induced phosphorylation of NF-AT transcription factor for IL-2 and possibly other T cell activation genes. Its introduction has revolutionized organ transplantation. Disadvantages include high cost and nephrotoxicity. Even with careful adjustment of the dose in response to trough blood levels, renal function may be adversely affected.

Tacrolimus, also a calcineurin inhibitor, blocks T-cell activation by a mechanism very similar to that of ciclosporin with the exception that tacrolimus forms a complex with immunophilin FK binding protein-12 (FKBP-12) instead of cyclophilin. The downstream actions are the same as with CSA. It is more potent than CSA and is therefore used both as a rescue agent for treating rejection and as a maintenance agent. Its side-effects are broadly similar to those of CSA except it is more diabetogenic.

Sirolimus and the structural analogue everolimus are newer immunosuppressants that are synergistic with CSA but lack nephrotoxicity. Sirolimus, like tacrolimus, binds to FKBP (particularly the -25 rather than the -12 isoform) but instead of calcineurin inhibition, acts on targets of rapamycin signalling (target of rapamycin - TOR) and prevents cell entry into Gl phase of the cell cycle. It may lead to poor wound healing and delay the recovery of proximal tubular cell injury sustained during transplantation. Its main side-effects are thombocytopenia and hyperlipidaemia. Its role in renal transplantation is being explored.

Antibodies. Both polyclonal anti-thymocytic globulin (ATG) and anti-lymphocytic globulin (ALG) and monoclonal (OKT3) antibodies are potent immunosuppressive agents. Antibodies may be derived from mouse, rabbit, horse, or 'humanized', and directed against any of a number of lymphocycte surface marker proteins, enabling neutralization or killing of lymphocytes with certain functions (e.g. T cells, activated T cells, cells expressing adhesion molecules). They are mainly used for the treatment of steroid-resistant rejections and as an induction therapy for high immunological risk patients (previously sensitized with circulating anti-HLA antibodies). Basiliximab (chimeric) and dacluzimab (humanized) anti-CD25 monoclonal antibodies bind to IL-2 receptors on activated T lymphocytes only (therefore having few side-effects), inhibiting IL-2-driven proliferative responses. They have largely replaced ATG and ALG in transplant induction protocols.

Complications

Acute tubular necrosis (ATN)

ATN is the commonest cause of cadaveric graft dysfunction (up to 40-50%), particularly after asystolic donation and prolonged cold ischaemia time (> 24 hours). Kidneys from elderly (> 55 years) donors and those with a history of hypertension are liable to develop ATN. Delayed graft function due to ATN is associated with worse long-term outcome and also predisposes the graft to rejection. It is usual practice to use induction with antibodies and use 50% of the starting dose of calcineurin inhibitors in recipient of grafts at high risk for ATN.

Technical failures

There may be occlusion or stenosis of the arterial anastomosis, occlusion of the venous anastomosis, and urinary leaks owing to damage to the lower ureter, or defects in the anastomosis between ureter and recipient bladder. If urine output drops, these diagnoses should be considered using Doppler ultrasonography, DTPA scanning and/or renal angiography. Surgical re-implantation may be required.

Acute rejection (AR)

AR is seen in up to 30% of transplant recipients and usually presents with declining renal function within the first 3 months. Renal biopsy confirms the diagnosis and also assesses the severity. Therapy in cellular rejection is high-dose pulse steroid; in acute vascular rejection, ATG, ALG or OKT3 is used. More than one rejection within the first 3 months, delayed rejection and failure of serum creatinine to return to baseline are associated with worse long-term outcome.

Infections

In the first month post-transplantation, infections tend to be from bacterial sources seen typically in the surgical population. Cytomegalovirus (CMV) infections develop weeks or months after transplantation in 70% of CMV-seronegative recipients receiving grafts from a seropositive donor and in patients receiving biological agents (antibodies) as induction or therapy for rejection, unless prophylaxis with valganciclovir or valaciclovir is given. Prophylaxis is also routinely given against *Pneumocystis carinii* (co-trimoxazole) and oral candidiasis (nystatin or amphotericin lozenges). Polyomavirus infections (BK nephropathy) result in graft dysfunction and eventual loss due to mainly tubulointerstitial nephritis. There is no known specific treatment with the exception of tapering immunosuppression.

Post-transplantation lymphoproliferative disorders

Epstein-Barr virus-associated malignancies are common in patients who received biological agents and in children. Cautious tapering of ciclosporin or tacrolimus and monitoring for the reappearance of cytotoxic lymphocytes has improved the outcome.

Chronic allograft nephropathy (CAN)

CAN remains the most common cause of late graft failure. The process is mediated by immunological and non-immunological factors and results in a progressive irreversible decline in graft function with mild to modest proteinuria (<3 g/day). Unfortunately there is no established therapy of proven efficiency.

Malignancy

Immunosuppressive therapy increases the risk of skin tumours, including basal and squamous cell carcinoma. In white recipients, exposure to ultraviolet light should be minimized and sun-block creams employed. Other common cancers are renal, cervical and vaginal. In female recipients, regular yearly cervical smears should be carried out.

Cardiovascular disease

Cardiovascular disease is the cause of death post-transplantation in 50% of cases. This is due to increased incidence of hypertension, obesity, diabetes and insulin resistance lipid disorders. Use of a statin (fluvastatin) was associated with reduction in cardiac end-points (myocardial infarction or revascularization) post-transplantation but overall mortality remained unchanged in a randomized prospective study.

Post-transplant osteoporosis

This is common following transplantation owing to treatment with steroids. Maximum bone loss occurs within the first 3 months and regular DXA scans are necessary. Bisphosphonates (alendronate, palmidronate), and alphacalcidol with or without calcium carbonate have proven to be effective in control studies.

Recurrent disease

Recurrence of renal disease is surprisingly common. Primary FSGS often recurs and causes early graft loss. Mesangiocapillary GN, diabetic nephropathy and IgA nephropathy also commonly recur but seldom cause renal insufficiency.

CYSTIC RENAL DISEASE

Solitary or multiple renal cysts are common, especially with advancing age: 50% of those aged 50 years or more have one or more such cysts. They have no special significance except in the differential diagnosis of renal tumours (see p. 684). Such cysts are often asymptomatic and are found on excretion urography or ultrasound examination performed for some other reason. Occasionally they may cause pain and/ or haematuria owing to their large size, or bleeding may occur into the cyst. Cystic degeneration (the formation of multiple cysts which enlarge with time) occurs regularly in the kidneys of patients with end-stage renal failure treated by dialysis and/or transplantation. Malignant tumour formation seems to be more common in such kidneys than in the general population.

Autosomal-dominant polycystic kidney disease

Autosomal-dominant polycystic kidney disease (ADPKD) is an inherited disorder usually presenting in adult life. It is characterized by the development of multiple renal cysts, variably associated with extrarenal (mainly hepatic and cardiovascular) abnormalities. ADPKD is by far the most common inherited nephropathy, with a prevalence rate ranging from 1 : 400 to 1 : 1000 in white populations. It accounts for 3-10% of all patients commencing regular dialysis in the West.

In about 85% of cases, the gene responsible *(PKD1)* has been located on chromosome 16. A second gene, *PKD2,* which has been mapped on chromosome 4, accounts for the vast majority of other cases. These genetic abnormalities are distinct from the autosomal recessive form of polycystic disease (due to mutations in the *PKHD1* gene on chromosome 6p21.1-pl2), which is often lethal in early life. The protein corresponding to the *PKD1* gene, polycystin 1, appears to be an integral membrane glycoprotein involved in cell-to-cell and/ or cell-to-matrix interaction and functions as a mechanosensor. The protein corresponding to the *PKD2* gene appears to function as a calcium ion channel, regulating calcium influx and/or release from intracellular stores. Polycystin-1 acts as the regulator of PKD2 channel activity by its co-localization on cilia of collecting tubular cells. Disruption of the polycystin pathway results in reduced cytoplasmic calcium, which in principal cells of the collecting duct causes increase in cAMP via stimulation of calcium-inhibitable adenyl cyclase and inhibition of cAMP phosphodiesterases.

Clinical features

Clinical presentation may be at any age from the second decade. Presenting symptoms include:

- acute loin pain and/ or haematuria owing to haemorrhage into a cyst, cyst infection or urinary tract stone formation

loin or abdominal discomfort owing to the increasing size of the kidneys
- subarachnoid haemorrhage associated with berry aneurysm rupture
- complications of hypertension
- complications of associated liver cysts
- symptoms of uraemia and/or anaemia associated with chronic renal failure.

Erythraemia is a rare complication and presentation of ADPKD.

The natural history of the disease is one of progressive renal impairment, sometimes punctuated by acute episodes of loin pain and haematuria, and commonly associated with the development of hypertension. The rate of progression to renal failure is variable. The determinants of progression are both genetic and non-genetic. In the PKD2 form, renal cysts develop more slowly and end-stage renal failure (ESRF) occurs 10-15 years later than in the PKD1 form. Gender affects renal prognosis. Males with ADPKD reach end-stage renal failure 5-6 years earlier than females. There is a large variability in the age at ESRF within families, even between affected monozygotic twins.

Complications and associations

Pain

A minority of patients suffer chronic renal pain resistant to common analgesics, presumably owing to the pressure effect of large cysts. Surgical decompression of such cysts appears to be of benefit in about two-thirds of patients. Laparoscopic cyst decortication is a minimally invasive alternative technique.

Cyst infection

The response to standard antibacterial therapy is often poor owing to poor penetration of conventional antibiotics across the cyst wall. Lipophilic antibiotics active against Gram-negative bacteria, such as co-trimoxazole and fluoroquinolones, penetrate into the cysts better and their use has greatly improved the treatment of this complication.

Renal calculi

These are diagnosed in about 10-20% of patients with ADPKD. Frequently they are composed of uric acid and hence radiolucent. Obstructing or painful stones are treated no differently than are stones in patients with normal urinary tracts. Percutaneous stone removal and extracorporeal lithotripsy may safely be employed.

Hypertension

Hypertension is an early and very common feature of ADPKD. Elevation of blood pressure, still within the normal range, is detectable in young affected individuals and is associated with an increase in left ventricular mass. It appears that left ventricular hypertrophy occurs to a greater degree for a given rise in blood pressure in ADPKD compared with other renal disorders and with essential hypertension. Intrarenal activation of the renin-angiotensin system is involved in pathogenesis, and ACE inhibitors are logical first-line agents in treatment. Early control of blood pressure is essential as cardiovascular complications are a major cause of death in ADPKD.

Progressive renal failure

This is the most serious complication of ADPKD. At glomerular filtration rates below 50 mL/min, the rate of decline in GFR averages 5 mL/min each year, which is more rapid than in other primary renal disorders. The probability of being alive without requiring dialysis or transplantation by the age of 70 years is of the order of 30%. Survival rates on regular haemodialysis and after renal transplantation in ADPKD are similar to those of patients with other primary renal diseases.

Hepatic cysts

Approximately 30% of patients have hepatic cysts and in a minority of patients massive enlargement of the polycystic liver is seen. Pain, infection of cysts and, more rarely, compression of the bile duct, portal vein or hepatic venous outflow occur. Rarely, percutaneous drainage of painful cysts, laparoscopic fenestration or even partial hepatectomy may be necessary. Infected cysts may require drainage.

Intracranial aneurysm formation

About 10% of ADPKD patients have an asymptomatic intracranial aneurysm and the prevalence is twice as high in the subgroup of patients with a family history of such aneurysms or of subarachnoid haemorrhage. Such haemorrhage is preceded in from 20% to 40% of cases by premonitory headaches from a few hours up to 2 weeks before the onset of subarachnoid bleeding. Headache of sudden onset or unusual character or severity in a patient with ADPKD should prompt investigation. Contrast-enhanced spiral CT or MR angiography are the best investigations. Screening for intracranial aneurysm in ADPKD is currently recommended for patients aged 18^10 years who have a positive family history.

Mitral valve prolapse

This is found in 20% of individuals with ADPKD.

Diagnosis

Physical examination commonly reveals large, irregular kidneys and possibly hepatomegaly. Definitive diagnosis is established by ultrasound examination (Fig. 11.53). However, such renal imaging techniques may be equivocal, especially in subjects under the age of 20 years.

Screening

The children and siblings of patients with established ADPKD should, in general, be offered screening. Affected individuals should have regular blood pressure checks and should be offered genetic counselling. Screening by ultrasonography should not be carried out before the age of 20 years, as excluding the condition may be difficult and hypertension is unusual before this age. Even at age 20, renal ultrasonography may give a false-negative

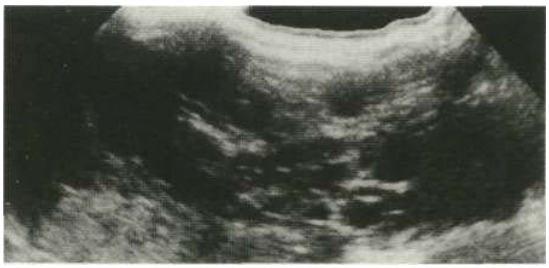

Fig. 11.53 Ultrasound scan of a polycystic kidney, showing an enlarged kidney with many cysts of varying size.

result. Gene linkage analysis can be utilized in many families.

Therapy

No therapy is yet available but potential agents include *vasopressin receptor antagonists,* which have been studied in animal models of polycystic kidney disease, which is closely related to human ADPKD, where they have halted cyst progression or caused disease regression. ADPKD kidneys may be particularly vulnerable to *adenylyl cyclase agonists* or *cAMP phosphodiesterase inhibitors.* Caffeine at clinically relevant concentrations has been found to enhance the effect of desmopressin to stimulate chloride secretion in cultured epithelial cells from ADPKD cysts.

Medullary cystic disease ('juvenile nephronophthisis')

Juvenile nephronophthisis that develops early in childhood is commonly inherited in an autosomal recessive manner. Mutations in the genes *NPHP1-4* have recently been found. The proteins mutated, nephrocystin and inversin, are co-localized in the cilia of the renal tubules. A similar condition developing later in childhood (medullary cystic disease) is inherited as an autosomal dominant trait, but sporadic cases occur in both conditions. Despite its name, the dominant histological finding is interstitial inflammation and tubular atrophy, with later development of medullary cysts. Progressive glomerular failure is a secondary consequence. The dominant features are polyuria, polydipsia and growth retardation. Diagnosis is based on the family history and renal biopsy, the cysts rarely being visualized by imaging techniques.

Medullary sponge kidney

Medullary sponge kidney is an uncommon but not rare condition that usually presents with renal colic or haematuria. Although it is most often sporadic, a few affected families have been reported. The condition is characterized by dilatation of the collecting ducts in the papillae, sometimes with cystic change. In severe cases the medullary area has a sponge-like appearance. The condition may affect one or both kidneys or only part of one kidney. Cyst formation is commonly associated with the development of small calculi within the cyst. In about 20% of patients there is associated hypercalciuria or renal tubular acidosis (see p. 716). Hemihypertrophy of the skeleton has been described in this condition.

The diagnosis is made by excretion urography, which shows small calculi in the papillary zones with an increase in radiodensity around these following injection of contrast medium as the dilated or cystic collecting ducts are filled with contrast (see Fig. 11.33).

The natural history is one of intermittent colic with passage of small stones or haematuria. Renal function is usually well maintained and renal failure is unusual, except where obstructive nephropathy develops owing to the presence of stones in the pelvis or ureters.

TUMOURS OF THE KIDNEY AND GENITOURir

MALIGNANT RENAL TUMOURS

These comprise 1-2% of all malignant tumours, and the male to female ratio is 2 : 1.

Renal cell carcinoma

Renal cell carcinomas (RCC) arise from proximal tubular epithelium. They are the most common renal tumour in adults. They rarely present before the age of 40 years, the average age of presentation being 55 years.

In von Hippel-Lindau disease, an autosomal dominant disorder, bilateral renal cell carcinomas are common and haemangioblastomas, phaeochromocytomas and renal cysts are also found. Polymorphic probes from chromosome 3p, the region implicated in renal cell carcinoma, have demonstrated genetic linkage between them and von Hippel-Lindau disease. It seems likely, therefore, that mutation of the same tumour suppressor gene may be responsible for both renal cell carcinoma and von Hippel-Lindau disease. Deletion of the short arm of chromosome 3 is the most consistent cytogenetic finding in sporadic tumours. Renal cell carcinomas are highly vascular tumours. Microscopically most tumours are composed of large cells containing clear cytoplasm.

Clinical features

Patients present with haematuria, loin pain and a mass in the flank. Malaise, anorexia and weight loss (30%) may occur, and 5% of patients have polycythaemia (see p. 454).

Thirty per cent of patients have hypertension due to secretion of renin by the tumour with anaemia due to depression of erythropoietin in approximately the same number. Pyrexia is present in about one-fifth of patients and approximately one-quarter present with metastases. Rarely, a left-sided varicocele may be associated with left-sided tumours that have invaded the renal vein and caused obstruction to drainage of the left testicular vein.

Diagnosis

Excretion urography will reveal a space-occupying lesion in the kidney; 10% of these show calcification. Ultrasonography is used to demonstrate the solid lesion and to examine the patency of the renal vein and inferior vena cava. A small (< 3 cm) renal cell carcinoma may be missed on excretion urography and ultrasonography. CT scanning can also be used to identify the renal lesion and involvement of the renal vein or inferior vena cava. MRI is better than CT for tumour staging. Renal arteriography will reveal the tumour's circulation but is now seldom employed. Urine cytology for malignant cells is of no value. The ESR is usually raised. Liver biochemistry may be abnormal, returning to normal after surgery.

Treatment

Treatment is by nephrectomy unless bilateral tumours are present or the contralateral kidney functions poorly, in which case conservative surgery such as partial nephrectomy may be indicated. If metastases are present, nephrectomy may still be warranted since regression of metastases has been reported after removal of the main tumour mass. Medroxyprogesterone acetate is of some value in controlling metastatic disease. Treatment with interleukin-2 and beta-interferon produces a remission in about 20% of cases. A striking regression of metastases has been reported after non-myeloablative chemotherapy followed by allogeneic (sibling) peripheral blood stem-cell transplantation. Given the frequency of mutation in tumour suppression gene *VHL* and oversecretion of vascular endothelial growth factor (VEGF) in RCC, a trial with neutralizing antibody to VEGF (bevacizumab) caused significant slowing in the rate of progression of metastatic renal cell carcinoma but did not prolong the overall patient survival. Similarly in a recent study, adjuvant autologous renal tumour cell vaccine given intradermally every 4 weeks for 6 months at the time of radical nephrectomy for non-metastatic RCC was associated with an increase in 5-year disease progression-free survival - 77% compared to 68% in the placebo group. These exciting new studies may help to improve the prognosis of RCC.

Prognosis

The prognosis depends upon the degree of differentiation of the tumour and whether or not metastases are present. The 5-year survival rate is 60-70% with tumours confined to the renal parenchyma, 15-35%, with lymph node involvement, and only approximately 5% in those who have distant metastases.

Nephroblastoma (Wilms' tumour)

This tumour is seen mainly within the first 3 years of life and may be bilateral. It presents as an abdominal mass, rarely with haematuria. Diagnosis is established by excretion urography followed by arteriography. A combination of nephrectomy, radiotherapy and chemotherapy has much improved survival rates, even in children, with metastatic disease. Overall, 5-year survival rate in UK children diagnosed between 1971 and 1985 was 79%.

UROTHELIAL TUMOURS

The calyces, renal pelvis, ureter, bladder and urethra are lined by transitional cell epithelium. Transitional cell tumours account for about 3% of deaths from all forms of malignancy. Such tumours are uncommon below the age of 40 years, and the male to female ratio is 4 : 1. Bladder tumours are about 50 times as common as those of the ureter or renal pelvis.

Predisposing factors include:

- cigarette smoking
- exposure to industrial carcinogens such as p-naphthylamine and benzidine (workers in the chemical, cable and rubber industries are at particular risk) or ingestion of aristolochic acid found in some herbal weight-loss preparations
- exposure to drugs (e.g. phenacetin, cyclophosphamide)
- chronic inflammation (e.g. schistosomiasis, usually associated with squamous carcinoma).

Presentation

Painless haematuria is the most common presenting symptom of bladder malignancy, although pain may occur owing to clot retention. Symptoms suggestive of UTI may develop in the absence of significant bacteriuria. In patients with bladder cancer, pain may also result from local nerve involvement. Presenting symptoms may result from local metastases.

Transitional cell carcinomas in the kidney and ureter may present with haematuria. They may also give rise to flank pain, particularly if urinary tract obstruction is present.

Investigations

Cytological examination of urine for malignant cells and renal imaging (ultrasonography and CT) should be performed in all patients. Cystoscopy is necessary unless pathology is found in the upper urinary tract. It may be omitted in men under 20 and women under 30 years if significant bacteriuria accompanies the haematuria and ceases following control of the infection, provided urine cytology and renal imaging are normal. With these exceptions, haematuria should always be investigated. In cases where the tumour is not clearly outlined on ultrasonography or CT, retrograde ureterography may be helpful.

Treatment

Pelvic and ureteric tumours. These are treated by nephroureterectomy. Radiotherapy and chemotherapy appear to be of little or no value. Subsequently, cystoscopy should be regularly carried out, since about half the patients will develop bladder tumours.

Bladder tumours. Treatment depends upon the stage of the tumour (in particular whether it has penetrated the bladder muscle) and its degree of differentiation.

Superficial bladder tumours are treated by transurethral resection or local diathermy with follow-up check cystoscopies and cytological examination of the urine. Bladder instillation of doxorubicin, mitomycin and thiotepa is used for recurrent tumours, as is instillation of BCG (bacille Calmette-Guerin).

Invasive bladder tumours are treated with radical cystectomy in patients under 70 years and radical radiotherapy in those over 70 years with salvage cystectomy for recurrences. Cystectomy requires a new bladder to be made out of small bowel, joining this to the urethra if possible or making an ileal conduit.

Prognosis

The prognosis ranges from a 5-year survival rate of 80-90% for lesions not involving bladder muscle to 5% for those presenting with metastases.

Testicular tumours are discussed on page 522.

DISEASES OF THE PROSTATE GLAND

Benign enlargement of the prostate gland

Benign prostatic enlargement occurs most often in men over the age of 60 years. Such enlargement is much less common in Asian individuals. It is unknown in eunuchs. The aetiology of the condition is unknown. Microscopically, hyperplasia affects the glandular and connective tissue elements of the prostate. Enlargement of the gland stretches and distorts the urethra, obstructing bladder outflow.

Clinical features

Frequency of urination, usually first noted as nocturia, is a common early symptom. Difficulty or delay in initiating urination, with variability and reduced forcefulness of the urinary stream and post-void dribbling, are often present. Acute retention of urine (see below) or retention with overflow incontinence may occur. Occasionally, severe haematuria results from rupture of prostatic veins or as a consequence of bacteriuria or stone disease. Occasional patients present with severe renal failure.

Abdominal examination for bladder enlargement together with examination of the rectum are essential. A benign prostate feels smooth. An accurate impression of prostatic size cannot be obtained on rectal examination.

Management and prognosis

Patients with mild-to-moderate symptoms should be managed by 'watchful waiting', because symptoms following therapy are sometimes greater than those with no therapy at all.

Patients with moderate prostatic symptoms can be treated medically. A number of drugs have been employed, including alpha-blockers such as tamsulosin. Finasteride is a competitive inhibitor of 5a-reductase, which is the enzyme involved in the conversion of testosterone to dihydrotestosterone. This is the androgen primarily responsible for prostatic growth and enlargement. Finasteride decreases prostatic volume with an increase in urine flow. Deterioration in renal function or the development of upper tract dilatation requires surgery.

In acute retention or retention with overflow, the first priorities are to relieve pain and to establish urethral catheter drainage. If urethral catheterization is impossible, suprapubic catheter drainage should be carried out. The choice of further management is then between immediate prostatectomy, a period of catheter drainage followed by prostatectomy, or the acceptance of a permanent indwelling suprapubic or urethral catheter.

Prostatic carcinoma

Prostatic carcinoma accounts for 7% of all cancers in men and is the fourth most common cause of death from malignant disease in men in England and Wales. Malignant change within the prostate becomes increasingly common with advancing age. By the age of 80 years, 80% of men have malignant foci within the gland, but most of these appear to lie dormant. Histologically, the tumour is an adenocarcinoma. Hormonal factors are thought to play a role in the aetiology.

Clinical features

Presentation may be with symptoms of lower urinary tract obstruction or of metastatic spread, particularly to bone. The diagnosis may be made by the incidental finding of a hard irregular gland on rectal examination, or as an unexpected histological result after prostatectomy for what was believed to be benign prostatic hypertrophy. In developed countries, patients now present as a result of screening for prostate cancer by measurement of prostate-specific antigen (PSA). However, on the evidence available, national programmes of screening are not justified. Treatment of well people carries a high morbidity of urinary incontinence and sexual dysfunction with no evidence as yet of increased survival. In future, screening of 'at-risk' groups may be useful.

Investigations

These include transrectal ultrasound of the prostate and prostatic biopsy. A histological diagnosis is essential before treatment. The Gleason scoring system is based on the histological appearances. If metastases are present, serum prostate-specific antigen levels are usually markedly elevated (> 16 ug/L); it is a myth that elevated levels occur as a result of rectal examination.

Ultrasonography and transrectal ultrasonography are also of value in defining the size of the gland and staging any tumour present. The upper renal tracts can be examined by ultrasonography for evidence of dilatation. Bone metastases may appear as osteosclerotic lesions on X-ray and are detected by isotopic bone scans.

Treatment (see also p. 685)

Prophylactic finasteride therapy can prevent or delay the appearance of prostatic carcinoma in men above the age of 55 years but usually at the expense of sexual side-effects and increased risk of high-grade prostatic cancer. Microscopic, impalpable tumours can sometimes be managed expectantly. Treatment for disease confined to the gland is radical prostatectomy (provided the patient is fit for the procedure) or radiotherapy. A randomized trial comparing radical prostatectomy with watching and waiting in early prostate cancer revealed radical prostatectomy significantly reduced disease-specific mortality, but there was no significant difference between surgery and watching and waiting in terms of overall survival. Locally extensive disease is managed with radiotherapy with or without androgen ablation therapy. Metastatic disease can be treated with orchidectomy, but many men refuse. Luteinizing hormone-releasing hormone (LHRH) analogues such as buserelin or goserelin are equally effective and preferred by many. Non-hormonal chemotherapy is usually unhelpful. The duration of survival depends on the age of the patient and the degree of differentiation and extent of the tumour.

RENAL DISEASE IN THE ELDERLY

Renal failure in the elderly more often results from renal vascular disease or urinary tract obstruction than in younger age groups. In males, obstruction is most often due to benign or malignant prostatic enlargement, while in females it results from pelvic cancer.

Progressive sclerosis of glomeruli occurs with ageing and this, together with the development of atheromatous renal vascular disease, accounts for the progressive reduction in GFR seen with advancing years. A GFR of 50-60 mL/min (about half the normal value for a young adult) may be regarded as 'normal' in patients in their eighties. The reduction in muscle mass often seen with ageing may mask this deterioration in renal function in that the serum creatinine concentration may be less than 0.12 mmol/L in an elderly patient whose GFR is 50 mL/min or lower. The use of serum creatinine as a measure of renal function in the elderly must take this into account. This is especially so in the elderly when prescribing drugs whose excretion is in whole or in part by the kidney.

Urinary tract infections

UTIs are common in the elderly, in whom impaired bladder emptying due to prostatic disease in males and neuropathic bladder - especially common in females - is frequently found. Symptoms may be atypical, the major complaints being incontinence, nocturia, smelly urine or vague change in well-being with little in the way of dysuria. Demonstration of significant bacteriuria in the presence of such symptoms requires treatment.

Urinary incontinence

This is defined as involuntary passage of urine sufficient to be a health or social problem. It is common in the elderly with 25% of women and 15% of men over 65 having a problem.

- *Urge incontinence* is usually due to detrusor over-activity with leakage of urine because the bladder is perceived to be full. This is common in the elderly; it occurs as an isolated event or secondary to local factors, e.g. bladder infection or stones, or to central factors, e.g. stroke, dementia or Parkinson's disease.
- Stress *incontinence* occurs when the intra-abdominal pressure is increased, e.g. after a cough or sneeze and there is a weak pelvic floor or urethral sphincter. It is common in women after childbirth.
- *Overflow incontinence* occurs with leakage of urine from a full distended bladder. It occurs commonly in men with prostatic obstruction, following spinal cord injury or in women with cystoceles or after gynaecological surgery.
- *Functional incontinence.* Passage of urine occurs owing to inability to get to a toilet because of disability, e.g. stroke, trauma, the unavailability of toilet facilities or dementia.

Management

- Physical examination for local problems, e.g. prostatic enlargement in men, gynaecological disorders in women, and for central problems, e.g. neurological disorders or dementia.
- Urine analysis, e.g. glycosuria and culture for UTI.
- Treatment of contributing causes, e.g. constipation, drug therapy, other co-existing disease.
- Urge incontinence - bladder training, antimuscarinics, e.g. oxybutynin and tolterodine.
- Stress incontinence — pelvic floor exercises.
- Overflow — removal of obstruction.
- Functional — improve facilities, regular urine voiding, absorbent padding.

Further evaluation with urodynamics is necessary in patients who do not respond and have a potentially curable problem. An expert and committed incontinence advisory and treatment service combining nursing and medical skills is invaluable for elderly patients with this distressing problem. Home visits to ensure the availability of commodes and toilets is essential. For established incontinence, catheterization may be necessary but should be avoided if at all possible. Incontinence and its treatment are matters of major importance and are by no means confined solely to the elderly.

Water, electrolytes and acid-base balance

In health, the volume and biochemical composition of both extracellular and intracellular fluid compartments in the body remains remarkably constant. Many different disease states result in changes of control, either of extracellular fluid volume or of the electrolyte composition of extracellular fluid. An understanding of these abnormalities is therefore essential for the management of a wide range of clinical disorders.

DISTRIBUTION AND COMPOSITION OF BODY WATER

In normal persons, the total body water constitutes 50-60% of lean body weight in men and 45-50% in women. In a healthy 70 kg male, total body water is approximately 42 L. This is contained in three major compartments:

- the intracellular fluid (28 L, about 35% of lean bodyweight)
- the interstitial fluid that bathes the cells (9.4 L, about 12%)
- plasma (4.6 L, about 4-5%).

In addition, small amounts of water are contained in bone, dense connective tissue, and epithelial secretions, such as the digestive secretions and cerebrospinal fluid.

The intracellular and interstitial fluids are separated by the cell membrane; the interstitial fluid and plasma are separated by the capillary wall (Fig. 12.1). In the absence of solute, water molecules move randomly and in equal numbers in either direction across a permeable membrane. However, if solutes are added to one side of the membrane, the intermolecular cohesive forces reduce the activity of the water molecules. As a result, water tends to stay in the solute-containing compartment because there is less free diffusion across the membrane. This ability to hold water in the compartment can be measured as the osmotic pressure.

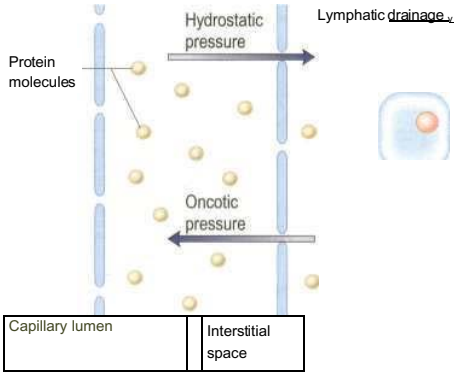

Fig. 12.1 **Distribution of water between the vascular and extravascular (interstitial) spaces.** This is determined by the equilibrium between hydrostatic pressure, which tends to force fluid out of the capillaries, and oncotic pressure, which acts to retain fluid within the vessel. The net flow of fluid outwards is balanced by 'suction' of fluid into the lymphatics, which returns it to the bloodstream. Similar principles govern the volume of the peritoneal and pleural spaces.

Osmotic pressure

Osmotic pressure is the primary determinant of the distribution of water among the three major compartments. The concentrations of the major solutes in these fluids differ, and each compartment has one solute that is primarily limited to that compartment and therefore determines its osmotic pressure: K^+ salts in the intra-

Table 12.1 Electrolyte composition of intracellular and extracellular fluids

	Plasma (mmol/L)	Interstitial fluid (mmol/L)	Intracellular fluid (mmol/L)
Na^+	142	144	10
K^+	4	4	160
Ca^{2+}	2.5	2.5	1.5
Mg^{2+}	1.0	0.5	13
cr	102	114	2
HCO3-	26	30	8
PO_4^{2-}	1.0	1.0	57
SO_4^{2-}	0.5	0.5	10
Organic acid	3	4	3
Protein	16	0	55

cellular fluid (most of the cell Mg^{2+} is bound and osmotically inactive), Na^+ salts in the interstitial fluid, and proteins in the plasma. Regulation of the plasma volume is somewhat more complicated because of the tendency of the plasma proteins to hold water in the vascular space by an oncotic effect which is in part counterbalanced by the hydrostatic pressure in the capillary that is generated by cardiac contraction (Fig. 12.1). The composition of intracellular and extracellular fluids is shown in Table 12.1.

A characteristic of an osmotically active solute is that it cannot freely leave its compartment. The capillary wall, for example, is relatively impermeable to plasma proteins, and the cell membrane is 'impermeable' to Na^+ and K^+ because the Na^+/K^+-ATPase pump largely restricts Na^+ to the extracellular fluid and K^+ to the intracellular fluid. By contrast, Na^+ freely crosses the capillary wall and achieves similar concentrations in the interstitium and plasma; as a result, it does not contribute to fluid distribution between these compartments. Similarly, urea crosses both the capillary wall and the cell membrane and is osmotically inactive. Thus, the retention of urea in renal failure does not alter the distribution of the total body water.

A conclusion from these observations is that body Na^+ stores are the primary determinant of the extracellular fluid volume. Thus the extracellular volume - and therefore tissue perfusion - are maintained by appropriate alterations in Na^+ excretion. For example, if Na^+ intake is increased, the extra Na^+ will initially be added to the extracellular fluid. The associated increase in extracellular osmolality will cause water to move out of the cells, leading to extracellular volume expansion. Balance is restored by excretion of the excess Na^+ in the urine.

Distribution of different types of replacement fluids

Figure 12.2 shows the relative effects on the compartments of the addition of identical volumes of water, saline and colloid solutions. Thus, 1 L of water given intravenously as 5% dextrose is distributed equally into all compartments, whereas the same amount of 0.9% saline remains in the extracellular compartment. The latter is thus the correct treatment for extracellular water depletion - sodium keeping the water in this compartment. The addition of 1 L of colloid with its high oncotic pressure stays in the vascular compartment and is the treatment for hypovolaemia.

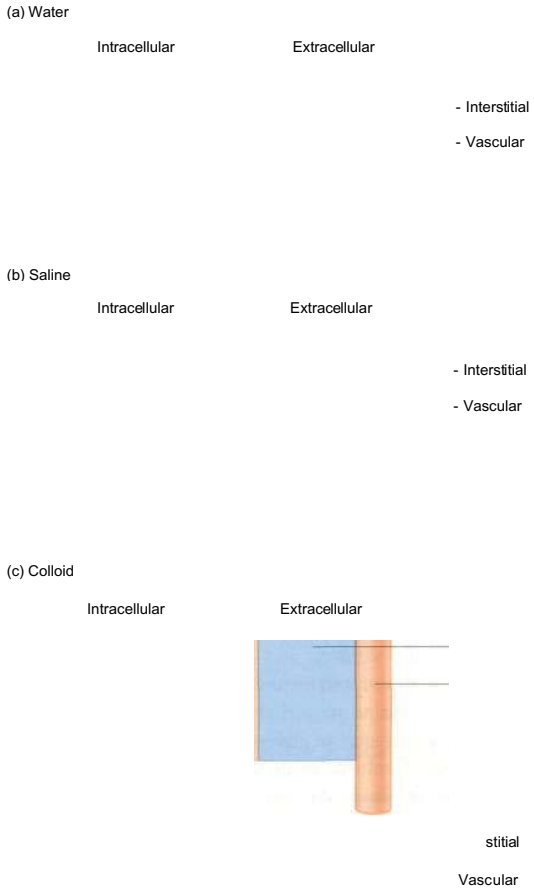

Fig. 12.2 Relative effects of the addition of 1 L of (a) water, (b) saline 0.9%, and (c) a colloid solution.

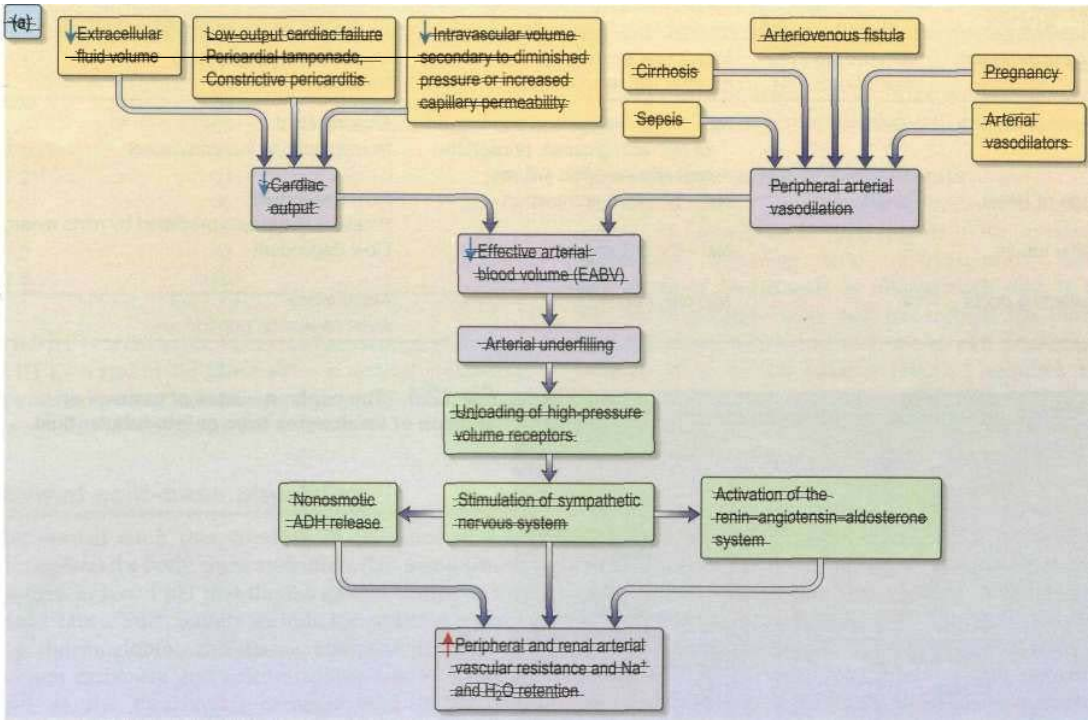
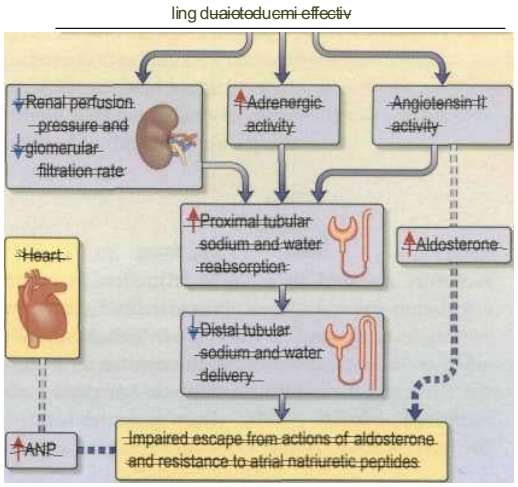
Regulation of extracellular volume (Fig. 12.3) The extracellular volume is determined by the sodium concentration. The regulation of extracellular volume is dependent upon a tight control of sodium balance, which is exerted by normal kidneys. Renal Na^+ excretion varies directly with the effective circulating volume. In a 70 kg man, plasma fluid constitutes one-third of extracellular volume (4.6 L), of which 85% (3.9 L) lies in the venous side and only 15% (0.7 L) resides in the arterial circulation. The unifying hypothesis of extracellular volume regulation in health and disease proposed by Schrier states that the fullness of the arterial vascular compartment — or the so-called effective arterial blood volume (EABV) - is the primary determinant of renal sodium and water excretion. Thus effective arterial blood volume constitutes effective circulatory volume for the purposes of body fluid homeostasis. The fullness of the arterial compartment depends upon a normal ratio between cardiac output and peripheral arterial resistance.





F/g. 12.3 (a) Sequence of events in which a decrease in cardiac output or peripheral arterial dilatation initiates renal sodium and water retention, (b) Mechanism of impaired escape from the actions of aldosterone and resistance to atrial natriuretic peptides (ANP). Modified from Schrier RW (1997) *Renal and Electrolyte Disorders,* 5th edn.

Thus, diminished EABV is initiated by a fall in cardiac output or a fall in peripheral arterial resistance (an increase in the holding capacity of the arterial vascular tree). When the EABV is expanded, the urinary Na^+ excretion is increased and can exceed 100 mmol/L. In contrast, the urine can be rendered virtually free of Na^+ in the presence of EABV depletion and normal renal function.

These changes in Na^+ excretion can result from alterations both in the filtered load, determined primarily by the glomerular filtration rate (GFR), and in tubular reabsorption, which is affected by multiple factors. In general, it is changes in tubular reabsorption that constitute the main adaptive response to fluctuations in the effective circulating volume. How this occurs can be appreciated from Table 12.2 and Figure 12.4, which depicts the sites and determinants of segmental Na^+ reabsorption. Although the loop of Henle and distal tubule make a major overall contribution to net Na^+ handling, transport in these segments primarily varies with the amount of Na^+ delivered; that is, reabsorption is flow-dependent. In comparison, the neurohumoral regulation of Na^+ reabsorption according to body needs occurs primarily in the proximal and collecting tubules.

Table 12.2 **Mechanisms of sodium transport in the various nephron segments**

Tubule segment	Filtered Na^+ reabsorbed (%)	Major mechanism of luminal Na^+ entry	Major factors regulating transport
Proximal tubule	60-70	Na^+ - H^+ exchange and cotransport of Na^+ with glucose, phosphate and other organic solutes	Angiotensin Norepinephrine (noradrenaline)
Loop of Henle	20-25	Na^+-K^+- 2Cr cotransport	Flow dependent Pressure natriuresis mediated by nitric oxide
Distal tubule	5	Na^+-Cl" cotransport	Flow dependent
Collecting ducts	4	Na^+ channels	Aldosterone Atrial natriuretic peptide

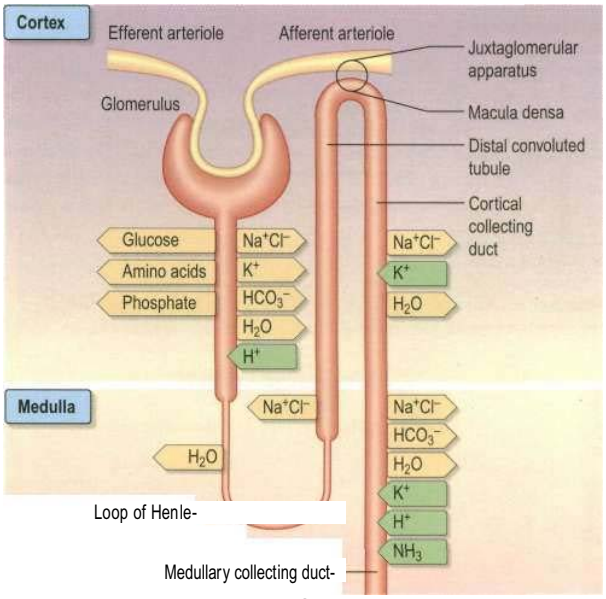


Fig 12.4 **The nephron - sites of removal or addition of electrolytes from or into tubular fluid.**

Neurohumoral regulation of extracellular volume

This is mediated by volume receptors that sense changes in the EABV rather than alterations in the sodium concentration. These receptors are distributed in both the renal and cardiovascular tissues.

- *Intmrenal receptors.* Receptors in the walls of the afferent glomerular arterioles respond, via the juxta-glomerular apparatus, to changes in renal perfusion, and control the activity of the renin—angiotensin—aldosterone system (p. 1096). In addition, sodium con centration in the distal tubule and sympathetic nerve activity alter renin release from the juxtaglomerular cells. Prostaglandins I_2 and E_2 are also generated within the kidney in response to angiotensin II, acting to maintain glomerular filtration rate and sodium and water excretion, modulating the sodium-retaining effect of this hormone.
- *Extrarenal receptors.* These are located in the vascular tree in the left atrium and major thoracic veins, and in the carotid sinus body and aortic arch. These volume receptors respond to a slight reduction in effective circulating volume and result in increased sympathetic nerve activity and a rise in catecholamines. In addition, volume receptors in the cardiac atria control the release of a powerful natriuretic hormone - atrial natriuretic peptide (ANP) - from granules located in the atrial walls (p. 1096).

High-pressure arterial receptors (carotid, aortic arch, juxtaglomerular apparatus) predominate over low-pressure volume receptors in volume control in mammals. The low-pressure volume receptors are distributed in thoracic tissues (cardiac atria, right ventricle, thoracic veins, pulmonary vessels) and their role in the volume regulatory system is marginal.

Aldosterone and possibly atrial natriuretic peptide (ANP) are responsible for day-to-day variations in Na^+ excretion, by their respective ability to augment and diminish Na^+ reabsorption in the collecting ducts.

- A *salt load,* for example, leads to an increase in the effective circulatory and extracellular volume, raising

both renal perfusion pressure, and atrial and arterial filling pressure. The increase in the renal perfusion pressure reduces the secretion of renin, and subsequently that of angiotensin II and aldosterone (Fig. 18.27), whereas the rise in atrial and arterial filling pressure increases the release of ANP. These factors combine to reduce Na^+ reabsorption in the collecting duct, thereby promoting excretion of excess Na^+. ■ In contrast, in patients on *low Na^+ intake* or in those who become volume-depleted as a result of vomiting and diarrhoea, the ensuing decrease in effective volume enhances the activity of the renin-angiotensin-aldosterone system and reduces the secretion of ANP. The net effect is enhanced Na^+ reabsorption in the collecting ducts, which accounts for the appropriate fall in Na^+ excretion in this setting. It tends to increase the extracellular volume towards normal.

With more marked hypovolaemia, a decrease in GFR leads to an increase in proximal and thin ascending limb Na^+ reabsorption which contributes to Na^+ retention. This is brought about by enhanced sympathetic activity acting directly on kidneys and indirectly by stimulating the secretion of renin/angiotensin II (see Fig. 12.3b) and nonosmotic release of antidiuretic hormone (ADH). The pressure natriuresis phenomenon may be the final defence against changes in the effective circulating volume. Marked persistent hypovolaemia leads to systemic hypotension and increased salt and water absorption in the proximal tubules and ascending limb of Henle. This process may be mediated by changes in renal interstitial hydrostatic pressure and local prostaglandin and nitric oxide production.

Volume regulation in oedematous conditions

Sodium and water are retained despite increased extracellular volume in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia. Here the principal mediator of salt and water retention is the concept of arterial underfilling due either to reduced cardiac output or diminished peripheral arterial resistance. Arterial underfilling in these settings leads to reduction of pressure or stretch (i.e. 'unloading' of arterial volume receptors) which results in activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone system and nonosmotic release of antidiuretic hormone (ADH). These neurohumoral mediators promote salt and water retention in the face of increased extracellular volume. The common nature of the degree of arterial fullness and neurohumoral pathway in the regulation of extracellular volume in health and disease states forms the basis of Schrier's unifying hypothesis of volume homeostasis (Fig. 12.3a).

Mechanism of impaired escape from actions of aldosterone and resistance to ANP

Not only is the activity of the renin-angiotensin-aldosterone system increased in oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia, but also the action of aldosterone is more persistent than in normal subjects and patients with Conn's syndrome, who have increased aldosterone secretion (p. 1097). In normal subjects, high doses of mineralocorticoids initially increase renal sodium retention so that the extracellular volume is increased by 1.5-2 litres. However, renal sodium retention then ceases, sodium balance is re-established, and there is no detectable oedema. This escape from mineralocorticoid-mediated sodium retention explains why oedema is not a characteristic feature of primary hyperaldosteronism (Conn's syndrome). The escape is dependent on an increase in delivery of sodium to the site of action of aldosterone in the collecting ducts. The increased distal sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal tubules and increased distal sodium delivery which overwhelms the sodium-retaining actions of aldosterone.

In patients with oedematous conditions such as cardiac failure, hepatic cirrhosis and hypoalbuminaemia escape from the sodium-retaining actions of aldosterone does not occur and therefore they continue to retain sodium in response to aldosterone. Accordingly they have substantial natriuresis when given spironolactone, which blocks mineralocorticoid receptors. Alpha-adrenergic stimulation and elevated angiotensin II increase sodium transport in the proximal tubule, and reduced renal hypoperfusion and GFR further increase sodium absorption from the proximal tubules by presenting less sodium and water in the tubular fluid. Sodium delivery to the distal portion of the nephron, and thus the collecting duct, is reduced. Similarly, increased cardiac ANP release in these conditions requires optimum sodium concentration at the site of its action in the collecting duct for its desired natriuretic effects. Decreased sodium delivery to the collecting duct is therefore the most likely explanation for the persistent aldosterone-mediated sodium retention, absence of escape phenomenon and resistance to natriuretic peptides in these patients (Fig. 12.3b).

Regulation of water excretion

Body water homeostasis is effected by thirst and the urine concentrating and diluting functions of the kidney. These in turn are controlled by intracellular osmoreceptors, principally in the hypothalamus, to some extent by volume receptors in capacitance vessels close to the heart, and via the renin-angiotensin system. Of these, the major and best-understood control is via osmoreceptors. Changes in the plasma Na^+ concentration and osmolality are sensed by osmoreceptors that influence both thirst and the release of ADH (also called vasopressin) from the supraoptic and paraventricular nuclei.

ADH plays a central role in urinary concentration by increasing the water permeability of the normally impermeable cortical and medullary collecting ducts. The ability of ADH to increase the urine osmolality is related

indirectly to transport in the ascending limb of the loop of Henle, which reabsorbs NaCl without water. This process, which is the primary step in the countercurrent mechanism, has two effects: it makes the tubular fluid dilute and the medullary interstitium concentrated. In the absence of ADH, little water is reabsorbed in the collecting ducts, and a dilute urine is excreted. In contrast, the presence of ADH promotes water reabsorption in the collecting ducts down the favourable osmotic gradient between the tubular fluid and the more concentrated interstitium. As a result, there is an increase in urine osmolality and a decrease in urine volume.

The cortical collecting duct has two cell types (see also p. 714) with very different functions:

- *Principal cells* (about 65%) have sodium and potassium channels in the apical membrane and, as in all sodium-reabsorbing cells, Na^+/K^+-ATPase pumps in the basolateral membrane.
- *Intercalated cells,* in comparison, do not transport NaCl (since they have a lower level of Na^+/K^+-ATPase activity) but play a role in hydrogen and bicarbonate handling and in potassium reabsorption in states of potassium depletion.

The ADH-induced increase in collecting duct water permeability occurs primarily in the principal cells. ADH acts on V2 (vasopressin) receptors located on the basolateral surface of principal cells, resulting in the activation of adenyl cyclase. This leads to protein kinase activation and to preformed cytoplasmic vesicles that contain unique water channels (called aquaporins) moving to and then being inserted into the luminal membrane. The water channels span the luminal membrane and permit water movement into the cells down a favourable osmotic gradient (Fig. 12.5). This water is then rapidly returned to the systemic circulation across the basolateral membrane. When the ADH effect has worn off, the water channels aggregate within clathrin-coated pits, from which they are removed from the luminal membrane by endocytosis and returned to the cytoplasm. A defect in any step in this pathway, such as in attachment of ADH to its receptor or the function of the water channel, can cause resistance to the action of ADH and an increase in urine output. This disorder is called *nephrogenic diabetes insipidus*.

Plasma osmolality

In addition to influencing the rate of water excretion, ADH plays a central role in osmoregulation because its release is directly affected by the plasma osmolality. At a plasma osmolality of less than 275 mOsm/kg, which usually represents a plasma Na^+ concentration of less than 135-137 mmol/L, there is essentially no circulating ADH. As the plasma osmolality rises above this threshold, however, the secretion of ADH increases progressively.

Two simple examples will illustrate the basic mechanisms of osmoregulation, which is so efficient that the plasma Na^+ concentration is normally maintained within 1-2% of its baseline value.

Ingestion of a water load leads to an initial reduction in the plasma osmolality, thereby diminishing the release of

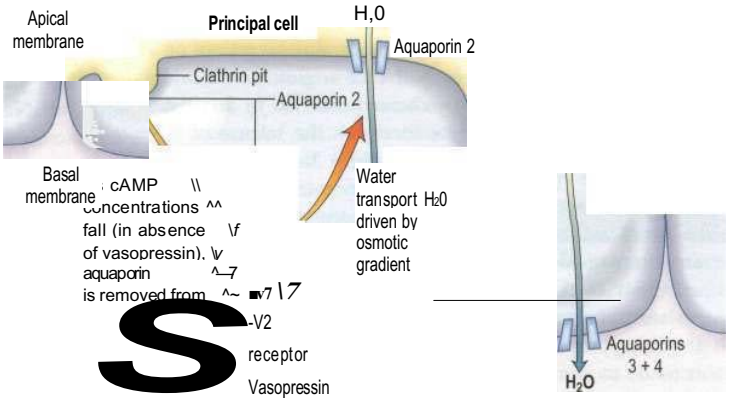

Fig. 12.5 **Aquaporin-mediated water transport in the renal collecting duct.** Stimulation of the vasopressin 2 receptor causes cAMP-mediated insertion of the aquaporin into the apical membrane, allowing water transport down the osmotic gradient. Adapted from Connolly DL, Shanahan CM, Weissberg PL (1996) *Lancet* **347:** 211.

ADH. The ensuing reduction in water reabsorption in the collecting ducts allows the excess water to be excreted in a dilute urine.

Water loss resulting from sweating is followed by, in sequence, a rise in both plasma osmolality and ADH secretion, enhanced water reabsorption, and the appropriate excretion of a small volume of concentrated urine. This renal effect of ADH minimizes further water loss but does not replace the existing water deficit. Thus, optimal osmoregulation requires an increase in water intake, which is mediated by a concurrent stimulation of thirst. The importance of thirst can also be illustrated by studies in patients with central diabetes insipidus, who are deficient in ADH. These patients often complain of marked polyuria, which is caused by the decline in water reabsorption in the collecting ducts. However, they do not typically become hypernatraemic, because urinary water loss is offset by the thirst mechanism.

Osmoregulation versus volume regulation

A common misconception is that regulation of the plasma Na^+ concentration is closely correlated with the regulation of Na^+ excretion. However, it is related to volume regulation, which has different sensors and effectors (volume receptors) from those involved in water balance and osmoregulation (osmoreceptors).

The roles of these two pathways should be considered separately when evaluating patients.

- *A water load* is rapidly excreted (in 4-6 hours) by inhibition of ADH release. This process is normally so efficient that volume regulation is not affected and there is no change in ANP release or in the activity of the renin-angiotensin-aldosterone system. Thus, a

dilute urine is excreted, and there is little alteration in the excretion of Na^+.

- *Isotonic saline* administration, in contrast, causes an increase in volume but no change in plasma osmolality. In this setting, ANP secretion is increased, aldosterone secretion is reduced, and ADH secretion does not change. The net effect is the appropriate excretion of the excess Na^+ in a relatively iso-osmotic urine.

In some cases, both volume and osmolality are altered and both pathways are activated. For example, if a person with normal renal function eats salted potato chips and peanuts without drinking any water, the excess Na^+ will increase the plasma osmolality, leading to osmotic water movement out of the cells and increased extracellular volume. The rise in osmolality will stimulate both ADH release and thirst (the main reason why many restaurants and bars supply free salted foods), whereas the hypervolaemia will enhance the secretion of ANP and suppress that of aldosterone. The net effect is increased excretion of Na^+ without water.

This principle of separate volume and osmoregulatory pathways is also evident in the syndrome of inappropriate ADH secretion (SIADH). Patients with SIADH (p. 1091) have impaired water excretion and hyponatraemia caused by the persistent presence of ADH. However, the release of ANP and aldosterone is not impaired and, thus, Na^+ handling remains intact. These findings have implications for the correction of the hyponatraemia in this setting and require restriction of water intake.

ADH is also secreted by nonosmotic stimuli such as stress (e.g. surgery, trauma), markedly reduced effective circulatory volume (cardiac failure, hepatic cirrhosis), psychiatric disturbance, and nausea, irrespective of plasma osmolality. This is mediated by the effects of sympathetic overactivity on supraoptic and paraventricular nuclei. In addition to water retention, ADH release in these conditions promotes vasoconstriction owing to the activation of VI (vasopressin) receptors distributed in the vascular tissue.

Regulation of cell volume

Maintenance of a constant volume in the face of extracellular and intracellular osmotic alterations is a critical problem faced by all cells. Most cells respond to swelling or shrinkage by activating specific metabolic or membrane-transport processes that return cell volume to its normal resting state. Within minutes after exposure to hypotonic solutions and resulting cell swelling, a common feature of many cells is the increase in plasma membrane potassium and chloride conductance. Although extrusion of intracellular potassium certainly contributes to a regulatory volume decrease, the role of chloride efflux itself is modest, given the relatively low intracellular chloride concentration. Indeed other intracellular osmolytes, such as taurine and other amino acids, are transported out of the cell to achieve a regulatory volume decrease. In contrast, these regulatory mechanisms are operative in reverse to protect cell volume under hypertonic conditions, as is the case in the renal medulla. The tubular cells at the tip of renal papillae, which are constantly exposed to a hypertonic extracellular milieu, maintain their cell volume on a long-term basis by actively taking up smaller molecules, such as betaine, taurine and myoinositol, and by synthesizing more sorbitol and glycerophosphocholine.

Increased extracellular volume

Increased extracellular volume occurs in numerous disease states. The physical signs depend on the distribution of excess volume and on whether the increase is local or systemic. According to Starling principles, distribution depends on:

- venous tone, which determines the capacitance of the blood compartment and thus hydrostatic pressure
- capillary permeability
- oncotic pressure - mainly dependent on serum albumin
- lymphatic drainage.

Depending on these factors, fluid accumulation may result in expansion of interstitial volume, blood volume, or both.

Clinical features

Peripheral oedema is caused by expansion of the extracellular volume by at least 2 L (15%). The ankles are normally the first part of the body to be affected, although they may be spared in patients with lipodermatosclerosis (where the skin is tethered and cannot expand to accommodate the oedema). Oedema may be noted in the face, particularly in the morning. In a patient in bed, oedema may accumulate in the sacral area. Expansion of the interstitial volume also causes pulmonary oedema, pleural effusion, pericardial effusion and ascites. Expansion of the blood volume (overload) causes a raised jugular venous pressure, cardiomegaly, added heart sounds, basal crackles as well as a raised arterial blood pressure in certain circumstances.

Causes

Extracellular volume expansion is due to sodium chloride retention. Increased salt intake does not normally cause volume expansion because of rapid homeostatic mechanisms which increase salt excretion. However, a rapid intravenous infusion of a large volume of saline will cause volume expansion. Thus, most causes of extracellular volume expansion are associated with renal sodium chloride retention.

Heart failure

Reduction in cardiac output and the consequent fall in effective circulatory volume and-arterial filling lead to activation of the renin-angiotensin-aldosterone system, nonosmotic release of ADH, and increased activity of the renal sympathetic nerves via volume receptors and baroreceptors (Fig. 12.3a). Sympathetic overdrive also indirectly augments ADH and renin-angiotensin-aldosterone response in these conditions. The cumulative

effect of these mediators results in increased peripheral and renal arteriolar resistance and water and sodium retention. These factors result in extracellular volume expansion and increased venous pressure, causing oedema formation.

Hepatic cirrhosis

The mechanism is again complex, but involves peripheral vasodilatation (possibly owing to increased nitric oxide generation) resulting in reduced effective arterial blood volume (EABV) and arterial filling. This leads to an activation of a chain of events common to cardiac failure and other conditions with marked peripheral vasodilatation (Fig. 12.3a and b). The cumulative effect results in increased peripheral and renal resistance, water and sodium retention, and oedema formation.

Nephrotic syndrome

Interstitial oedema is a common clinical expression of hypoalbuminaemia and particularly nephrotic syndrome. Expansion of the interstitial compartment is secondary to the accumulation of sodium in the extracellular compartment. This is due to an imbalance between oral (or parenteral) sodium intake and urinary sodium output, as well as alterations of fluid transfer across capillary walls. The intrarenal site of sodium retention is the cortical collecting duct (CCD) where Na^+/K^+-ATPase expression and activity are increased threefold along the basolateral surface (Fig. 12.4). In addition, amiloride-sensitive epithelial sodium channel activity is also increased in the CCD. The renal sodium retention should normally be counterbalanced by increased secretion of sodium in the inner medullary collecting duct, brought about by the release of ANP. This regulatory pathway is curtailed in patients with nephrotic syndrome by enhanced catabolism of cyclic GMP (the second messenger for ANP) following phosphodiesterase activation.

Oedema generation was classically attributed to the decrease in the plasma oncotic pressure and the subsequent increase in transcapillary oncotic gradient. However, the oncotic pressure and transcapillary oncotic gradient remain unchanged and the transcapillary hydrostatic pressure gradient is not altered. Conversely, capillary hydraulic conductivity (a measure of permeability) is increased. This is determined by intercellular macromolecular complexes between the endothelial cells consisting of tight junctions (made of occludins, claudins and ZO proteins) and adherens junctions (made of cadherin, catenins and actin cytoskeleton). It seems that elevated TNF-cx levels in nephrotic syndrome activate protein kinase C, which changes phosphorylation of occludin and capillary permeability. In addition, increased circulating ANP can increase capillary hydraulic conductivity by altering the permeability of intercellular junctional complexes. Furthermore, reduction in effective circulatory volume and the consequent fall in cardiac output and arterial filling can lead to a chain of events as in cardiac failure and cirrhosis (see above and Fig. 12.3). These factors result in extracellular volume expansion . and oedema formation.

Sodium retention

A decreased GFR decreases the renal capacity to excrete sodium. This may be acute, as in the acute nephritic syndrome (p. 629), or may occur as part of the presentation of chronic renal failure. In end-stage renal failure, extracellular volume is controlled by the balance between salt intake and its removal by dialysis.

Numerous drugs may cause renal sodium retention, particularly in patients whose renal function is already impaired:

- *Oestrogens* cause mild sodium retention, which has a weak aldosterone-like effect. This is the cause of weight gain in the premenstrual phase.
- *Minemlocorticoids and liquorice* (the latter potentiates the sodium-retaining action of cortisol) have aldosterone-like actions.
- *NSAIDs* cause sodium retention in the presence of activation of the renin-angiotensin-aldosterone system by heart failure, cirrhosis and in renal artery stenosis.

Substantial amounts of sodium and water may accumulate in the body without clinically obvious oedema or evidence of raised venous pressure. In particular, several litres may accumulate in the pleural space or as ascites; these spaces are then referred to as 'third spaces'. Bone may also act as a 'sink' for sodium and water.

Other causes of oedema

m Initiation of insulin treatment for type 1 diabetes and refeeding after malnutrition are both associated with the development of transient oedema. The mechanism is complex.

- Oedema may result from increased capillary pressure owing to relaxation of precapillary arterioles. The best example is the peripheral oedema caused by dihydropyridine calcium-channel blockers such as nifedipine.
- Oedema may be caused by increased interstitial oncotic pressure as a result of increased capillary permeability to proteins. This can occur as part of a rare complement-deficiency syndrome; with therapeutic use of interleukin-2 in cancer chemotherapy; or in ovarian hyperstimulation syndrome (p. 1061).

Idiopathic oedema of women

This, by definition, occurs in women without heart failure, hypoalbuminaemia, renal or endocrine disease. Oedema is intermittent and often worse in the premenstrual phase. The condition remits after the menopause. Patients complain of swelling of the face, hands, breasts and thighs, and a feeling of being bloated. Sodium retention during the day and increased sodium excretion during recumbency are characteristic; an abnormal fall in plasma volume on standing caused by increased capillary permeability to proteins may be the cause of this. The oedema may respond to diuretics, but returns when they

are stopped. A similar syndrome of diuretic-dependent sodium retention can be caused by abuse of diuretics, for instance as part of an attempt to lose weight; but not all women with idiopathic oedema admit to having taken diuretics, and the syndrome was described before diuretics were introduced for clinical use.

Local increase in oedema

This does not reflect disturbances of extracellular volume control per se, but can cause clinical confusion. Examples are ankle oedema due to venous damage following thrombosis or surgery, ankle or leg oedema due to immobility, oedema of the arm due to subclavian thrombosis, and facial oedema due to superior vena caval obstruction. Local loss of oncotic pressure may result from increased capillary permeability to proteins, caused by inflammatory mediators such as histamine and interleukins (e.g. a bee sting). Lastly, local loss of lymphatic drainage causes lymphoedema (see p. 1356).

Treatment

The underlying cause should be treated where possible. Heart failure, for example, should be treated, and offending drugs such as NSAIDs withdrawn.

Sodium restriction has only a limited role, but is useful in patients who are resistant to diuretics. Sodium intake can easily be reduced to approximately 100 mmol daily; reductions below this are often difficult to achieve without affecting the palatability of food.

Manoeuvres that increase venous return stimulate salt and water excretion by effects on cardiac output and ANP release. This is the rationale for strict bed rest in congestive cardiac failure. Water immersion also causes redistribution of blood towards the central veins, but is seldom of practical use. Venous compression stockings or bandages may help to mobilize oedema in heart failure.

The mainstay of treatment is the use of diuretic agents, which increase sodium, chloride and water excretion in the kidney (Table 12.3). These agents act by interfering with membrane ion pumps which are present on numerous cell types; they mostly achieve specificity for the kidney by being secreted into the proximal tubule, resulting in much higher concentrations in the tubular fluid than in other parts of the body.

Clinical use of diuretics *Loop diuretics* (see Kg. 12.6, p. 705) These potent diuretics are useful in the treatment of any cause of systemic extracellular volume overload. They stimulate excretion of both sodium chloride and water by blocking the sodium-potassium-2-chloride channel in the thick ascending limb of Henle and are useful in stimulating water excretion in states of relative water overload. They also act by causing increased venous capacitance, resulting in rapid clinical improvement in patients with left ventricular failure, preceding the diuresis. Unwanted effects include:

- urate retention causing gout
- hypokalaemia
- hypomagnesaemia ,
- decreased glucose tolerance
- allergic tubulo-interstitial nephritis and other allergic reactions
- myalgia - especially with bumetanide
- ototoxicity (due to an action on sodium pump activity in the inner ear) — particularly with furosemide (frusemide)

Table 12.3 **Types and clinical uses of diuretics**

Class	Major action	Examples	Clinical uses	Potency
Loop diuretics	4 Na^+-Cl -K^+ cotransport in thick ascending limb of loop of Henle	Furosemide Bumetanide Torasemide	Volume overload (CCF, nephrotic syndrome, CRF) ?Acute renal failure SIADH	+4
Thiazide and related diuretics	4 Na^+-Cl cotransport in early distal convoluted tubule	Bendroflumethiazide Chlortalidone Metolazone Indapamide	Hypertension Volume overload (CCF) Hypercalciuria	++
Potassium sparing	4 Na^+ reabsorption (in exchange for K^+) in collecting duct (principal cells)	Aldosterone antagonist, e.g. spironolactone, eperenone Others: amiloride triamterene Acetazolamide	Hyperaldosteronism (primary and secondary) Barrier's syndrome Heart failure Cirrhosis with fluid overload Prevention of K^+ deficiency in combination with loop or thiazide Metabolic alkalosis	+
Carbonic anhydrase inhibitors	4 Na^+ HCO_3 reabsorption in proximal collecting duct 4 Aqueous humour formation		Glaucoma	+

CCF, congestive cardiac failure; CRF, chronic renal failure; SIADH, syndrome of inappropriate antidiuretic hormone secretion

interference with excretion of lithium, resulting in toxicity.

In most situations there is little to choose between the drugs in this class. Bumetanide has a better oral bioavailability than furosemide, particularly in patients with severe peripheral oedema, and has more beneficial effects than furosemide on venous capacitance in left ventricular failure. It can cause severe muscle cramps when used in high doses.

Thiazide diuretics (see Fig. 12.7, p. 706) These are less **potent than** loop diuretics. They act by blocking a sodium chloride channel in the distal convoluted tubule They cause relatively more urate retention, glucose intolerance and hypokalaemia than loop diuretics. They interfere with water excretion and may cause hyponatraemia, particularly if combined with amiloride or triamterene. This effect is clinically useful in diabetes insipidus. Thiazides reduce peripheral vascular resistance by mechanisms that are not completely understood but do not appear to depend on their diuretic action, and are widely used in the treatment of essential hypertension. They are also used extensively in mild to moderate cardiac failure. Thiazides reduce calcium excretion. This effect is useful in patients with idiopathic hypercalciuria, but may cause hypercalcaemia. Numerous agents are available, with varying half-lives but little else to choose between them. Metolazone is not dependent for its action on glomerular filtration, and therefore retains its potency in renal impairment.

Potassium-sparing diuretics (see Fig. 12.8) These are relatively weak and are most often used in combination with thiazides or loop diuretics to prevent potassium depletion. They are of two types.

- *Aldosterone antagonists,* which compete withaldosterone in the collecting ducts and reduce sodium absorption, e.g. spironolactone and eplerenone (which has a shorter half-life). Spironolactone is used in patients with heart failure because it significantly reduces the mortality in these patients by antagonizing the fibrotic effect of aldosterone on the heart. Eplerenone, which is devoid of antiandrogenic or antiprogesterone properties, is likely to be used as the first-line aldosterone antagonist in the future.
- *Amiloride and triamterene* inhibit sodium uptake by blocking epithelial sodium channels in the collecting duct and reduce renal potassium excretion by reducing lumen-negative transepithelial voltage. They are mainly used as potassium sparing agents with thiazide or loop diuretics.

Carbonic anhydrase inhibitors
These are relatively weak diuretics and are seldom used except in the treatment of glaucoma. They may cause metabolic acidosis and hypokalaemia.

Aquaretics (vasopressin or ADH receptor blockers)
Vasopressin V2 receptor antagonists may become very useful agents in the treatment of conditions associated with elevated levels of vasopressin, such as heart failure, cirrhosis and SIADH (see p. 1091). Non-peptide vasopressin V2 receptor antagonists are efficacious in producing free water diuresis in humans. Studies in patients with heart failure and cirrhosis suggest that such agents will allow normalization of serum osmolality with less water restriction. Additional benefits of combined VI and V2 **receptor antagonism** in **heart** failure are possible but remain unproven in patients. Safe use of these agents will require avoidance in hypovolaemic patients and caution with regard to rate of correction of dilutional hyponatraemia commonly present in heart failure and cirrhosis.

Resistance to diuretics

Resistance may occur as a result of:

- poor bioavailability
- reduced GFR, which may be due to decreased circulating volume despite oedema (e.g. nephrotic syndrome, local causes of oedema) or intrinsic renal disease
- activation of sodium-retaining mechanisms, particularly aldosterone.

Management. Intravenous administration may establish a diuresis. High doses of loop diuretics may be required to achieve adequate concentrations in the tubule if GFR is depressed. However, the daily dose of furosemide (frusemide) must be limited to a maximum of 2 g for an adult, because of ototoxicity. *Intravenous albumin* solutions restore plasma oncotic pressure temporarily in the nephrotic syndrome and may allow mobilization of oedema but fail to potentiate the natriuretic effect of loop diuretics.

Combinations of various classes of diuretics are extremely helpful in patients with resistant oedema. A loop diuretic plus a thiazide inhibit two major sites of sodium reabsorption; this effect may be further potentiated by addition of a potassium-sparing agent. Metolazone in combination **with** a loop diuretic is **particularly useful in** refractory congestive cardiac failure, because its action is less dependent on glomerular filtration. However, this potent combination can cause severe electrolyte imbalance. Both aminophylline and dopamine increase renal blood flow and may be useful in refractory cardiogenic sodium retention. In addition, theophyllines, by inhibiting phosphodiesterase activity in the inner medullary collecting duct, prolong the action of cyclic GMP (a second messenger of ANP).

Effects on renal function

All diuretics may increase plasma urea concentrations by increasing urea reabsorption in the medulla. Thiazides may also promote protein breakdown. In certain situations diuretics may also decrease GFR:

- Excessive diuresis may cause volume depletion and prerenal failure.
- Diuretics may cause allergic tubulo-interstitial nephritis.

- Thiazides may directly cause a drop in GFR; the mechanism is complex and not fully understood.

Decreased extracellular volume

Deficiency of sodium and water causes shrinkage both of the interstitial space and of the blood volume and may have profound effects on organ function.

Clinical features

Symptoms are variable. Thirst, muscle cramps, nausea and vomiting, and postural dizziness may occur. Severe depletion of circulating volume causes hypotension and impairs cerebral perfusion, causing confusion and eventual coma.

Signs can be divided into those due to loss of interstitial fluid and those due to loss of circulating volume.

- Loss *of interstitial fluid* leads to loss of skin elasticity fturgor') - the rapidity with which the skin recoils to normal after being pinched. Skin turgor decreases with age, particularly at the peripheries. The turgor over the anterior triangle of the neck or on the fore head is a very useful sign in all ages.
- Loss *of circulating volume* leads to decreased pressure in the venous and (if severe) arterial compartments. Loss of up to 1 L of extracellular fluid in an adult may be compensated for by venoconstriction and may cause no physical signs. Loss of more than this causes the following:

Postural hypotension

Normally the blood pressure rises if a subject stands up, as a result of increased venous return due to veno-constriction (this maintains cerebral perfusion). Loss of extracellular fluid (underfill) prevents this and causes a fall in blood pressure. This is one of the earliest and most reliable signs of volume depletion, as long as the other causes of postural hypotension are excluded (Table 12.4).

Low jugular venous pressure

In hypovolaemic patients, the jugular venous pulsation can be seen only with the patient lying completely flat, or even head down, because the left atrial pressure is lower than 5 cmH_2O.

Peripheral venoconstriction

This causes cold skin with empty peripheral veins, which are difficult to cannulate just when the patient needs intravenous therapy the most! This sign is often absent in sepsis, where peripheral vasodilatation contributes to effective hypovolaemia.

Tachycardia

This is not always a reliable sign. Beta-blockers and other antiarrhythmics may prevent tachycardia, and hypo-volaemia may activate vagal mechanisms and actually cause bradycardia.

Causes

Salt and water may be lost from the kidneys, from the gastrointestinal tract, or from the skin. Examples are given in Table 12.5.

In addition, there are a number of situations where signs of volume depletion occur despite a normal or increased body content of sodium and water.

- Septicaemia causes vasodilatation of both arterioles and veins, resulting in greatly increased capacitance of the vascular space. In addition, increased capillary permeability to plasma proteins leads to loss of fluid from the vascular space to the interstitium.
- Diuretic treatment of heart failure or nephrotic syn drome may lead to rapid reduction in plasma volume. Mobilization of oedema may take much longer.
- There may be inappropriate diuretic treatment of oedema (e.g. when the cause is local rather than systemic).

Investigations

Blood tests are in general not helpful in the assessment of extracellular volume. Plasma urea may be raised owing to increased urea reabsorption and, later, to prerenal failure (when the creatinine rises as well), but this is very non-specific. Urinary sodium is low if the kidneys are functioning normally, but is misleading if the cause of the volume depletion involves the kidneys (e.g. diuretics, intrinsic renal disease). Urine osmolality is high in

  chest X-ray.

volume depletion (owing to increased water reabsorption), but may also often mislead.

Treatment

The overriding principle is to aim to replace what is missing.

Haemorrhage

This involves the loss of blood. The rational treatment of acute haemorrhage is therefore the infusion of a combination of red cells and a plasma substitute or (if unavailable) whole blood. (Chronic anaemia causes salt and water retention rather than volume depletion by a mechanism common to conditions with peripheral vasodilatation.)

Loss of plasma

Loss of plasma, as occurs in burns or severe peritonitis, should be treated with human plasma or a plasma substitute (see p. 463).

Loss of water and electrolytes

Loss of water and electrolytes, as occurs with vomiting, diarrhoea, or excessive renal losses, should be treated by replacement of the loss. If possible, this should be done with oral water and sodium salts. These are available as slow sodium (600 mg, approximately 10 mmol of each Na^+ and Cl" per tablet), the usual dose of which is 6-12 tablets per day with 2-3 L of water. It is used in mild or chronic salt and water depletion, such as that associated with renal salt wasting.

Sodiumbicarbonate (500 mg, 6 mmol each of Na^+ and HCO_3" per tablet) is used in doses of 6-12 tablets per day with 2-3 L of water. This is used in milder chronic sodium depletion with acidosis (e.g. chronic renal failure, post-obstructive renal failure, renal tubular acidosis). Sodium bicarbonate is less effective than sodium chloride in causing positive sodium balance.

Oral rehydration solutions are described in Box 2.9 (see p. 71). Intravenous fluids may sometimes be required (Table 12.6). Rapid infusion (e.g. 1000 mL per hour or even faster) is necessary if there is hypotension and evidence of impaired organ perfusion (e.g. oliguria, confusion); in these situations, plasma expanders (colloids) are often used in the first instance to restore an adequate circulating volume (see p. 974). Repeated clinical assessments are vital in this situation, usually complemented by frequent measurements of central venous pressure (see Ch. 15, p. 968, for the management of shock). Severe hypovolaemia induces venoconstriction, which maintains venous return; over-rapid correction does not give time for this to reverse, resulting in signs of circulatory overload (e.g. pulmonary oedema) even if a total body ECF deficit remains. In less severe ECF depletion (such as in a patient with postural hypotension complicating acute tubular necrosis), the fluid should be replaced at a rate of 1000 mL every 4—6 hours, again with repeated clinical assessment. If all that is required is avoidance of fluid depletion during surgery, 1-2 L may be given over 24 hours, remembering that surgery is a stimulus to sodium and water retention and that over-replacement may be as dangerous as under-replacement. Regular monitoring by fluid balance charts, bodyweight and plasma biochemistry is mandatory.

Loss of water alone

This causes extracellular volume depletion only in severe cases, because the loss is spread evenly among all the compartments of body water. In the rare situations where there is a true deficiency of water alone, as in diabetes insipidus or in a patient who is unable to drink (after surgery, for instance), the correct treatment is to give water.

If intravenous treatment is required, water is given as 5% dextrose, because pure water would lead to osmotic lysis of blood cells.

***Table 12.6* Intravenous fluids in general use for fluid and electrolyte disturbances**

	Na^+ (mmol/L)	K^+ (mmol/L)	HCO_3" (mmol/L)	Cr (mmol/L)	Indication (see footnote)
		4.5		**103**	
Normal plasma values	142		26	**150**	**1**
Sodium chloride 0.9%	150			**30**	**2**
Sodium chloride 0.18% + glucose 4%	30			**40**	**3**
Glucose 5% + potassium chloride 0.3%		40			**4**
Sodium bicarbonate 1.26%	150		150		

1. Volume expansion in hypovolaemic patients. Rarely to maintain fluid balance when there are large losses of sodium. The sodium (150 mmol/L) is higher than in plasma and hypernatraemia can result. It is often necessary to add KCl 20-40 mmol/L.
2. Maintenance of fluid balance in normovolaemic, normonatraemic patients.
3. To replace *water*. Can be given with or without potassium chloride. May be alternated with 0.9% saline as an alternative to (2).
4. For volume expansion in hypovolaemic, acidotic patients alternating with (1). Occasionally for maintenance of fluid balance combined with (2) in salt-wasting, acidotic patients.

DISORDERS OF SODIUM CONCENTRATION

These are best thought of as disorders of body water content. As discussed above, sodium content is regulated by volume receptors; water content is adjusted to maintain, in health, a normal osmolality and (in the absence of abnormal osmotically active solutes) a normal sodium concentration. Disturbances of sodium concentration are caused by disturbances of water balance.

HYPONATRAEMIA

Hyponatraemia (Na < 135 mmol/L) is one of the most common abnormalities detected in biochemistry laboratories. It may be associated with normal extracellular volume and total body sodium content (Table 12.7). The differential diagnosis of hyponatraemia depends on an assessment of extracellular volume.

Rarely, hyponatraemia may be a 'pseudo-hyponatraemia'. This occurs in hyperlipidaemia (either high cholesterol or high triglyceride) or hyperproteinaemia where there is a spuriously low measured sodium concentration, the sodium being confined to the aqueous phase but having its concentration expressed in terms of the total volume of plasma. In this situation, plasma osmolality is normal and therefore treatment of 'hyponatraemia' is unnecessary. Artefactual 'hyponatraemia' caused by taking blood from the limb into which fluid of low sodium concentration is being infused should be excluded!

Salt-deficient hyponatraemia

This is due to salt loss in excess of water; the causes are listed in Table 12.8. In this situation, ADH secretion is initially suppressed (via the hypothalamic osmoreceptors); but as fluid volume is lost, volume receptors override the osmoreceptors and stimulate both thirst and the release of ADH. This is an attempt by the body to defend circulating volume at the expense of osmolality.

Table 12.7 **Causes of hyponatraemia with normal extracellular volume**

Abnormal ADH release
Vagal neuropathy (failure of inhibition of ADH release)
Deficiency of adrenocorticotrophic hormone (ACTH) or glucocorticoids (Addison's disease)
Hypothyroidism Severe potassium depletion

Syndrome of inappropriate antidiuretic hormone (see Table 18.36)

Major psychiatric illness
'Psychogenic polydipsia'
Nonosmotic ADH release?
Antidepressant therapy

Increased sensitivity to ADH
Chlorpropamide
Tolbutamide

ADH-like substances
Oxytocin
Desmopressin

Unmeasured osmotically active substances stimulating osmotic ADH release
Glucose
Chronic alcohol abuse
Mannitol
Sick-cell syndrome (leakage of intracellular ions)

Table 12.8 **Causes of hyponatraemia with decreased extracellular volume**

Gut	Kidney
Vomiting	Osmotic diuresis (e.g. hyperglycaemia, severe uraemia)
Diarrhoea	Excessive use of diuretics
Haemorrhage	Adrenocortical insufficiency Tubulo-interstitial renal disease Unilateral renal artery stenosis Recovery phase of acute tubular necrosis

With extrarenal losses and normal kidneys, the urinary excretion of sodium falls in response to the volume depletion, as does water excretion, leading to concentrated urine containing less than 10 mmol/L of sodium. However, in salt-wasting kidney disease, renal compensation cannot occur and the only physiological protection is increased water intake in response to thirst.

Clinical features

With sodium depletion the clinical picture is usually dominated by features of volume depletion (see p. 699). The diagnosis is usually obvious where there is a history of gut losses, diabetes mellitus or diuretic abuse.

Table 12.9 shows the potential daily losses of water and electrolytes from the gut. Losses due to renal or adrenocortical disease may be less easily identified and are suggested by a urinary sodium concentration of more than 20 mmol/L in the presence of clinically evident volume depletion.

Treatment

This is directed at the primary cause whenever possible.
In a healthy patient:

m give oral electrolyte—glucose mixtures (p. 71)
■ increase salt intake with slow sodium 60-80 mmol/ day.

Table 12.9 Average concentrations and potential daily losses of water and electrolytes from the gut

	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	Volume (mL in 24 hours)
Stomach	50	10	110	2500
Small intestine				
Recent ileostomy	12	5	110	1500
Adapted ileostomy	50	4	25	500
Bile	14	5	105	500 2000
Pancreatic juice	14	5	60	1000-2000+
Diarrhoea	13	10-30	95	

In a patient with vomiting or severe volume depletion:

m give intravenous 0.9% saline with potassium supplements ■ correction of acid-base abnormalities is usually not required.

Hyponatraemia due to water excess (dilutional hyponatraemia)

This results from an intake of water in excess of the kidney's ability to excrete it. With normal kidney function, dilution hyponatraemia is uncommon even if a patient drinks approximately 1L per hour. The most common iatrogenic cause is overgenerous infusion of 5% glucose into postoperative patients; in this situation it is exacerbated by an increased ADH secretion in response to stress. Postoperative hyponatraemia is a common clinical problem (almost 1% of patients) with symptomatic hyponatraemia occurring in 20% of these patients. Marathon runners drinking excess water and 'sports drinks' can become hyponatraemic. Premenopausal females are at most risk for developing hyponatraemic encephalopathy postoperatively, with postoperative ADH values in young females being 40 times higher than in young males. To prevent hyponatraemia, avoid using hypotonic fluids postoperatively and administer isotonic saline unless otherwise clinically contraindicated. The serum sodium should be measured daily in any patient receiving continuous parenteral fluid.

Some degree of hyponatraemia is usual in acute oliguric renal failure, while in chronic renal failure it is most often due to ill-given advice to 'push' fluids. The most common presentation of hyponatraemia due to water excess is in patients with severe cardiac failure, hepatic cirrhosis or the nephrotic syndrome in which there is evidence of volume overload (Table 12.10). In all these conditions there is usually an element of reduced glomerular filtration rate with avid reabsorption of sodium and chloride in the proximal tubule. This leads to reduced delivery of chloride to the 'diluting' ascending limb of Henle's loop and a reduced ability to generate 'free water', with a consequent inability to excrete dilute urine. This is commonly compounded by the administration of diuretics that block chloride reabsorption and interfere with the dilution of filtrate either in Henle's loop (loop diuretics) or distally (thiazides).

Table 12.10 Causes of hyponatraemia with increased extracellular volume

Heart failure Liver failure Oliguric renal failure Hypoalbuminaemia

Clinical features

Dilutional hyponatraemia symptoms are common when this develops acutely. Symptoms rarely occur until the serum sodium is less than 120 mmol/L and are more usually associated with values around 110 mmol/L or lower. They are principally neurological and are due to the movement of water into brain cells in response to the fall in extracellular osmolality.

Hyponatraemic encephalopathy symptoms and signs are non-specific and include headache, confusion, and restlessness leading to drowsiness, myoclonic jerks, generalized convulsions, and eventually coma. Other features depend on the cause, such as signs of congestive cardiac failure or liver disease.

Risk factors for developing hyponatraemic encephalopathy. The brain's adaptation to hyponatraemia initially involves extrusion of blood and CSF, as well as sodium, potassium and organic osmolytes, in order to decrease brain osmolality. Various factors can interfere with successful adaptation. These factors rather than the absolute change in serum sodium predict whether a patient will suffer hyponatraemic encephalopthy. *Children* under 16 years are at increased risk due to their relatively larger brain-to-intracranial volume ratio compared to adults. *Premenopausal women* are more likely to develop encephalopthy than postmenopausal females and males because of inhibitory effects of sex hormones and the effects of vasopressin on cerebral circulation resulting in vasoconstriction and hypoperfusion of brain. *Hypoxaemia* is a major risk factor for hyponatraemic encephalopathy. Patients with hyponatraemia can develop hypoxia due to either non-cardiac pulmonary oedema or hypercapnic respiratory failure. Respiratory failure in symptomatic hyponatraemia can be of very sudden onset. Recent data have shown that hypoxia is the strongest predictor of mortality in patients with symptomatic hyponatraemia.

Investigations

No further investigation of hyponatraemia is usually necessary if it is associated with clinically detectable

extracellular volume excess. The cause of hyponatraemia with apparently normal extracellular volume is usually less obvious, and this category requires careful investigations to:

- exclude Addison's disease
- exclude hypothyroidism
- consider 'syndrome of inappropriate ADH secretion' (SIADH) and drug-induced water retention.

Remember, potassium and magnesium depletion potentiate ADH release and are causes of diuretic-associated hyponatraemia.

The syndrome of inappropriate ADH secretion is often over-diagnosed. Some causes are associated with a lower set-point for ADH release, rather than completely autonomous ADH release; an example is chronic alcohol abuse.

Treatment

The underlying cause should be corrected where possible. Most cases are simply managed by restriction of water intake (to 1000 or even 500 mL per day) with review of diuretic therapy. Magnesium and potassium deficiency must be corrected. In mild sodium deficiency, 0.9% saline given slowly is sufficient. Hypertonic saline (3%, 513mmol/L) should be used with extreme care and restricted only for patients with acute water retention in whom there are severe neurological signs, such as fits or coma. It should be given very slowly (not more than 70 mmol per hour), the aim being to increase the serum sodium by 8-10mmol/L in the first 4 hours, but the absolute change should not exceed 15-20 mmol/L over 48 hours. In general, the plasma sodium should not be corrected to greater than 125-130 mmol/L. Assuming that total body water comprises 50% of total body weight, lmL/kg of 3% sodium chloride will raise the plasma sodium by 1 mmol/L. In some cases furosemide can be used to prevent pulmonary congestion and to increase the rate of sodium correction. Hypertonic saline must *not* be given to patients who are already fluid overloaded because of the risk of acute heart failure; in this situation, 100 mL of 20% mannitol may be infused in an attempt to increase renal water excretion (see below).

If hyponatraemia has developed slowly, as it does in the majority of patients, the brain will have adapted by decreasing intracellular osmolality. A rapid rise in extracellular osmolality, particularly if there is an 'overshoot' to high serum sodium and osmolality, will result in severe shrinking of brain cells and in the syndrome of 'central pontine myelinolysis', which may be fatal. However, recent evidence suggests that the development of demyelination lesions is not associated with the rate of correction of sodium in hyponatraemic states. The factors associated with demyelination are pre-existing hypoxaemia, liver disease and CNS radiation. A new approach which holds promise in aiding the treatment of hyponatraemic encephalopathy is the use of vasopressin V2 receptor antagonists (see p. 691) which produce a free water diuresis. V2 antagonists are currently available for research purposes only.

Syndrome of inappropriate ADH secretion

This is described in Chapter 18.

HYPERNATRAEMIA

This is much rarer than hyponatraemia and nearly always indicates a water deficit. This may be due to (Table 12.11):

- impaired thirst or impaired conscious state
- pituitary diabetes insipidus (see p. 1090) (failure of ADH secretion)
- nephrogenic diabetes insipidus (failure of response to ADH)
- osmotic diuresis, e.g. diabetic ketoacidosis
- excessive loss of water through the skin or lungs.

Excessive administration of hypertonic sodium may also contribute, for example:

- excessive reliance on 0.9% (150 mmol/L) saline for volume replacement
- administration of drugs with a high sodium content (e.g. piperacillin)
- use of 8.4% sodium bicarbonate after cardiac arrest.

Hypernatraemia is always associated with increased plasma osmolality, which is a potent stimulus to thirst. None of the above cause hypernatraemia unless thirst sensation is abnormal or access to water limited. For instance, a patient with diabetes insipidus will maintain a normal serum sodium concentration by maintaining a high water intake until an intercurrent illness prevents this. Thirst is frequently deficient in elderly people, making them more prone to water depletion. Hypernatraemia may occur in the presence of normal, reduced or expanded extracellular volume, and does not necessarily imply that total body sodium is increased.

Clinical features

Symptoms of hypernatraemia are non-specific. Nausea, vomiting, fever and confusion may occur. A history of long-standing polyuria, polydipsia and thirst suggests diabetes insipidus. There may be clues to a pituitary cause. A drug history may reveal ingestion of nephrotoxic drugs. Assessment of extracellular volume status guides

Table 12.11 **Causes of hypernatraemia**

PLUS
Deficient water intake

resuscitation. Mental state should be assessed. Convulsions occur in severe hypernatraemia.

Investigations

Simultaneous urine and plasma osmolality and sodium should be measured. Plasma osmolality is high in hypernatraemia. Passage of urine with an osmolality lower than that of plasma in this situation is clearly abnormal and indicates diabetes insipidus. In pituitary diabetes insipidus, urine osmolality will increase after administration of desmopressin; the drug (a vasopressin analogue) has no effect in nephrogenic diabetes insipidus. If urine osmolality is high this suggests either an osmotic diuresis due to an unmeasured solute (e.g. in parenteral feeding) or excessive extrarenal loss of water (e.g. heat stroke).

Treatment

Treatment is that of the underlying cause, for example:

- in ADH deficiency, replace ADH in the form of desmopressin, a stable non-pressor analogue of ADH
- remember to withdraw nephrogenic drugs where possible and replace water either orally or, if necessary, intravenously.

In severe (> 170 mmol/L) hypernatraemia, 0.9% saline (150 mmol/L) should be used initially. Avoid too rapid a drop in serum sodium concentration; the aim is correction over 48 hours, as over-rapid correction may lead to cerebral oedema.

In less severe (e.g. > 150 mmol/L) hypernatraemia, the treatment is 5% dextrose or 0.45% saline; the latter is obviously preferable in hyperosmolar diabetic coma. Very large volumes - 5 L a day or more - may need to be given in diabetes insipidus.

If there is clinical evidence of volume depletion (see p. 699, this implies that there is a sodium deficit as well as a water deficit. Treatment of this is discussed on page 700.

DISORDERS OF POTASSIUM CONTENT AND CONCENTRATION

Regulation of serum potassium concentration

The usual dietary intake varies between 80 and 150 mmol daily, depending upon fruit and vegetable intake. Most of the body's potassium (3500 mmol in an adult man) is intracellular. Serum potassium levels are controlled by:

- uptake of K^+ into cells
- renal excretion
- extrarenal losses (e.g. gastrointestinal).

Uptake of potassium into cells is governed by the activity of the Na^+/K^+-ATPase in the cell membrane and by H^+ concentration.

Uptake is *stimulated* by:

- insulin
- |3-adrenergic stimulation
- theophyllines.

Uptake is *decreased* by:

- oc-adrenergic stimulation
- acidosis - K^+ exchanged for H^+ across cell membrane
- cell damage or cell death - resulting in massive K^+ release.

Renal excretion of potassium is increased by aldosterone, which stimulates K^+ and H^+ secretion in exchange for Na^+ in the collecting duct (see Fig. 12.8). Because H^+ and K^+ are interchangeable in the exchange mechanism, acidosis decreases and alkalosis increases the secretion of K^+. Aldosterone secretion is stimulated by hyperkalaemia and increased angiotensin II levels, as well as by some drugs, and this acts to protect the body against hyperkalaemia and against extracellular volume depletion. The body adapts to dietary deficiency of potassium by reducing aldosterone secretion. However, because aldosterone is also influenced by volume status, conservation of potassium is relatively inefficient, and significant potassium depletion may therefore result from prolonged dietary deficiency.

A number of drugs affect K^+ homeostasis by affecting aldosterone release (e.g. heparin, NSAIDs) or by directly affecting renal potassium handling (e.g. diuretics).

Normally only about 10% of daily potassium intake is excreted in the gastrointestinal tract. Vomit contains around 5-10 mmol/L of K^+, but prolonged vomiting may cause hypokalaemia by inducing sodium depletion, stimulating aldosterone, which increases renal potassium excretion. Potassium is secreted by the colon, and diarrhoea contains 10-30 mmol/L of K^+; profuse diarrhoea can therefore induce marked hypokalaemia. Colorectal villous adenomas may rarely produce profuse diarrhoea and K^+ loss.

HYPOKALAEMIA

Causes

The most common causes of chronic hypokalaemia are diuretic treatment (particularly thiazides) and hyperaldosteronism. Acute hypokalaemia is often caused by intravenous fluids without potassium and redistribution into cells. The common causes are shown in Table 12.12.

Rare causes

Bartter's syndrome

This consists of metabolic hypokalaemia, alkalosis,

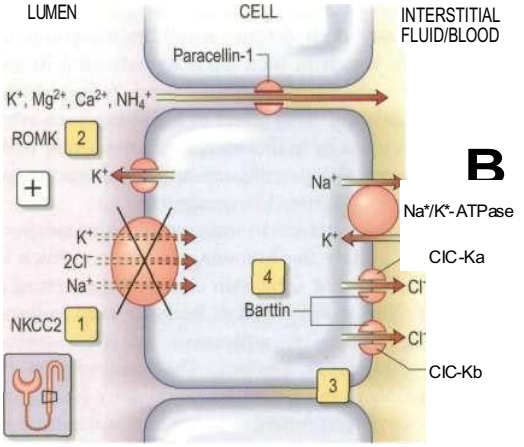

Fig. 12.6 **Transport mechanisms in the thick ascending limb of the loop of Henle.** Sodium chloride is reabsorbed in the thick ascending limb by the bumetanide-sensitive sodium-potassium-2-chloride cotransporter (NKCC2). The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the Na7K^+-ATPase and the kidney-specific basolateral chloride channel (ClC-Kb). The availability of luminal potassium is rate-limiting for NKCC2, and recycling of potassium through the ATP-regulated potassium channel (ROMK - rat outer medulla K^+ channel) ensures the efficient functioning of the NKCC2 and generates a lumen-positive transepithelial potential.

Genetic studies have identified putative loss-of-function mutations in the genes encoding NKCC2 [T], ROMK \2\, ClC-Kb [3], and barttin \A\ in subgroups of patients with **Bartter's syndrome.** In contrast to the normal condition, loss of function of NKCC2 Q] impairs reabsorption of sodium and potassium. Inactivation of the basolateral ClC-Kb [3] and barttin HI reduces transcellular reabsorption of chloride. Loss of function of any of these will reduce the transepithelial potential and thus decrease the driving force for the paracellular reabsorption of cations (K^+, Mg^{2+}, Ca^{2+} and Na_+). Paracellin-1 is necessary for the paracellular transport of Ca^{2+} and Mg^{2+}. In most patients with Bartter's syndrome, urinary calcium excretion is increased. Hypercalcaemia or increased activation of calcium-sensing receptor inactivates ROMK and causes Bartter's syndrome. Ka and Kb, kidney-specific basolateral chloride channel. ROMK, renal outer medullary potassium channel.

hypercalciuria, normal blood pressure, and an elevated plasma renin and aldosterone. The primary defect in this disorder is an impairment in sodium and chloride reabsorption in the thick ascending limb of the loop of Henle (Fig. 12.6). Mutation in the genes encoding either the sodium-potassium-2-chloride cotransporter (NKCC2), the ATP-regulated renal outer medullary potassium channel (ROMK) or kidney-specific basolateral chloride channels (CIC-Kb) - Bartter's types I, II and III respectively - causes loss of function of these channels, with consequent impairment of sodium and chloride reabsorption. There is also an increased intrarenal production of prostaglandin E_2 which is secondary to sodium and volume depletion, hypokalaemia and the consequent neurohumoral response rather than a primary defect. PE_2 causes vasodilatation and may explain why the blood pressure remains normal.

A recent molecular finding was the identification of barttin, a beta-subunit for CIC-Ka and CIC-Kb chloride channels. Barttin is a protein encoded by the *BSND* (Barter's syndrome with sensori-neural deafness) gene; a loss of function mutation causes type IV Bartter's syndome associated with sensorineural deafness and renal failure. Barttin co-localizes with a subunit of the chloride channel in basolateral membranes of the renal tubule and inner ear epithelium. It appears to mediate chloride exit in the thick ascending limb (TAL) of the loop of Henle and chloride recycling in potassium-secreting strial marginal cells in the inner ear. A very rare variant of type IV is a disorder with an impairment of both chloride channels (CIC-Ka and CIC-Kb) produces the same phenotypic defects.

A gain of function mutation of the calcium sensing receptor (CaSR) which leads to autosomal dominant hypocalcaemia has also been recognized in Bartter's syndrome. In the kidney, the CaSR is expressed mainly in the basolateral membrane of cortical TAL. Activation of CaSR by high calcium or magnesium or by gain-of-function mutation triggers intracellular signalling,

including release of arachidonic acid and inhibition of adenylate cyclase. Both actions result in inhibition of ROMK activity, which in turn leads to reduction in the lumen-positive electrical potential and transcellular absorption of calcium. This effect of CaSR explains why patients with mutations in this receptor may present with both hypocalcaemia, hypercalciuria and renal wasting of NaCl, resulting in a Bartter-like syndrome.

In summary, these defects in sodium chloride transport are thought to initiate the following sequence, which is almost identical to that seen with chronic ingestion of a loop diuretic. The initial salt loss leads to mild volume depletion, resulting in activation of the renin-angiotensin-aldosterone system. The combination of hyperaldosteronism and increased distal flow (owing to the reabsorptive defect) enhances potassium and hydrogen secretion at the secretory sites in the collecting tubules, leading to hypokalaemia and metabolic alkalosis.

Diagnostic pointers include high urinary potassium and chloride despite low serum values as well as increased plasma renin (NB: in primary aldosteronism, renin levels are low). Hyperplasia of the juxtaglomerular apparatus is seen on renal biopsy (careful exclusion of diuretic abuse is necessary). Hypercalciuria is a common feature but magnesium wasting, though rare, may also occur. *Treatment* is with combinations of potassium supplements, amiloride and indometacin.

Gitelman's syndrome

Gitelman's syndrome is a phenotype variant of Bartter's syndrome characterized by hypokalaemia, metabolic alkalosis, hypocalciuria, hypomagnesaemia, normal blood pressure, and elevated plasma renin and aldosterone. There are striking similarities between the Gitelman syndrome and the biochemical abnormalities induced by chronic thiazide diuretic administration. Thiazides act in the distal convoluted tubule to inhibit the function of the apical sodium-chloride cotransporter (NCCT) (Fig. 12.7). Analysis of the gene encoding the NCCT has identified loss of function mutations in Gitelman's syndrome.

Like Bartter's syndrome, defective NCCT function leads to increased solute delivery to the collecting duct, with resultant solute wasting, volume contraction and an aldosterone-mediated increase in potassium and hydrogen secretion. Unlike Bartter's syndrome, the degree of volume depletion and hypokalaemia is not sufficient to stimulate prostaglandin E_2 production. Impaired function of NCCT is predicted to cause hypocalciuria, as does thiazide administration. Impaired sodium reabsorption across the apical membrane coupled with continued intracellular chloride efflux across the basolateral membrane, causes the cell to become hyperpolarized. This in turn stimulates calcium reabsorption via apical, voltage-activated calcium channels. Decreased intracellular sodium also facilitates calcium efflux via the basolateral sodium-calcium exchanger. The mechanism for urinary magnesium losses is not known. *Treatment* consists of potassium and magnesium supplementation ($MgCl_2$) and a potassium-sparing diuretic. Volume resuscitation is usually not necessary, because patients are not dehydrated. Elevated prostaglandin E_2 does not occur (see above) and, therefore, NSAIDs are not indicated in this disorder.

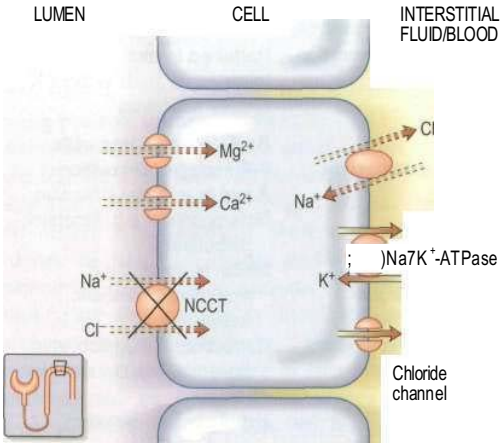

Fig. 12.7 **Transport mechanisms in the distal convoluted tubule.** Under normal conditions, sodium chloride is reabsorbed by the apical thiazide-sensitive sodium-chloride cotransporter (NCCT) in the distal convoluted tubule. The electroneutral transporter is driven by the low intracellular sodium and chloride concentrations generated by the $Na7K^+$-ATPase and an, as yet, undefined basolateral chloride channel. In this nephron segment, there is an apical calcium channel and a basolateral sodium-coupled exchanger. Physiological evidence indicates that the mechanisms for the transport of magnesium are similar to those for calcium.

In **Gitelman's syndrome,** putative loss-of-function mutations in the sodium-chloride cotransporter {*NCCT* (X)) lead to decreased reabsorption of sodium chloride and increased reabsorption of calcium. Functional overactivity of NCCT leads to **Gordon's syndrome** by a new mechanism (see text).

Liddle's syndrome

This is characterized by potassium wasting, hypokalaemia and alkalosis, but is associated with low renin and aldosterone production, and high blood pressure. There is a mutation in the gene encoding for the amiloride-sensitive epithelial sodium channel in the distal tubule/collecting duct. This leads to constitutive activation of the epithelial sodium channel, resulting in excessive sodium reabsorption with coupled potassium and hydrogen secretion. Unregulated sodium reabsorption across the collecting tubule results in volume expansion, inhibition of renin and aldosterone secretion and development of low renin hypertension (Fig. 12.8).

Therapy consists of sodium restriction along with amiloride or triamterene administration, both potassium-sparing diuretics which directly close the sodium channels. The mineralocorticoid antagonist spironolactone is ineffective, since the increase in sodium-channel activity is not mediated by aldosterone.

Hypoka/aem/c *periodic paralysis* (p. 1271)

This condition may be precipitated by carbohydrate intake, suggesting that insulin-mediated potassium .

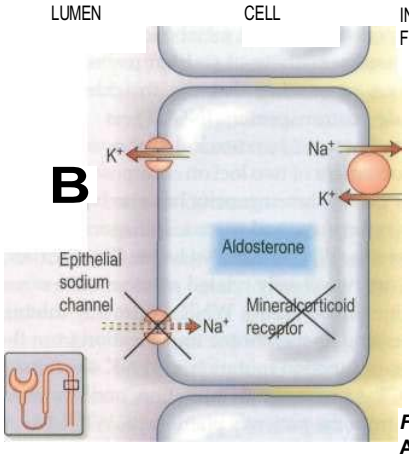

Fig. 12.8 **Aldosterone-regulated transport in the cortical collecting ducts.** Under normal conditions, the epithelial sodium channel is the rate-limiting barrier for the normal entry of sodium from the lumen into the cell. The resulting lumen-negative transepithelial voltage (indicated by the minus sign) drives potassium secretion from the principal cells and proton secretion from the a-intercalated cells (see Fig. 12.12).

In **Liddle's syndrome,** a mutation in the gene encoding the epithelial sodium channel results in persistent unregulated reabsorption of sodium and increased secretion of potassium (not shown).

In **pseudo-hypoaldosteronism type I autosomal recessive,** loss-of-function mutations (X) in this gene inactivate the channel.

In the **autosomal dominant variety,** the mutation is in the gene encoding the mineralocorticoid regulation of the activity of the epithelial sodium channel. Either mechanism reduces the activity of the epithelial sodium channel, thus causing salt wasting and decreasing the secretion of potassium and protons.

influx into cells may be responsible. This syndrome also occurs in association with hyperthyroidism in Chinese patients.

Clinical features

Hypokalaemia is usually asymptomatic, but severe hypokalaemia (< 2.5 mmol) may cause muscle weakness. Potassium depletion may also cause symptomatic hyponatraemia (see p. 701).

Hypokalaemia is associated with an increased frequency of atrial and ventricular ectopic beats. This association may not always be causal, because adrenergic activation (for instance after myocardial infarction) causes both hypokalaemia and increased cardiac irritability. Hypokalaemia in patients without cardiac disease is unlikely to lead to serious arrhythmias.

Hypokalaemia seriously increases the risk of digoxin toxicity by increasing binding of digoxin to cardiac cells, potentiating its action, and decreasing its clearance.

Chronic hypokalaemia is associated with interstitial renal disease, but the pathogenesis is not completely understood.

Table 12.13 **Treatment of hypokalaemia**

Cause	Treatment
Dietary deficiency	Increase intake of fresh fruit/vegetables or oral potassium supplements (20-40 mmol daily)
Hyperaldosteronism, e.g. cirrhosis, thiazide therapy	(Potassium supplements can cause gastrointestinal irritation) Spironolactone
Intravenous fluid replacement	Co-prescription of a potassium-sparing diuretic with a similar onset and duration of action Add 20 mmol/L of K^+ with monitoring

Treatment

The underlying cause should be identified and treated where possible. Table 12.13 shows some examples.

Acute hypokalaemia may correct spontaneously. In most cases, withdrawal of oral diuretics or purgatives, accompanied by the oral administration of potassium supplements in the form of slow-release potassium or effervescent potassium, is all that is required. Intravenous potassium replacement is required only in conditions such as cardiac arrhythmias, muscle weakness or severe diabetic ketoacidosis. When using intravenous therapy in the presence of poor renal function, replacement rates > 20 mmol per hour should be used only, with hourly monitoring of serum potassium and ECG changes. Ampoules of potassium should be thoroughly mixed in 0.9% saline; do not use glucose solution as this would make hypokalaemia worse.

The treatment of adrenal disorders is described on page 1086.

Failure to correct hypokalaemia may be due to concurrent hypomagnesaemia. Serum magnesium should be measured and any deficiency corrected.

HYPERKALAEMIA

Causes

Acute self-limiting hyperkalaemia occurs normally after vigorous exercise and is of no pathological significance. Hyperkalaemia in all other situations is due either to increased release from cells or to failure of excretion (Table 12.14). The most common causes are renal impairment and drug interference with potassium excretion. The combination of ACE inhibitors with potassium-sparing diuretics or NSAIDs is particularly dangerous.

Rare causes

Hyporeninaemic hypoaldosteronism

This is also known as type 4 renal tubular acidosis (see p. 717). Hyperkalaemia occurs because of acidosis and hypoaldosteronism.

Table 12.14 **Causes of hyperkalaemia**

Decreased excretion

Increased release from muscles
Vigorous fist clenching during phlebotomy

"Common causes

Pseudo-hypoaldosteronism type 1 (autosomal recessive and dominant types)
This is a disease of infancy, apparently due to resistance to the action of aldosterone. It is characterized by hyperkalaemia and evidence of sodium wasting (hyponatraemia, extracellular volume depletion). Autosomal recessive forms result from loss of function because of mutations in the gene for epithelial sodium channel activity (opposite to Liddle's syndrome). This disorder involves multiple organ systems and is especially marked in the neonatal period. With aggressive salt replacement and control of hyperkalaemia, these children can survive and the disorder appears to become less severe with age. The autosomal dominant type is due to mutations affecting the mineralocorticoid receptor (Fig. 12.8). These patients present with salt wasting and hyperkalaemia but do not have other organ-system involvement.

Hyperkalaemic periodic paralysis (see p. 1271)
This is precipitated by exercise, and is caused by an autosomal dominant mutation of the skeletal muscle sodium channel gene. >

Gordon's syndrome (familial hyperkalaemic hypertension, pseudohypoaldosteronism type 2)
This appears to be a mirror image of Gitelman's syndrome (see p. 706), in which primary renal retention of sodium causes hypertension, volume expansion, low renin/aldosterone, hyperkalaemia and metabolic acidosis. There is also an increased sensitivity of sodium reabsorption to thiazide diuretics, suggesting that the thiazide-sensitive sodium-chloride cotransporter (NCCT) is involved. Genetic analyses, however, have excluded abnormalities in NCCT. The involvement of two loci on chromosomes 1 and 12 and a further genetic heterogeneity has also been found. These genes do not correspond to ionic transporters but to unexpected proteins, WNK (With *No* lysine Kinase) 1 and WNK 4, which are two closely related members of a novel serine - threonine kinase family. WNK 4 normally inhibits NCCT by preventing its membrane translocation from the cytoplasm. Loss of function mutation in WNK 4 results in escape of NCCT from normal inhibition and its overactivity as seen from the patient's phenotype. WNK 1 is an inhibitor of WNK 4 and in some patients with Gordon's syndrome, gain of function mutation in WNK 1 results in functional deficiency of WNK 4 and overactivity of NCCT.

Suxamethonium and other depolarizing muscle relaxants
These cause release of potassium from cells. Induction of muscle paralysis during general anaesthesia may result in a rise of plasma potassium of up to 1 mmol/L. This is not usually a problem unless there is pre-existing hyperkalaemia.

Clinical features

Serum potassium of greater than 7.0 mmol/L is a medical emergency and is associated with ECG changes (Fig. 12.9). Severe hyperkalaemia may be asymptomatic and may predispose to sudden death from asystolic cardiac arrest. Muscle weakness is often the only symptom, unless (as is commonly the case) the hyperkalaemia is associated with metabolic acidosis, causing Kussmaul respiration. Hyperkalaemia causes depolarization of cell membranes, leading to decreased cardiac excitability, hypotension, bradycardia, and eventual asystole.

Treatment

Treatments for severe hyperkalaemia require both urgent measures to save lives and maintenance therapy to keep potassium down, as summarized in Emergency box 12.1. The cause of the hyperkalaemia should be found and treated.

High potassium levels are cardiotoxic as they inactivate sodium channels. Divalent cations, e.g. calcium, restore the voltage dependability of the channels.

Calcium ions protect the cell membranes from the effects of hyperkalaemia but do not alter the potassium concentration. Supraphysiological *insulin* (20 units) drives potassium into the cell and lowers plasma potassium by 1 mmol in 60 minutes, but must be accompanied by glucose to avoid hypoglycaemia. Regular measurements of blood glucose for at least 6 hours after use of insulin should be performed and extra glucose must be available for immediate use. The use of glucose alone in non-diabetic patients, to stimulate endogenous

Emergency Box 12.1
Correction of severe hyperkalaemia

IMMEDIATE
Attach ECG monitor and IV access

Protect myocardium
10 mL of 10% calcium gluconate IV over 5 mins
Effect is temporary but dose can be repeated after 15 mins

Drive K^+ into cells
Insulin 10 units + 50 mL of 50% glucose IV over 10-15 mins followed by regular checks of blood glucose and plasma K^+
Repeat as necessary

and/or correction of severe acidosis (pH < 6.9) - infuse $NaHCO_3$(1.26%)

and/or salbutamol 0.5 mg in 100 mL of 5% glucose over 15 min (rarely used)

LATER

Deplete body K^+ (to decrease plasma K^+ over next 24 h)
Polystyrene sulphonate resins:
15 g orally up to three times daily with laxatives 30 g rectally followed 3-6 hours later by an enema
Haemodialysis or peritoneal dialysis if the above fails

(d) 'Sine wave' pattern (pre-cardiac arrest)

Fig. 12.9 **Progressive ECG changes with increasing hyperkalaemia.**

insulin release does not produce the high levels of insulin required and therefore is not recommended.

Intravenous or nebulized salbutamol (10-20 mg) has not yet found widespread acceptance and may cause disturbing muscle tremor at the doses required.

Correction of acidosis with hypertonic (8.4%) sodium bicarbonate causes volume expansion and should not be used; 1.26% is used with severe acidosis (pH < 6.9) (p. 719). *Gastric aspiration* will remove potassium and leads to alkalosis.

Ion-exchange resins (polystyrene sulphonate resins) are used as maintenance therapy to keep potassium down *after* emergency treatment. They make use of the ion fluxes which occur in the gut to remove potassium from the body, and are the only way short of dialysis of removing potassium from the body. They may cause fluid overload (resonium contains Na^+) or hypercalcaemia (calcium resonium). Recent evidence suggests that resins do not significantly enhance the excretion of potassium beyond the effect of diarrhoea induced by osmotic or secretory cathartics.

In general, all of these measures are simply ways of buying time either to correct the underlying disorder or to arrange removal of potassium by dialysis, which is the definitive treatment for hyperkalaemia.

DISORDERS OF MAGNESIUM CONCENTRATION

Plasma magnesium levels are normally maintained within the range 0.7-1.1 mmol/L. Magnesium balance is a function of intake and excretion. The average daily magnesium intake is 15 mmol. One-third of this magnesium is absorbed, principally in the small bowel. In the healthy adult, there is no net gain or loss of magnesium from bone, so that balance is achieved by the urinary excretion of the net magnesium absorbed.

Primary disturbance of magnesium balance is uncommon; hypo- or hypermagnesaemia usually developing on a background of more obvious fluid and electrolyte disturbances. Disturbance in magnesium balance should always be suspected in association with other fluid and electrolyte disturbances when the patient develops unexpected neurological signs or symptoms.

Renal handling of magnesium

Magnesium transport differs from that of most other ions in that the proximal tubule is not the major site of reabsorption. Only 15-25% of the filtered magnesium is reabsorbed passively in the proximal tubule and 5-10% in the distal tubule. The major site of magnesium transport is the cortical thick ascending limb (cTAL) of the loop of Henle, where 60-70% of the filtered load is reabsorbed (Fig. 12.6). It was demonstrated that this transport is passive and paracellular, driven by the lumen positive electrochemical gradient, characteristic of this segment. Conversely, magnesium reabsorption in the distal convoluted tubule (DCT) is of transcellular and active

nature (Fig 12.7). The reabsorption rate in the DCT (5-15%) is much lower than in the cTAL, but it defines the final urinary excretion, as there is no significant reabsorption in the collecting duct. Three to five per cent of filtered magnesium is finally excreted in the urine. TAL magnesium reabsorption varies with changes in the plasma magnesium concentration, which is the main physiological regulator of urinary magnesium excretion. Hypermagnesaemia inhibits loop transport, while hypomagnesaemia stimulates magnesium transport. Hypercalcaemia inhibits magnesium loop transport by an unknown mechanism.

Another factor that can influence loop magnesium transport is the rate of sodium chloride reabsorption. This effect is relatively unimportant in normal subjects, but decreased reabsorption and magnesium wasting can be induced by the administration of a loop diuretic (Fig. 12.6).

HYPOMAGNESAEMIA

This most often develops as a result of deficient intake, defective gut absorption, or excessive gut or urinary loss (Table 12.15). It can also occur with acute pancreatitis, possibly owing to the formation of magnesium soaps in the areas of fat necrosis. Calcium deficiency usually develops with hypomagnesaemia. The serum magnesium is usually < 0.7 mmol/L.

Isolated dominant hypomagnesaemia (IDH)

IDH follows an autosomal dominant mode of inheritance, presenting as hypomagnesaemia and hypocalciuria. It has similarities with Gitelman's syndrome but lacks hypokalaemia and metabolic alkalosis. The *FXYD2* gene, encoding the gamma-subunit of Na^+/K^+-ATPase which is mainly expressed in TAL and DCT, is mutated, resulting in the inhibition of Na^+/K^+-ATPase activity and limiting the amount of potassium entry into the cell. Closing of potassium-sensitive apical magnesium channels cause reduced magnesium absorption and hypomagnesaemia in patients with IDH.

Table 12.15 **Causes of hypomagnesaemia**

SIADH, syndrome of inappropriate antidiuretic hormone secretion

Familial hypomagnesaemia, hypercalciuria and nephrocalcinosis (FHHNC)

This disorder is characterized by excessive renal magnesium and calcium wasting. In addition, affected individuals develop bilateral nephrocalcinosis and progressive renal failure. Patients also have elevated PTH levels, which precedes any reduction in GFR. A substantial proportion of patients show incomplete distal renal tubular acidosis, hypocitraturia and hyperuricaemia. Extrarenal involvement such as myopia, nystagmus, chorioretinitis has been reported. Based on clinical observation and clearance studies, the main defect in magnesium and calcium reabsorption lies in cTAL. Ten different mutations have been identified in a novel gene *(CLND16)* which encodes for paracellin-1 (claudin 16), a member of the claudin family of tight junction proteins.

Clinical features

Symptoms and signs include irritability, tremor, ataxia, carpopedal spasm, hyperreflexia, confusional and hallucinatory states, and epileptiform convulsions. An ECG may show a prolonged QT interval, broad flattened T waves, and occasional shortening of the ST segment.

Treatment

This involves the withdrawal of precipitating agents such as diuretics or purgatives and the parenteral infusion of 50 mmol of magnesium chloride in 1 L of 5% dextrose or other isotonic fluid over 12-24 hours. This should be repeated daily until the plasma magnesium level is normal.

HYPERMAGNESAEMIA

This primarily occurs in patients with acute or chronic renal failure given magnesium-containing laxatives or antacids. It can also be induced by magnesium-containing enemas. Mild hypermagnesaemia may occur in patients with adrenal insufficiency. Causes are given in Table 12.16.

Clinical features

Symptoms and signs relate to neurological and cardiovascular depression, and include weakness with hyporeflexia proceeding to narcosis, respiratory paralysis and cardiac conduction defects. Symptoms usually develop when the plasma magnesium level exceeds 2 mmol/L.

Treatment

Treatment requires withdrawal of any magnesium

Table 12.16 Causes of hypermagnesaemia

therapy. An intravenous injection of 10 mL of calcium gluconate 10% (2.25 mmol calcium) is given to antagonize the effects of hypermagnesaemia, along with dextrose and insulin (as for hyperkalaemia) to lower the plasma magnesium level. Dialysis may be required in patients with severe renal failure.

DISORDERS OF PHOSPHATE CONCENTRATION

Phosphate forms an essential part of most biochemical systems, from nucleic acids downwards. About 80% of all body phosphorus is within bone, plasma phosphate normally ranging from 0.80 to 1.40 mmol/L. Phosphate reabsorption from the kidney (85% from the proximal tubule) is decreased by parathyroid hormone (PTH) mediated by a cyclic AMP-dependent mechanism; thus hyperparathyroidism is associated with low plasma levels of phosphate. Other factors that are known to control phosphate reabsorption in the proximal tubule are 1,25-dihydroxyvitamin D_3, sodium delivery to the proximal tubule, serum concentrations of calcium, bicarbonate, carbon dioxide tension, glucose, alanine, serotonin, dopamine and sympathetic activity. The regulation of plasma phosphate level is closely linked to calcium.

HYPOPHOSPHATAEMIA

Significant hypophosphataemia (< 0.4 mmol/L) occurs in a number of clinical situations, owing to redistribution into cells, to renal losses, or to decreased intake (Table 12.17). It may cause:

- muscle weakness, e.g. diaphragmatic weakness, decreased cardiac contractility, skeletal muscle rhabdomyolysis
- a left-shift in the oxyhaemoglobin dissociation curve (reduced 2,3-bisphosphoglycerate (2,3-BPG)) and rarely haemolysis
- confusion, hallucinations and convulsions.

Mild hypophosphataemia often resolves without specific treatment. However, diaphragmatic weakness may be severe in acute hypophosphataemia, and may impede weaning a patient from a ventilator. Interestingly, chronic hypophosphataemia (in X-linked hypophosphataemia) is associated with normal muscle power.

Diseases associated with altered serum phosphate concentrations

Decreased reabsorption of phosphate occurs in patients with tumour-induced osteomalacia (TIO), X-linked dominant hypophosphataemic rickets (XLR) and autosomal-dominant hypophosphataemic rickets (ADHR). These syndromes have similar biochemical and osseous phenotypes. Patients have osteomalacia or rickets, reduced tubular phosphate reabsorption, hypophosphataemia, normal or low serum calcium, normal PTH and PTH-related protein concentrations and normal or low 1,25-dihydroxyvitamin D_3. Urinary cyclic AMP levels are generally in the normal range.

In TIO, there is excessive production of phosphatonins, e.g. fibroblast growth factor 23 (FGF-23), matrix extracellular phosphoglycoprotein (MEPG) and frizzled related protein 4 (FRP-4). These cannot be degraded by normal concentrations of PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome). This results in net excess of inhibitors of the sodium-phosphate cotransporter in the proximal tubule, and phosphaturia.

In ADHR, FGF-23 is mutated so that it is resistant to PHEX proteolysis. *In XLR,* mutations in PHEX prevent binding to FGF-23 and FRP-4, resulting in a net relative excess of phosphatonins.

Normal adaptive increases in 1,25-dihydroxyvitamin D_3 synthesis in response to low phosphate levels do not occur in TIO, ADHR and XLR, aggravating phosphaturia (Fig. 12.10).

Dent's disease is now the generally accepted name for a group of hereditary tubular disorders including X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphataemic rickets and idiopathic low-molecular-weight proteinuria. Dent's disease is characterized by low-molecular-weight proteinuria, hypercalciuria, hyperphosphaturia, nephrocalcinosis, kidney stones and eventual renal failure, with some patients developing rickets or osteomalacia. It is caused by loss of

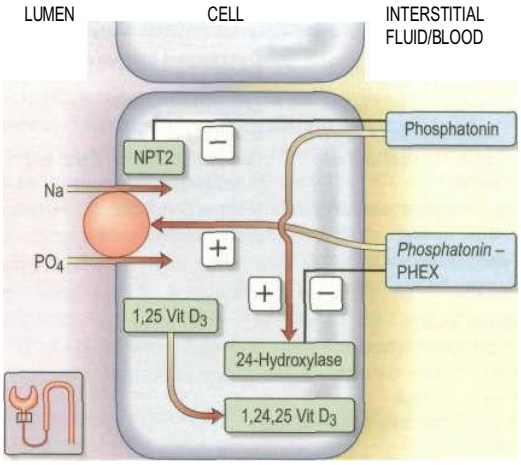

Fig. 12.10 **PHEX regulation of phosphate transport and vitamin D metabolism in the proximal tubule.** The hormone, phosphatonin is an inhibitor of sodium-phosphate cotransporter (NPT2). When bound to PHEX (phosphate-regulating gene with homologies to endopeptidase on the X chromosome) it is bioinactive and is thought to stimulate phosphate reabsorption via the sodium-phosphate cotransporter (NPT2) and to retard the degradation of 1,25-dihydroxyvitamin D by downregulating 24-hydroxylase activity. Over-production of phosphatonins occurs in tumour-induced osteomalacia, gain of function mutation as in autosomal dominant hypophosphataemic rickets and loss of function mutation in PHEX as X-linked hypophosphataemia. This causes renal phosphate wasting, as well as increased 1,25-dihydroxyvitamin D degradation. Modified from Rowe PSN(1998). ■ , . - -. . .

function mutation of a proximal tubular endosomal chloride channel, C1C5. This chloride channel, along with the proton pump is essential for acidification of proximal tubular endosomes. The process is linked with normal endocytosis, degradation and recycling of absorbed proteins, vitamins and hormones. Defective endosomal acidification (owing to the mutated *CLCN5* gene) results in impaired endosomal degradation and recycling of endocytosed hormones such as PTH. High PTH concentration activates apical receptors, increases endocytosis of the sodium-phosphate cotransporter and produces increased phosphaturia. It also results in increased lahydoxylase activity, causing excess production of 1,25-$(OH)_2$ D_3, hypercalciuria, renal stones and nephrocalcinosis. Moreover, the receptors (megalin and cubilin) for reabsorption of low-molecular-weight proteins and albumin in the proximal tubules are decreased in Dent's disease. This is secondary to the defective acidification of endosomes, which can explain low-molecular-weight proteinuria and excessive urinary leaks of cytokines, hormones and chemokines. This urinary profile is associated with progressive renal fibrosis and more rapid decline in renal function.

Treatment includes combined therapy with phosphate supplementation and calcitriol (1,25-dihydroxyvitamin D) administration.

Treatment of acute hypophosphataemia, if warranted, is with intravenous phosphate at a maximum rate of 9 mmol every 12 hours, with repeated measurements of calcium and phosphate, as over-rapid administration of phosphate may lead to severe hypocalcaemia, particularly in the presence of alkalosis. Chronic hypophosphataemia can be corrected, if warranted, with oral effervescent sodium phosphate.

HYPERPHOSPHATAEMIA

Hyperphosphataemia is common in patients with chronic renal failure (see p. 668 and Table 12.18). Hyperphosphataemia is usually asymptomatic but may result in precipitation of calcium phosphate, particularly in the presence of a normal or raised calcium or of alkalosis. Uraemic itching may be caused by a raised calcium x phosphate product. Prolonged hyperphosphataemia causes hyperparathyroidism, and periarticular and vascular calcification.

Usually no treatment is required for acute hyperphosphataemia, as the causes are self-limiting. Treatment of chronic hyperphosphataemia is with gut phosphate binders and dialysis (see p. 672).

ACID-BASE DISORDERS

The concentration of hydrogen ions in both extracellular and intracellular compartments is extremely tightly controlled, and very small changes may lead to major cell dysfunction. The blood pH is tightly regulated and is normally maintained at between 7.38 and 7.42. Any deviation from this range indicates a change in the hydrogen ion concentration $[H^+]$ because blood pH is the negative logarithm of $[H^+]$ (Table 12.19). The $[H^+]$ at a physiological blood pH of 7.40 is 40 nmol/L. An increase

Table 12.19 Relationship between [H+] and pH

pH	[H+] (nmol/L)
6.9	126
7.0	100
7.1	79
7.2	63
7.3	50
7.4	40
7.5	32
7.6	25

in the [H^+] - a fall in pH - is termed acidaemia. A decrease in [H^+] - a rise in the blood pH - is termed alkalaemia. The disorders that cause these changes in the blood pH are acidosis and alkalosis, respectively.

Normal acid-base physiology

The normal adult diet contains 70-100 mmol of acid. Throughout the body, there are buffers that minimize any changes in blood pH that these ingested hydrogen ions might cause. Such buffers include inrracellular proteins (e.g. haemoglobin) and tissue components (e.g. the calcium carbonate and calcium phosphate in bone) as well as the bicarbonate-carbonic acid buffer pair generated by the hydration of carbon dioxide. This buffer pair is clinically most relevant, in part because its contribution can be measured and because alterations in this buffer pair reveal changes in all other buffer systems. Bicarbonate ions [HCOjf] and carbonic acid (H_2CO_3) exist in equilibrium; and in the presence of carbonic anhydrase, carbonic acid dissociates to carbon dioxide and water, as expressed in the following equation:

$$H^+ + HCO_3^- \underset{\text{carbonic anhydrase}}{\rightleftharpoons} H_2CO_3 \rightleftharpoons CO_2 \uparrow + H_2O$$

The addition of hydrogen ions drives the reaction to the right, decreasing the plasma bicarbonate concentration [HCO3"] and increasing the arterial carbon dioxide pressure (P_aco_2). As shown in the following Henderson-Hasselbalch equation, a fall in the plasma [HCO_3~] increases [H^+] and thus lowers blood pH:

$$[H^+] = 181 \times P_aco_2 / [HCO3-]$$

where [H^+] is expressed in nmol per litre, P_aco_2 in kilopascals, [HCO_3~] in mmol per litre, and 181 is the dissociation coefficient of carbonic acid. Alternatively the equation can be expressed as:

$$pH = pK + \log [HCO_3]/[H_2CO_3]$$

where pK = 6.1. Thus, the bicarbonate used in the buffering process must be regenerated to maintain normal acid-base balance.

Although the acidaemia stimulates an increase in ventilation, which blunts this change in pH, increased ventilation does not regenerate the bicarbonate used in the buffering process. Consequently, the kidney must excrete hydrogen ions to return the plasma [HCO_3~] to normal. Maintenance of a normal plasma [HCO_3~] under physiological conditions depends not only on daily regeneration of bicarbonate but also on reabsorption of all bicarbonate filtered across the glomerular capillaries.

Renal reabsorption of bicarbonate

The plasma [HCO_3~] is normally maintained at approximately 25 mmol/L. In individuals with a normal glomerular filtration rate (120 mL/min), about 4500 mmol of bicarbonate is filtered each day. If this filtered bicarbonate were not reabsorbed, the plasma [HCO3"] would fall, along with blood pH. Thus, maintenance of a normal plasma [HCO_3~] requires that essentially all of the bicarbonate in the glomerular filtrate be reabsorbed (Fig. 12.11).

The proximal convoluted tubule reclaims 85-90% of filtered bicarbonate; in contrast, the distal nephron reclaims very little. This difference is caused by the greater quantity of luminal carbonic anhydrase in the proximal tubule than in the distal nephron. As a result of these quantitative differences, bicarbonate that escapes reabsorption in the proximal tubule is excreted in the urine.

Proximal tubular bicarbonate reabsorption is catalysed by the Na^+/K^+-ATPase pump located in the basolateral cell membrane. By exchanging peritubular potassium ions for intracellular sodium ions, the pump keeps the inrracellular sodium concentration low, allowing sodium ions to enter the cell by moving down the sodium concentration gradient from the tubule lumen to the cell interior. Hydrogen ions are transported in the

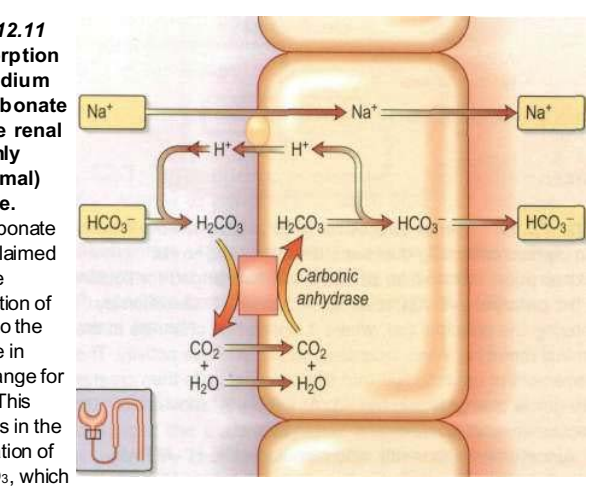

Fig. 12.11 **Resorption of sodium bicarbonate in the renal (mainly proximal) tubule.** Bicarbonate is reclaimed by the secretion of H^+ into the tubule in exchange for Na^+. This results in the formation of H_2CO_3, which is then broken down to CO_2. This is reabsorbed and converted back to H_2CO_3, which now dissociates into H^+ and HCO_3". The net result is reabsorption of Na^+ and HCO_3". This process is dependent on carbonic anhydrase within the cells and on the luminal surface of the tubular cell.

direction (at the Na^+-H^+ antiporter), thereby maintaining electroneutrality. Before bicarbonate enters the proximal tubule, it combines with secreted hydrogen ions, forming carbonic acid. In the presence of luminal carbonic anhydrase (CA-IV) carbonic acid rapidly dissociates into carbon dioxide and water, which can then rapidly enter the proximal tubular cell. In the cell, carbon dioxide is hydrated by cytosolic carbonic anhydrase (CA-II), ultimately forming bicarbonate, which is then transported down an electrical gradient from the cell interior, across the membrane into the peritubular fluid, and into the blood. In this process, each hydrogen ion secreted into the proximal tubule lumen is reabsorbed and can be resecreted; there is no net loss of hydrogen ions or net gain of bicarbonate ions.

Renal excretion of $[H^+]$ (Fig. 12.12) More acid is secreted into the proximal tubule (up to 4500 nmol of hydrogen ions each day) than into any other nephron segment. However, the hydrogen ions secreted into the proximal tubule are almost completely reabsorbed with bicarbonate; consequently, proximal tubular hydrogen ion secretion does not contribute significantly to hydrogen ion elimination from the body. The excretion of the daily acid load requires hydrogen ion secretion in more distal nephron segments.

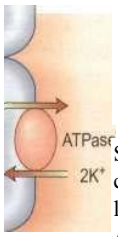
Most dietary hydrogen ions come from sulphur-containing amino acids that are metabolized to sulphuric acid (H_2SO_4), which then reacts with sodium bicarbonate as follows:

$$H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2CO_2 + 2H_2O.$$

Excess sulphate is excreted in the urine, whereas excess hydrogen ions are buffered by bicarbonate and lower the plasma [HCO_3"]. This fall in plasma [HCO_3"] leads to a slight decrease in the blood pH, although a smaller decrease in the blood pH than would have occurred if buffer were unavailable. The subsequent excretion of hydrogen ions takes place primarily in the collecting duct and results in the regeneration of 1 mmol of bicarbonate for every mmol of hydrogen ions excreted in the urine.

The collecting duct has two types of cell:

- *The principal cell* with an aldosterone-sensitive Na^+ absorption site. These cells reabsorb Na^+ and H_2O and secrete K^+ under the influence of aldosterone.
- *The a-intercalated cell,* which possesses the proton pump for the active secretion of hydrogen ions in exchange for reabsorption of K^+ ions. Aldosterone increases H^+ ion secretion.



Secretion of hydrogen ions from the cortical collecting duct is indirectly linked to sodium reabsorption. Aldosterone has several facilitating effects on hydrogen ion secretion. Aldosterone opens sodium channels in the luminal membrane of the principal cell and increases Na^+/K^+-ATPase activity. The subsequent movement of cationic sodium into the principal cell creates a negative charge within the tubule lumen. Potassium ions from the principal cells and hydrogen ions from the a-intercalated cells move out from the cells down the electrochemical gradient and into the lumen. Aldosterone also stimulates directly the H^+-ATPase in the a-intercalated cell, further enhancing hydrogen ion secretion.

When hydrogen ions are secreted into the lumen of the collecting tubule, a tiny, but physiologically critical, fraction of these excess hydrogen ions remains in solution. Here, they increase the urinary $[H^+]$ and lower urinary pH below 4.0. Nevertheless, below this urine pH, inhibition of proton-secreting pumps such as H^+-ATPase severely restricts kidney secretion of more hydrogen ions. Consequently, secretion of hydrogen ions depends on the presence of buffers in the urine that maintain the urine pH at a level higher than 4.0.

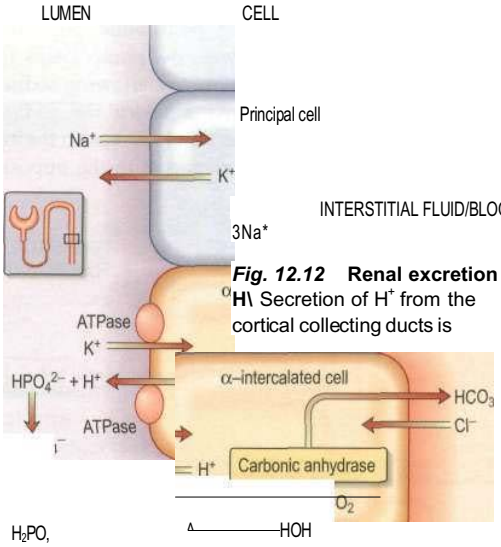


Fig. 12.12 **Renal excretion of H** Secretion of H^+ from the cortical collecting ducts is indirectly linked to Na^+ reabsorption. Intracellular potassium is exchanged for sodium in the principal cell. Aldosterone stimulates H^+ secretion by entering the principal cell, where it opens Na^+ channels in the luminal membrane and increases Na^+K^+-ATPase activity. The movement of cationic Na^+ into the principal cells then creates a negative charge within the tubule lumen. K^+ moves from the electrochemical gradient and into the lumen.

Aldosterone apparently also stimulates the H^+-ATPase directly in the intercalated cell, further enhancing H^+ secretion. When the urinary pH falls to 4.0-4.5, further H^+ secretion by the a-intercalated cells ceases. The filtration of titratable acids (e.g. phosphoric acid) raises the intraluminal pH and permits this process to continue. Secreted H^+ binds to the conjugate anion of a titratable acid (HPO_4^{2-} in this case) and is excreted in the urine. The H^+ to be secreted arises from the reassociation of H_2O and CO_2 in the presence of carbonic anhydrase; thus, a bicarbonate molecule is regenerated each time an H^+ is eliminated in the urine.

Buffer systems in acid excretion

Two buffer systems are involved in acid excretion: the titratable acids such as phosphate, and the ammonia system. Each system is responsible for excreting about half of the daily acid load of 50-100 mmol under physiological conditions (Fig. 12.12).

Titratable acid

A titratable acid is a filtered buffer substance having a conjugate anion that can be titrated within the pH range occurring physiologically in the urine. Phosphoric acid (pK_a 6.8) is the usual titratable urinary buffer. Hydrogen ions bind to the conjugate anions of the titratable acids and are excreted in the urine. For each hydrogen ion excreted in this form, a bicarbonate ion is regenerated within the cell and returned to the blood (Fig. 12.12).

Ammonium (NH_4^+)

In the setting of metabolic acidosis, titratable acids cannot increase significantly because the availability of titratable acid is fixed by the plasma concentration of the buffer and by the GFR. The ammonia buffer system, in contrast, can increase several 100-fold when necessary. Consequently, impaired renal excretion of hydrogen ions is always associated with a defect in ammonium excretion (Fig. 12.13).

All ammonia used to buffer urinary hydrogen ions in the collecting tubule is synthesized in the proximal convoluted tubule. Glutamine is the primary source of ammonia. It undergoes deamination catalysed by glutaminase, resulting in a-ketoglutaric acid (see Fig. 12.13) and ammonia. Once formed, ammonia can diffuse into the proximal tubule lumen and become acidified, forming ammonium. Once in the proximal tubule lumen, ammonium flows along the tubule to the thick ascending limb of Henle's loop. Here, it is transported out of the tubule into the medullary interstitium. Ammonium then dissociates to ammonia, leading to a high interstitial ammonia concentration. Ammonia diffuses down its concentration gradient into the lumen of the collecting tubule. Here, it reacts with the hydrogen ions secreted by the collecting tubular cells to form ammonium. Because ammonium (NH_4) is not lipid-soluble, it is trapped in the lumen and excreted in the urine as ammonium chloride. Two conditions predominantly promote ammonia synthesis by the proximal tubular cell: systemic acidosis and hypokalaemia.

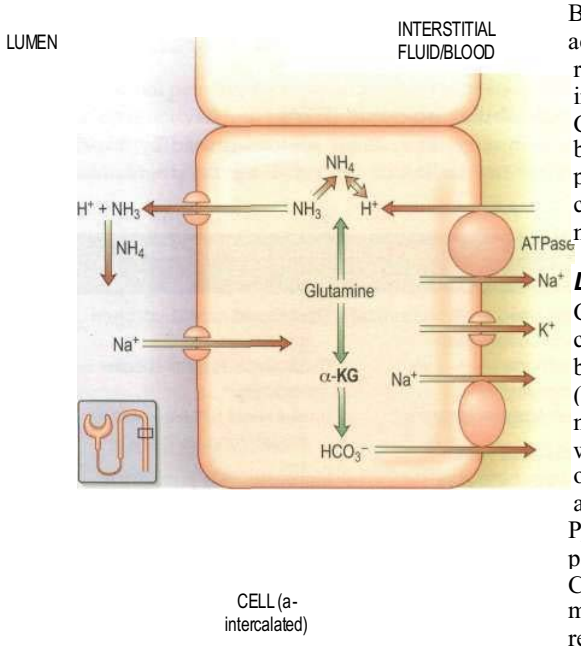

Fig. 12.13 The ammonia buffering system in the **kidney.** All ammonia used to buffer H^+ in the collecting duct is synthesized in the proximal convoluted tubule, and glutamine is the main source of this ammonia. As glutamine is metabolized, a-ketoglutarate (a-KG) is formed, which ultimately breaks down to bicarbonate that is then secreted **into the** peritubular fluid at an **Na^+-HCO_3^-** cotransporter.

Controversy still exists about whether glutamine metabolism and ureagenesis in the liver play a role in acid-base homeostasis. Ureagenesis in the liver consumes up to 1000 mmol of bicarbonate/day in humans as a result of $2NH_4 + 2HCO_3 = \text{urea} + CO_2 + H_2O$. The liver is believed to contribute to regulation of acid-base balance by controlling the rate of ureagenesis and therefore bicarbonate consumption in response to changes in plasma acidity. Recent studies in human volunteers have shown that metabolic acidosis increases ureagenesis and potentially makes it worse by consuming more bicarbonate. Similarly, metabolic alkalosis decreases ureagenesis, whereby less bicarbonate is consumed, resulting in an increase of alkali load in the face of alkalosis. In the light of these new human data it is concluded that ureagenesis is a maladaptive process for acid-base regulation and that ureagenesis has no discernible homeostatic effect on acid-base equilibrium in humans.

Causes of acid-base disturbance

Acid-base disturbance may be caused by:

- abnormal CO_2 removal in the lungs ('respiratory' acidosis and alkalosis)
- abnormalities in the regulation of bicarbonate and other buffers in the blood ('metabolic' acidosis and alkalosis).

Both may, and usually do, coexist. For instance, metabolic acidosis causes hyperventilation (via medullary chemoreceptors, see p. 877), leading to increased removal of CO_2 in the lungs and partial compensation for the acidosis. Conversely, respiratory acidosis is accompanied by renal bicarbonate retention, which could be mistaken for primary metabolic alkalosis. The situation is even more complex if a patient has both respiratory disease and a metabolic disturbance.

Diagnosis

Clinical history and examination usually point to the correct diagnosis. Table 12.20 shows the typical changes, but in complicated patients the acid—base nomogram (Fig. 12.14) is invaluable. The $[H^+]$ and P_aCO_2 are measured in arterial blood (for precautions see p. 713) as well as the bicarbonate. If the values from a patient lie in one of the bands in the diagram, it is likely that only one abnormality is present. If the $[H^+]$ is high (pH low) but the P_aCO_2 is normal, the intercept lies between two bands: the patient has respiratory dysfunction, leading to failure of CO_2 elimination, but this is partly compensated for by metabolic acidosis, stimulating respiration and CO_2 removal (this is the most common 'combined' abnormality in practice).

Table 12.20 Changes in arterial blood gases

	PH	P_aco_2	HCO_3
Respiratory acidosis	N or!	TT	t (compensated)
Respiratory alkalosis	N orT	41	i (slight)
Metabolic acidosis	N or 4	i	14
Metabolic alkalosis	N ort	t (slight)	n

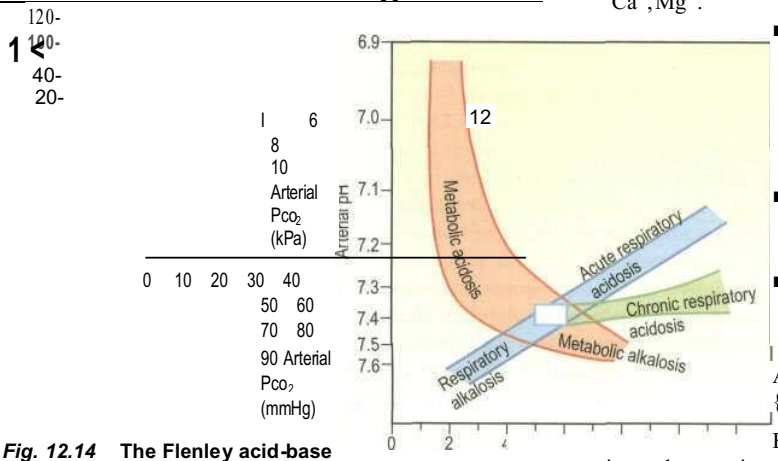

Fig. 12.14 **The Flenley acid-base nomogram.** This was derived from a large number of observations in patients with 'pure' respiratory or metabolic disturbances. The bands show the 95% confidence limits representing the individual varieties of acid-base disturbance. The central white box shows the approximate limits of arterial pH and Pco_2 in normal individuals.

RESPIRATORY ACIDOSIS AND ALKALOSIS

Respiratory acidosis

This is caused by retention of CO_2. The P_aco_2 and $[H^+]$ rise. Renal retention of bicarbonate may partly compensate, returning the $[H^+]$ towards normal (see p. 713).

Respiratory alkalosis

Increased removal of CO_2 is caused by hyperventilation, so there is a fall in P_aco_2 and $[H^+]$ (see p. 877).

METABOLIC ACIDOSIS

This is due to the accumulation of any acid other than carbonic acid, and there is a primary decrease in the plasma $[HCO_3\sim]$. Several disorders can lead to metabolic acidosis: acid administration, acid generation (e.g. lactic acidosis during shock or cardiac arrest), impaired acid excretion by the kidneys, or bicarbonate losses from the gastrointestinal tract or kidneys. From a diagnostic viewpoint, calculation of the plasma anion gap is extremely useful in narrowing this differential diagnosis.

The anion gap

The first step is to identify whether the acidosis is due to retention of $H^+Cl\sim$ or to another acid. This is achieved by calculation of the anion gap. The principles underlying this calculation are straightforward:

- The normal cations present in plasma are Na^+, K^+, Ca^{2+}, Mg^{2+}.
- The normal anions present in plasma are $Cl\sim$, HCO_3", negative charges present on albumin, phosphate, sulphate, lactate, and other organic acids.
- The sums of the positive and negative charges are equal.
- Measurement of plasma $[Na^+]$, $[K^+]$, [Cl"] and $[HCO_3$"] is usually easily available.

$$\text{ANION GAP} = \{[Na^+] + [K^+]\} - \{[HCOf] + [Cl"]\}$$

Because there are more unmeasured anions than cations, the normal anion gap is 10-18 mmol/L, although calculations with more sensitive methods place this at 6-12 mmol/L. Albumin normally makes up the largest portion of these unmeasured anions. As a result, a fall in the plasma albumin concentration from the normal value of about 40 g/L to 20 g/L may reduce the anion gap by as much as 6 mmol/L, because each 1 g/L of albumin has a negative charge of 0.2-0.28 mmol/L.

Metabolic acidosis with a normal anion gap

If the anion gap is normal in the presence of acidosis, this suggests that H^+C1" is being retained or that Na^+HCO_3" is being lost. Causes of a normal-anion-gap acidosis are given in Table 12.21. In these conditions, plasma bicarbonate decreases and is replaced by chloride to maintain electroneutrality. Consequently, these disorders are sometimes referred to collectively as hyperchloraemic acidoses.

Renal tubular acidosis (RTA)

This term refers to systemic acidosis caused by impairment of the ability of the renal tubules to maintain

Table 12.21 Causes of metabolic acidosis with a normal anion gap

Increased gastrointestinal bicarbonate loss
Diarrhoea Ileostomy
Ureterosigmoidostomy

Increased renal bicarbonate loss
Acetazolamide Proximal (type 2) renal tubular acidosis
Hyperparathyroidism Tubular damage, e.g. drugs, heavy metals, paraproteins

Decreased renal hydrogen ion excretion
Distal (type 1) renal tubular acidosis Type 4 renal tubular acidosis (aldosterone deficiency)

Increased HCl production
Ammonium chloride ingestion
Increased catabolism of lysine, arginine

acid-base balance. This group of disorders is uncommon and only rarely a cause of significant clinical disease. Renal tubular acidosis may be secondary to immunological, drug-induced or structural damage to the tubular cells, an inherited abnormality, or an isolated ('primary') abnormality. As with most disorders that are not well understood, the nomenclature is confusing.

Type 4 renal tubular acidosis

Also called 'hyporeninaemic hypoaldosteronism', this is probably the most common of these disorders. The cardinal features are hyperkalaemia and acidosis occurring in a patient with mild chronic renal insufficiency, usually caused by tubulo-interstitial disease (e.g. reflux nephropathy) or diabetes (Gordon's syndrome shares biochemical abnormalities but differs in having normal GFR and hypertension). Plasma renin and aldosterone are found to be low, even after measures which would normally stimulate their secretion (Table 12.22). An identical syndrome may be caused by chronic ingestion of NSAIDs, which impair renin and aldosterone secretion. In the presence of acidosis, urine pH may be low. Treatment is with fludrocortisone, sodium bicarbonate, diuretics, or ion exchange resins to remove potassium, or some combination of these. Dietary potassium restriction alone is ineffective.

Type 3 renal tubular acidosis (RTA)

This condition is vanishingly rare, and represents a combination of type 1 and type 2. Inherited type 3 RTA is caused by mutations resulting in carbonic anhydrase type II deficiency, which is characterized by osteopetrosis, RTA of mixed type, cerebral calcification and mental retardation. Typical radiographic features of osteopetrosis are present and histopathological study of the iliac crest reveals unreabsorbed calcified primary spongia.

Type 2 ('proximal') renal tubular acidosis

This is very rare in adult practice (Table 12.23). It is caused by failure of sodium bicarbonate reabsorption in the proximal tubule. The cardinal features are acidosis, hypokalaemia, an inability to lower the urine pH below 5.5 despite systemic acidosis, and the appearance of bicarbonate in the urine despite a subnormal plasma bicarbonate. This disorder normally occurs as part of a generalized tubular defect, together with other features such as glycosuria and amino-aciduria. Inherited forms of isolated type 2 RTA are described as both autosomal dominant and recessive patterns of inheritance, where putative mutations are in the Na^+-H^+ antiporter in the apical membrane and Na^+-HCO_3^- cotransporter in the basolateral membrane of proximal tubular cells respectively (Fig. 12.11) Treatment is with sodium bicarbonate: massive doses may be required to overcome the renal 'leak'.

Table 12.22 **Diagnosis of hyporeninaemic hypoaldosteronism (type 4 renal tubular acidosis)**

Hyperkalaemia

(In the absence of drugs known to cause hyperkalaemia)

Low plasma bicarbonate and hyperchloraemia

Normal ACTH stimulation test

Low basal 24-hour urinary aldosterone

Subnormal response of plasma renin and plasma aldosterone to stimulation
Samples taken over 2 hours supine and again after 40 mg furosemide (80 mg if creatinine > 120)j.mol/L) and 4 hours upright posture

Correction of hyperkalaemia by fludrocortisone 0.1 mg daily

Table 12.23 **Causes of proximal renal tubular acidosis (type 2 RTA)**

Cystinosis

Tyrosinaemia

Wilson's disease

Glycogen storage disease, type I

Pyruvate carboxylase deficiency

Multiple myeloma

Vitamin D deficiency/ hyperparathyroidism

Toxins and drugs
Carbonic anhydrase inhibitors
Lead
Cadmium
Mercury
Uranium
Copper
Outdated tetracycline ingestion

Type 1 ('distal') renal tubular acidosis

This is due to a failure of H^+ excretion in the distal tubule (Table 12.24). It consists of:

- acidosis
- hypokalaemia (few exceptions)
- inability to lower the urine pH below 5.3 despite systemic acidosis
- low urinary ammonium production.

Table 12.24 **Causes of distal renal tubular acidosis (type 1 RTA)**

Primary
Idiopathic

NSAIDs Lead

Autoimmune diseases
Sjogren's syndrome*
Thyroiditis
Autoimmune hepatitis
Primary biliary cirrhosis
Systemic lupus erythematosus

Renal transplant rejection*

*May also cause proximal renal tubular acidosis

Practical Box 12.1
Diagnosis of renal tubular acidosis

Plasma HCO_3 < 21 mmol/L, urine pH > 5.3 = renal tubular acidosis To differentiate between proximal (very rare) and distal (rare) requires bicarbonate infusion test Plasma HCCV - 21 mmol/L but suspicion of partial renal tubular acidosis (e.g. nephrocalcinosis-associated diseases): **acid load test** required as follows: Give 100 mg/kg ammonium chloride by mouth Check urine pH hourly and plasma HCO_3" at 3 hours Plasma HCO_3~ should drop below 21 mmol/L unless the patient vomits (in which case the test should be repeated with an antiemetic) If urine pH remains > 5.3 despite a plasma HCO_3~ of 21 mmol/L, the diagnosis is confirmed

These features may be present only in the face of increased acid production; hence the need for an acid load test in diagnosis (Practical box 12.1). Other features include:

- low urinary citrate (owing to increased citrate absorption in the proximal tubule where it can be converted to bicarbonate)
- hypercalciuria.

These abnormalities result in osteomalacia, renal stone formation and recurrent urinary infections. Osteomalacia is caused by buffering of H^+ by Ca^{2+} in bone, resulting in depletion of calcium from bone. Renal stone formation is caused by hypercalciuria, hypocitraturia (citrate inhibits calcium phosphate precipitation), and alkaline urine (which favours precipitation of calcium phosphate). Recurrent urinary infections are caused by renal stones. Both autosomal dominant and recessive inheritance patterns have been reported in primary distal RTA. Patients in South East Asia with an autosomal dominant type have a milder phenotype and may have an associated ovalocytosis. In this form the O-HCO," exchanger in the basolateral surface of intercalated cells is mutated. However, in the autosomal recessive distal RTA, a substantial proportion of patients have sensorineural deafness, and this is associated with a loss of function mutation in the H^+-ATPase at the apical surface of intercalated cells.

Treatment is with sodium bicarbonate, potassium supplements and citrate. Thiazide diuretics are useful by causing volume contraction and increased proximal sodium bicarbonate reabsorption.

Urinary anion gap

Another useful tool in the evaluation of metabolic acidosis with a normal anion gap is the urinary anion gap:

URINARY ANION GAP =
{urinary[Na^+] + urinary[K^+]} - urinary[CI~].

This calculation can be used to distinguish the normal-anion-gap acidosis caused by diarrhoea (or other gastrointestinal alkali loss) from that caused by distal renal tubular acidosis. In both disorders, the plasma [K^+] is characteristically low. In patients with renal tubular acidosis, urinary pH is always greater than 5.3.

Although excretion of urinary hydrogen ions in the patient with diarrhoea should acidify the urine, hypokalaemia leads to enhanced ammonia synthesis by the proximal tubular cells. Despite acidaemia, the excess urinary buffer increases the urine pH to a value above 5.3 in some patients with diarrhoea.

Whenever urinary acid is excreted as ammonium chloride, the increase in urinary chloride excretion decreases the urinary anion gap. Thus, the urinary anion gap should be negative in the patient with diarrhoea, regardless of the urine pH. On the other hand, although hypokalaemia may result in enhanced proximal tubular ammonia synthesis in distal renal tubular acidosis, the inability to secrete hydrogen ions into the collecting duct in this condition limits ammonium chloride formation and excretion; thus, the urinary anion gap is positive in distal renal tubular acidosis.

Metabolic acidosis with a high anion gap

If the anion gap is increased, one may conclude that an unmeasured anion is present in increased quantities. This may be either one of the acids normally present in small, but unmeasured quantities, such as lactate, or an exogenous acid. Causes of a high-anion-gap acidosis are given in Table 12.25.

Table 12.25 **Causes of metabolic acidosis with an increased anion gap**

Renal failure (sulphate, phosphate)

Accumulation of organic acids

Lactic acidosis
L-lactic
Type A - anaerobic metabolism in tissues
Hypotension/cardiac arrest Sepsis
Poisoning - e.g. ethylene glycol, methanol Type
B - decreased hepatic lactate metabolism
Insulin deficiency (decreased pyruvate dehydrogenase activity)
Metformin accumulation (chronic renal failure) Haematological malignancies Rare inherited enzyme defects D-lactic (fermentation of glucose in bowel by abnormal bowel flora, complicating abnormal small bowel anatomy, e.g. blind loops)

Ketoacidosis
Insulin deficiency
Alcohol excess
Starvation

Exogenous acids
Salicylate

Lactic acidosis

Increased lactic acid production occurs when cellular respiration is abnormal, because of either a lack of oxygen in the tissues ('type A') or a metabolic abnormality, such as drug-induced ('type B') (Table 12.25). The most common cause in clinical practice is type A lactic acidosis, occurring in septic or cardiogenic shock. Significant acidosis can occur despite a normal blood pressure and P_aCO_2, owing to splanchnic and peripheral vasoconstriction. Acidosis worsens cardiac function and vasoconstriction further, contributing to a downward spiral and fulminant production of lactic acid.

Diabetic ketoacidosis (see p. 1119) This is a high-anion-gap acidosis resulting from the accumulation of organic acids, acetoacetic acid and hydroxybutyric acid, owing to increased production and some reduced peripheral utilization.

Uraemic acidosis

Kidney disease may cause acidosis in several ways. Reduction in the number of functioning nephrons decreases the capacity to excrete ammonia and H^+ in the urine. In addition, tubular disease may cause bicarbonate wasting. Acidosis is a particular feature of those types of chronic renal failure in which the tubules are particularly affected, such as reflux nephropathy and chronic obstructive uropathy.

Chronic acidosis is most often caused by chronic renal failure, where there is a failure to excrete fixed acid. Up to 40 mmol of hydrogen ions may accumulate daily. These are buffered by bone, in exchange for calcium. Chronic acidosis is therefore a major risk factor for renal osteodystrophy and hypercalciuria.

Chronic acidosis has also been shown to be a risk factor for muscle wasting in renal failure, and may also contribute to the inexorable progression of some types of renal disease.

Uraemic acidosis should be corrected because of the effects of chronic acidosis on growth, muscle turnover and bones. Oral sodium bicarbonate 2-3 mmol/kg daily is usually enough to maintain serum bicarbonate above 20mmol/L, but may contribute to sodium overload. Calcium carbonate improves acidosis and also acts as a phosphate binder and calcium supplement, and is commonly used. Acidosis in end-stage renal failure is usually fully corrected by adequate dialysis.

Mixed metabolic acidosis

Both types of acidosis may coexist. For instance, cholera would be expected to cause a normal-anion-gap acidosis owing to massive gastrointestinal losses of bicarbonate, but the anion gap is often increased owing to renal failure and lactic acidosis as a result of hypovolaemia.

Clinical features

Clinically the most obvious effect is stimulation of respiration, leading to the clinical sign of 'air hunger', or Kussmaul respiration. Interestingly, patients with profound hyperventilation may not complain of breathlessness, although in others it may be a presenting complaint.

Acidosis increases delivery of oxygen to the tissues by shifting the oxyhaemoglobin dissociation curve to the right, but it also leads to inhibition of 2,3-BPG production, which returns the curve towards normal (see p. 960). Cardiovascular dysfunction is common in acidotic patients, although it is often difficult to dissociate the numerous possible causes of this. There is no doubt that acidosis is negatively inotropic. Severe acidosis also causes venoconstriction, resulting in redistribution of blood from the peripheries to the central circulation, and increased systemic venous pressure, which may worsen pulmonary oedema caused by myocardial depression. Arteriolar vasodilatation also occurs, further contributing to hypotension.

Cerebral dysfunction is variable. Severe acidosis is often associated with confusion and fits, but numerous other possible causes are usually present.

As mentioned earlier, acidosis stimulates potassium loss from cells, which may lead to potassium deficiency if renal function is normal, or to hyperkalaemia if renal potassium excretion is impaired.

General treatment of acidosis

Treatment should be aimed at correcting the primary cause. In lactic acidosis caused by poor tissue perfusion ('type A'), treatment should be aimed at maximizing oxygen delivery to the tissues by protecting the airway, improving breathing and circulation. This usually requires inotropic agents, mechanical ventilation and invasive monitoring. In 'type B' lactic acidosis, treatment is that of the underlying disorder; e.g.

- insulin in diabetic ketoacidosis
- treatment of methanol and ethylene glycol poisoning with ethanol
- removal of salicylate by dialysis.

The question of whether severe acidosis should be treated with bicarbonate is extremely controversial. Severe acidosis ($[H^+] > 100$ nmol/L, pH < 7.0) is associated with a very high mortality, which makes many doctors keen to correct it. Since acidosis is known to impair cardiac contractility, it would seem sensible to correct acidosis with bicarbonate in a sick patient. However:

- Rapid correction of acidosis may result in tetany and fits owing to a rapid decrease in ionized calcium.
- Administration of sodium bicarbonate (8.4%) provides 1 mmol/mL of sodium, which may lead to extracellular volume expansion, exacerbating pulmonary oedema.
- Bicarbonate therapy increases CO_2 production and will therefore correct acidosis only if ventilation can be increased to remove the added CO_2 load.
- The increased amounts of CO_2 generated may diffuse more readily into cells than bicarbonate, worsening intracellular acidosis.

Administration of sodium bicarbonate (50 mmol, as 50 mL of 8.4% sodium bicarbonate intravenously) is still occasionally given during cardiac arrest and is often

necessary before arrhythmias can be corrected. Correction of hyperkalaemia associated with acidosis is also of undoubted benefit. In other situations there is no clinical evidence to show that correction of acidosis improves outcome, but it is standard practice to administer sodium bicarbonate when $[H^+]$ is above 126nmol/L (pH < 6.9), using intravenous 1.26% (150mmol/L) bicarbonate. Intravenous sodium lactate should never be given.

METABOLIC ALKALOSIS

Metabolic alkalosis is common, comprising half of all the acid-base disorders in hospitalized patients. This observation should not be surprising since vomiting, the use of diuretics, and nasogastric suction are common among hospitalized patients. The mortality associated with metabolic alkalosis is substantial; the mortality rate is 45% in patients with an arterial pH of 7.55 and 80% when the pH is greater than 7.65. Although this relationship is not necessarily causal, severe alkalosis should be viewed with concern.

Classification and definitions

Metabolic alkalosis has been classified on the basis of underlying pathophysiology (Table 12.26).

The most common group is due to chloride depletion which can be corrected without potassium repletion. The other major grouping is that due to potassium depletion, usually with mineralocorticoid excess. Metabolic alkalosis due to both potassium and chloride depletion also occurs.

Table 12.26 **Causes of metabolic alkalosis**

Chloride depletion
Gastric losses: vomiting, mechanical drainage, bulimia
Chloruretic diuretics: e.g. bumetanide, furosemide
chlorothiazide, metolazone Diarrhoeal
states: villous adenoma, congenital
chloridorrhoea Cystic fibrosis
(high sweat chloride)

Potassium depletion/mineralocorticoid excess
Primary aldosteronism Secondary
aldosteronism Apparent
mineralocorticoid excess
Primary deoxycorticosterone excess: 11a- and
17a-hydroxylase deficiencies
Drugs: liquorice (glycyrrhizic acid) as a confection or
flavouring, carbenoxolone
Liddle's syndrome
Bartter's and Gitelman's syndromes and their variants
Laxative abuse, clay ingestion

Hypercalcaemia states
Hypercalcaemia of malignancy Acute or
chronic milk-alkali syndrome

Others
Ampicillin, penicillin therapy
Bicarbonate ingestion: massive or with renal insufficiency
Recovery from starvation
Hypoalbuminaemia

Chloride may be lost from the gut, kidney or skin. The loss of gastric fluid rich in acid results in alkalosis because bicarbonate generated during the production of gastric acid returns to the circulation. In Zollinger-Ellison syndrome (p. 416) or gastric outflow obstruction these losses can be massive. Although sodium and potassium loss in the gastric juice is variable, the obligate urinary loss of these cations is intensified by bicarbonaturia, which occurs during disequilibrium.

Chloruretic agents all directly produce loss of chloride, sodium and fluid in the urine. These losses in turn promote metabolic alkalosis by several mechanisms:

- diuretic-induced increases in sodium delivery to the distal nephron enhance potassium and hydrogen ion secretion
- extracellular volume contraction stimulates renin and aldosterone secretion, which blunts sodium losses but accelerates potassium and hydrogen ion secretion
- potassium depletion augments bicarbonate reabsorption in the proximal tubule, and
- stimulates ammonia production which in turn will increase urinary net acid excretion.

Urinary losses of chloride exceed those for sodium and are associated with alkalosis even when potassium depletion is prevented. The cessation of events that generate alkalosis is not necessarily accompanied by resolution of the alkalosis. A widely accepted hypothesis for the maintenance of alkalosis is chloride depletion rather than volume depletion. Although normal functioning of the proximal tubule is essential for bicarbonate absorption, the collecting duct appears to be the major nephron site for altered electrolyte and proton transport in both maintenance and recovery from metabolic alkalosis. During maintenance, the cc-intercalated cells in the cortical collecting duct do not secrete bicarbonate because insufficient chloride is available for bicarbonate exchange. When chloride is administered and luminal or cellular chloride concentration increases, bicarbonate is promptly excreted and alkalosis is corrected.

Metabolic alkalosis in hypokalaemia is generated primarily by an increased intracellular shift of hydrogen ion causing intracellular acidosis. Potassium depletion is also associated with enhanced ammonia production with increased obligate net acid excretion. However, the role of intracellular acidosis is supported by the correction of the alkalosis by infusion of potassium without any suppression of renal net excretion. The correction is assumed to occur by the movement of potassium into and of hydrogen ion out of the cell, which titrates extracellular fluid bicarbonate.

Milk-alkali syndrome in which both bicarbonate and calcium are ingested produces alkalosis by vomiting, calcium-induced bicarbonate absorption and reduced GFR. Cationic antibiotics in high doses can cause alkalosis by obligatory bicarbonate loss in the urine.

Clinical features

The symptoms of metabolic alkalosis per se are difficult to separate from those of chloride, volume, or potassium

depletion. Tetany (see p. 1095), apathy, confusion, drowsiness, cardiac arrhythmias and neuromuscular irritability are common when alkalosis is severe. The oxyhaemoglobin dissociation curve is shifted to the left. Respiration may be depressed.

Treatment

Chloride-responsive metabolic alkalosis. Although replacement of the chloride deficit is essential in chloride depletion states, selection of the accompanying cation - sodium, potassium or proton - is dependent on the assessment of extracellular fluid volume status (p. 699), the presence or absence of associated potassium depletion, and the degree and reversibility of any depression of GFR. If kidney function is normal, bicarbonate and base equivalents will be excreted with sodium or potassium, and metabolic alkalosis will be rapidly corrected as chloride is made available.

If chloride and extracellular depletion coexist then isotonic saline solution is appropriate therapy.

In the clinical settings of fluid overload, saline is contraindicated. In such situations, intravenous use of hydrochloride acid or ammonium chloride can be given. If GFR is adequate, acetazolamide, which causes bicarbonate diuresis by inhibiting carbonic anhydrase, can also be used. When the kidney is incapable of responding to chloride repletion, dialysis is necessary.

Chloride-resistant metabolic alkalosis. Metabolic alkalosis due to potassium depletion is managed by the correction of the underlying cause (see hypokalaemia). Mild to moderate alkalosis requires oral potassium chloride administration. However, the presence of cardiac arrhythmia or generalized weakness requires intravenous potassium chloride.

CASE STUDIES

Case 12.1 [_1

A 44-year-old patient with known chronic liver disease secondary to hepatitis B presented with marked exertional dyspnoea. Examination revealed: blood pressure 130/80, elevated JVP at 8 cm, bilateral pleural effusions, ascites and marked pitting pedal oedema. Investigations revealed: plasma sodium 136 mmol/L, potassium 3.6 mmol/L, bicarbonate 32 mmol/L, chloride 96 mmol/L, urinary sodium <10 mmol/day, urinary potassium 60 mmol/day.

Question

(a) Explain the persistent retention of sodium in the face of salt and water overload?

Answer

(a) In crisis, arterial vasodilatation due to nitric oxide overactivity leads to arterial underfilling. This is perceived by the pressure and volume receptors as hypovolaemia, with consequent activation of the sympathetic system, nonosmotic release of ADH and activation of the renin-angiotensin-aldosterone system. These mediators lead to salt and water reduction (see Fig. 12.3a, p. 691).

Case 12.2 _1

A 32-year-old patient was referred for investigation of refractory hypertension. His blood pressure was elevated at 210/110 with grade 3 hypertensive retinopathy despite taking beta-blockers, a calcium antagonist and an ACE inhibitor. The rest of the examination was normal. Investigations revealed: sodium 148 mmol/L, potassium 3 mmol/L, bicarbonate 32 mmol/L, urea 4 mmol/L, glucose 4 mmol/L, urine dipstick negative for proteins.

Questions

(a) What is the likely diagnosis?

(b) What is the cause of absence of oedema in this patient?

Answers

(a) Conn's syndrome (p. 1097).

(b) This is due to the escape from the action of aldosterone. The escape is dependent on an increase in delivery of sodium to the site of aldosterone in the collecting duct. The increase in sodium delivery is achieved by high extracellular volume-mediated arterial overfilling. This suppresses sympathetic activity and angiotensin II generation, and increases cardiac release of ANP with resultant increase in renal perfusion pressure and GFR. The net result of these events is reduced sodium absorption in the proximal

tubules and increased sodium delivery, which overwhelms the sodium-retaining actions of aldosterone (see Fig. 12.3b, p. 691).

Case 12.3

A 62-year-old woman is found lying on the floor of her house. On examination she is bradycardic and peripherally shut down. ECG confirms sinus bradycardia with changes consistent with inferior myocardial infarction. Emergency electrolyte measurements revealed: sodium 136 mmol/L, potassium 4 mmol/L, bicarbonate 10 mmol/L, chloride 102 mmol/L, urea 7.5 mmol/L.

Question

(a) Comment on the biochemistry and how you will confirm your diagnosis?

Answer

(a) The biochemical picture is one of high-anionic-gap metabolic acidosis. In the presence of myocardial infarction and hypotension, the likely cause would be lactic acidosis. Measurement of plasma lactate (normally < 2 mmol/L) would confirm the diagnosis. Correction of the underlying cause will correct the acidosis by itself.

Case 12.4 L

The plasma biochemistry of a patient who presented with severe loin pain is as follows: sodium 138 mmol/L, potassium 2.5 mmol/L, urea 3.8 mmol/L, chloride 114 mmol/L, bicarbonate 14.5 mmol/L, urinary pH 6.5.

Questions

(a) What is the cause of this metabolic abnormality?
(b) What is the cause of the loin pain?

Answers

(a) Distal renal tubular acidosis (see the section on renal tubular acidosis).
(b) Nephrocalcinosis and renal colic due to renal stones are characteristic features of renal tubular acidosis.

Case 12.5 L\

An 18-year-old boy was referred for the investigation of chronic fatigue syndrome. His mother comments that he is easily tired by sport and is not doing well at school. He is normotensive. Investigations revealed: sodium 145 mmol/L, potassium 2.8 mmol/L, bicarbonate 35 mmol/L, chloride 80 mmol/L, magnesium 0.6 mmol/L (normal range > 0.8 mmol/L), urea 5 mmol/L, glucose 5.2 mmol/L, urinary sodium excretion of 60 mmol and potassium excretion of 60 mmol/day.

Question

(a) What is the likely diagnosis?

Answer

(a) This patient has classic Gitelman's syndrome. It is similar to Bartter's but hypomagnesaemia favours Gitelman's syndrome.

Case 12.6 L\

A 36-year-old woman with a past medical history of peptic ulceration presented with a history of 3 days of vomiting. She looked unwell and investigations revealed: haemoglobin 16.3 mmol/L, sodium 138 mmol/L, potassium 2.8 mmol/L, urea 14.3 mmol/L, pH 7.52, bicarbonate 36 mmol/L, chloride 75 mmol/L.

Questions

(a) What is the likely metabolic abnormality?
(b) What is the likely diagnosis?
(c) What is the pH of the patient's urine?

Answers

(a) This patient suffers from hypochloraemic metabolic alkalosis.
(b) The underlying cause is pyloric stenosis.
(c) The patient's urine is paradoxically acid, despite alkalosis.

Case 12.7 t\

A 72-year-old man was admitted with a 3-week history of feeling unwell, poor appetite and diarrhoea. On examination, he was clearly dehydrated and had acidotic breathing. His blood pressure was 90/70; the postural drop to 60/30. He was frail. The rest of the general and system examination was unremarkable. The initial biochemistry revealed: sodium 121 mmol/L, potassium 1.9 mmol/L, chloride 83 mmol/L, bicarbonate 4 mmol/L, urea 90 mmol/L, creatinine 960 umol/L, pH 7.1, Po_2 15.7 kPa, Pco_2 2.2 kPa, serum osmolality 334 mOsm/kg, urine osmolality 404 mOsm/kg, urinary sodium 2 mmol/L and potassium 28 mmol/L. He continued to pass between 50-80 mL of urine per hour.

Questions

(a) How would you describe the metabolic abnormality?
(b) What was the likely cause?
(c) Why did this patient remain polyuric in the face of severe dehydration?

Answers

(a) This patient suffers from volume depletion syndrome characterized by dehydration, hypokalaemia, and hypochloraemic metabolic acidosis with high ionic gap. He has severe acute prerenal failure with normal urine output and dilute urine.
(b) The only single diagnosis which can explain this abnormality is secretory villous adenoma.
(c) His polyuria in the face of severe dehydration is due to nephrogenic diabetes insipidus secondary to chronic hypokalaemia. Hypokalaemia downregulates aquaporin II, which is essential for ADH-dependent water absorption from the collecting duct.

13 Cardiovascular disease

ESSENTIAL ANATOMY, PHYSIOLOGY AND EMBRYOLOGY OF THE HEART

introduction

Myocardial cells constitute 75% of the heart mass but only about 25% of the cell number. They are designed to perform two fundamental functions: initiation and conduction of electrical impulses and contraction. Although most myocardial cells are able to perform both these functions, the vast majority are predominantly contractile cells (myocytes) and a small number are specifically designed as electrical cells. The latter, collectively known as the conducting system of the heart, are not nervous tissue but modified myocytes lacking in myofibril components. They have the ability to generate electrical impulses which are then conducted to the myocytes, leading to contraction by a process known as excitation-contraction coupling. The rate of electrical impulse generation and the force of myocardial contraction are modified by numerous factors including autonomic input and stretch.

Three epicardial coronary arteries supply blood to the myocardium, and a more complex network of veins is responsible for drainage. In the face of continuous arterial pressure fluctuations, blood vessels, especially in the cerebral circulation, maintain constant tissue perfusion by a process known as "*autoregulation*"; blood vessel control is, however, complex involving additional local and central mechanisms.

The conduction system of the heart

The sinus node

The sinus node is a complex spindle-shaped structure that lies in the lateral and epicardial aspects of the junction between the superior vena cava and the right atrium (Fig. 13.1). Physiologically, it generates impulses automatically by spontaneous depolarization of its membrane at a rate quicker than any other cardiac cell type. It is therefore the natural pacemaker of the heart.

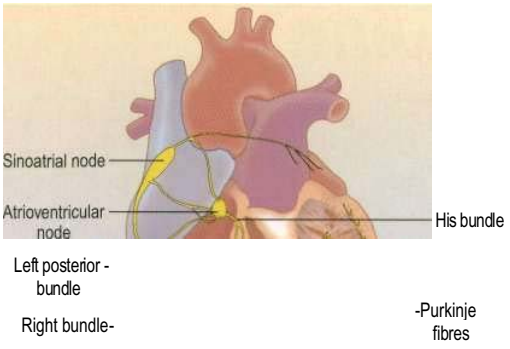

Fig. 13.1 **The conducting system of the heart.**

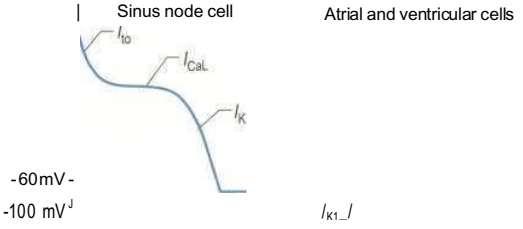

Fig. 13.2 **Myocardial action potentials.** I_b, background inward sodium current; I_f, 'funny' current; I_{CaT}, transient (or 'T' type) and I_{CaL}, long-lasting (or 'L' type) calcium channels; I_{Na}, inward sodium current; I_{to}, transient outward potassium current; I_{K1}, rectifier current; I_K delayed inwards rectifier potassium current.

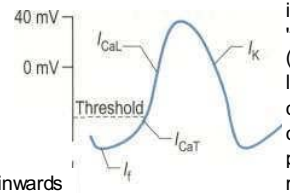

A number of factors are responsible for the spontaneous decay of the sinus node cell membrane potential ('the pacemaker potential'), the most significant of which is a small influx of sodium ions into the cells. This small sodium current has two components: the background inward current (7_b) and the 'funny' *(I_f)* current (or pacemaker current) (Fig. 13.2). The term 'funny' current denotes ionic flow through channels activated in *hyperpolarized* cells (-60 mV or greater), unlike other time- and voltage-dependent channels activated by *depolarization*. The rate of depolarization of the sinus node membrane potential is modulated by autonomic tone (i.e. sympathetic and parasympathetic input), stretch, temperature, hypoxia, blood pH and in response to other hormonal influences (e.g. triiodothyronine and serotonin).

Atrial and ventricular myocyte action potentials

Action potentials in the sinus node trigger depolarization of the atrial and subsequently the ventricular myocytes. These cells have a different action potential from that of sinus node cells. Their resting membrane potential is a consequence of a small flow of potassium ions into the cells through open 'inward rectifier' channels; at this stage sodium and calcium channels are closed. The arrival of adjacent action potentials triggers the opening of voltage-gated, fast, self-inactivating sodium channels, resulting in a sharp depolarization spike. This is followed by a partial repolarization of the membrane due to activation of 'transient outward' potassium channels.

The plateau phase which follows is unique to myocytes and results from a small, but sustained inward calcium current through L-type calcium channels lasting 200-400 ms. This calcium influx is caused by a combined increase in permeability of the cell and especially the sarcolemmal membranes to calcium (Fig. 13.3). This plateau (or refractory) phase in myocyte action potential prevents early reactivation of the myocytes and directly determines the strength of contraction. The gradual inactivation of the calcium channels activates delayed rectifier potassium channels repolarizing the membrane. Atrial tissue is activated like a 'forest fire', but the activation peters out when the insulating layer between the atrium and the ventricle - the annulus fibrosus - is reached. Controversy still exists about whether impulses from the sinoatrial (SA) node travel over specialized conducting 'pathways' or over ordinary atrial myocardium.

The AV node, His bundle and Purkinje fibres

The depolarization continues to conduct slowly through the atrioventricular (AV) node. This is a small, bean-shaped structure that lies beneath the right atrial endocardium within the lower inter-atrial septum. The AV node continues as the His bundle, which penetrates the annulus fibrosus and conducts the cardiac impulse rapidly towards the ventricle. The His bundle reaches the crest of the interventricular septum and divides into the right bundle branch and the main left bundle branch.

The right bundle branch continues down the right side of the interventricular septum to the apex, from where it radiates and divides to form the Purkinje network, which spreads throughout the subendocardial surface of the right ventricle. *The main left bundle branch* is a short structure, which fans out into many strands on the left side of the interventricular septum. These strands can be grouped into an anterior superior division (the anterior hemi-bundle) and a posterior inferior division (the posterior hemi-bundle). The anterior hemi-bundle supplies the subendocardial Purkinje network of the anterior and superior surfaces of the left ventricle, and the inferior hemi-bundle supplies the inferior and posterior surfaces. Impulse conduction through the AV node is slow and depends on action potentials largely produced by slow transmembrane calcium flux. In the atria, ventricles and His-Purkinje system, conduction is rapid and is due to action potentials generated by rapid transmembrane sodium diffusion.

The cellular basis of myocardial contraction - excitation contraction coupling

Each myocyte, approximately 100 u.m long, branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction to adjacent cells. Myocytes contain bundles of parallel myofibrils. Each myofibril is made up of a series of sarcomeres (Fig. 13.4). A sarcomere (which is the basic unit of contraction) is bound by two

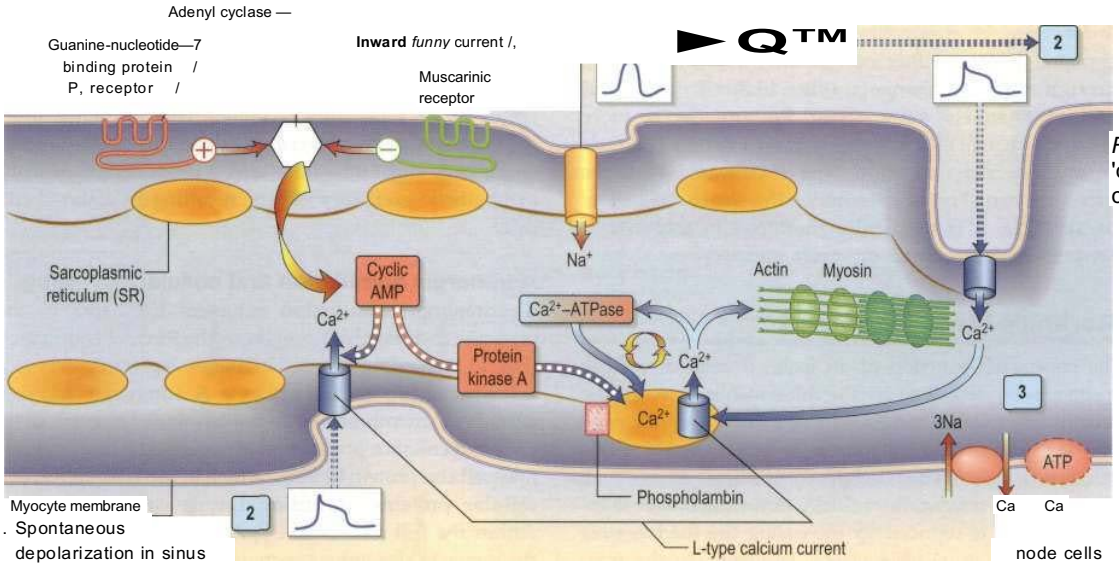

Fig. 13.3 The 'complete' cardiac cell.

1. Spontaneous depolarization in sinus due to sodium (Na) influx through the 'funny' current generates the 'pacemaker' potential.
2. This activates other atrial and ventricular myocytes, triggering action potentials and activating L -type calcium (Ca) channels in the surface and transverse tubule membranes (at top and bottom of figure).
3. The resulting Ca influx acts on Ca -induced Ca release channels (RyR2) on the sarcoplasmic reticulum (SR), resulting in release of stored Ca and acts together on actin and myosin fibrils, resulting in contraction. Ca reuptake pumps in the SR, regulated by phospholambin replenish the stores; various exchange pumps also expel Ca from the cell.
4. Autonomic input has either a positive chronotropic/inotropic effect (f), receptors) or a negative chronotropic/inotropic effect (muscarinic receptors).

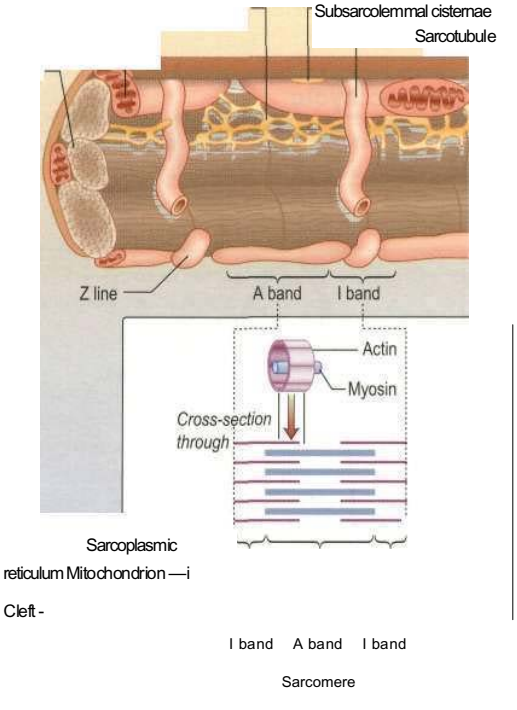

***Fig. 13.4* Schematic diagram showing the structure of a myofibril within a myocyte.** The myofibrils are made up of a series of sarcomeres joined at the Z line.

transverse Z lines, to each of which is attached a perpendicular filament of the protein actin. The actin filaments from each of the two Z bands overlap with thicker parallel protein filaments known as myosin. Actin and myosin filaments are attached to each other by cross-bridges that contain ATPase, which breaks down adenosine triphosphate (ATP) to provide the energy for contraction.

Two chains of actin molecules form a helical structure, with another molecule, tropomyosin, in the grooves of the actin helix, and a further molecule, troponin, is attached to every seven actin molecules. During cardiac contraction the length of the actin and myosin monofilaments does not change. Rather, the actin filaments slide between the myosin filaments when ATPase splits a high-energy bond of ATP. To supply the ATP, the myocyte (which cannot stop for a rest) has a very high mitochondrial density (35% of the cell volume). As calcium ions bind to troponin C, the activity of troponin I is inhibited, which induces a conformational change in tropomyosin. This event unlocks the active site between actin and myosin, enabling contraction to proceed.

Calcium is made available during the plateau phase of the action potential by calcium ions entering the cell and by being mobilized from the sarcoplasmic reticulum through the ryanodine receptor (RyR2) calcium-release channel. RyR2 activity is regulated by the protein

Zline '■ Zline

calstabin 2 (see p. 852) and nitric oxide. The force of cardiac muscle contraction ('inotropic state') is thus regulated by the influx of calcium ions into the cell through calcium channels (Fig. 13.3). T (transient) calcium channels open when the muscle is more depolarized, whereas L (long-lasting) calcium channels require less depolarization. The extent to which the sarcomere can shorten determines the stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or severe exercise.

Starling's law of the heart

The contractile function of an isolated strip of cardiac tissue can be described by the relationship between the velocity of muscle contraction, the load that may be moved by the contracting muscle, and the extent to which the muscle is stretched before contracting. As with all other types of muscle, the velocity of contraction of myocardial tissue is reduced by increasing the load against which the tissue must contract. However, in the non-failing heart, pre-stretching of cardiac muscle improves the relationship between the force and velocity of contraction (Fig. 13.5).

This phenomenon was described in the intact heart as an increase of stroke volume (ventricular performance) with an enlargement of the diastolic volume (preload), and is known as 'Starling's law of the heart' or the 'Frank-Starling relationship'. It has been transcribed into more clinically relevant indices. Thus, stroke work (aortic pressure x stroke volume) is increased as ventricular end-diastolic volume is raised. Alternatively, within certain limits, cardiac output rises as pulmonary capillary wedge pressure increases. This clinical relationship is described by the ventricular function curve (Fig. 13.5), which also shows the effect of sympathetic stimulation.

Nerve supply of the myocardium

Adrenergic nerves supply atrial and ventricular muscle fibres as well as the conduction system. (VReceptors predominate in the heart with both epinephrine (adrenaline) and norepinephrine (noradrenaline) having positive inotropic and chronotropic effects. Cholinergic nerves from the vagus supply mainly the SA and AV nodes via M_2 muscarinic receptors. The ventricular myocardium is sparsely innervated by the vagus. Under basal conditions, vagal inhibitory effects predominate over the sympathetic excitatory effects, resulting in a slow heart rate.

Adrenergic stimulation and cellular signalling

(3_rAdrenergic stimulation enhances Ca^{2+} flux in the myocyte and thereby strengthens the force of contraction (Fig. 13.3). Binding of catecholamines, e.g. norepinephrine (noradrenaline), to the myocyte p5,adrenergic receptor stimulates membrane-bound adenylate kinases. These enzymes enhance production of cyclic AMP that activates intracellular protein kinases, which in turn phosphorylate cellular proteins, including L-type calcium channels within the cell membrane. pVAdrenergic stimulation of the myocyte also enhances myocyte relaxation.

The return of calcium from the cytosol to the sarcoplasmic reticulum (SR) is regulated by phospholamban (PL), a low-molecular-weight protein in the SR membrane. In its dephosphorylated state, PL inhibits Ca^{2+} uptake by the SR ATPase pump (Fig. 13.3). However, pYadrenergic activation of protein kinase phosphorylates PL, and blunts its inhibitory effect. The subsequently greater uptake of calcium ions by the SR hastens Ca^{2+} removal from the cytosol and promotes myocyte relaxation.

The increased cAMP activity also results in phosphorylation of troponin I, an action that inhibits actin-myosin interaction, and further enhances myocyte relaxation.

The cardiac cycle

The cardiac cycle (Fig. 13.6) consists of precisely timed rhythmic electrical and mechanical events that propel

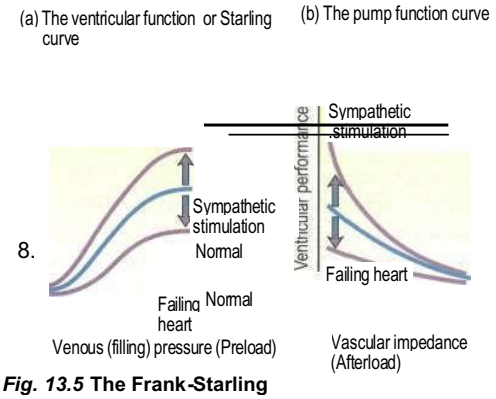

Fig. 13.5 **The Frank-Starling mechanism,** showing the effect on ventricular contraction of alteration in filling pressures and outflow impedance in the normal, failing and sympathetically stimulated ventricle.

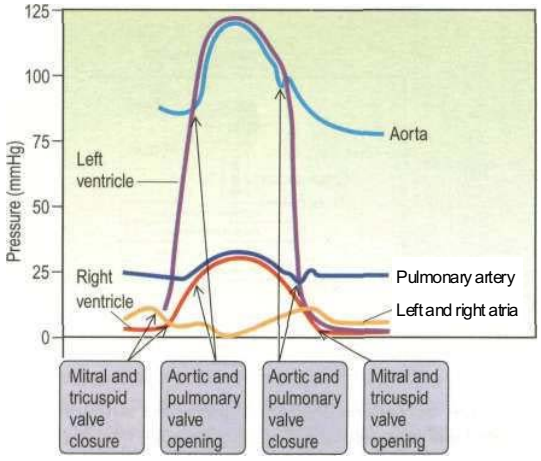

Fig. 13.6 The cardiac cycle.

blood into the systemic and pulmonary circulations. The first event in the cardiac cycle is atrial depolarization (a P wave on the surface ECG) followed by right atrial and then left atrial contraction. Ventricular activation (the QRS complex on the ECG) follows after a short interval (the PR interval). Left ventricular contraction starts and shortly thereafter right ventricular contraction begins. The increased ventricular pressures exceed the atrial pressures, and close first the mitral and then the tricuspid valves.

Until the aortic and pulmonary valves open, the ventricles contract with no change of volume (isovolumetric contraction). When ventricular pressures rise above the aortic and pulmonary artery pressures, the pulmonary valve and then the aortic valve open and ventricular ejection occurs. As the ventricles begin to relax, their pressures fall below the aortic and pulmonary arterial pressures, and aortic valve closure is followed by pulmonary valve closure. Isovolumetric relaxation then occurs. After the ventricular pressures have fallen below the right atrial and left atrial pressures, the tricuspid and mitral valves open. The cardiac cycle can be graphically depicted as the relationship between the pressure and volume of the ventricle. This is shown in Figure 13.7, which illustrates the changing pressure-volume relationships in response to increased contractility and to exercise.

The coronary circulation

The coronary arterial system (Fig. 13.8) consists of the right and left coronary arteries. These arteries branch from the aorta, arising immediately above two cusps of the aortic valve. These arteries are unique in that they fill during diastole, when not occluded by valve cusps and

Fig. 13.8 (a) Diagram of the normal coronary arterial anatomy, (b) Angiogram of non-dominant right coronary system, (c) Angiogram of dominant left coronary system from the same patient. Right anterior oblique projection.

when not squeezed by myocardial contraction. The right coronary artery arises from the right coronary sinus and courses through the right side of the atrioventricular groove, giving off vessels that supply the right atrium and the right ventricle. The vessel usually continues as the posterior descending coronary artery, which runs in the posterior interventricular groove and supplies the posterior part of the interventricular septum and the posterior left ventricular wall.

Within 2.5 cm of its origin from the left coronary sinus, the left main coronary divides into the left anterior descending artery and the circumflex artery. The left anterior descending artery runs in the anterior interventricular groove and supplies the anterior septum and the anterior left ventricular wall. The left circumflex artery travels along the left atrioventricular groove and gives off branches to the left atrium and the left ventricle (marginal branches).

The sinus node and the AV node are supplied by the right coronary artery in about 60% and 90% of people, respectively. Therefore, disease in this artery may cause sinus bradycardia and AV nodal block. The majority of the left ventricle is supplied by the left coronary artery, so that stenosis in the left main artery is extremely dangerous; total obstruction of this vessel is rarely compatible with life.

Some blood from the capillary beds in the wall of the heart drains directly into the cavities of the heart by tiny veins, but the majority returns by veins which accompany the arteries, to empty into the right atrium via the coronary sinus. An extensive lymphatic system drains into vessels that travel along the coronary vessels and then into the thoracic duct.

Blood vessel control and functions of the vascular endothelium

In functional terms, the tunica intima with the vascular endothelium and the smooth-muscle-cell-containing tunica media are the main constituents of blood vessels. These two structures are closely interlinked by a variety of mechanisms to regulate vascular tone. The central control of blood vessels is achieved via the neuroendocrine system. Sympathetic vasoconstrictor and parasympathetic vasodilator nerves regulate vascular tone in response to daily activity. Where neural control is impaired, or in various pathological states, e.g. haemorrhage, endocrine control of blood vessels mediated through epinephrine (adrenaline), angiotensin and vasopressin takes over.

At a local level, tissue perfusion is maintained automatically and by the effect of various factors synthesized and/ or released in the immediate vicinity. In the face of fluctuating arterial pressures, blood vessels vasoconstrict independently of nervous input when blood pressure drops and vice versa. This process of *autoregulation* is a consequence of:

- the *Bayliss myogenic* response - the ability of blood vessels to constrict when distended
- the *vasodilator washout* effect - the vasoconstriction triggered by a decrease in the concentration of tissue metabolites.

The vascular endothelium is a cardiovascular endocrine organ, which occupies a strategic interface between blood and other tissues. It produces various compounds (e.g. nitrous oxide (NO), prostacyclin (PGI_2), endothelin, endothelial derived hyperpolarizing factor (ERHF), adhesion molecules, vascular endothelial growth factor (VEGF)) and has enzymes located on the surface controlling the levels of circulating compounds such as angiotensin, bradykinin and serotonin. It has many regulatory roles:

Vasomotor control

NO is a diffusible gas with a very short half-life, produced in endothelial cells from the amino acid L-arginine via the action of the enzyme NO synthase (NOS), which is controlled by cytoplasmic calcium/calmodulin (Fig. 13.9). It is produced in response to various stimuli (Table. 13.1), triggering vascular smooth muscle relaxation through activation of guanylate cyclase, leading to an increase in the intracellular levels of cyclic 3,5-guanine monophosphate (cGMP). Its cardiovascular effects protect against atherosclerosis, high blood pressure, heart failure and thrombosis. NO is also the neurotransmitter in various 'nitrergic' nerves in the central and peripheral

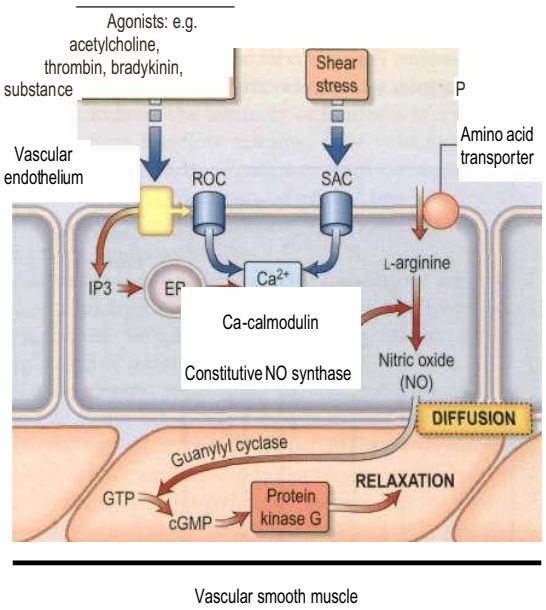

***Fig. 13.9* Nitric oxide: the stimulus for production and function of nitric oxide (NO).** Various stimuli lead to the production of nitric oxide via cytoplasmic calcium/calmodulin. NO triggers smooth muscle relaxation via the activation of guanylyl cyclase. ROC, receptor-operated Ca^{2+} channel; SAC, stretch-activated Ca^{2+} channel; IP3, inositol triphosphate; ER, endoplasmic reticulum; GTP, guanine triphosphate; cGMR cyclic guanine monophosphate.

Table 13.1 Some of the products and functions of the vascular endothelium

Endothelial product	Function(s)	Stimulus
Nitrous oxide (NO)	Vasodilatation Inhibits platelet aggregation Inhibits transcription of adhesion molecules Inhibits vascular smooth muscle proliferation	Shear stress, e.g. induced by exercise Agonists: thrombin, acetylcholine, endothelin, bradykinin, serotonin, substance P Inflammation/endotoxin shock
Prostacyclin (PGI_2)	Vasodilatation Inhibits platelet aggregation	Agonist: thrombin Inflammation
Prostanoids	Vasoconstriction	Hypoxia
Endothelin	Vasoconstriction	Thrombin, angiotensin II, vasopressin Hypoxia *NB:* Inhibited by shear stress
Endothelial-derived hyperpolarizing factor	Vasodilatation	Agonists: bradykinin, acetylcholine
Angiotensin-converting enzyme	Vasoconstriction	Expressed naturally
Von Willebrand factor	Promotes platelet aggregation Stabilizes factor VIII	Agonists: thrombin, epinephrine (adrenaline)
Adhesion molecules P, L, E selectins	Margination of white blood cells (WBC)	Inflammatory mediators: histamine, thrombin, TNF, IL-6
ICAM,VCAM,PECAM	Binding and diapedesis of WBC into vessel wall	
Vascular endothelial growth factor (VEGF)	Angiogenesis Vasodilatation Increased vascular permeability	Pregnancy Hypoxia Inflammation: rheumatoid arthritis, trauma, tumours

ICAM, intracellular adhesion molecule; VCAM, vascular cell adhesion molecule; PECAM, platelet/endothelial cell adhesion molecule; TNF, tumour necrosis factor; IL, interleukin

nervous systems and may play a role in the central regulation of vascular tone. The new class of drugs used to treat erectile dysfunction, the phosphodiesterase (PDE_5) inhibitors, prevent the breakdown of cGMP and promote vasodilatation.

PGI_2 is synergistic to NO and also plays a role in the local regulation of vasomotor tone. *Endothelin* is a 21-amino-acid peptide that counteracts the effects of NO. Its production is inhibited by shear stress, i.e. the stress exerted on the vessel wall by the flowing blood, and it causes profound vasoconstriction and vascular smooth muscle hypertrophy. It is thought to play a role in the genesis of hypertension and atheroma. *Angiotensin-converting enzyme* located on the endothelial cell membrane converts circulating angiotensin I (synthesized by the action of renin on angiotensinogen) to angiotensin II which has vasoconstrictor properties and leads to aldosterone release (Fig. 18.27). Aldosterone promotes sodium absorption from the kidney and together with the angiotensin-induced vasoconstriction provides haemodynamic stability. Other factors which influence vasomotor tone include histamine (released by mast cells), bradykinin (synthesized from kininogen by the action of coagulation factor Xlla) and serotonin released by platelets.

Anti- and prothrombotic mechanisms

PGI_2, produced from arachidonic acid in the endothelial cell membrane by the action of the enzyme cyclo-oxygenase (Fig. 14.32), inhibits platelet aggregation. Low-dose aspirin prevents activation of the cyclo-oxygenase pathway in platelets but only to a degree that does not affect PGI_2 synthesis, unlike higher doses. Other anti-thrombotic agents such as clopidogrel (ADP receptor antagonist) and glycoprotein lib/Ilia inhibitors achieve their effects by acting directly on platelet receptors. The antithrombotic effect of PGI_2 is aided by NO, affecting platelets via activation of guanylate cyclase. The endothelial cell membrane also produces other anticoagulant molecules such as thrombomodulin, heparin sulphate and various fibrinolytic factors. Clinically used, fast-acting, heparin preparations are identical to this naturally occurring molecule; slower-acting warfarin inhibits the synthesis of various coagulation factors from vitamin K in the liver; ximelagatran is a direct thrombin inhibitor.

In addition to their ability to prevent clotting, endothelial cells also aid thrombosis. They are responsible for the production of von Willebrand factor through a unique organelle called the Weibal-Palade body, which not only acts as a carrier for factor VIII but also promotes platelet adhesion by binding to exposed collagen (p. 479).

Modulation of immune responses

In response to various inflammatory mediators, the vascular endothelium expresses various so-called 'adhesion molecules' which promote leucocyte attraction, adhesion and infiltration into the blood vessel wall (p. 149).

Regulation of vascular cell growth

The endothelial cells are also responsible for the development of new blood vessels ('angiogenesis') in the placenta, wound healing, tissue repair and tumour growth. This process is facilitated by the vascular endothelial growth factor(VEGF).

Fetal circulation

In utero, the pulmonary circulation is largely unnecessary because fetal blood is oxygenated by placental blood flow, a parallel and integral element in the systemic circulation. In the fetus, systemic venous blood returning to the right atrium is partly deflected through the foramen ovale to the left atrium. Blood that passes through the right ventricle is diverted from the pulmonary artery to the aorta through the ductus arteriosus. Thus, the systemic venous return, which is a mixture of oxygenated and deoxygenated blood, is mostly returned to the systemic arterial system.

At birth, inspiration dilates the pulmonary arterioles, resulting in a dramatic reduction of pulmonary vascular resistance. Blood therefore flows through the pulmonary circulation. The increased oxygen tension and reduced levels of prostaglandins trigger closure of the ductus arteriosus, and the reduced right atrial pressure and increasing left atrial pressure tend to close the foramen ovale. Thus, the circulation is divided into two separate circuits connected in series.

In the fetus the left and right heart both propel blood from the systemic veins to the systemic arteries; thus, severe abnormalities of the heart may not compromise fetal blood flow.

SYMPTOMS OF HEART DISEASE

Eliciting a good history is invaluable in diagnosing, and managing heart disease. There is overlap between symptoms arising from cardiovascular disease and those originating from other pathology. The following symptoms occur with heart disease:

- chest pain
- dyspnoea
- palpitations *
- syncope
- fatigue
- peripheral oedema

The severity of anginal pain, dyspnoea, palpitations or fatigue may be classified according to the New York Heart Association grading of 'cardiac status' (Table 13.2).

Chest pain

This is the symptom most commonly associated with heart disease.

The pain of angina pectoris and myocardial infarction is due to myocardial hypoxia. Classically, it is felt as crushing, gripping or heavy pain behind the sternum in the centre of the chest, radiating to the neck, shoulder or jaw, or more rarely to the teeth, back or abdomen. It may be associated with pain, paraesthesia or heaviness in one (commonly the left) or both arms. Typically, the pain of angina pectoris is provoked by exercise and promptly relieved by rest or short-acting nitrates. Angina occurring on lying flat is termed decubitus angina. The level of exertion required to provoke pain - for example, after walking on the flat for 200 yards - should be elicited.

Angina that is becoming more frequent or unpredictable, or occurs at rest is classified as unstable, a component of the 'acute coronary syndrome' (p. 808). Even quite significant ischaemia/infarction may not be associated with chest pain but rather with dyspnoea, nausea and sweating. This is 'silent' ischaemia due to loss of pain-sensing fibres within the heart, and is more common in the diabetic and elderly. Ischaemia may also present with atypical (e.g. dyspeptic) pain.

Central chest pain *radiating to the back* may be due to cardiac ischaemia but a dissecting or enlarging thoracic aortic aneurysm also produces a similar pain and sometimes ECG changes.

Pericarditis pain is also felt at the centre of the chest. However, its character is similar to pleuritic pain, i.e. sharp, exacerbated by movement, respiration and cough-

Table 13.2 **The New York Heart Association grading of 'cardiac status' (modified)**

Grade 1	Uncompromised (no breathlessness)
Grade 2	Slightly compromised (on severe exertion)
Grade 3	Moderately compromised (on mild exertion)
Grade 4	Severely compromised (breathless at rest)

Table 13.3 Differential diagnosis of chest pain

Central	Lateral/peripheral
Cardiac	**Pulmonary**
Ischaemic heart disease (infarction or angina)	Infarction
Coronary artery spasm	Pneumonia
Pericarditis/myocarditis Mitral valve prolapse Aortic aneurysm/dissection	Pneumothorax
	Lung cancer
	Mesiothelioma
Non-cardiac	**Non-pulmonary**
Pulmonary embolism	Bornholm disease (epidemic myalgia) Herpes zoster Trauma (ribs/muscular)
Oesophageal disease

ing. Unlike pleuritic pain, however, some relief may be afforded by sitting forwards.

Left submammary stabbing pain, so-called 'precordial catch', is usually associated with anxiety (called effort syndrome or Da Costa's syndrome), although cardiac conditions such as mitral valve prolapse may produce a similar sensation. Oesophageal disease may also produce central (retrosternal) chest pain, which can be difficult to differentiate from cardiac pain (see Box 6.4). The differential diagnosis of chest pain is listed in Table 13.3.

Dyspnoea

Dyspnoea is an abnormal awareness of breathlessness. Pain, particularly within the chest and abdomen, may also lead to dyspnoea. However, the main causes are cardiac and pulmonary pathologies; in the cardiovascular system, this is most commonly due to left ventricular failure (LVF).

Left ventricular failure causes dyspnoea due to oedema of the pulmonary interstitium and alveoli. This makes the lungs stiff (less compliant), thus increasing the respiratory effort required to ventilate the lungs. Tachypnoea (increased respiratory rate) is usually also present owing to stimulation of pulmonary stretch receptors.

It is clinically valuable to grade dyspnoea in a similar manner to chest pain (see above), by the level of exertion required to provoke its onset and by the patient's cardiac status (Table 13.2) as this is an indication of severity. As LVF worsens, other forms of breathlessness such as orthopnoea and paroxysmal nocturnal dyspnoea occur.

Orthopnoea refers to breathlessness on lying flat. Blood is redistributed from the legs into the torso leading to an increase in central and pulmonary blood volume, worsening pulmonary oedema. Furthermore, whilst recumbent, the abdominal contents push up against the diaphragm, restricting its movement (splinting). Orthopnoea is usually overcome by the patient using an increasing number of pillows to sleep. The number of pillows required indicates the severity.

Paroxysmal nocturnal dyspnoea (PND) occurs when a patient is woken from sleep fighting for breath, a dramatic and frightening experience. The patient sits up, stands or opens the window for fresh air. PND is in essence a variation of orthopnoea, in that it is due to the same mechanisms. However, as sensory awareness is reduced whilst asleep, the pulmonary oedema can become quite severe before the patient is awoken.

Some symptoms of LVF may mimic *respiratory pathology* leading to diagnostic difficulty. Most notoriously, oedema of the bronchial endothelium can cause a 'cardiac wheeze' leading to the misdiagnosis of airways disease. Pulmonary oedema may also produce a cough, productive of a frothy blood-tinged sputum. Conversely, PND-like episodes with coughing may occur in asthma, but conventionally the term PND is reserved for cardiac problems.

In severe heart failure, alternate episodes of hyperventilation and apnoea may occur *(Cheyne-Stokes respiration).* If hypopnoea occurs rather than apnoea, the phenomenon is termed 'periodic breathing', but the two variations are known together as *central sleep apnoea syndrome (CSAS).* This occurs due to malfunctioning of the respiratory centre in the brain, caused by poor cardiac output with concurrent cerebrovascular disease.

The symptoms of CSAS, such as daytime somnolence and fatigue, are similar to those of obstructive sleep apnoea syndrome (OSAS, p. 907) and there is considerable overlap with the symptoms of heart failure. CSAS is believed to lead to myocardial hypertrophy and fibrosis, deterioration in cardiac function and complex arrhythmias including non-sustained ventricular tachycardia, hypertension and stroke. Studies conducted on patients with heart failure show that patients with CSAS have a worse prognosis compared to similar patients without CSAS.

Palpitations

Palpitations represent an increased awareness of the normal heartbeat or the sensation of slow, rapid or irregular heart rhythms.

The normal heartbeat may be sensed because of anxiety, excitement, exercise or recumbency on the left side. Therefore, a careful history may help to rule out a pathological cause for palpitations. The most common arrhythmias felt as palpitations are premature ectopic beats and paroxysmal tachycardias. A useful trick is to ask patients to tap out the rate and rhythm of their palpitations, as the different arrhythmias have different characteristics.

Premature beats are felt by the patient as a pause followed by a forceful beat. This is because premature beats are usually followed by a pause before the next normal beat, as the heart resets itself. The next beat is more forceful as the heart has had a longer diastolic period and therefore filled with more blood before this beat. These premature beats may occur in clusters and may lead to great anxiety although they are usually benign.

Paroxysmal tachycardias start abruptly and may be felt as a sudden racing heartbeat. They may terminate as suddenly, but often tend to slow down first, therefore leading to the sensation of the palpitations fading away. Paroxysmal atrial fibrillation is irregular in rhythm whereas other supraventricular or ventricular tachycardias are regular. Paroxysmal tachycardias, especially when prolonged, may lead to other symptoms such as syncope, presyncope, dyspnoea or chest pain. Supraventricular arrhythmias, especially atrial fibrillation and AV nodal re-entry, may also produce polyuria after the palpitations owing to the release of atrial natriuretic peptide (ANP), which leads to sodium and water loss from the kidneys.

Some patients experience *tachycardia on standing,* associated with a mild drop in blood pressure and symptoms of dizziness or near syncope. This is due to a form of autonomic dysfunction termed the postural orthostatic tachycardia syndrome (POTS) and is due to sinus tachycardia (p. 766).

Bradycardias may be appreciated as slow, regular, heavy or forceful beats. Most often, however, they are simply not sensed. All palpitations may be graded by the NYHA cardiac status (Table 13.2).

Syncope

Transient loss of consciousness due to inadequate cerebral blood flow is termed syncope, and may be due to a variety of causes. The cardiovascular causes, which may be grouped as vascular, obstructive or arrhythmic, are listed in Table 13.4.

Vascular. The most common cause of syncope is the *vasovagal attack,* also known as neurocardiogenic or situational syncope (p. 1226), or more commonly as a simple faint. It may be triggered by prolonged orthostatic (standing upright) stress or strong emotion. The mechanism begins with peripheral vasodilatation and venous pooling of blood leading to a reduction in the amount of blood returned to the heart. The near-empty heart responds by contracting vigorously, which in turn stimulates mechanoreceptors (stretch receptors) in the inferoposterior wall of the left ventricle. These in turn trigger reflexes via the central nervous system, which act to reduce ventricular stretch (i.e. further vasodilatation and sometimes profound bradycardia), but this causes a drop in blood pressure and therefore syncope. These episodes are usually associated with a prodrome of dizziness, nausea, sweating, tinnitus, yawning and a sinking feeling. Recovery occurs within a few seconds, especially if the patient lies down.

Table 13.4 Cardiovascular causes of syncope

Vascular
Neurocardiogenic (vasovagal)
Postural hypotension
Postprandial hypotension
Micturition syncope Carotid sinus syncope
Obstructive
Aortic stenosis
Hypertrophic obstructive cardiomyopathy
Pulmonary stenosis
Tetralogy of Fallot
Pulmonary hypertension/embolism
Atrial myxoma/thrombus
Defective prosthetic valve
Arrhythmias
Rapid tachycardias
Profound bradycardias (Stokes-Adams)
Significant pauses (in rhythm) Artificial pacemaker failure

A drop in systolic blood pressure of 20 mmHg or more on standing from a sitting or lying position is termed *postural (orthostatic) hypotension.* This occurs as blood pools in the legs because of gravity. Usually, reflex vasoconstriction prevents a drop in pressure but if this is absent or the patient is fluid-depleted, postural hypotension can occur. This condition is more prevalent in the elderly because of age-related autonomic dysfunction, but also may be related to *vasodilating* or *diuretic drugs.*

Postprandial hypotension is commonly defined as a drop in systolic blood pressure of 20 mmHg or more within 2 hours of the start of a meal. It is also said to occur if the systolic blood pressure drops from above 100 mmHg to under 90 mmHg in the same time period. It is thought to occur very commonly, even more so than postural hypotension, especially in the elderly and hypertensive populations. The mechanism has not been firmly established but it is believed to commence with pooling of blood in the splanchnic vessels. In normal subjects, this elicits a homeostatic response via activation of baroreceptors and the sympathetic system, peripheral vasoconstriction and an increase in cardiac output. Abnormalities in these mechanisms are believed to cause postprandial hypotension.

Micturition syncope refers to loss of consciousness whilst micturating. Some cases occur due to orthostatic hypotension. Bladder evacuation may produce parasympathetic overactivity, resulting in bradycardia and vasodilatation.

Carotid sinus syncope occurs when there is an exaggerated vagal response to carotid sinus stimulation, again leading to bradycardia and vasodilatation. It may be so severe as to provoke syncope by wearing a tight collar, looking upwards or turning the head.

Obstructive. Obstructive cardiac causes listed in Table 13.4 all lead to syncope due to restriction of blood flow from the heart into the rest of the circulation, or between the different chambers of the heart.

Arrhythmias. Stokes-Adams attacks have been defined as sudden loss of consciousness unrelated to posture. It is usually due to intermittent high-grade atrioventricular block, profound bradycardia or ventricular standstill. Without warning, the patient falls to the ground, pale and deeply unconscious. The pulse is usually very slow or

absent. After a few seconds the patient flushes brightly and recovers consciousness as the pulse quickens. Often there are no sequelae, but patients may injure themselves during falls.

Occasionally a generalized convulsion may occur if the period of cerebral hypoxia is prolonged, leading to a misdiagnosis of epilepsy.

Fatigue

Fatigue may be a symptom of inadequate systemic perfusion in heart failure. However, other factors may be responsible:

- poor sleep due to paroxysmal nocturnal dyspnoea, orthopnoea, decubitus angina, nocturia (due to diuretic therapy) or nightmares (due to amiodarone therapy)
- direct side-effect of medication, particularly beta-blockers
- electrolyte imbalance due to diuretic therapy
- as a systemic manifestation of infection such as endocarditis.

Peripheral oedema

Heart failure results in salt and water retention due to renal underperfusion and consequent activation of the renin-angiotensin-aldosterone system (p. 1096). This leads to dependent pitting oedema.

EXAMINATION OF THE CARDIOVASCULAR SYSTEM

GENERAL EXAMINATION

General features of the patient's well-being should be noted as well as the presence of conjunctival pallor, obesity, jaundice and cachexia.

Clubbing (p. 884)

The most common cardiac cause of clubbing is congenital cyanotic heart disease, particularly Fallot's tetralogy. Clubbing is seen in 10% of patients with subacute infective endocarditis. Clubbing takes months to develop and is not seen in acute endocarditis or in neonates or infants with cyanotic heart disease. Clubbing in cor pulmonale is due to the underlying pulmonary disease (e.g. bronchiectasis or fibrosing alveolitis).

Splinter haemorrhages

These small, subungual linear haemorrhages are frequently due to trauma, but are also seen in infective endocarditis.

Cyanosis

This is a dusky blue discoloration of the skin (particularly at the extremities) or of the mucous membranes when the capillary oxygen saturation is less than 85%.

Central cyanosis is seen in the tongue and lips, and is due to desaturation of central arterial blood. This occurs in cardiac and respiratory disorders associated with shunting of deoxygenated venous blood into the systemic circulation, as in the presence of a right-to-left heart shunt.

Peripheral cyanosis is seen in the hands and feet, which are cold. A patient who is centrally cyanosed will also be peripherally cyanosed but isolated peripheral cyanosis occurs in conditions associated with peripheral vasoconstriction and stasis of blood in the extremities leading to increased peripheral oxygen extraction. Such conditions include congestive heart failure, circulatory shock, exposure to cold temperatures and abnormalities of the peripheral circulation.

THE ARTERIAL PULSE

A pulse is felt by compressing an artery against a bone. The first pulse to be examined is the right radial pulse. The timings of the left radial and femoral pulses are then compared with that of the right radial pulse. Delayed femoral pulsation occurs because of a proximal stenosis, particularly of the aorta (coarctation).

Pulse rate

The pulse rate should be between 60 and 80 beats per minute (b.p.m.) when an adult patient is lying quietly in bed. Young children may have higher pulse rates, and athletes and elderly adults may have slower rates. The exact rate is often less valuable than the changes in heart rate observed over time (seen on a pulse chart). When the pulse is irregular, not all ventricular systolic beats may be detected by palpation of the radial pulse. Such apex-radial pulse deficits may be appreciated by counting the radial pulse whilst simultaneously listening to the heartbeat with a stethoscope, and are commonly associated with atrial fibrillation and ventricular ectopy.

Rhythm

In normal subjects the pulse is regular except for a slight quickening in early inspiration and a slowing in expiration (sinus arrhythmia). Irregularities of the pulse rhythm are usually due to premature beats, intermittent heart block or atrial fibrillation.

Premature beats occur as occasional or repeated irregularities superimposed on a regular pulse rhythm. Similarly, intermittent heart block is revealed by occasional beats dropped from an otherwise regular rhythm. A more irregular pattern (irregularly irregular) of heartbeats in which no pattern is recognizable occurs in atrial fibrillation. This irregular pattern persists when the pulse quickens in response to exercise, in contrast to pulse irregularity due to ectopic beats, which usually disappears on exercise. However, this is not a reliable way to distinguish ectopic beats from other causes of pulse irregularity.

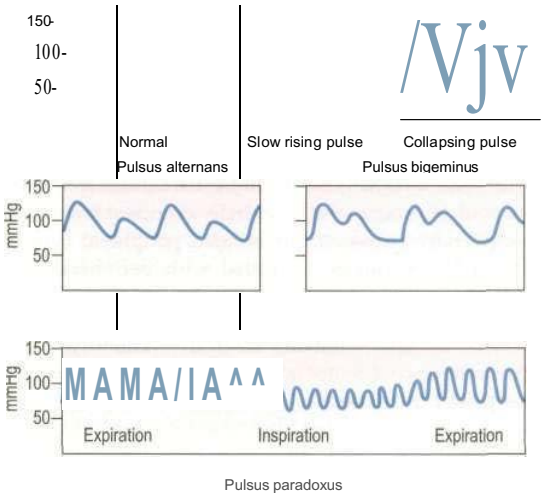

Fig. 13.10 Arterial waveforms.

Carotid pulse

Carotid pulsations are not normally apparent on inspection of the neck but may be visible (Corrigan's sign) in conditions associated with a large-volume pulse, including high output states (such as thyrotoxicosis, anaemia or fever) and in aortic regurgitation. The carotid pulse may also be visible when the carotid artery is aneurysmal or kinked. The amplitude and shape of the carotid pulse is normally examined by palpation of the right carotid artery. Light palpation should be used to detect the presence of a thrill.

A large-volume pulse may also be associated with the large stroke volume that is necessary if bradycardia is present. *A 'collapsing'* or *'water hammer' pulse* is a large-volume pulse characterized by a short duration with a brisk rise and fall. This is best appreciated by palpating the radial artery with the palmer aspect of four fingers whilst elevating the patient's arm above the level of the heart. A collapsing pulse is characteristic of aortic valvular regurgitation or a persistent ductus arteriosus.

A small-volume pulse is seen in cardiac failure, shock and obstructive valvular or vascular disease. It may also be present during tachyarrhythmias. The pulse of aortic stenosis is not only small in volume but is slow in rising to a peak *{plateau pulse)* and is often associated with a notch on the upstroke (anacrotic pulse) or a systolic shudder or thrill (Fig. 13.10).

Paradoxical pulse

Paradoxical pulse is a misnomer, as it is actually an exaggeration of the normal pattern (Fig. 13.10). In normal subjects, the systolic pressure and the pulse pressure (the difference between the systolic and diastolic blood pressures) fall during inspiration. The normal fall of systolic pressure is less than 10 mmHg, and this can be measured using a sphygmomanometer. It is due to increased pulmonary intravascular volume during inspiration. In severe airflow limitation (especially severe asthma) there is an increased negative intrathoracic pressure on inspiration which enhances the normal fall in blood pressure. In patients with cardiac tamponade, the fluid in the pericardium increases the intrapericardial pressure, thereby impeding diastolic filling of the heart. The normal inspiratory increase in venous return to the right ventricle is at the expense of the left ventricle, as both ventricles are confined by the accumulated pericardial fluid within the pericardial space. Paradox can occur through a similar mechanism in constrictive pericarditis but is less common.

Alternating pulse (pulsus alternans)

This is characterized by regular alternate beats that are weak and strong. It is a feature of severe myocardial failure and is due to the prolonged recovery time of damaged myocardium; it indicates a very poor prognosis. It is easily noticed when taking the blood pressure because the systolic pressure may vary from beat to beat by as much as 50 mmHg. Pulsus alternans may also occur when there is rapid, abnormal tachycardia. In this case it acts as a compensatory mechanism and does not indicate a poor prognosis. Pulsus alternans should be distinguished from a bigeminal pulse (see below).

Bigeminal pulse (pulsus bigeminus)

This is due to a premature ectopic beat following every sinus beat. The rhythm is not regular (Fig. 13.10) because every weak pulse is premature.

Pulsus bisferiens

This is a pulse that is found in hypertrophic obstructive cardiomyopathy and in mixed aortic valve disease (regurgitation combined with stenosis). The first systolic wave is the 'percussion' wave produced by the transmission of the left ventricular pressure in early systole. The second peak is the 'tidal' wave caused by recoil of the vascular bed. This normally happens in diastole (the dicrotic wave), but when the left ventricle empties slowly or is obstructed from emptying completely, the tidal wave occurs in late systole. The result is a palpable double pulse.

THE BLOOD PRESSURE

The peak systemic arterial blood pressure is produced by transmission of left ventricular systolic pressure. Vascular tone and an intact aortic valve maintain the diastolic blood pressure. The normal blood pressure is discussed on page 737. How to take the blood pressure is outlined in Practical box 13.1.

Variations in blood pressure

The systolic blood pressure varies by up to 10 mmHg between the right and left brachial arteries. Standing

***Practical Box 13.1* Taking the blood pressure**

1. The blood pressure is taken in the (right) arm with the patient relaxed and comfortable.
2. The sphygmomanometer cuff is wrapped around the upper arm with the inflation bag placed over the brachial artery.
3. The cuff is inflated until the pressure exceeds the arterial pressure - when the radial pulse is no longer palpable.
4. The diaphragm of the stethoscope is positioned over the brachial artery just below the cuff.
5. The cuff pressure is slowly reduced until sounds (Korotkoff sounds) can be heard (phase 1). This is the **systolic pressure.**
6. The pressure is allowed to fall further until the Korotkoff sounds become suddenly muffled (phase 4).
7. The pressure is allowed to fall still further until they disappear (phase 5).

The **diastolic pressure** is usually taken as phase 5 because this phase is more reproducible and nearer to the intravascular diastolic pressure. The Korotkoff sounds may disappear (phase 2) and reappear (phase 3) between the systolic and diastolic pressures. Do not mistake phase 2 for the diastolic pressure or phase 3 for the systolic pressure.

usually causes a slight reduction of the systolic pressure (< 20 mmHg) and an increase in the diastolic pressure (< 10 mmHg). In postural (orthostatic) hypotension, a large postural fall of both the systolic and diastolic pressures is associated with dizziness. When an irregular heart rhythm such as atrial fibrillation is present, the blood pressure is variable. Because the blood pressure is normally liable to variation, it must be estimated on several occasions before it can be declared elevated.

JUGULAR VENOUS PRESSURE

There are no valves between the internal jugular vein and the right atrium. Observation of the column of blood in the internal jugular system is therefore a good measure of right atrial pressure. The external jugular cannot be relied upon because of its valves and because it may be obstructed by the fascial and muscular layers through which it passes; it can only be used if typical venous pulsation is seen, indicating no obstruction to flow.

Measurement of jugular venous pressure (JVP)

(Practicalbox 13.2)

Hepatojugular reflux can be seen when the abdomen is compressed causing a temporary increase in central and hence jugular venous pressure. It is a simple way of confirming the venous nature of a pulsation in the neck.

An abnormally low jugular venous pressure cannot be measured clinically. Causes include haemorrhage and other forms of hypovolaemia.

Elevation of the jugular venous pressure occurs in heart failure. It is also produced by:

***Practical Box 13.2* Measurement of jugular venous pressure**

The patient is positioned at about 45° to the horizontal (between 30° and 60°), wherever the top of the venous pulsation can be seen in a good light.

The jugular venous pressure is measured as the vertical distance between the manubriosternal angle and the top of the venous column.

The normal jugular venous pressure is usually less than 3 cm H_2O, which is equivalent to a right atrial pressure of 8 cm H_2O when measured with reference to a point midway between the anterior and posterior surfaces of the chest. The venous pulsations are not usually palpable (except for the forceful venous distension associated with tricuspid regurgitation).

- constrictive pericarditis
- cardiac tamponade
- renal disease with salt and water retention
- overtransfusion or excessive infusion of fluids
- superior vena caval obstruction (but in this case pulsation is absent).

In constrictive pericarditis or cardiac tamponade, ventricular filling is reduced during inspiration because the ventricles are squeezed by the pericardial fluid or non-compliant pericardium, which tightens as the diaphragm descends. Thus, the level of venous pressure increases during inspiration (Kussmaul's sign). Other causes of an increased jugular pressure also distort the shape of the pressure wave and are considered below.

The jugular venous pressure wave

This consists of three peaks and two troughs (Fig. 13.11). The peaks are described as *a, c* and *v* waves and the troughs are known as *x* and y descents:

- The *a* wave is produced by atrial systole.
- The *x* **descent** occurs when the atrial contraction finishes.
- As the pressure falls there is a small transient increase that produces a positive deflection called the c **wave.** This is caused by transmission of the rapidly increasing right ventricular pressure before the tricuspid valve closes.

a The *v* **wave** develops as the venous return fills the right atrium during continued ventricular systole.

- The *y* **descent** follows the *v* wave when the tricuspid valve opens.

The *a* wave can be distinguished from the *v* wave by observing the venous pulse while palpating the carotid artery. The *a* wave occurs immediately before carotid pulsation and the *v* wave occurs simultaneously with carotid pulsation.

The main abnormalities of the shape of the jugular venous pressure wave are elevations of the *a* and *v* waves and steepness of the *y* descent (Fig. 13.11).

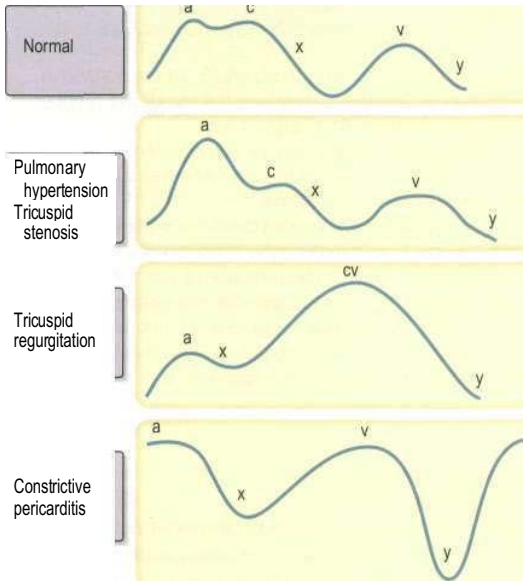

Fig. 13.11 Jugular venous waveforms.

Large a waves

These are caused by increased resistance to ventricular filling, as seen with right ventricular hypertrophy due to pulmonary hypertension or pulmonary stenosis. They may also be caused by tricuspid stenosis, but this is unusual because patients with tricuspid stenosis are usually in atrial fibrillation and therefore do not have *a* waves.

A very large *a* wave occurs when the atrium contracts against a closed tricuspid valve; this is known as a 'cannon wave'. Cannon waves occur irregularly in complete heart block and in ventricular tachycardia. In both these situations there is atrioventricular dissociation, and by random chance there is occasional simultaneous atrial and ventricular contraction. In junctional rhythms the atria and ventricles usually contract simultaneously and rapid, regular cannon waves are produced.

Large *v* waves

Tricuspid regurgitation results in giant *v* waves (systolic waves) because the right ventricular pressure is transmitted directly to the right atrium and the great veins.

Steep y descent

Diastolic collapse of elevated venous pressure can occur in right ventricular failure but is more dramatic in constrictive pericarditis and tricuspid regurgitation. At the end of ventricular systole the elevated atrial pressure suddenly falls when the tricuspid valve opens. However, the ventricles are stiff and cannot be distended and therefore, the venous pressure rapidly rises again. This rapid fall and rise of the jugular venous pulse is known as Friedreich's sign.

EXAMINATION OF THE PRECORDIUM

Inspection

Look for deformities like pectus excavatum and kyphoscoliosis, which can give rise to an ejection systolic murmur arising from compression of the large vessels. Place the patient at 45° and look tangentially for any precordial bulge of cardiac enlargement. Note the position of the apex beat and any other cardiac pulsations; a left ventricular aneurysm may produce eccentric pulsations separate from the apex beat, while a heave may be seen over the left parasternal region due to right ventricular hypertrophy or from an enlarged left atrium.

Palpation

Localize the apex beat, which is the most outward and downward point of cardiac impulse. It can be classified into several abnormal forms:

- **Tapping** apex is a palpable first sound and is felt as a sudden but brief cardiac impulse. It is typically present in early mitral stenosis (when valve leaflets are still pliable), but can also be felt in tachycardic states, e.g. following exercise, especially in thin-built persons.
- **Forceful** apex is vigorous in volume overload conditions, e.g. mitral or aortic regurgitation, or sustained (heaving) in pressure overload situations arising from left ventricular hypertrophy, e.g. aortic stenosis, systemic hypertension and hypertrophic cardiomyopathy.
- The apex beat is **impalpable** in emphysema, obesity and pericardial or pleural effusions.
- **Double pulsation** - two apical impulses with each heartbeat - may be felt in hypertrophic cardiomyopathy, the first pulsation being from atrial contraction. A double impulse can also be due to an outward movement of the myocardium in late systole in a ventricular aneurysm.

A sustained left parasternal impulse or heave is felt with right ventricular hypertrophy or left atrial enlargement. A left atrial impulse can be distinguished from that due to right ventricular hypertrophy as it occurs just before the apex beat or carotid pulsation.

Pulsations from a dilated pulmonary artery may be felt in the second left interspace as a palpable second sound in severe pulmonary hypertension. Similarly, in systemic hypertension, the aortic component of the second sound may be palpable.

Thrills are palpable murmurs and imply a definite abnormality, e.g. systolic thrill of aortic stenosis or mitral regurgitation and diastolic thrill of mitral stenosis.

Auscultation

Use the bell of the stethoscope to hear low-pitched sounds, i.e. heart sounds and the mid-diastolic murmur of mitral stenosis. High-pitched systolic murmurs, early diastolic murmurs, ejection clicks and opening snaps are best appreciated with the help of the diaphragm.

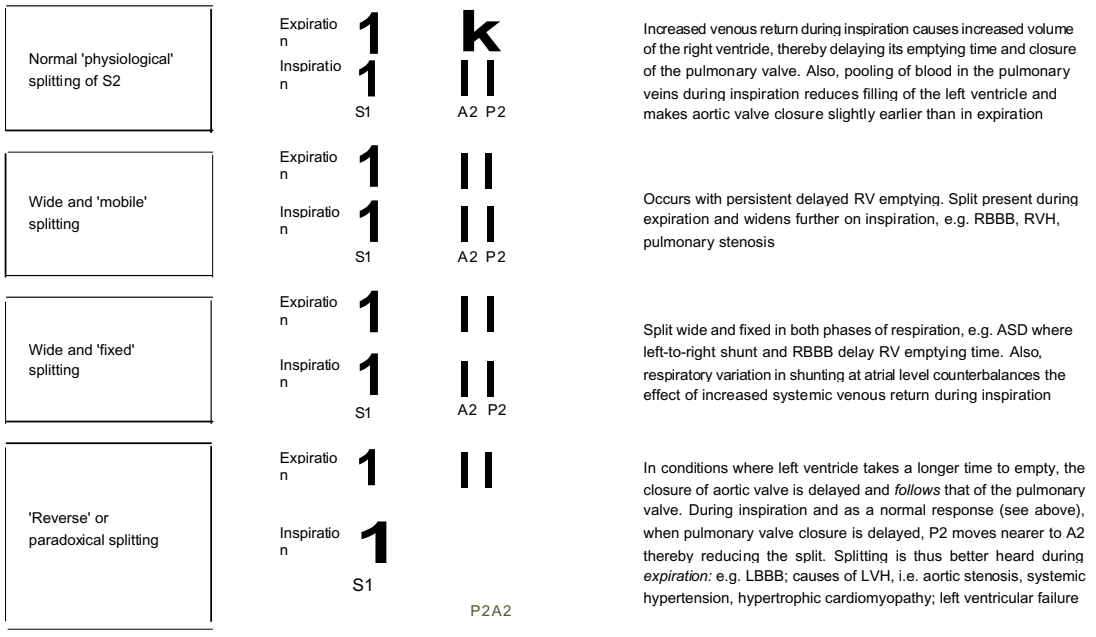

Fig. 13.13 **Variations of the second sound.** S1, first heart sound; A2, aortic component and P2, pulmonary component of the second sound; ASD, atrial septal defect; RBBB, right bundle branch block; LBBB, left bundle branch block; RVH, right ventricular hypertrophy; LVH, left ventricular hypertrophy.

Analyse each sound and murmur separately and time them with the carotid pulse. Follow a routine and examine the mitral, tricuspid, pulmonary and aortic areas in turn.

Characteristics of heart sounds (Fig. 13.12)

First heart sound (S1). This is best heard at the apex. It is usually single or narrowly split.

Loud SI is heard in thin-built persons and hyperdynamic circulation (exercise, fever, anaemia, and thyrotoxicosis). It is also loud if valve leaflets are still widely open when ventricular systole begins, e.g. tachycardia, mild or moderate mitral stenosis and conditions with short PR interval (Wolff-Parkinson-White syndrome).

Soft SI is heard in obesity, emphysema, pericardial effusion, severe calcific mitral stenosis (immobile leaflets), mitral or tricuspid regurgitation, heart failure and cardiogenic shock. It is also soft when the leaflets are already partly closed due to prolonged diastolic filling before ventricular systole begins, e.g. bradycardia and conditions where the PR interval is prolonged (first-degree heart block).

Variable intensity of SI is heard when the relationship between atrial and ventricular systole is not constant (e.g. ventricular tachycardia, complete heart block).

Second heart sound (S2). The pulmonary component of S2 (P2) closely follows the aortic component (A2), as right heart emptying usually finishes after the stronger left heart has emptied. Normal or physiological splitting of S2 during inspiration is commonly heard in children or young adults (Fig. 13.13).

For additional sounds see Figure 13.12 and Figure 3.13.

Heart murmurs (Fig. 13.14)

Murmurs are caused by turbulent blood flow, which can occur because of high blood flow through a normal valve or normal flow through an abnormal valve (or into a dilated chamber). The intensity or loudness of a murmur depends upon the flow volume, flow velocity and the distance of the source of murmur from the stethoscope. Thus, systolic murmurs can be graded between 1 and 6, and diastolic between 1 and 4 according to their increasing loudness.

Murmurs due to high-velocity blood flow, e.g. mitral or aortic regurgitation, are often described as 'blowing' or high-pitched in quality and are best heard with the diaphragm of the stethoscope.

Low-velocity murmurs, e.g. mitral stenosis, are 'rumbling' and low-pitched in quality and are best heard with the bell of the stethoscope. Right-sided murmurs become louder on inspiration, since inspiration increases venous return to the right heart. Innocent or flow murmurs are soft, early systolic, short and non-radiating in nature. These are best heard **with** the **diaphragm** near the left sternal edge and originate from either the left or right ventricular outflow tracts. They arise in normal hearts and are commonly heard in children and young adults. Flow murmurs are accentuated by physiological manoeuvres that increase the cardiac output, such as exercise, and are also present in other high cardiac output states, e.g. fever, chronic anxiety, anaemia, thyrotoxicosis, beriberi and pregnancy. Skeletal abnormalities like kyphoscoliosis or funnel chest can also produce similar murmurs.

Murmur	Timing and duration	Characteristics	Conditions
Ejection systolic	Systole Diastole S1 S2 S1	Crescendo—decrescendo intensity pattern with peaking in mid-systole S1 and S2 clearly audible May follow aortic or pulmonary ejection clicks Best heard over left sternal border and base | Radiates to carotids and suprasternal notch	Aortic stenosis Pulmonary stenosis Aortic or pulmonary flow murmurs (e.g. atrial septal defect) Left (e.g. hypertrophic cardiomyopathy) or right (Fallofs tetralogy) outflow tract obstruction
Pansystolic	S1 S1	*i* Loud and 'blowing' in nature Maintains a constant intensity Extends from S1 throughout systole, up to and beyond S2 Best heard at apex (MR) or lower left sternal edge (TR; VSD) Radiates to axilla (MR), base (TR; MR) or whole precordium (VSD)	Mitral regurgitation (MR) Tricuspid regurgitation (TR) Ventricular septal defects (VSD) (harsh murmur and usually a thrill palpable)
Late systolic	S1	Unusual and occurs when prolapsed valve leaflets become incompetent in mid-late	Mitral valve prolapse (may be associated with a mid-systolic click) Hypertrophic cardiomyopathy with dynamic outflow tract obstruction
Early diastolic	S2 S1	High-pitched murmurs Decrescendo pattern Best heard with the diaphragm at upper and mid left sternal edge with patient sitting forwards and breath held in expiration	Aortic regurgitation (AR) Pulmonary regurgitation (Graham Steell murmur due to severe pulmonary hypertension secondary to mitral stenosis)
Mid-diastolic	id-systolic click S1 S1 S2	Low-pitched rumbling murmurs Due to increased or turbulent flow across mitral or tricuspid valves Best heard with bell of stethoscope at apex with the patient turned in left lateral position (mitral stenosis), or lower left sternal edge (tricuspid stenosis)	Mitral stenosis (MS) Austin Flint murmur (in severe AR, the regurgitant jet impinges on the anterior mitral leaflet causing partial obstruction of mitral valve) Tricuspid stenosis (TS) Increased flow across mitral or tricuspid valve as in severe MR and TR; left-to-right shunts, e.g. large atrial septal defect
Continuous murmurs	S2 S1 S1	Occur due to combination of systolic and diastolic flow owing to a connection between arterial and venous system or due to high rates of venous flow (e.g. venous hums)	Patent ductus arteriosus Arteriovenous fistulae (congenital, iatrogenic and those associated with increased collateral circulation, as in coarctation of aorta) 'Mammary souffle' due to high mammary blood flow in pregnancy or lactation Venous hum in the neck due to high venous flow in young children or severe anaemia

Opening snap

S2

S1

S2

Fig. 13.14 Types of cardiac murmurs. MR, mitral regurgitation; TR, tricuspid regurgitation; ASD, atrial septal defect; VSD, ventricular septal defect.

Murmurs should be assessed by careful systematic auscultation. While examining, the timing of the murmur, its behaviour during respiration, the point and position where murmur is best heard, the direction of selective propagation (radiation) and the character of murmur must be noted. The presence or absence of any valvular or structural cardiac abnormality should be confirmed by echocardiography.

Extracardiac sounds

Bruits are high-pitched, blowing murmurs that arise from stenosis of a peripheral artery, including the distal aorta.

Pericardial friction rub is a high-pitched, scratching or crunching noise caused by the movement of the inflamed pericardium. It is best heard over the left lower sternal edge in systole, but can also be heard in early diastole or synchronously with atrial contraction.

CARDIAC INVESTIGATIONS

Chest X-ray

Ideally, this is taken in the postero-anterior (PA) direction at maximum inspiration with the heart close to the X-ray

film to minimize magnification with respect to the thorax. A lateral may give additional information if the PA is abnormal. The cardiac structures and great vessels that can be seen on these X-rays are indicated in Figure 13.15. An antero-posterior (AP) view is only taken in an emergency.

Heart size

Heart size can be reliably assessed only from the PA chest film. The maximum transverse diameter of the heart is compared with the maximum transverse diameter of the thorax measured from the inside of the ribs (the cardiothoracic ratio).

The cardiothoracic ratio (CTR) is usually less than 50%, except in neonates, infants, athletes and patients with skeletal abnormalities such as scoliosis and funnel chest. A transverse cardiac diameter of more than 15.5 cm is abnormal. Pericardial effusion or cardiac dilatation causes an increase in the ratio.

A *pericardial effusion* produces a globular, sharp-edged shadow (Fig. 13.113, p. 855). This enlargement may occur quite suddenly and, unlike in heart failure, there is no associated change in the pulmonary vasculature. The echocardiogram is more specific than the chest X-ray for the diagnosis of pericardial effusion, partly because at least 250 mL of fluid must accumulate before X-ray changes are apparent.

Certain patterns of specific chamber enlargement may be seen on the chest X-ray:

Left atrial dilatation. This results in prominence of the left atrial appendage and a straightening or convex bulging of the upper left heart border, a double atrial shadow to the right of the sternum, and splaying of the carina because a large left atrium elevates the left main bronchus (Fig. 13.16). On a lateral chest X-ray an enlarged left atrium bulges backwards, impinging on the oesophagus.

Left ventricular enlargement. This results in an increase in the CTR and a smooth elongation and increased convexity of the left heart border. A left ventricular aneurysm may produce a distinct bulge or distortion of the left heart border (see Fig. 13.17, p. 743).

Right atrial enlargement. This results in the right border of the heart projecting into the right lower lung field.

Right ventricular enlargement. This can be due to congenital heart disease. It results in an increase of the CTR and an upward displacement of the apex of the heart because the enlarging right ventricle pushes the left ventricle leftwards, upwards and eventually backwards. Differentiation of left from right ventricular enlargement may be difficult from the shape of the left heart border alone, but the lateral view shows enlargement anteriorly for the right ventricle and posteriorly for the left ventricle.

Ascending aortic dilatation or enlargement. This is seen as a prominence of the aortic shadow to the right of the mediastinum between the right atrium and superior vena cava.

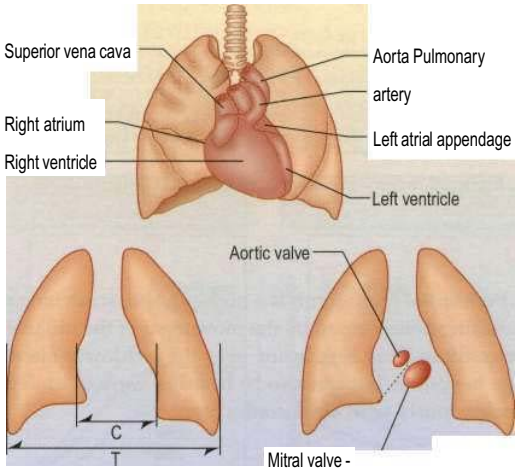

Fig. 13.15 **Diagrams to show the heart silhouette on the chest X-ray,** measurements of the cardiothoracic ratio (CTR) and the location of the cardiac valves. The dotted line is an arbitrary line from the left hilum to the right cardiophrenic angle: a calcified aortic valve is seen above this line. CTR = (C/T) x 100%; normal CTR < 50%.

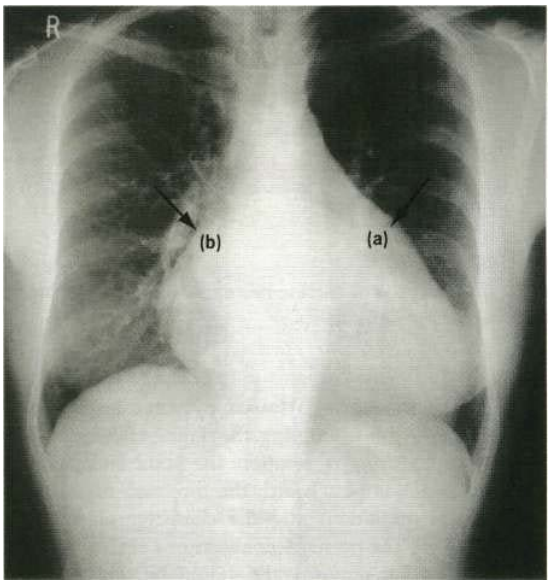

Fig. 13.16 **Plain PA chest X-ray of a patient with mixed mitral valve disease.** The left atrium is markedly enlarged (a). Note the large bulge on the left heart border (left atrium) and the 'double shadow' (border of the right and left atria) (b) on the right side of the heart. There is cardiac (left ventricular) enlargement due to mitral regurgitation.

Dissection of the ascending aorta. This is seen as a widening of the mediastinum, although it is often difficult to assess on an AP chest X-ray. A left-sided pleural effusion may be evident if the aneurysm is leaking or there may be blood around the apex of the lung ('capping').

Enlargement of the pulmonary artery. Enlargement of the pulmonary artery in pulmonary hypertension, pulmonary artery stenosis and left-to-right shunts produces a prominent bulge on the left-hand border of the mediastinum below the aortic knuckle.

Calcification

Calcification in the cardiovascular system occurs because of tissue degeneration. Calcification is visible on a lateral or a penetrated PA film, but is best studied by fluoroscopy or CT scanning. Various types of calcification can occur.

Pericardial calcification. This is seen as plaque-like opacities over the surface of the heart, but particularly concentrated in the atrioventricular groove. Such calcification often results from tuberculous pericarditis and may be associated with pericardial constriction (see Fig. 13.114, p. 856).

Valvular calcification. This results from long-standing rheumatic or bicuspid aortic valve disease. On a frontal view a calcified aortic valve is seen above a line joining the left hilum to the right cardiophrenic angle (Fig. 13.15, p. 742). On the lateral film, a calcified aortic valve is seen on or above a line joining the carina to the sternophrenic angle. Mitral valvular calcification is seen below and behind this line.

Myocardial calcification. This occurs after myocardial infarction, especially in association with a left ventricular aneurysm (Fig. 13.17).

Calcification of the aorta. Calcification of the aorta is a common, normal finding in patients over the age of 40 years and appears as a curvilinear opacity around the circumference of the aortic knuckle. Calcification in the ascending aorta usually denotes syphilitic aortitis, whereas in the descending aorta it is due to atheroma or, in the younger patient, to non-specific aortitis.

Coronary arterial calcification. Coronary arterial calcification, especially of the proximal left coronary artery, is associated with coronary atheroma but does not necessarily correspond to the site of maximal stenosis. Electron beam computed tomography is a technique which is now often used to grade coronary calcification. A high score (corrected for age and gender) predicts coronary atherosclerosis.

Lung fields

Pulmonary plethora results from left-to-right shunts (e.g. atrial or ventricular septal defects). It is seen as a general increase in the vascularity of the lung fields and as an increase in the size of hilar vessels (e.g. in the right lower lobe artery), which normally should not exceed 16 mm diameter.

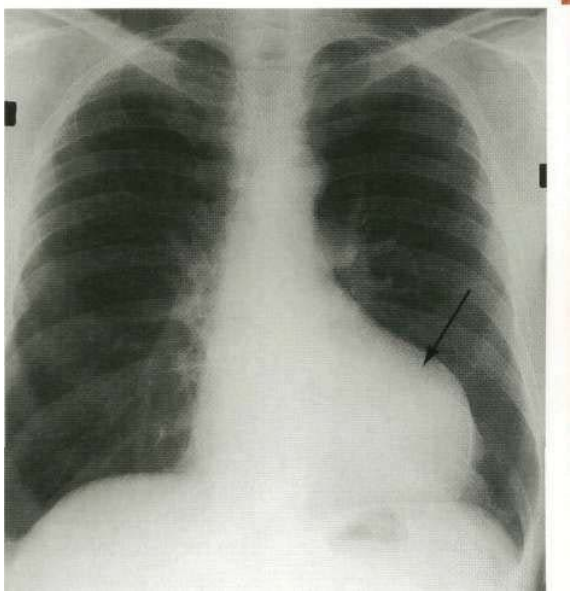

Fig. 13.17 **Left ventricular aneurysm: plain PA chest X-ray demonstrating a cardiac silhouette with a 'bulge' (arrow) on the left lateral border.** This bulge is due to aneurysm formation of many years following a myocardial infarction. A thin line of calcification can be seen along the edge of this bulge.

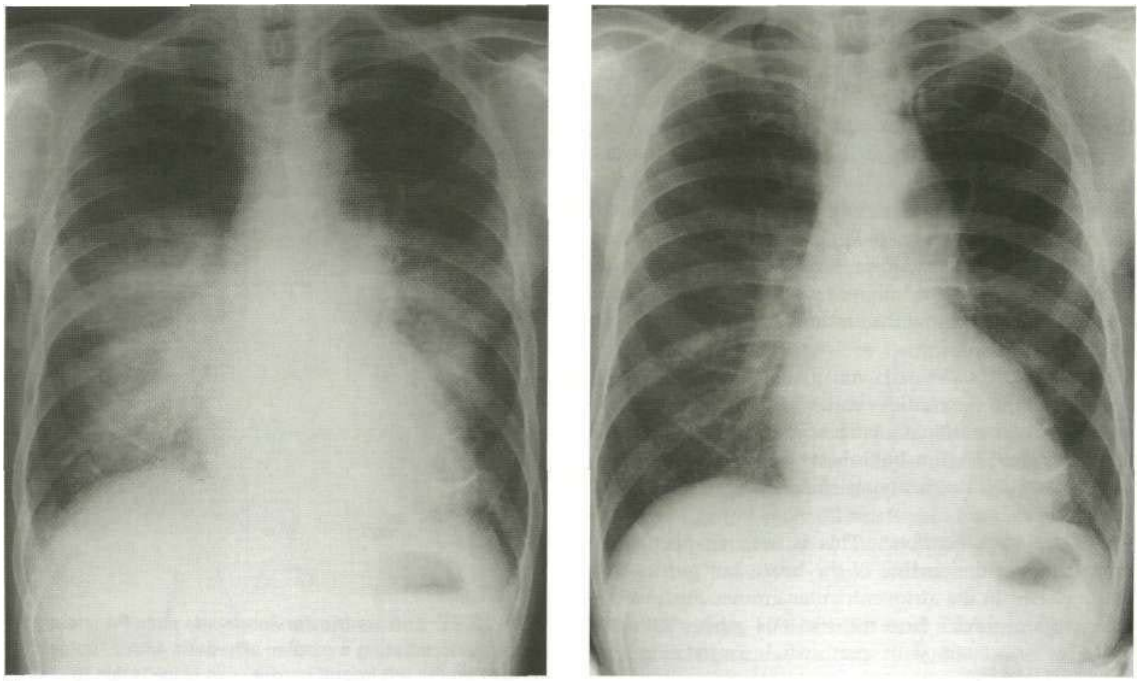
Pulmonary oligaemia is a paucity of vascular markings and a reduction in the width of the arteries. It occurs in situations where there is reduced pulmonary blood flow, such as pulmonary embolism, severe pulmonary stenosis and Fallot's tetralogy.

Pulmonary arterial hypertension may result from pulmonary embolism, chronic lung disease or chronic left heart disease, such as shunts due to a ventricular septal defect or mitral valve stenosis. In addition to X-ray features of these conditions, the pulmonary arteries are prominent close to the hila but are reduced in size (pruned) in the peripheral lung fields. This pattern is usually symmetrical.

Pulmonary venous hypertension occurs in left ventricular failure or mitral valve disease. Normal pulmonary venous pressure is 5-14 mmHg at rest. Mild pulmonary venous hypertension (15-20 mmHg) produces isolated dilatation of the upper zone vessels. Interstitial oedema occurs when the pressure is between 21 and 30 mmHg. This manifests as fluid collections in the interlobar fissures, interlobular septa (Kerley B lines) and pleural spaces. This gives rise to indistinctness of the hilar regions and haziness of the lung fields. Alveolar oedema occurs when the pressure exceeds 30 mmHg, appearing as areas of consolidation and mottling of the lung fields (Fig. 13.18) and pleural effusions. Patients with long-standing elevation of the pulmonary venous pressure have reactive



(a) (b)

Fig. *13.18* Acute pulmonary oedema. This pair of chest X-rays were taken from a patient before (a) and after (b) treatment of acute pulmonary oedema. The X-ray taken when the oedema was present demonstrates hilar haziness, Kerley B lines, upper lobe venous engorgement and fluid in the right horizontal interiobar fissure. These abnormalities are resolved on the film taken after successful treatment.

thickening of the pulmonary arteriolar intima, which protects the alveoli from pulmonary oedema. Thus, in these patients the pulmonary venous pressure may increase to well above 30 mmHg before frank pulmonary oedema develops.

Fluoroscopy

Fluoroscopy is an X-ray procedure used to observe the form and motion of deep structures of the body. It has been largely superseded by echocardiography. However, it is still essential for the insertion of cardiac catheters and pacemaker electrodes, and sometimes used to assess mechanical prosthetic valves.

Electrocardiography

The electrocardiogram (ECG) is a recording of the electrical activity of the heart. It is the vector sum of the depolarization and repolarization potentials of all myocardial cells (Fig. 13.2). At the body surface these generate potential differences of about 1 mV, and the fluctuations of these potentials create the familiar P-QRS-T pattern. At rest the intracellular voltage of the myocardium is polarized at -90 mV compared with that of the extracellular space. This diastolic voltage difference occurs because of the high intracellular potassium concentration, which is maintained by the sodium-potassium pump despite the free membrane permeability to potassium. Depolarization of cardiac cells occurs when there is a sudden increase in the permeability of the membrane to sodium. Sodium rushes into the cell and the negative resting voltage is lost (phase 0 in Fig. 13.39, p. 765). The depolarization of a myocardial cell causes the depolarization of adjacent cells and, in the healthy heart, the entire myocardium is depolarized in a coordinated fashion. During repolarization, cellular electrolyte balance is slowly restored (phases 1, 2 and 3). Slow diastolic depolarization (phase 4) follows until the threshold potential is reached. Another action potential then follows.

The ECG is recorded from two or more simultaneous points of skin contact (electrodes). When cardiac activation proceeds towards the positive contact, an upward deflection is produced on the ECG. Correct representation of a three-dimensional spatial vector requires recordings from three mutually perpendicular (orthogonal) axes. The shape of the human torso does not make this easy, so the practical ECG records 12 projections of the vector, called 'leads' (Fig. 13.19 and Practical box 13.3).

Six of the leads are obtained by recording voltages from the limbs (I, II, III, AVR, AVL and AVF). The other six leads record potentials between points on the chest surface and an average of the three limbs: RA, LA and LL. These are designated V_1-V_6 and aim to select activity

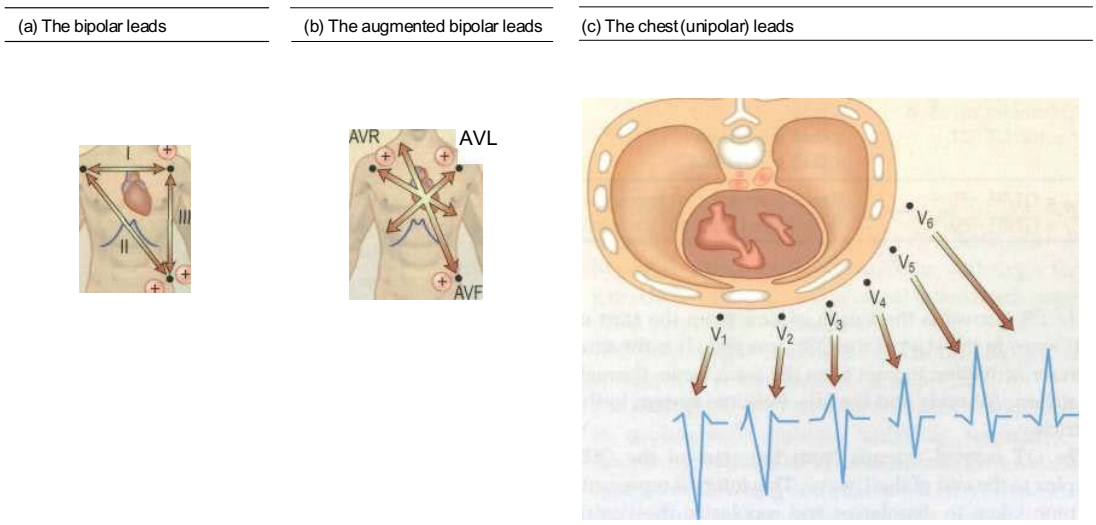


Fig. 13.19 **The connections or directions that comprise the 12-lead electrocardiogram.**

from the right ventricle (Vj-V^, interventricular septum (V3-V4) and left ventricle (V_5-V_6). Note that leads AVR and V-, are oriented towards the cavity of the heart, leads II, III and AVF face the inferior surface, and leads I, AVL and V_6 face the lateral wall of the left ventricle. A V_4 on the right side of the chest (V_4R) is occasionally useful (e.g. for the diagnosis of right ventricular infarction).

Most ECG machines are simultaneous three-channel recorders with output either as a continuous strip or with automatic channel switching. Many ECG machines also analyse the recordings and print the analysis on the record. Usually the machine interpretation is correct, but many arrhythmias still defy automatic analysis.

Practical Box 13.3,
ECG leads

Standard leads (bipolar): Lead I Right arm (-ve) to left arm (+ve) Lead II Right arm (-ve) to left leg (+ve) Lead III Left arm (-ve) to left leg (+ve)

Augmented leads (augmented bipolar):

AVR	Right arm (+ve) to left arm and left leg (-ve)
AVL	Left arm (+ve) to left leg and right arm (-ve)
AVF	Left leg (+ve) to left arm and right arm (-ve)

Chest leads (unipolar) are derived by connecting the V lead against the three extremity leads - the exploring electrodes are placed as follows:

V.,	4th intercostal space just to the right of the sternum
V_2	4th intercostal space just to the left of the sternum
V_3	Halfway between V_2 and V_4
V_4	5th intercostal space in the left mid-clavicular line
V_5	On same horizontal as V_4 in anterior axillary line
V_6	On same horizontal as V_4 in mid-axillary line

The ECG waveform

The shape of the normal ECG waveform (Fig. 13.20) has similarities, whatever the orientation. The first deflection is caused by atrial depolarization, and it is a low-amplitude slow deflection called a *P wave*. The *QRS complex* reflects ventricular activation or depolarization and is sharper and larger in amplitude than the P wave. An initial downward deflection is called the *Q wave.* An initial upward deflection is called an *R wave.* The *S wave* is the last part of ventricular activation. The *T wave* is another slow and low-amplitude deflection that results from ventricular repolarization.

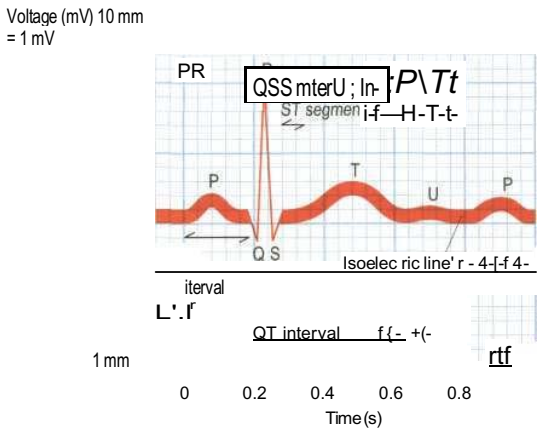

Fig. 13.20 **The waves and elaboration of the normal electrocardiogram.** From Goldman MJ (1976) *Principles of Clinical Electrocardiography,* 9th edn. Los Altos: Lange.

Table 13.5 Normal ECG intervals

P wave duration	<0.12 s	
PR interval	0.12-0.22 s	
QRS complex duration		< 0.10 s
Corrected QT (QTJ		
	< 0.44 s in males	
		< 0.46 s in female
$QT_{cB} = QT/(R-R)V^2$		
$QT_{cF} = QT/(R-RW^3$		
	Bazett's square root formula	Fridericia's cube root formula

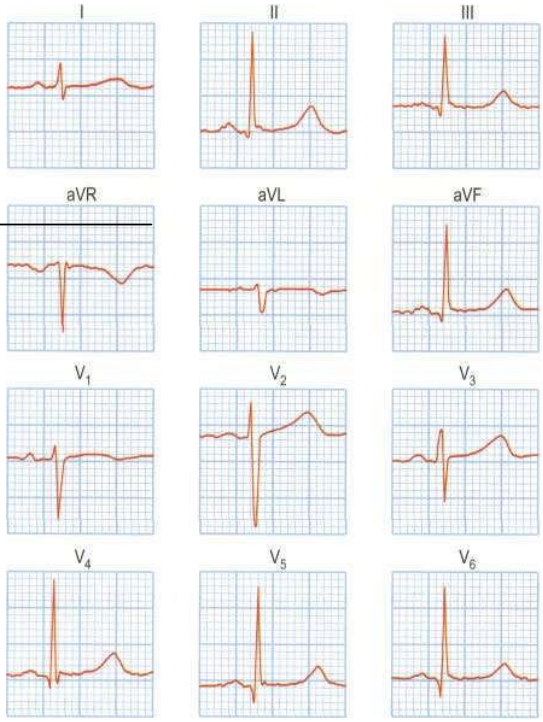

Fig. 13.21 **A normal 12-lead electrocardiogram.**

The PR interval is the length of time from the start of the P wave to the start of the QRS complex. It is the time taken for activation to pass from the sinus node, through the atrium, AV node and the His-Purkinje system to the ventricle.

The QT interval extends from the start of the QRS complex to the end of the T wave. This interval represents the time taken to depolarize and repolarize the ventricular myocardium. QT interval varies greatly with heart rate and is often represented as a corrected QT interval (or QTc) for a given heart rate. There are a number of formulae that exist for derivation of QTc, but the most widely accepted are Bazett's formula and Fridericia's correction (Table 13.5).

Abnormally prolonged QTc can predispose to a risk of dangerous ventricular arrhythmias. Prolongation of QT interval may be congenital or can occur in many acquired conditions (see Table 13.14, p. *777).*

The *ST segment* is the period between the end of the QRS complex and the start of the T wave. In the normal heart, all cells are depolarized by this phase of the ECG, i.e. the ST segment represents ventricular repolarization.

A normal ECG is shown in Fig. 13.21, and the normal values for the electrocardiographic intervals are indicated in Table 13.5. Leads that face the lateral wall of the left ventricle have predominantly positive deflections, and leads looking into the ventricular cavity are usually negative. Detailed patterns depend on the size, shape and rhythm of the heart and the characteristics of the torso.

Cardiac vectors

At any point in time during depolarization and repolarization, electrical potentials are being propagated in different directions. Most of these cancel each other out and only the net force is recorded. This net force in the frontal plane is known as the cardiac vector.

The mean QRS vector can be calculated from the six standard leads (Fig. 13.22):

- normal between -30° and +90°
- left axis deviation between -30° and -90°
- right axis deviation between +90° and +150°.

Calculation of this vector is useful in the diagnosis of some cardiac disorders.

Exercise electrocardiography

This is a technique used to assess the cardiac response to exercise. The ECG is recorded whilst the patient walks or runs on a motorized treadmill. The test is based upon the principle that exercise increases myocardial demand on coronary blood supply which may be inadequate during exercise, and at peak stress can result in relative myocardial ischaemia. Most exercise tests are performed according to a standardized method, e.g. the Bruce protocol. Recording an ECG after exercise is not an adequate form of stress test. Normally there is little change in the T wave or ST segment during exercise.

The patient's exercise capacity (the total time achieved) will depend on many factors; however, patients who can only exercise for less than 6 minutes generally have a poorer prognosis.

Myocardial ischaemia provoked by exertion results in ST segment depression (> 1 mm) in leads facing the affected area. The form of ST segment depression provoked by ischaemia is characteristic: it is either planar or shows down-sloping depression (Fig. 13.23). Up-sloping depression is a non-specific finding. The degree of ST segment depression is positively correlated to the degree of myocardial ischaemia.

ST segment elevation during an exercise test is induced much less frequently than ST depression. When it occurs, it reflects transmural ischaemia caused by coronary spasm or critical stenosis.

Although most abnormalities are detected in leads V_5 (anterior and lateral ischaemia) or AVF (inferior ischaemia), it is best to record a full 12-lead ECG. During an exercise test the blood pressure and rhythm responses to exercise are also assessed. Exercise normally causes an increase in heart rate and blood pressure. A sustained fall in blood

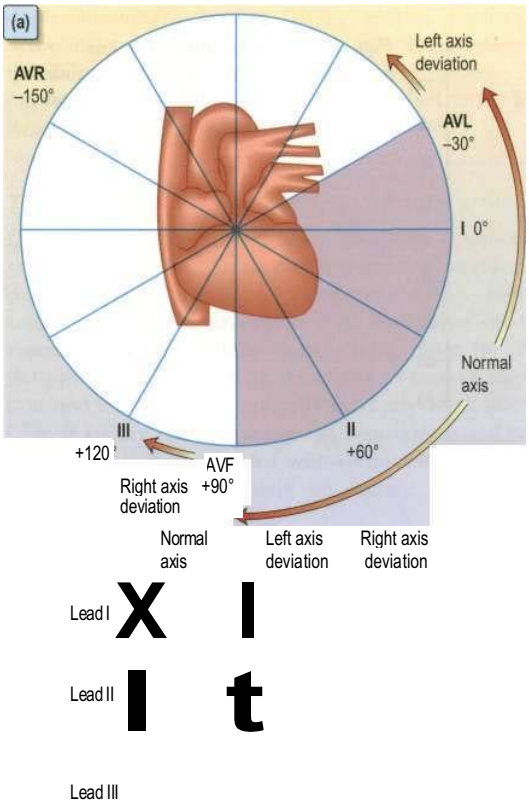

Fig. 13.22 **Cardiac vectors, (a) The hexaxial reference system,** illustrating the six leads in the frontal plane, e.g. lead I is 0°, lead II is +60°, lead III is +120°. **(b) Calculating the direction of the cardiac vector.** In the first column the QRS complex with zero net amplitude (i.e. when the positive and negative deflections are equal) is seen in lead III. The mean QRS vector is therefore perpendicular to lead III and is either -150° or +30°. Lead I is positive, so the axis must be +30°, which is normal. In left axis deviation (second column) the main deflection is positive (R wave) in lead I and negative (S wave) in lead III. In right axis deviation (third column) the main deflection is negative (S wave) in lead I and positive (R wave) in lead III. The frontal plane QRS axis is normal only if the QRS complexes in leads I and II are predominantly positive.

pressure usually indicates severe coronary artery disease. A slow recovery of the heart rate to basal levels has also been reported to be a predictor of mortality.

Frequent premature ventricular depolarizations during the test are associated with a long-term increase in the risk of death from cardiovascular causes and further testing is required in these patients. Use of the exercise test in angina is described on page 805.

24-Hour ambulatory taped electrocardiography

This is a technique for recording transient changes such as a brief paroxysm of tachycardia, an occasional pause in the rhythm, or intermittent ST segment shifts (Fig. 13.24). A conventional 12-lead ECG is recorded in less than a minute and usually samples less than 20 complexes. In a 24-hour period over 100 000 complexes are recorded. Such a large amount of data must be analysed by automatic or semi-automatic methods. This technique is called 'Holter' electrocardiography after its inventor.

Fig. 13.23 **Electrocardiographs changes during exercise test.** Upper trace - significant horizontal ST segment depression during exercise. Lower trace - ST elevation during exercise.

Event recording is another technique that is used to record less frequent arrhythmias. The patient is provided with a pocket-sized device that can record and store a short segment of the ECG. The device may be kept for several days or weeks until the arrhythmia is recorded. Most units of this kind will also allow transtelephonic ECG transmission so that the physician can determine the need for treatment or the continued need for monitoring.

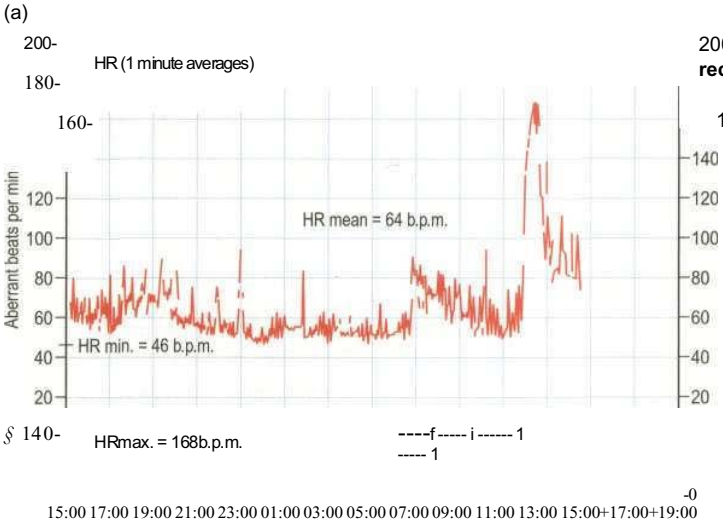
A very small event recorder, known as an implantable loop recorder (ILR), can also be implanted subcutaneously, triggered by events or a magnet, and interrogated by the physician.

Other tests

Non-invasive methods that make use of digitalized Holter recordings to identify increased risk of ventricular arrhythmias include assessment of heart rate variability, signal averaged ECG (SAECG), and T-wave alternans.

Heart rate variability (HRV) can be assessed from a 24-hour ECG. HRV is decreased in some patients following myocardial infarction and represents an abnormality of autonomic tone or cardiac responsiveness. Low HRV is a major risk factor for sudden death and ventricular arrhythmias in patients discharged following myocardial infarction.

Signal-averaged ECG (SAECG) is a technique that requires amplification and averaging of abnormal low-amplitude signals which occur beyond the end of the QRS complex and extend well into the ST segment. These signals are therefore also known as late potentials and are too small to be detected on a surface ECG. They arise in



200 ***Fig. 13.24*** **Examples of Holter _.. recordings, (a)** Tachograph showing sudden increase in heart rate between 1100 and -160 1300 hours.

(b) Ambulatory ECG record of the same patient, revealing supraventricular tachycardia.

(c) Ambulatory ECG showing ST depression in a patient with silent myocardial ischaemia.

areas of slow conduction in the myocardium, such as the border zone of an infarct, where re-entrant ventricular arrhythmias can originate.

T-wave alternans (TWA) is a valuable technique used as a non-invasive marker of susceptibility to ventricular arrhythmias and sudden cardiac death. TWA represents microvolt level changes in the morphology of the T waves in every other beat and can be detected during acute myocardial ischaemia using amplification techniques. Visible TWA on an ordinary surface ECG is quite a rare phenomenon, except in patients with long QT syndromes, particularly during emotion or exercise.

Tilt testing

Patients with suspected neurocardiogenic (vasovagal) syncope should be investigated by upright tilt testing. The patient is secured to a table which is tilted to + 60° to the vertical for 45 minutes or more. The ECG and blood

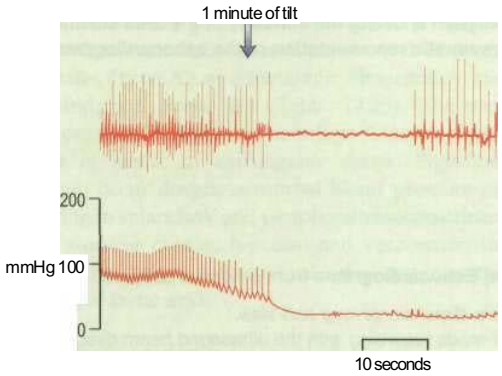


Fig. 13.25 **Tilt test.** The ECG (top trace) and arterial blood pressure recorded during a tilt test. After 1 minute of tilt, hypotension, bradycardia and syncope occur.

pressure are monitored throughout. If neither symptoms nor signs develop, isoprenaline may be slowly infused or glyceryl trinitrate inhaled and the tilt repeated. A positive test results in hypotension, sometimes bradycardia (Fig. 13.25) and presyncope/syncope, and supports the diagnosis of neurocardiogenic syncope. If symptoms and signs appear, placing the patient flat can quickly reverse them. The effect of treatment can be evaluated by repeating the tilt test, but it is not always reproducible.

Carotid sinus massage

Carotid sinus massage (p. 772, Practical box 13.4) may lead to asystole (> 3 s) and/or a fall of blood pressure (> 50 mmHg). This hypersensitive response occurs in many of the normal (especially elderly) population, but may also be responsible for loss of consciousness in some patients with carotid sinus syndrome (p. 766). In one-third of cases carotid sinus massage is only positive when the patient is standing. Atherosclerosis can cause narrowing and stenosis of carotid arteries. Carotid sinus massage should thus be avoided in patients with carotid bruits.

Echocardiography

Echocardiography is a non-invasive diagnostic technique that is widely used in clinical cardiology. It involves the use of ultrasound (either alone or with contrast agent) to assess cardiac structure and function.

Physics

Echocardiography uses transmitted ultrasound wavelengths of 1 mm or less, which correspond to frequencies of approximately 2 MHz (2 million cycles per second) or more. At such high frequencies, the ultrasound waves can be focused into a 'beam' and aimed at a particular region of the heart. The waves are generated in very short bursts or pulses a few microseconds long by a crystal transducer, which also detects returning echoes and converts them into electrical signals.

When the handheld crystal transducer is placed on the body surface the emitted ultrasound pulses encounter interfaces between various body tissues as they pass through the body. In crossing each interface, some of the wave energy is reflected, and if the beam path is approximately at right angles to the plane of the interface, the reflected waves return to the transducer as an echo. Since the velocity of sound in body tissues is almost constant (1550 m/s), the time delay for the echo to return measures the distance of the reflecting interface. Thus, if a single ultrasound pulse is transmitted, a series of echoes return, the first of which is from the closest interface.

Echocardiographic modalities

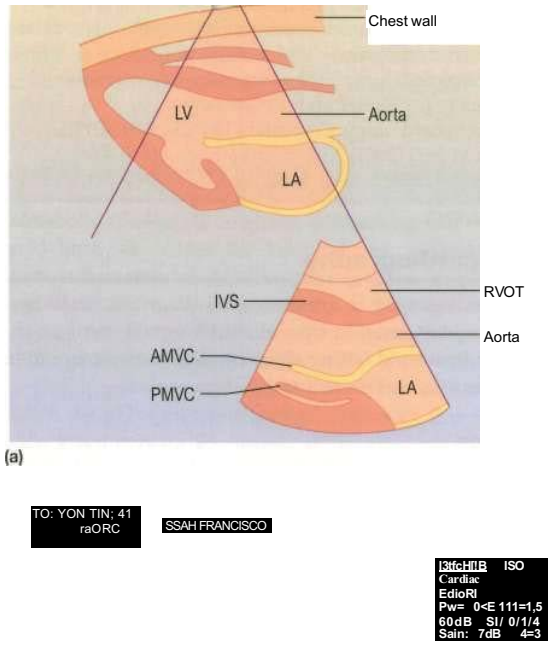
M mode

M mode echocardiography is a technique that details the changing motion of structures along the ultrasound beam with time. Thus the motion of the interventricular septum during the cardiac cycle (either towards or away from the transducer placed on the chest wall) can be assessed and quantified. Stationary structures thus generate horizontal straight lines, the distances of which from the top of the screen indicate their depths, and movements, such as those of heart valves, are indicated by zigzag lines (Fig. 13.26c).

Two-dimensional echocardiography

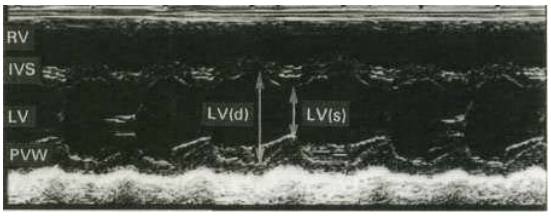
Alternatively, a series of views from different positions can be obtained in the form of a two-dimensional image (cross-sectional 2-D echocardiography) (Fig. 13.26a, b, d).

Fig. 13.26 **Echocardiograms.**
(a) Diagram showing the anatomy of the area scanned and a diagrammatic representation of the echocardiogram.



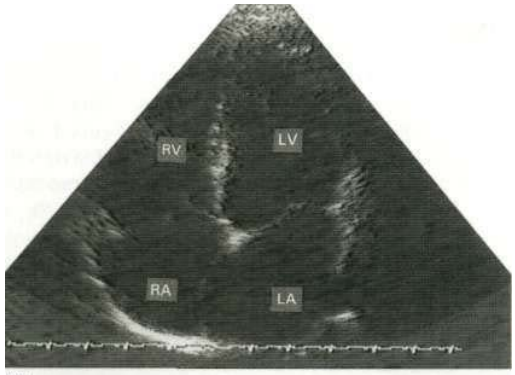
(b)-(e) Echocardiograms from a normal subject:

(b) *Two-dimensional long-axis view.*
(c) *M-mode recording* with the ultrasound beam directed across the left ventricle, just below the mitral valve.
(d) *Two-dimensional short-axis view* at the level of the tips of the papillary muscles.
(e) *Apical four-chamber view.* Note that the convention that shows the position of the transducer (the apex of the sector image) at the top of the paper causes the heart to appear 'upside down' in these views. AMVC, anterior mitral valve cusp; Ao, aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; LV(d), LV(s), left ventricular end-diastolic and end-systolic dimensions; MV, mitral valve; PM, papillary muscle; PMVC, posterior mitral valve cusp; PVW, posterior ventricular wall; RA, right atrium; RV, right ventricle; RVOT, right ventricular outflow tract.



(b)

(d)



(e)

This method is useful for delineating anatomical structures and for quantifying volumes of cardiac chambers. It is conventional for different imaging planes to be used to create standard 2-D views. Ultrasound machines are commercially available that create moving three-dimensional images of the heart in real time. The clinical use of 3-D is evolving and is likely to involve better assessment of valve morphology.

Doppler echocardiography

Echocardiography imaging utilizes echoes from tissue interfaces. Using high amplification, it is also possible to detect weak echoes scattered by small targets, including those from red blood cells. Blood velocity in the heart chambers is typically much more rapid (> 1 m/s) than the movement of myocardial tissue. If the blood is moving in the same direction as the direction of the ultrasound beam, the frequency of the returning echoes will be changed according to the Doppler phenomenon. The Doppler shift frequency is directly proportional to the blood velocity. Blood velocity data can be acquired and displayed in several ways.

Pulsed-wave (PW) Doppler extracts velocity data from the pulse echoes used to form a two-dimensional image and gives useful qualitative information. PW echoes can be specified from locations within an image identified by a sample volume cursor placed on the screen. Such information from the left ventricular outflow tract (LVOT) and right ventricular outflow tract provides the stroke distance, and is used to estimate cardiac output (CO) and also to quantify intracardiac shunts.

Cardiac output can then be derived using the formula: CO = stroke volume x heart rate. Stroke volume is the stroke distance multiplied by the area of the LVOT, which can also be measured echocardiographically. PW Doppler of the flow across the mitral valve and into the left atrium through the pulmonary veins can be used as part of the estimation of left ventricular filling pressure.

Colour flow Doppler. Doppler colour flow imaging uses one colour for blood flowing towards the transducer and another colour for blood flowing away. This technique allows the direction, velocity and timing of the flow to be measured with a simultaneous view of cardiac structure and function. Colour flow Doppler is used to help assess valvular regurgitation (Fig. 13.27) and may be useful in the assessment of coronary blood flow.

Continuous-wave (CW) Doppler collects all the velocity data from the path of the beam and analyses it to generate a spectral display. This is unlike PW Doppler, which provides information from a particular sample volume at one location along a line. Thus, CW Doppler does not provide any depth information.

The outline of the envelope of the spectral display is used to estimate the value of peak velocity throughout the cardiac cycle. CW Doppler is used typically to assess valvular obstruction, which then causes increased velocities. For example, normal velocities are of the order

***Fig. 13.27* Colour Doppler** shows blood flowing away from the echocardiography probe as a blue signal and towards the probe as a red signal. In this patient with tricuspid regurgitation, blood leaks from the right ventrical to the right atrium during cardiac systole.

of 1 m/s across the normal aortic valve, but if there is a severe obstructive lesion, such as a severely stenotic aortic valve, velocities of 4 m/s or more can occur (Fig. 13.28a, b). These velocities are generated by the pressure gradient that exists across the lesion.

According to the Bernoulli equation, the pressure difference between two chambers is calculated as: 4 multiplied by the square of the CW Doppler velocity between chambers. Thus a velocity of 5 m/s across the aortic valve suggests a peak gradient of 4 x 5 x 5 = 100 mmHg between the ascending aorta and the left ventricle. This equation has been validated in a wide variety of clinical situations, including valve stenoses, ventricular septal defects and mtraventricular obstruction (as in hypertrophic cardiomyopathy). It is often clinically unnecessary to resort to invasive methods such as cardiac catheterization to measure intracardiac pressure gradients.

Similarly, pulmonary artery (PA) systolic pressure and right ventricular diastolic pressure can be calculated using the Bernoulli equation. In this case, CW Doppler tracing of the tricuspid regurgitant jet is used to estimate the pressure gradient between the right ventricle and the right atrium. The PA systolic pressure is then calculated by adding the estimated right atrial pressure to the pressure gradient between the right ventricle and the right atrium.

Tissue Doppler. Tissue Doppler is similar to PW Doppler. It measures myocardial tissue velocities within a particular sample volume placed on the image. Such velocities are of the order of 1 cm/s. Currently, tissue Doppler of the mitral annulus is used as part of the estimation of left ventricular filling pressure.

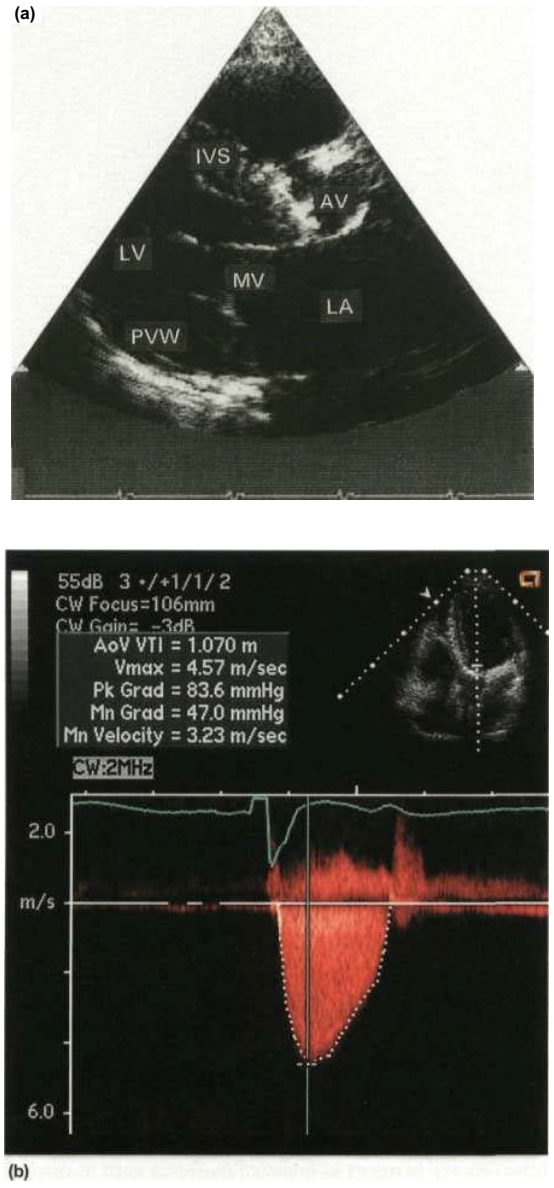


Fig. 13.28 **(a) Two-dimensional echocardiogram (long-axis view)** in a patient with **calcific aortic stenosis.** The calcium in the valve generates abnormally intense echoes. There is some evidence of the associated left ventricular hypertrophy. **(b) Continuous-wave (CW) Doppler signals** obtained from the right upper parasternal edge, where the high-velocity jet from the stenotic valve is coming towards the transducer. AV, aortic valve; LA, left atrium; MV, mitral valve; LV, left ventricle; IVS, interventricular septum; PVW, posterior ventricular wall.

Other ultrasound modalities. Harmonic power Doppler, pulse inversion Doppler and ultraharmonics are used to detect and amplify microsphere-specific signals as part of the echocardiographic assessment of myocardial perfusion.

The echocardiographic examination

Transthomcic echocardiography is a 'non-invasive' procedure that causes the patient no discomfort and is harmless. A physician or technician performs the studies and a comprehensive examination takes 15^5 minutes. The ultrasound machines are either mobile on wheels, or are handheld.

The technical issue associated with echocardiography is that the lungs and rib cage obstruct the passage of ultrasound to the heart in the adult subject. Small 'windows' can usually be found in the third and fourth left intercostal spaces (termed left parasternal); just below the xiphoid process of the sternum (subcostal); and, with the subject turned to the left and exhaling, from the point where the apical beat is palpated (apical). By positioning the transducer successively over these sites and angling and rotating it to line up with the scan plane, a series of standard sectional views is obtained. In children, and some adults, the aortic arch can be visualized from a suprasternal position.

The standard nomenclature for two-dimensional echocardiographic images is shown in Figure 13.26a. The parasternal position of the transducer gives access to the long-axis and short-axis planes. The apical approach gives a second view of the long-axis plane, but with the apex in the foreground, and also shows the four-chamber plane (Fig. 13.26e). A three-chamber apical view is some times also obtained. The convention adopted in most adult cardiology units of showing the transducer position at the top of the image results in the apical views being 'upside-down' compared to the anatomic position of the heart. M-mode recordings are obtained from the para sternal position to document motion patterns of the aorta, aortic valve and left atrium, the mitral valve, and the left and right ventricles (Fig. 13.26c). ■

Quantification in echocardiography

Quantification is helpful because of the relative inaccuracy of *subjective* assessment of chamber size and cardiac function. M mode is used to assess lengths in a single plane. The 1 cm calibration markers on M-mode recordings permit measurement of cardiac dimensions at any point in the cardiac cycle with a typical accuracy of ± 2-3 mm. M mode can be used to estimate LV systolic function by comparing end-diastolic and end-systolic dimensions. For example, the percentage reduction in the left ventricular cavity size ('shortening fraction' - SF) is given by:

$$SF = \frac{LVDD - LVSD}{LVDD} \times 100\%$$

where LVDD is left ventricular diastolic diameter and LVSD is left ventricular systolic diameter, at the base of the heart. The normal range is 30^5%.

This method is easy to perform, but is an inaccurate measure of ejection fraction (EF) because it does not take account of reduced regional function of the mid or apical myocardium, due to infarction for example. For this reason, estimation of EF based upon the difference in LV volumes from systole to diastole, derived from

planimetered measurements of LV area in at least two planes, is more accurate. A normal EF is > 55%. This method is helpful in assessing the response of the patient with heart failure to therapy. This method also permits estimation of LV mass.

Transoesophageal echocardiography (TOE)

This involves placing the transducer mounted on a flexible tube into the oesophagus. This involves the use of local anaesthesia and sometimes intravenous sedation. High-resolution images can be obtained because of the close proximity of the heart to the transducer in the oesophagus, and also because of the higher frequencies that are used relative to transthoracic imaging.

TOE is most commonly used in the assessment of valve structure and function (to assess for reparability of mitral valve prolapse), for features and complications of infective endocarditis, to assess the aorta for aortic dissection, and to assess for cardiac source of embolus.

Wall motion stress echocardiography

Echocardiography can be used clinically to evaluate the patient for the presence of myocardial scars and for the presence of reversible ischaemia. Since ultrasound cannot directly detect red blood cells in capillaries, myocardial wall motion is used as a surrogate for perfusion. Myocardial segments that demonstrate a change in function (defined as a change or reduction in thickening) from rest to stress can be assumed to be supplied by a flow-limiting stenosis in the epicardial artery or graft.

Stress for this indication needs to be inotropic to induce true ischaemia. Physiological stress includes treadmill exercise, which is complicated by the difficulty in obtaining reliable images rapidly as the patient comes off the treadmill, before heart rate reduces back to submaximal levels. Alternatively, pharmacological stress can be induced with dobutamine at graded doses. This is relatively safe but complications such as ventricular arrhythmia have been reported.

This technique can also be used to assess for viability of the myocardium and for hibernating or stunned myocardium.

Myocardial perfusion echocardiography

In order to assess myocardial perfusion by echocardiography (MPE), microspheres of similar size to red blood cells are used as an intravenous contrast agent. Microsphere-specific ultrasound modes such as harmonic power Doppler can be used for detection. MPE involves the use of intravenous infusion of contrast to fill the myocardium. A pulse of ultrasound destroys microspheres within the capillaries (and not the LV cavity), and the time taken to replenish the capillaries is a measure of myocardial blood flow. The time taken to fill should be significantly shorter at stress than at rest.

Clinical use of echocardiography

The echocardiographic findings in particular conditions are discussed in relevant sections, but a brief overview is given below.

Valve stenosis

Congenitally abnormal aortic or pulmonary valves show a characteristic 'dome' shape in systole because the cusps cannot separate fully and a bicuspid configuration may be demonstrated. The presence of calcium in a valve gives rise to intense echoes that generate multiple, parallel lines on M-mode recordings. CW Doppler (p. 751) directed from the apex measures velocity of the jet crossing the diseased valve, from which the pressure gradient can be calculated (Fig. 13.28b).

Mitral stenosis

The M-mode shows restriction and reversal of direction of the posterior leaflet motion (Fig. 13.29c). A short-axis view shows the shape of the mitral orifice in diastole, and its area can be measured directly from the image. Peak, mean and end-diastolic pressure gradients can be obtained from CW Doppler. Additional imaging views indicate the size of the left atrium, and may show the presence of left atrial thrombus.

Valve regurgitation

Doppler is extremely sensitive for detecting valve regurgitation and care must be taken not to overestimate severity of regurgitation. Transthoracic echocardiography is as accurate as angiography in the evaluation of valvular regurgitation, provided appropriate algorithms for interpretation are used. Echocardiography can determine the underlying cause such as rheumatic disease or mitral valve prolapse.

Aortic aneurysms and dissections

Dilatation of the aortic root can be measured accurately and the presence of a reflecting structure within the lumen of the aorta is strongly suggestive of an intimal flap associated with dissection. Transoesophageal views are particularly suitable for detecting pathology in the ascending and descending aorta. In some hospitals this is the investigation of first choice when aortic dissection is suspected although MRI is increasingly used.

Prosthetic heart valves

Each type of mechanical heart valve prosthesis has characteristic echocardiographic features. Irregularity or restriction of movement can be shown. Bioprostheses can also be assessed echocardiographically. The presence of stenosis or regurgitation may be documented by colour flow and continuous wave Doppler. Prosthetic valves imaged transthoracically cast acoustic shadows that obscure the area behind the valve. For this reason a transoesophageal approach is often used to inspect a prosthetic mitral valve for evidence of endocarditis or thrombosis.

Infective endocarditis

Vegetations > 2 mm can be detected (Fig. 13.87a, p. 831). Complications of endocarditis such as valvar regurgitation and abscess can be identified.

Cardiac failure

Left ventricular function and response to treatment is

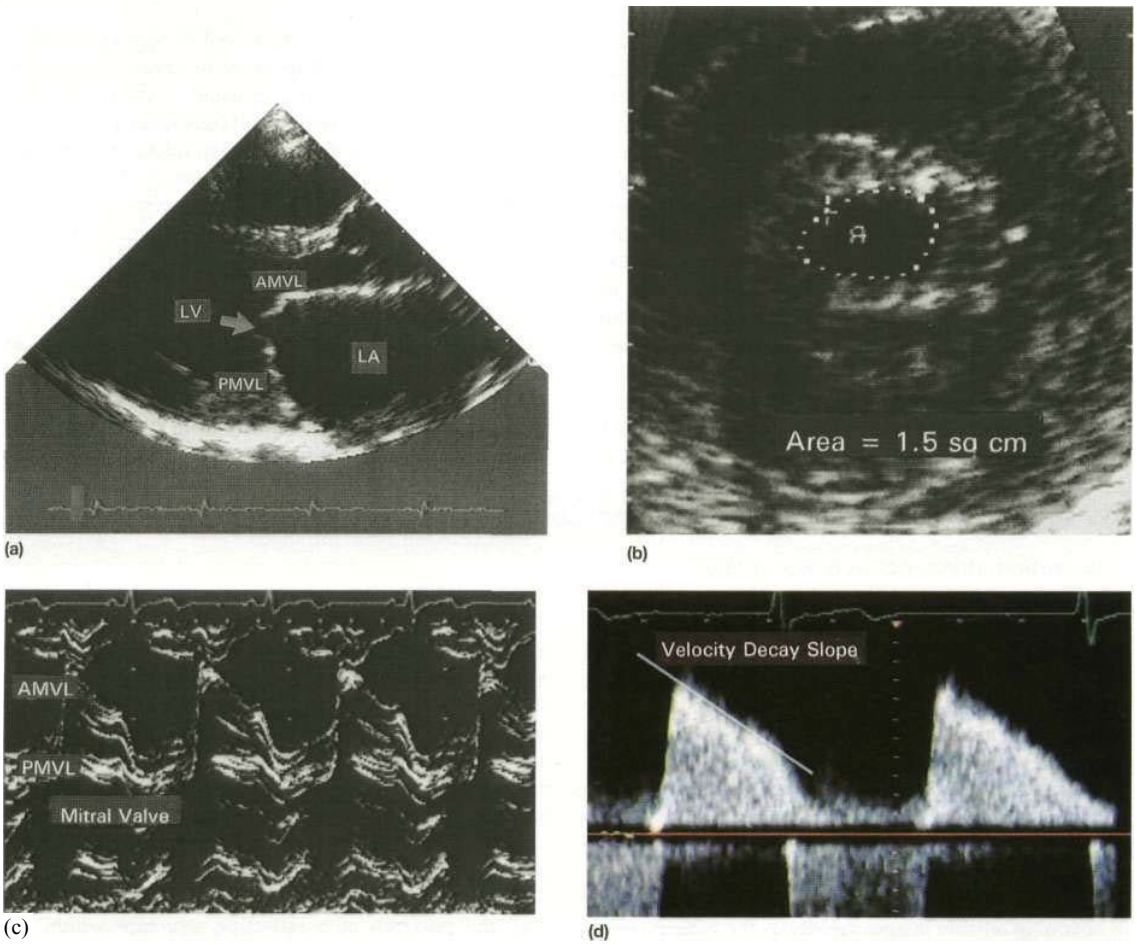

Fig. 13.29 **Echocardiograms in rheumatic mitral valve disease, (a)** *Two-dimensional long-axis view* showing enlarged left atrium and 'hooked' appearance of the mitral valve leaflets resulting from commissural fusion.
(b) *Magnified short-axis* view showing the mitral valve orifice as seen from the direction of the arrow in (a). The orifice area can be planimetered to assess the severity; in this case it is 1.5 cm^2, indicating moderately severe disease.
(c) *M-mode recording* of the mitral valve showing restricted motion of the thickened leaflets.
(d) *Continuous-wave (CW) Doppler recording* showing slow rate of decay of flow velocity from the left atrium to the left ventricle during diastole. It is also possible to derive the valve orifice area from the velocity decay rate. LA, left atrium; LV, left ventricle; AMVL, PMVL, anterior and posterior mitral valve leaflets.

readily assessed and should be performed in all patients with known or suspected heart failure. Left- and right-sided heart cardiac output and filling pressures can also be estimated.

Cardiomyopathies

Dilated cardiomyopathy is characterized by an enlarged, globular shaped, thin-walled left ventricle with poor function and low stroke output shown by reduced movements of the valves (Fig. 13.107, p. 850).

Hypertrophic cardiomyopathy (HCM) (Fig. 13.109, p. 851) shows that the left ventricle is typically small and hypertrophied, with a thickened, interventricular septum (asymmetric septal hypertrophy - ASH). There is a characteristic, displacement of the mitral valve apparatus towards the septum in systole (systolic anterior motion - SAM). Some patients have outflow tract or other LV obstruction and others have regional hypertrophy of other segments.

Restrictive cardiomyopathy shows the typical appearances of conditions such as amyloid, and LV diastolic function can be evaluated.

Pericardial effusion

Fluid in the pericardial cavity shows as an echo-free region between the myocardium and the intense echo of the parietal pericardium (Fig. 13.30). The most severe manifestation of pericardial effusion is tamponade, which is a clinical and not an echocardiographic diagnosis. The size of a pericardial effusion alone does not indicate tamponade. Echocardiographic features of haemodynamically significant effusions include marked (> 25%) respiratory variation of tricuspid, aortic or mitral Doppler tracings. If the inferior vena cava is small and collapses

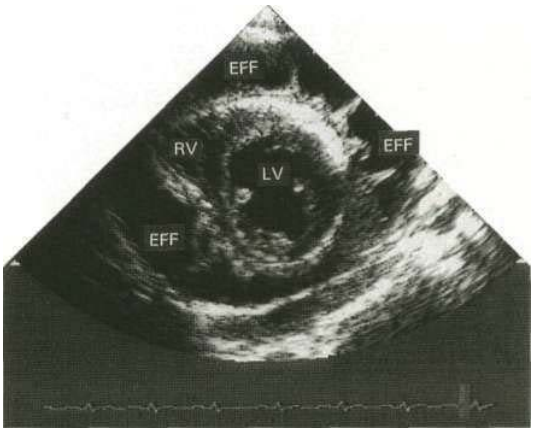

Fig. 13.30 **Two-dimensional echocardiogram (short-axis view)** from a patient with a large **pericardial effusion** associated with pulmonary tuberculosis. The exudate is seen between the visceral and parietal layers of the pericardium and would give a false impression of cardiomegaly on a chest X-ray. Note the multiple fibrous strands within the effusion, showing that it is consolidating and will probably lead to constriction of cardiac function. LV, left ventricle; RV, right ventricle; EFF, effusion.

with respiration it is unlikely that the patient is in tamponade.

Masses within the heart

Echocardiography is a sensitive method for detecting masses within the heart (Fig. 13.103, p. 847), and their haemodynamic significance.

Ischaemic disease

Coronary arteries cannot be imaged adequately using echo techniques, but images may be useful for the diagnosis of complications related to myocardial infarction, such as mitral papillary muscle rupture, tamponade or ventricular septal rupture. The use of stress echocardiography to identify chronic coronary artery disease is discussed above (p. 753).

In the post-infarction period, echocardiography and Doppler are used to diagnose left ventricular aneurysm, left ventricular thrombus, mitral regurgitation and pericardial effusion as well as to assess left ventricular function (ejection fraction).

Congenital heart disease

Echocardiography has largely replaced cardiac catheterization and angiography. The aim of the examination is first to establish the sequence of blood flow through the heart, and to define anatomical abnormalities as well to evaluate the postoperative status of the operated congenital heart patients.

Contrast echo for LV opacification

Intravenous contrast agents are available that permit opacification of the left ventricle and definition of the endocardial border. Their clinical utility has reduced with the advent of harmonic imaging, which has improved image quality in previously difficult to image patients. It is likely that the use of ultrasound contrast agents in echocardiography will increase when there is approval for perfusion imaging.

Intravascular (coronary) ultrasound

Intravascular (coronary) ultrasound probes can be used to image proximal coronary arteries as part of a percutaneous transluminal coronary angioplasty (PTCA) procedure, for example to assess for adequacy of deployment of intracoronary stents.

Nuclear imaging

Nuclear imaging may be used to detect myocardial infarction or to measure myocardial function, perfusion or viability, depending on the radiopharmaceutical used and the technique of imaging. These data are particularly valuable when used in combination.

Image type

Gamma cameras produce a planar image in which structures are superimposed as in a standard radiograph. Single-photon-emission computed tomography (SPECT) imaging uses similar raw data to construct tomographic images, just as a CT image is reconstructed from X-rays. This gives finer anatomical resolution, but is technically demanding. These methods may be used with any of the radiopharmaceuticals.

Myocardial perfusion and viability

Thallium-201 is rapidly taken up by the myocardium, so an image taken immediately after injection reflects the distribution of blood flow to the myocardium. Areas of ischaemia or infarction receive less ^{201}Tl and appear dark. Between 2 and 24 hours after injection, ^{201}Tl is redistributed so that all cardiac myocytes contain a comparable concentration. Images at this time show dark areas where the myocardium has infarcted, but normal density in ischaemic areas. Comparison of the early and late images is one method of predicting whether an ischaemic area of myocardium contains enough viable tissue to justify coronary bypass or angioplasty.

Technetium-99-labelled tetrofosmin (Fig. 13.31) is also taken up rapidly by cardiac myocytes, but does not undergo redistribution. When this substance is injected during exercise, its distribution in the myocardium reflects the distribution of blood at the time of the exercise, even if the image is taken several hours later. This is a sensitive method of detecting myocardial viability. Images produced following injection of ^{99m}Tc-tetrofosmin during exercise can be compared to images produced following injection at rest to decide which areas of ischaemia are reversible (p. 795). In patients unable to exercise, the heart can be stressed with drugs, e.g. dipyridamole or dobutamine.

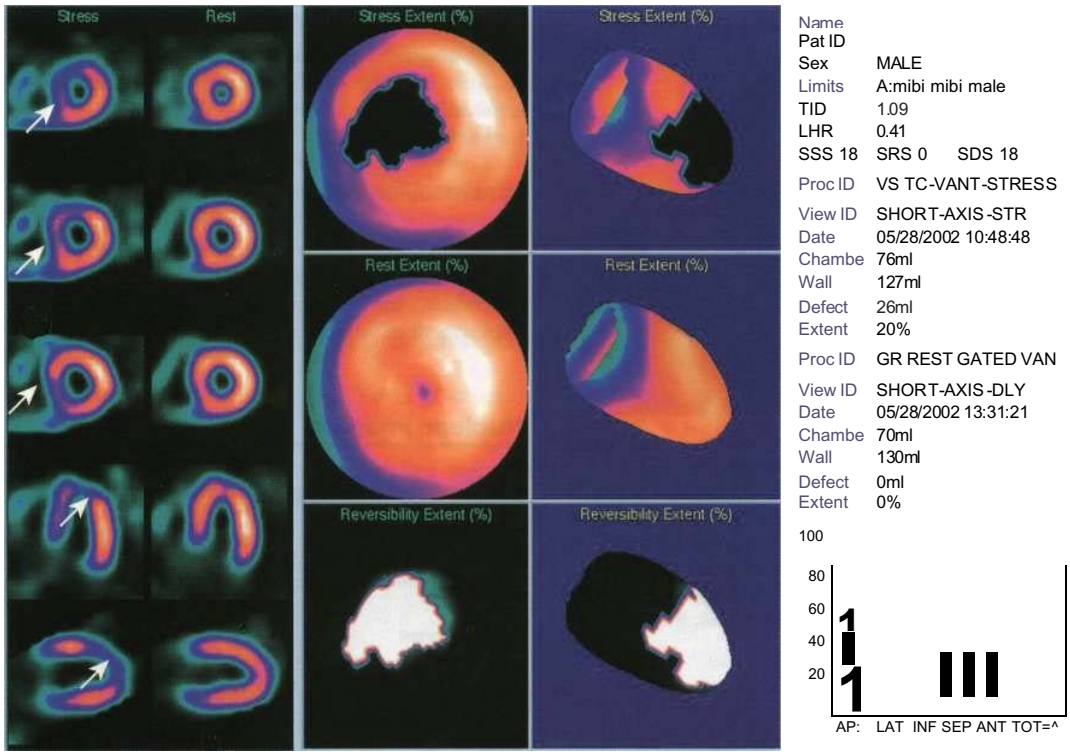

Fig. 13.31 **Myocardial SPECT study acquired with "Tc tetrofosmin tracer.** Left panel - three short axis slices, a horizontal and a vertical axis plane of the left ventricle after stress and following a resting re-injection of tracer. The rest images demonstrate normal tracer uptake (orange signal) in the whole of the left ventricle. The stress images demonstrate reduced tracer uptake (purple-blue signal) in the anterior and septal walls consistent with a significant stenosis in the left anterior descending artery. Middle panel - polar maps of the whole myocardium can localize the ischaemic territory. Right panel - quantitative analysis can help define the extent and reversibility of the ischaemia.

Infarct imaging

Perfusion images produced using compounds labelled with ^{201}Tl or ^{99m}Tc-sestamibi show a myocardial infarction as a perfusion defect or 'cold spot'. These methods are sensitive for detecting and localizing the infarct, but give no information about its age. ^{99m}Tc pyrophosphate is preferentially taken up by myocardium which has undergone infarction within the previous few days. Images are difficult to interpret because the isotope is also concentrated by bone and cartilage.

Radionuclide angiography

Two methods are used to obtain blood pool images:

- A MUGA (multigated acquisition) or equilibrium image is obtained by intravenous injection of ^{99m}Tc, which attaches to the patient's own red cells in vivo and which is therefore retained in the vascular space. Over 200 heartbeats are imaged. Comparison of the study with the ECG allows systolic and diastolic points of the cycle to be identified.
- A first-pass study images the heart as a bolus of isotope makes a single pass through the circulation.

These techniques are complementary, but both outline the cardiac chambers, particularly the left ventricle, by imaging the isotope within the central circulation during systole and diastole. The percentage of the left ventricular volume ejected with each systole (the ejection fraction) can be measured accurately, and any section of the left ventricular wall that contracts abnormally (a wall motion defect) can be visualized (Fig. 13.32).

Positron emission tomography (PET)

This is a technique based on detection of high-energy emissions caused by annihilation of positrons released from unstable isotopes. There are several advantages of PET over other techniques, e.g. improved spatial resolution, accurate quantification, the use of biological isotopes of carbon, nitrogen, and oxygen. However, PET is expensive and requires a cyclotron to produce the short-lived tracers. PET has become a useful investigation in the detection of viable myocardium in patients who are suitable for revascularization.

Myocardial perfusion and ischaemia can be determined with ^{13}N-ammonia or oxygen-15 with greater sensitivity

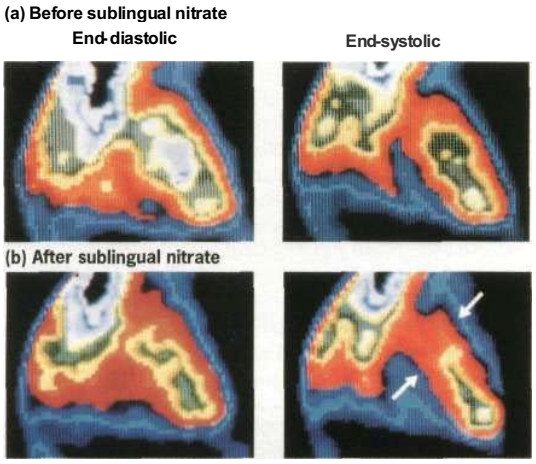

Fig. 13.32 **MUGA scan of patient with left ventricular aneurysm.** End-diastolic and end-systolic images were recorded (a) before administration of sublingual nitrate and (b) again after administration. The apical aneurysm is not altered by administration of nitrate, although the remainder of the left ventricle shows a reduced end-systolic size (arrows).

than SPECT. Myocardial metabolism and viability can be detected with the use of ^{18}F-fluorodeoxyglucose (FDG), which the cardiac myocyte utilizes for energy production in the presence of reduced oxygen supply and blood flow. There may be reduced perfusion to infarcted or fibrotic myocardium, but also reduced FDG uptake. In hibernating myocardium, with viable but dysfunctional myocardium, PET can demonstrate reduced myocardial perfusion but with preserved or increased FDG uptake.

Cardiac catheterization

Cardiac catheterization is the introduction of a thin radio-opaque tube (catheter) into the circulation. The right heart is catheterized by introducing the catheter into a peripheral vein (usually the right femoral or internal jugular vein) and advancing it through the right atrium and ventricle into the pulmonary artery. The pressures in the right heart chambers, and pulmonary artery can be measured directly. An indirect measure of left atrial pressure can be obtained by 'wedging' a catheter into the distal pulmonary artery (p. 971). In this position the pressure from the right ventricle is obstructed by the catheter and only the pulmonary venous and left atrial pressures are recorded.

Left heart catheterization is usually performed via the right femoral artery, although the brachial and radial arteries are sometimes used in patients with significant peripheral vascular disease. A pigtail catheter is advanced up the aorta and manipulated through the aortic valve into the left ventricle. Pressure tracings are taken from the left ventricular cavity. The end-diastolic pressure is invariably elevated in patients with left ventricular dysfunction. A power injection of radio-opaque contrast material is used to opacify the left ventricular cavity (left ventriculography) and thereby assesses left ventricular systolic function. Figure 13.33 presents a normal angiogram showing normal left ventricular function. The catheter is then withdrawn across the aortic valve into the aorta and the 'pullback' gradient across the valve is measured.

Aortography (a power injection into the aortic root) can be performed to assess the aortic root and the presence and severity of aortic regurgitation.

Specially designed catheters are then used to selectively engage the left and right coronary arteries, and contrast cine-angiograms are taken in order to define the coronary circulation and identify the presence and severity of any coronary artery disease. Coronary angiography is described further on page 805.

During cardiac catheterization, blood samples may be withdrawn to measure the concentration of ischaemic metabolites (e.g. lactate) and the oxygen content. These estimations are used to gauge ischaemia, quantify intracardiac shunts, and measure cardiac output.

Digital subtraction angiography

This technique permits the injection of small volumes of radio-contrast agents during cardiac catheterization with the production of computer-analysed high-quality angiograms.

Unfortunately, peripheral injection of contrast does not give adequate visualization of the coronary arteries, but aortic lesions can be visualized.

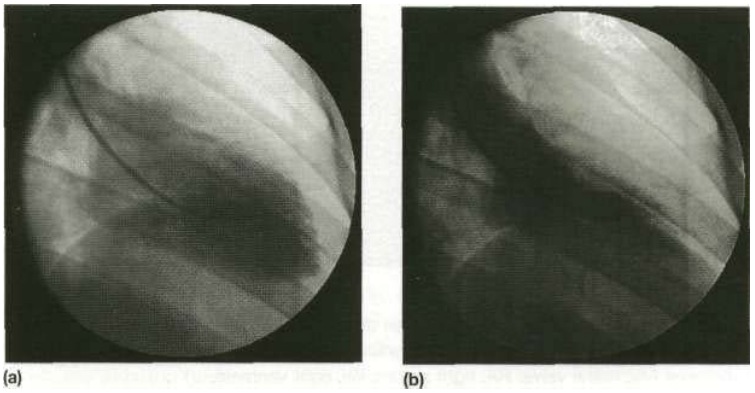

Fig. 13.33 **Normal angiogram.** Diastolic (left) and systolic (right) frames recorded after X-ray contrast was injected into the left ventricle (contrast left ventriculogram). Normal left ventricular function is demonstrated.

CT scanning

CT scanning is limited because an image must be obtained in approximately 50 ms to eliminate cardiac motion. Both conventional and spiral CT are used to image the thoracic aorta and mediastinum. CT involves ionizing radiation, requires intravascular contrast media and has been largely superseded by MRI. Electron-beam CT, which produces a faster beam image, has been developed, but is expensive.

Cardiovascular magnetic resonance (CMR)

mm?

Cardiovascular magnetic resonance (a non-invasive imaging technique that does not involve harmful radiation) is a rapidly developing investigation in cardiology. CMR scanners employ cardiac and respiratory gating to effectively suspend cardio-respiratory motion. The use of different CMR sequences can provide black-blood or white-blood images, still or moving images, anatomical and functional information. Synchronization with the ECG allows cardiac images in systole and diastole to be obtained (Fig. 13.34). Intravenous gadolinium can be used with a myocardial perfusion study, contrast-enhanced angiography or for myocardial infarct imaging. The major contraindications are permanent pacemaker or defibrillator, intracerebral clips, significant claustrophobia. Patients with coronary stents and prosthetic valves can be safely scanned. The current indications for CMR are provided in Table 13.6.

Table 13.6 **Cardiovascular magnetic resonance (CMR)**

Indications

1. Congenital heart disease: (CHD)
   - anatomical assessment following echocardiography, particularly in patients with complex CHD or following surgical intervention
   - follow-up/surveillance studies
   - anomalous pulmonary or systemic venous return
   - assessment of right or left ventricular function/dilatation
2. Cardiomyopathies/cardiac infiltration/pericardial disease
3. Disease of the aorta, including aortic dissection, aneurysm, coarctation
4. Valvular heart disease:
   - quantification of stenosis and regurgitation
   - accurate ventricular dimensions/function
   - planimetry of valvular stenosis
5. Coronary artery disease:
   - left and right ventricular function
   - wall motion assessment during dobutamine stress
   - myocardial perfusion during adenosine stress
   - coronary artery and coronary artery bypass graft imaging
   - myocardial infarct imaging and viability assessment with dobutamine CMR or delayed enhancement
6. Pulmonary vessels

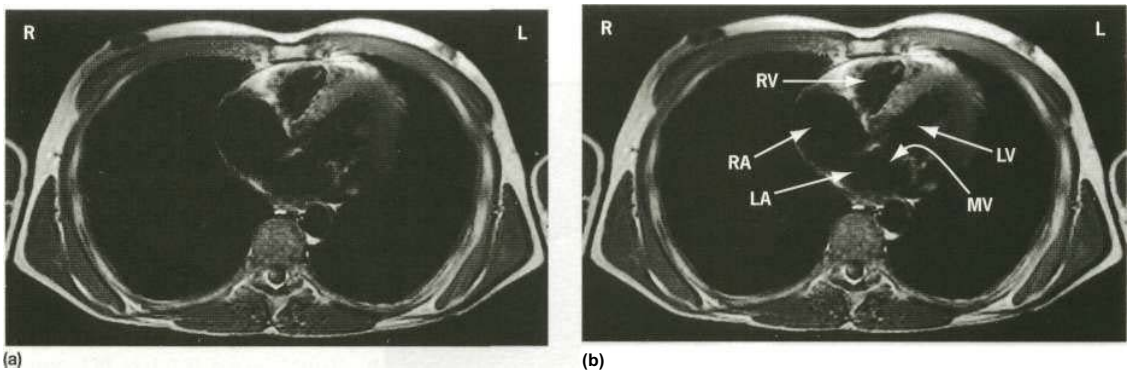

Fig. 13.34 **Magnetic resonance image (MRI),** showing a pair of axial images taken through the mid-thorax at the level of the mitral valve, (a) A view of end-systole, (b) Taken at end-diastole. Note the clear differentiation between the atria and ventricles. This is a normal study. LA, left atrium; LV, left ventricle; MV, mitral valve; RA, right atrium; RV, right ventricle.

THERAPEUTIC PROCEDURES

Cardiac resuscitation

When cardiac arrest occurs, basic life support must be started immediately. The longer the period of respiratory and circulatory arrest, the lower is the chance of restoring healthy life. After 3 minutes, irreversible anoxic cerebral damage occurs.

All healthcare professionals should be familiar with basic procedures. Organization and teamwork are essential to a successful outcome. In hospitals the prior identification of patients who should be resuscitated ensures that treatment is appropriately focused. Medical emergency teams and critical care outreach teams have increasing roles to play in the prevention of cardiac arrests.

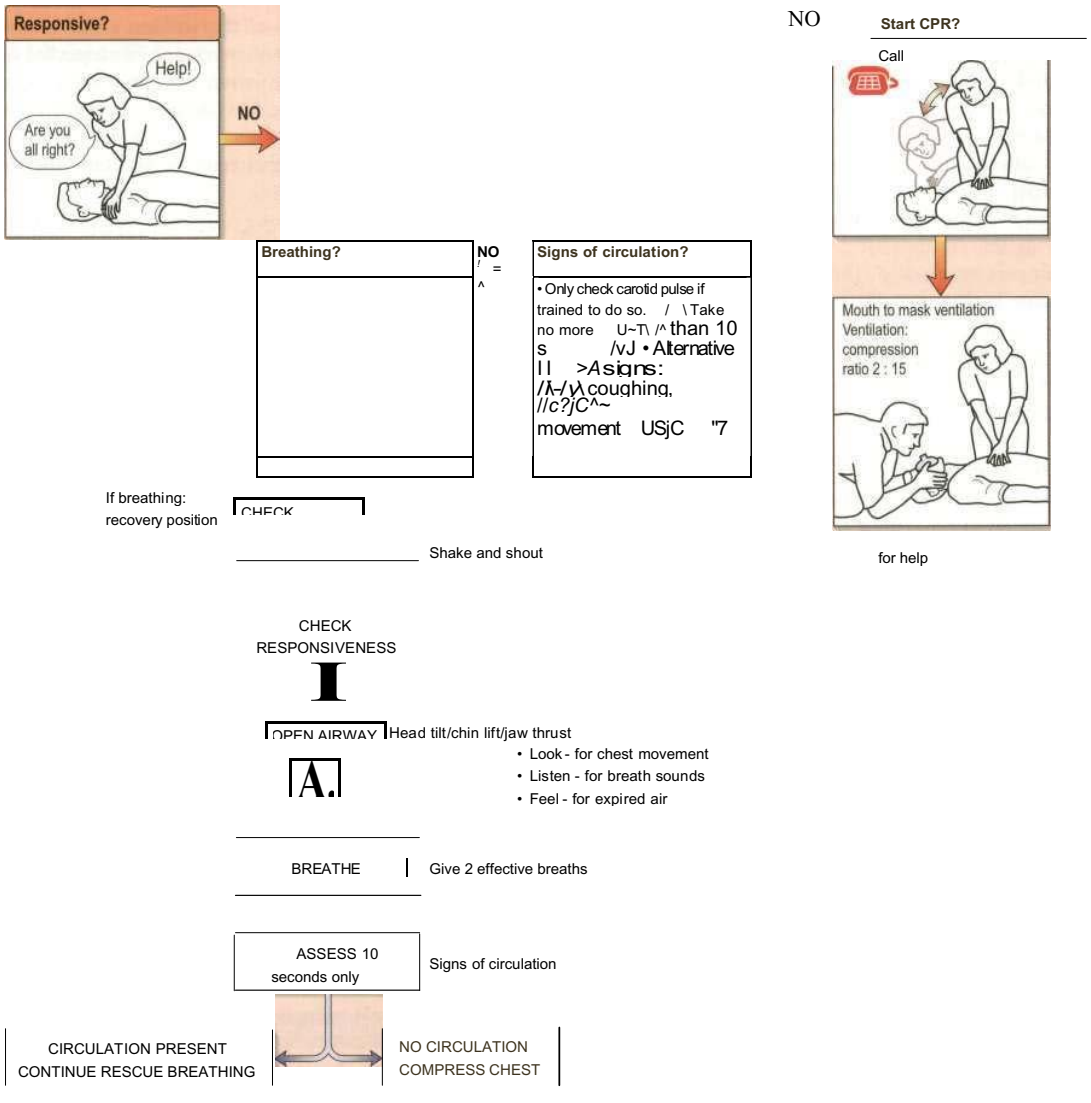
Basic life support (BLS)

The first step is to ensure the safety of the victim and rescuer. The next is to ascertain that the victim is unresponsive by shaking him/her and shouting into one ear. If no response is obtained, help should be sought immediately prior to commencement of basic life support. If the likely cause of the unconsciousness is due to a breathing problem (e.g. trauma, drowning, choking, drug/alcohol intoxication or if the victim is an infant or child) then the rescuer should perform resuscitation for about 1 minute before going for help. Basic life support is easily remembered as A (airway), B (breathing) and C (circulation) (Emergency box 13.1).

Airway

Debris (e.g. blood and mucus) in the mouth and pharynx should be removed. Loose or ill-fitting dentures should be removed. The airway should be opened gently by flexing the neck and extending the head ('sniffing the morning air' position). This manoeuvre is not recommended if a cervical spine injury is suspected. Any obstruction deep in the oral cavity or upper respiratory tract may require abdominal and or chest thrusts (Heimlich manoeuvre, p. 899).

Emergency Box 13.1
Basic life support



Check circulation every minute	100 per minute 15:2 ratio

Send or go for help as soon as possible according to guidelines. Use your mobile!

Breathing

Once a clear airway has been established the victim's breathing should be assessed by the 'look, listen and feel' method. By placing a cheek close to the victim's mouth, breath sounds can be felt and heard and the rise and fall of the chest and abdomen observed. If there is no evidence of breathing, expired air ventilation should be commenced.

With the head of the victim tilted backwards *(head tilt),* the chin pulled forward *(chin lift)* or *jaw thrust* and the nostrils pinched firmly, the rescuer takes a deep breath and seals his/her lips around the mouth of the victim. Two effective breaths are given over 2 seconds each. Expired air respiration is the only method of artificial respiration that successfully ventilates the patient. If resistance to these puffs is experienced, the airway needs to be reassessed and/or the head tilt and jaw lift corrected.

If the rescuer feels reluctant to give mouth-to-mouth resuscitation because of safety concerns (e.g. potentially infective material such as blood or vomitus in the oropharynx) it is acceptable to perform chest compressions alone.

Circulation

Cardiac arrest is accompanied by circulatory collapse. Absence of the carotid pulse confirms this and should be assessed for at least 10 seconds by someone trained to do so. The carotid pulse lies lateral and posterior to the thyroid cartilage and medial to the medial border of sternocleidomastoid: it can sometimes be difficult to palpate.

If absent, the circulation is best re-established by external chest compression. The heel of one hand is placed over the lower half of the victim's sternum and the heel of the second hand is placed over the first with the fingers interlocked. The arms are kept straight and the sternum is rhythmically depressed by 2-5 cm at a rate of approximately 100 per minute. Chest compressions do not massage the heart. The thorax acts as a pump and the heart provides a system of one-way valves to ensure forward circulation. Respiratory and circulatory support is continued by providing two effective breaths for every 15 cardiac compressions (15 : 2 for one or two persons).

It is better to give compressions without interruption. This maintains adequate cerebral and coronary perfusion pressures. There is evidence to suggest that if the person performing compressions tires, the quality of resuscitation deteriorates.

Advanced cardiac life support

By the time effective life support has been established, more help should have arrived and advanced cardiac life support can begin. This consists of ECG monitoring, endotracheal intubation and setting up an intravenous infusion in a large peripheral vein or a central vein. Immediate therapy includes defibrillation, oxygen and cardioactive drugs. It is not possible to recommend an exact sequence of management because it will depend on the arrival of skilled personnel and equipment and the nature of the cardiac arrest.

As soon as possible the cardiac rhythm should be established. At first this is easily achieved by monitoring the ECG through the paddles of a defibrillator. Later, ECG monitoring can be set up. If the ECG shows ventricular fibrillation or if there is any doubt as to the nature of the rhythm (e.g. 'fine' VF may be confused with asystole), no time should be lost before defibrillating the patient. If initial defibrillation attempts are unsuccessful, time can then be spent intubating the patient and setting up an intravenous infusion whilst the circulation is supported by external chest compression.

If there is any difficulty in intubating the patient, ventilation should be continued by means of an airway, a ventilating bag and oxygen. Intravenous epinephrine (adrenaline) results in vasoconstriction and increases the proportion of the cardiac output delivered to the brain.

Causes of unexpected cardiac arrest

Each year in the UK there are approximately 100 000 unexpected deaths occurring within 24 hours of the development of cardiac symptoms. About half of these deaths are almost instantaneous. There are several causes (see Table 13.7).

Most deaths are due to ventricular fibrillation or rapid ventricular tachycardia, and a small proportion are due to severe bradyarrhythmias. Coronary artery disease accounts for approximately 80% of the sudden cardiac death in western society. Transient ischaemia is suspected as the major trigger factor; however, only a small proportion of survivors have clinical evidence of acute myocardial infarction.

There are two mechanisms of sudden unexpected cardiac arrest:

- ventricular fibrillation or pulseless ventricular tachycardia (VF/VT)
- non-VF/VT (asystole and pulseless electrical activity also known as electromechanical dissociation).

The principal difference in the management of these two groups of arrhythmias is the need for attempted defibrillation in those patients with VF/VT (Fig. 13.35).

Three-quarters of arrests are due to ventricular fibrillation or rapid ventricular tachycardia. Only a very small proportion are due to pulseless electrical activity. The remainder are due to asystole. An agonal rhythm is characterized by an inexorable slowing and widening of the QRS complexes associated with falling blood pressure and cardiac output. This type of arrhythmia is very difficult to reverse and usually no attempt should be made because it is the result rather than the cause of death.

Table 13.7 **Causes of unexpected cardiac arrest**

Cardiac arrhythmias (e.g. ventricular fibrillation) Sudden pump failure (e.g. acute myocardial infarction) Acute circulatory obstruction (e.g. pulmonary embolism) Cardiovascular rupture (e.g. aortic dissection, myocardial rupture) Vasomotor collapse (e.g. in pulmonary hypertension)

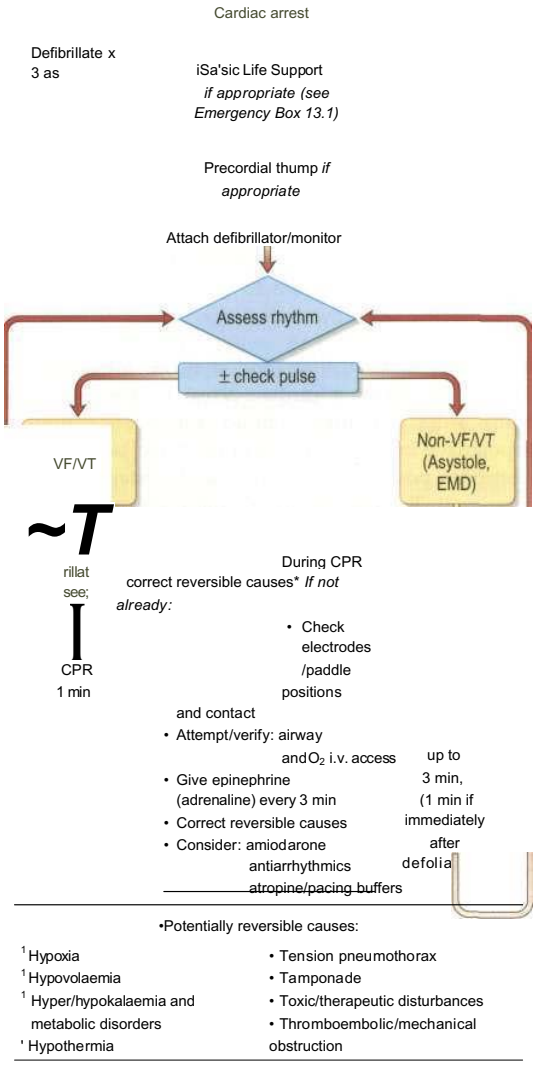


Fig. 13.35 **Universal advanced life-support algorithm.** Reproduced by permission of the European Resuscitation Council and Laerdal Medical Ltd. CPR, cardiopulmonary resuscitation; EMD, electromechanical dissociation; VF/VT, ventricular fibrillation/ventricular tachycardia.

Arrests are treated in the following ways:

Ventricular fibrillation or pulseless ventricular tachycardia is readily treated with IMMEDIATE defibrillation, CPR and drugs. Intravenous amiodarone is the first-line drug in refractory VF/ pulseless VT. Asystole is more difficult to treat but the heart may respond to atropine or epinephrine (adrenaline). Recently vasopressin has been shown to be successful. If there is any sign of slow electromechanical activity (e.g. bradycardia with a weak pulse), emergency pacing should be used.

Pulseless electrical activity: several potentially reversible causes are listed in the universal algorithm. It carries a very poor prognosis. Effective treatment involves addressing the underlying cause.

Figure 13.35 shows the treatments recommended by the European Resuscitation Council and the Resuscitation Council UK.

Defibrillation

This technique is used to convert ventricular fibrillation to sinus rhythm. When the defibrillator is discharged, a high-voltage field envelopes the heart which depolarizes the myocardium and allows an organized heart rhythm to emerge. Electrical energy is discharged through two paddles placed on the chest wall. Initially 200 J is used for defibrillation.

The paddles are placed in one of two positions:

- One paddle is placed to the right of the upper sternum and the other over the cardiac apex.
- One paddle is placed under the tip of the left scapula and the other is placed over the anterior wall of the left chest.

Electrode jelly or electrolyte gel pads should be used to ensure good contact between the electrode paddles and the skin. Jelly smeared carelessly across the chest may cause short-circuits and arcing of the charge. All personnel should stand clear of the patient. The person performing defibrillation has the responsibility for ensuring the safety of the patient and other people present.

Conventional defibrillators employ a damped monophasic waveform. Biphasic defibrillators which require less energy are becoming increasingly common. Automated external defibrillators (AEDs) which recognize ventricular fibrillation automatically deliver a shock if indicated. These are available in some public places. It is the responsibility of all healthcare practitioners to be familiar with the range of defibrillators they may be called on to use in their workplace.

DC-cardioversion (DCC)

Tachyarrhythmias that do not respond to medical treatment or that are associated with haemodynamic compromise (e.g. hypotension, worsening heart failure) may be converted to sinus rhythm by the use of a transthoracic electric shock. A short-acting general anaesthetic is used. Muscle relaxants are not usually given.

When the arrhythmia has definite QRS complexes, the delivery of the shock should be timed to occur with the downstroke of the QRS complex (synchronization) (Fig. 13.36). The machine being used to perform the cardioversion will do this automatically if the appropriate button is pressed. There is a crucial difference between defibrillation and cardioversion: a non-synchronized shock is used to defibrillate. Accidental defibrillation of a patient who does not require it may itself precipitate ventricular fibrillation.

Typical indications for DCC include:

- atrial fibrillation
- atrial flutter

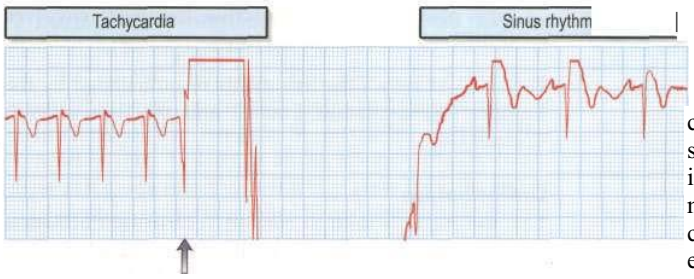

Fig. 13.36 DC-cardioversion of a supraventricular tachycardia to sinus rhythm. The direct current shock is delivered synchronously with the QRS complex.

- sustained ventricular tachycardia
- junctional tachyarrhythmias.

If atrial fibrillation or flutter has been present for more than a few days, it is necessary to anticoagulate the patient adequately for 4 weeks before elective cardioversion to reduce the risk of embolization. The duration of anticoagulation after successful cardioversion for atrial fibrillation is a complex issue and depends on a number of factors: it should be at least for 6 weeks after the procedure and may well be for much longer.

Digoxin toxicity may lead to ventricular arrhythmias or asystole following cardioversion. Therapeutic digitalization does not increase the risks of cardioversion, but it is conventional to omit digoxin several days prior to elective cardioversion in order to be sure that toxicity is not present.

Cardiac enzyme levels may rise after a cardioversion.

Temporary pacing

Therapeutic cardiac pacing is employed in any patient with sustained symptomatic or haemodynamically compromising bradycardia. Bradycardias may be due to either a slow intrinsic heart rate (e.g. sinus node dysfunction) or atrioventricular block. Prophylactic cardiac pacing is employed in asymptomatic patients with either bradycardia or conduction abnormalities in whom the risk of progression to symptomatic bradycardia justifies such a strategy.

Transvenous pacing is the preferred method in patients with symptomatic bradycardias. In summary a thin (French gauge 5 or 6), bipolar pacing electrode wire is inserted via an internal jugular vein, a femoral vein or a subclavian vein and is positioned at the right ventricular apex using cardiac fluoroscopy. The energy needed for successful pacing (the pacing threshold) is assessed by reducing the energy until the pacemaker fails to stimulate the tissue (loss of capture). The output energy is then set at three times the threshold value to prevent inadvertent loss of capture. If the threshold increases above 5 V, the pacemaker wire should be resited. A temporary pacemaker unit (Fig. 13.37a) is almost always set to work 'on demand' - to fire only when a spontaneous beat has not occurred. The rate of temporary pacing is usually 60-80 per minute.

Transcutaneous pacing is the preferred method in selected patients with asymptomatic bradycardia or conduction abnormalities and may be life-saving for patients in whom a cardiac arrest is precipitated by bradycardia. In this method the myocardium is depolarized by current flow between two large adhesive electrodes positioned anteriorly and posteriorly on the chest wall. Transcutaneous pacing is uncomfortable for the conscious patient. However, it can usually be tolerated until a temporary transvenous pacemaker is inserted.

Permanent pacing

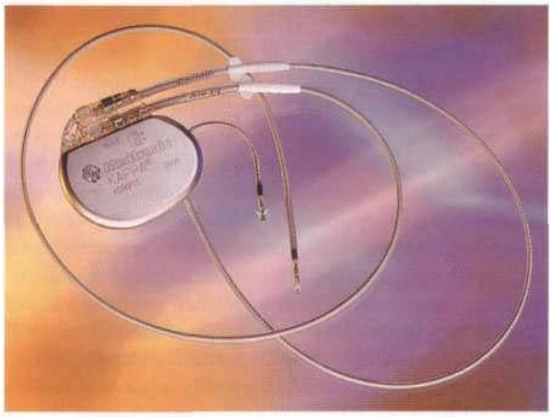
Permanent pacemakers are fully implanted in the body and connected to the heart by one or two electrode leads (Fig. 13.37b). The pacemaker is powered by solid-state lithium batteries, which usually last 5-10 years. Pacemakers are 'programmable' in that their operating characteristics (e.g. the pacing rate) can be changed by a programmer that transmits specific electromagnetic signals through the skin. The pacemaker leads are passed transvenously to the right heart chambers.

Pacemakers are designed to both pace and sense either the ventricles or the atria or more commonly both chambers. A single chamber ventricular pacemaker is described as a 'WF unit because it paces the ventricle (V), senses the ventricle (V) and is inhibited (I) by a spontaneous ventricular signal. Occasionally (e.g. in symptomatic sinus bradycardia), an atrial pacemaker (AAI) may be implanted. Pacemakers that are connected to both the right atrium and ventricle ('dual chamber' pacemakers) are used to simulate the natural pacemaker and activation sequence of the heart. This form of pacemaker is called DDD because it paces the two (dual) chambers, senses both (D) and reacts in two (D) ways - pacing in the same chamber is inhibited by spontaneous atrial and ventricular signals, and ventricular pacing is triggered by spontaneous atrial events (Fig. 13.37c).

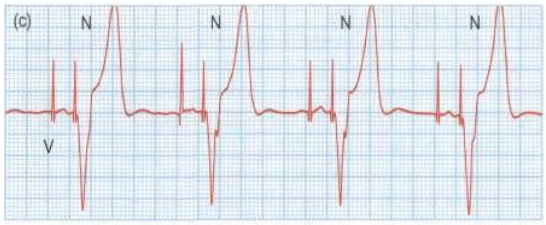
In addition, pacemakers may be 'rate responsive' (R). A rate-responsive pacemaker detects motion (level of vibration or acceleration), respiration, or changes in QT interval, and by employing one or more biosensors, changes its rate of pacing so that it is appropriate to the level of exertion.

The choice of pacemaker mostly depends on the underlying rhythm abnormality and the general condition of the patient. For example, complete heart block in patients with sinus rhythm should be treated with a dual-chamber device in order to maintain AV synchrony,

(a)



(b)



(c)

Fig. 13.37 **Pacemakers, (a)** A temporary pacemaker unit. (b) A permanent pacemaker with atrial (placed in the right atrium, usually in its high lateral wall) and ventricular (placed in the right ventricular apex) leads.
(c) An electrocardiogram showing dual (atrial and ventricular) chamber pacing. A wide QRS complex results from abnormal activation of the ventricles from the right ventricular apex.

whereas inactive or infirm patients may not benefit from the most sophisticated units. Specialized biventricular pacemakers have been introduced for the treatment of severe heart failure.

Permanent pacemakers are inserted under local anaesthetic using fluoroscopy to guide the insertion of the electrode leads via the cephalic or subclavian veins.

Perioperative prophylactic antibiotics are routinely prescribed. The pacemaker is usually positioned subcutaneously in front of the pectoral muscle. Following surgery, which usually takes 60-90 minutes, the patient rests in bed for 6-12 hours before being discharged. Patients may not drive for at least 1 week after implantation, and must inform the licensing authorities and their motor insurers.

Complications are few but can prove to be very difficult to manage, and patients should be referred to the pacemaker clinic. They include the following:

- infection
- erosion
- pocket haematoma
- lead displacement
- electromagnetic interference.

Pericardiocentesis

A pericardial effusion is an accumulation of fluid between the parietal and visceral layers of pericardium. Fluid is removed to relieve symptoms that are due to haemodynamic embarrassment or for diagnostic purposes. This can be a technically difficult procedure, particularly in the acute setting. In an emergency it can be performed at the bedside.

Pericardial aspiration or pericardiocentesis is performed by inserting a needle into the pericardial space, usually via a subxiphisternal route under ultrasound guidance. Certain effusions, particularly posterior ones, require surgical drainage under a general anaesthetic. If a large volume of fluid is to be removed, a wide-bore needle and cannula are inserted. The needle may be removed and the cannula left in situ to drain the fluid. Fluid that is removed is sent for chemical analysis, microscopy, including cytology, Gram-stain, and culture. If a reaccumulation of pericardial fluid is anticipated, the cannula may be left in place for several days or an operation can be performed to cut a window in the parietal pericardium (fenestration) or to remove a large section of the pericardium.

Right-heart bedside catheterization

(Fig. 15.19)

Bedside catheterization of the pulmonary artery with a pulmonary artery balloon flotation catheter (Swann-Ganz catheter) is performed in patients with:

- cardiac failure
- cardiogenic shock
- doubtful fluid status.

Intra-aortic balloon pumping

This is a technique used to assist temporarily the failing left ventricle. A catheter with a long sausage-shaped balloon at its tip is introduced percutaneously into the femoral artery and manipulated under X-ray control so that the balloon lies in the descending aorta just below the

aortic arch. The balloon is rhythmically deflated and inflated with carbon dioxide gas. Using the ECG or intra-aortic pressure changes, the inflation is timed to occur during ventricular diastole to increase diastolic aortic pressure and consequently to improve coronary and cerebral blood flow. During systole the balloon is deflated, resulting in a reduction in the resistance to left ventricular emptying. Intra-aortic balloon pumping is used for circulatory support in the following acute situations:

- *Cardiogenic shock.* Balloon pumping is used to improve cardiac output when there is a transient or reversible depression of left ventricular function, such as in a patient with severe mitral valve regurgitation who is awaiting surgical replacement of the mitral valve, or in a patient with a ventricular septal defect that is due to septal infarction. It may also be used to support patients awaiting heart transplantation.
- *Unstable angina pectoris.* Balloon pumping is used to treat unstable angina pectoris by improving coronary flow and decreasing myocardial oxygen consumption by reducing the 'afterload'. This technique may be successful, even when medical therapy has failed. It is followed by early angiography and appropriate definitive therapy such as surgery or coronary angioplasty.

Balloon pumping should not be used when there is no remediable cause of cardiac dysfunction. It is also unsuitable in patients with severe aortic regurgitation, aortic dissection and severe peripheral vascular disease. Complications of balloon pumping occur in about 20% of patients and include aortic dissection, leg ischaemia, emboli from the balloon, and balloon rupture. Embolic complications are reduced by anticoagulation with heparin.

CARDIAC ARRHYTHMIAS

An abnormality of the cardiac rhythm is called a cardiac arrhythmia. Arrhythmias may cause sudden death, syncope, heart failure, dizziness, palpitations or no symptoms at all. There are two main types of arrhythmia:

- bradycardia: the heart rate is slow (< 60 b.p.m.)
- tachycardia: the heart rate is fast (> 100 b.p.m.).

Tachycardias are more symptomatic when the arrhythmia is fast and sustained. Tachycardias are subdivided into supraventricular tachycardias, which arise from the atrium or the atrioventricular junction, and ventricular tachycardias, which arise from the ventricles.

Some arrhythmias occur in patients with apparently normal hearts, and in others arrhythmias originate from scar tissue as a result of underlying structural heart disease. When myocardial function is poor, arrhythmias are more symptomatic and are potentially life-threatening.

SINUS NODE FUNCTION

The normal cardiac pacemaker is the sinus node (p. 725) and, like most cardiac tissue, it depolarizes spontaneously. The rate of sinus node discharge is modulated by the autonomic nervous system. Normally the parasympathetic system predominates, resulting in slowing of the spontaneous discharge rate from approximately 100 to 70 b.p.m. A reduction of parasympathetic tone or an increase in sympathetic stimulation leads to tachycardia; conversely, increased parasympathetic tone and decreased sympathetic stimulation produces bradycardia. The sinus rate in women is slightly faster than in men. Normal sinus rhythm is characterized by P waves that are upright in leads I, and II of the ECG (Fig. 13.21, p. 746), but inverted in the cavity leads AVR and VI (Fig. 13.38a).

Sinus arrhythmia

Fluctuations of autonomic tone result in phasic changes of the sinus discharge rate. During inspiration, parasympathetic tone falls and the heart rate quickens, and on expiration the heart rate falls. This variation is normal, particularly in children and young adults. Typically sinus arrhythmia results in a regularly irregular pulse.

Sinus bradycardia

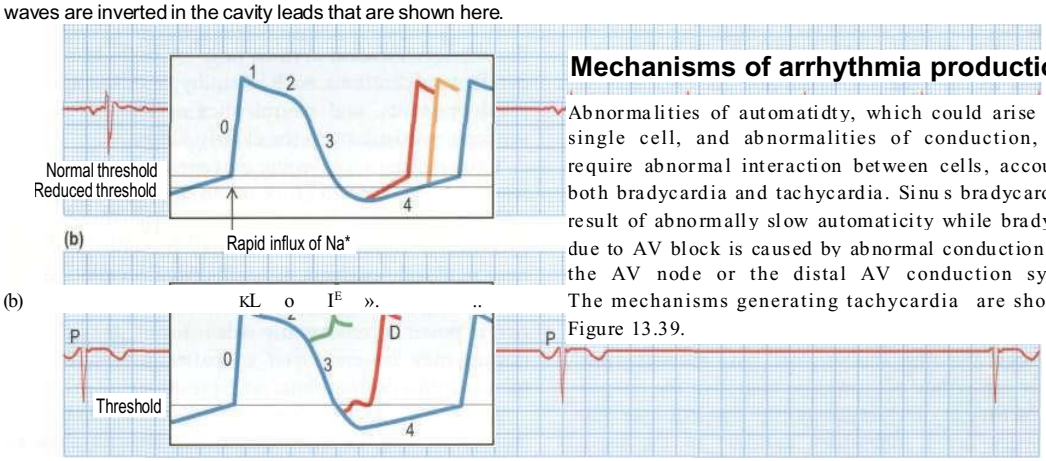
A sinus rate of less than 60 b.p.m. during the day or less than 50 b.p.m. at night is known as sinus bradycardia.

It is usually asymptomatic unless the rate is very slow. It is normal in athletes owing to increased vagal tone. Other causes may be divided into systemic or cardiac and are discussed under Bradycardias and heart block (p. 766).

Sinus tachycardia

Sinus rate acceleration to more than 100 b.p.m. is known as sinus tachycardia. Again, causes may be divided into systemic or cardiac and are discussed under Supraventricular tachycardias (p. 770).

Fig. 13.38 (a) An ECG showing normal sinus rhythm (PR interval < 0.2 s). P wave preceding each QRS complex.
(b) A patient with sick sinus syndrome. This shows sinus arrest (only occasional sinus P waves) and junctional escape beats (J). P waves are inverted in the cavity leads that are shown here.



Mechanisms of arrhythmia production

Abnormalities of automatidty, which could arise from a single cell, and abnormalities of conduction, which require abnormal interaction between cells, account for both bradycardia and tachycardia. Sinus bradycardia is a result of abnormally slow automaticity while bradycardia due to AV block is caused by abnormal conduction within the AV node or the distal AV conduction system. The mechanisms generating tachycardia are shown in Figure 13.39.

(c)

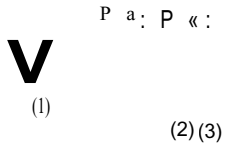


Fig. 13.39 Mechanisms of arrhythmogenesis (a) and (b) Action potentials (i.e. the potential difference between intracellular and extracellular fluid) of ventricular myocardium after stimulation.
(a) Increased (accelerated) automaticity due to reduced threshold potential or an increased slope of phase 4 depolarization (see p. 744).
(b) Triggered activity due to early (E) or delayed (D) 'after depolarizations' reaching threshold potential.
(c) Mechanism of circus movement or re-entry. In panel (1) the impulse passes down both limbs of the potential tachycardia circuit. In panel (2) the impulse is blocked in one pathway (a) but proceeds slowly down pathway p, returning along pathway a until it collides with refractory tissue. In panel (3) the impulse travels so slowly along pathway fi that it can return along pathway a and complete the re-entry circuit, producing a circus movement tachycardia.

Accelerated automaticity (Fig. 13.39a)

The normal mechanism of spontaneous cardiac rhythmicity is slow depolarization of the transmembrane voltage during diastole until the threshold potential is reached and the action potential of the pacemaker cells takes off. This mechanism may be accelerated by increasing the rate of diastolic depolarization or changing the threshold potential. For example, sympathetic stimulation releases epinephrine (adrenaline), which enhances automaticity. Abnormal automaticity can occur in virtually all cardiac tissues and may initiate arrhythmias. Such changes are thought to produce sinus tachycardia, escape rhythms and accelerated AV nodal (junctional) rhythms.

Triggered activity (Fig. 13.39b)

Myocardial damage can result in oscillations of the transmembrane potential at the end of the action potential. These oscillations, which are called 'after depolarizations', may reach threshold potential and produce an arrhythmia. If they occur before the transmembrane potential reaches its threshold (at the end of phase 3 of the action potential), they are called 'early afterdepolarizations' (E in Fig. 13.39b). When they develop after the transmembrane potential is completed, they are called 'delayed afterdepolarizations' (D in the figure).

The abnormal oscillations can be exaggerated by pacing, catecholamines, electrolyte disturbances, and

some medications, which may then trigger arrhythmia. The atrial tachycardias produced by digoxin toxicity are due to triggered activity. The initiation of ventricular arrhythmia in the long QT syndrome (p. *777)* may be caused by this mechanism.

Re-entry (or circus movements) (Fig. 13.39c) The mechanism of re-entry occurs when a 'ring' of cardiac tissue surrounds an inexcitable core (e.g. in a region of scarred myocardium). Tachycardia is initiated if an ectopic beat finds one limb refractory (a) resulting in unidirectional block and the other limb excitable. Provided conduction through the excitable limb ((3) is slow enough, the other limb (a) will have recovered and will allow retrograde activation to complete the re-entry loop. If the time to conduct around the ring is longer than the recovery times (refractory periods) of the tissue within the ring, circus movement will be maintained, producing a run of tachycardia. The majority of regular paroxysmal tachycardias are produced by this mechanism.

BRADYCARDIAS AND HEART BLOCK

Bradycardias may be due to failure of impulse formation (sinus bradycardia) or failure of impulse conduction from the atria to the ventricles (atrioventricular block).

Bradycardia

Sinus bradycardia

Sinus bradycardia is due to extrinsic factors influencing a relatively normal sinus node or due to intrinsic sinus node disease. The mechanism can be acute and reversible or chronic and degenerative. Common causes of sinus bradycardia include:

Extrinsic causes

- Hypothermia, hypothyroidism, cholestatic jaundice and raised intracranial pressure.
- Drug therapy with beta-blockers, digitalis and other antiarrhythmic drugs.
- Neurally mediated syndromes (see below).

Intrinsic causes

- Acute ischaemia and infarction of the sinus node (as a complication of acute myocardial infarction).
- Chronic degenerative changes such as fibrosis of the atrium and sinus node (sick sinus syndrome).

Sick sinus syndrome or *sinoatricd disease* is usually caused by idiopathic fibrosis of the sinus node. Other causes of fibrosis such as ischaemic heart disease, cardiomyopathy or myocarditis can also cause the syndrome. Patients develop episodes of sinus bradycardia or sinus arrest (Fig. 13.38b) and commonly, owing to diffuse atrial disease, experience paroxysmal atrial tachyarrhythmias (tachy-brady syndrome).

Neurally mediated syndromes

Neurally mediated syndromes are due to a reflex (called Bezold-Jarisch) that may result in both bradycardia (sinus bradycardia, sinus arrest and AV block) and reflex peripheral vasodilatation. These syndromes usually present as syncope or presyncope (dizzy spells).

Carotid sinus syndrome occurs in the elderly and mainly results in bradycardia. Syncope occurs (see p. 734).

Neurocardiogenic (vasovagal) syncope (syndrome) usually presents in young adults but may present for the first time in elderly patients. It results from a variety of situations (physical and emotional) that affect the autonomic nervous system. The efferent output may be predominantly bradycardic, predominantly vasodilatory or mixed.

Postural orthostatic tachycardia syndrome (POTS) is a sudden and significant increase in heart rate associated with normal or mildly reduced blood pressure produced by standing. The underlying mechanism is a failure of the peripheral vasculature to appropriately constrict in response to orthostatic stress, which is compensated by an excessive increase in heart rate.

Many medications, such as antihypertensives, tricyclic antidepressants, and neuroleptics can be the cause of syncope, particularly in the elderly. Careful dose titration and avoidance of combining two agents with potential to cause syncope help to prevent iatrogenic syncope.

Treatment

The management of sinus bradycardia is first to identify and if possible remove any extrinsic causes. Temporary pacing may be employed in patients with reversible causes until a normal sinus rate is restored and in patients with chronic degenerative conditions until a permanent pacemaker is implanted.

Chronic symptomatic sick sinus syndrome requires permanent pacing (AAI), with additional antiarrhythmic drugs (or ablation therapy) to manage any tachycardia element. Thromboembolism is common in tachy-brady syndrome and patients should be anticoagulated unless there is a contraindication.

Patients with carotid sinus hypersensitivity (asystole > 3 s), especially if symptoms are reproduced by carotid sinus massage, and in whom life-threatening causes of syncope have been excluded, benefit from pacemaker implantation.

Treatment options in neurocardiogenic syndrome include avoidance, if possible, of situations known to cause syncope in a particular patient. Increased salt intake, compression of the lower legs with hose, and drugs such as beta-blockers, alpha-agonists or myocardial negative inotropes (such as disopyramide) may be helpful. In selected patients with 'malignant' neurocardiogenic syncope (syncope associated with injuries) permanent pacemaker therapy is helpful. These patients benefit from dual chamber pacemakers with a feature called 'rate drop response' which, once activated, paces the heart at a fast rate for a set period of time in order to prevent syncope.

Fig. 13.40 An ECG showing first-degree atrioventricular block with a prolonged PR interval. In this trace coincidental ST depression is also present.

Heart block

Heart block or conduction block may occur at any level in the conducting system. Block in either the AV node or the His bundle results in atrioventricular (AV) block, whereas block lower in the conduction system produces bundle branch block.

Atrioventricular block

There are three forms:

First-degree AV block

This is simple prolongation of the PR interval to more than 0.22 s. Every atrial depolarization is followed by conduction to the ventricles but with delay (Fig. 13.40).

Second-degree AV block

This occurs when some P waves conduct and others do not. There are several forms (Fig. 13.41):

- *Mobitz I block* (Wenckebach block phenomenon) is progressive PR interval prolongation until a P wave fails to conduct. The PR interval before the blocked P wave is much longer than the PR interval after the blocked P wave.
- *Mobitz II block* occurs when a dropped QRS complex is not preceded by progressive PR interval prolongation.
- 2 : *1 or 3 : 1 (advanced) block* occurs when every second or third P wave conducts to the ventricles. This form of second-degree block is neither Mobitz I nor II.

Wenckebach AV block in general is due to block in the AV node, whereas Mobitz II block signifies block at an infra-nodal level such as the His bundle. The risk of progression to complete heart block is greater and the reliability of the resultant escape rhythm is less with Mobitz II block. Therefore pacing is usually indicated in Mobitz II block, whereas patients with Wenckebach AV block are usually monitored.

Acute myocardial infarction may produce *second-degree heart block.* In inferior myocardial infarction, close monitoring and transcutaneous temporary back-up pacing are all that is required. In anterior myocardial infarction, second-degree heart block is associated with a high risk of progression to complete heart block, and temporary pacing followed by permanent pacemaker implantation is usually indicated. 2 : 1 Heart block may either be due to block in the AV node or at an infra-nodal level. Management depends on the clinical setting in which it occurs.

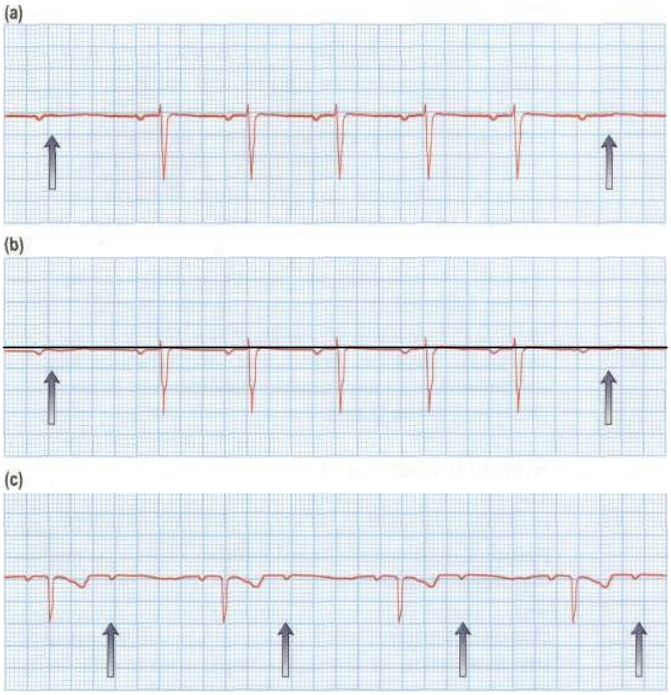

Fig. 13.41 Three varieties of second-degree atrioventricular (AV) block.
(a) *Wenckebach (Mobitz type I) AV block.* The PR interval gradually prolongs until the P wave does not conduct to the ventricles (arrow).
(b) *Mobitz type II AV block.* The P waves that do not conduct to the ventricles (arrows) are not preceded by gradual PR interval prolongation.
(c) *Two P waves to each QRS complex.* The PR interval prior to the dropped P wave is always the same. It is not possible to define this type of AV block as type I or type II Mobitz block and it is, therefore, a third variety of second-degree AV block (arrows show P waves).

Cardiovascular disease

Third-degree (complete) AV block

Complete heart block occurs when all atrial activity fails to conduct to the ventricles (Fig. 13.42). In patients with complete heart block the aetiology needs to be established (Table 13.8). In this situation life is maintained by a spontaneous escape rhythm.

Narrow complex escape rhythm (< 0.125 QRS complex), implies that it originates in the His bundle and therefore that the region of block lies more proximally in the AV node. The escape rhythm occurs with an adequate rate (50-60 b.p.m.) and is relatively reliable.

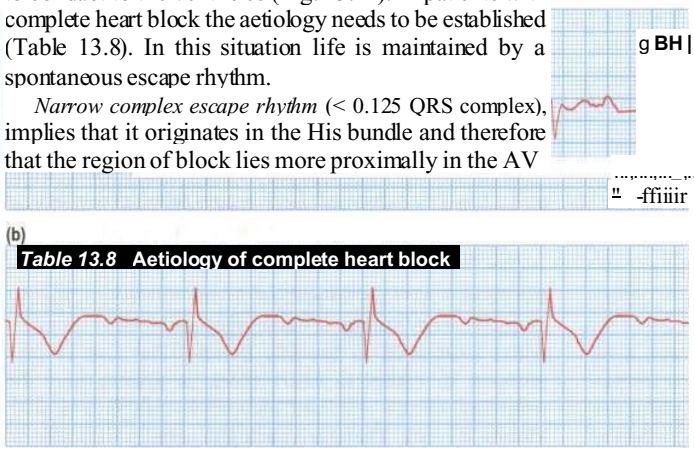

Fig. 13.42 **Two examples of complete heart block.** **(a) Congenital** complete heart block. The QRS complex is narrow (0.08 s) and the QRS rate is relatively rapid (52 b.p.m.). **(b) Acquired** complete heart block. The QRS complex is broad (0.13 s) and the QRS rate is relatively slow (38 b.p.m.).

Table 13.8 **Aetiology of complete heart block**

Congenital
Autoimmune (e.g. maternal SLE) Structural heart disease (e.g. transposition of the great vessels)

Idiopathic fibrosis
Lev's disease (progressive fibrosis of distal His-Purkinje system in elderly patients)
Lenegre's disease (proximal His-Purkinje fibrosis in younger patients)

Ischaemic heart disease
Acute myocardial infarct
Ischaemic cardiomyopathy

Cardiac surgery
e.g. following aortic valve replacement, CABS, VSD repair

Iatrogenic
Radiofrequency AV node ablation and pacemaker implantation

Drug-induced
e.g. digoxin, amiodarone

Infections
Endocarditis Lyme disease Chagas' disease

Connective tissue diseases
e.g. SLE, rheumatoid arthritis

SLE, systemic lupus erythematosus; CABS, coronary artery bypass surgery; VSD, ventricular septal defect; AV, atrioventricular

Non-ischaemic heart disease
Calcific aortic stenosis
Idiopathic dilated cardiomyopathy
Infiltrations (e.g. amyloidosis, sarcoidosis, neoplasia)

Neuromuscular diseases
e.g. Duchenne muscular dystrophy

Treatment depends on the aetiology. Recent-onset narrow-complex AV block due to transient causes may respond to intravenous atropine, but temporary pacing facilities should be available for the management of these patients. Chronic narrow-complex AV block requires permanent pacing (dual chamber, p. 762) if it is symptomatic or associated with heart disease. Pacing is also advocated for isolated, congenital AV block, even if asymptomatic.

Broad complex escape rhythm (> 0.125) implies that the escape rhythm originates below the His bundle and therefore that the region of block lies more distally in the His-Purkinje system.

The resulting rhythm is slow (15^0 b.p.m.) and relatively unreliable. Dizziness and blackouts (Stokes-Adams attacks) often occur. In the elderly, it is usually caused by degenerative fibrosis and calcification of the distal conduction system (Lev's disease). In younger individuals, a proximal progressive cardiac conduction disease due to the inflammatory process is known as Lenegre's syndrome. Sodium channel abnormalities have recently been identified in both syndromes. Broad-complex AV block may also be caused by ischaemic heart disease, myocarditis or cardiomyopathy. Temporary pacing followed by permanent pacemaker implantation (p. 762) is indicated, as pacing considerably reduces the mortality. Because ventricular arrhythmias are not uncommon, an implantable cardioverter-defibrillator (ICD) may be indicated.

Bundle branch block

The His bundle gives rise to the right and left bundle branches. The left bundle subdivides into the anterior and posterior divisions of the left bundle. Various conduction disturbances can occur.

Bundle branch conduction delay. This produces trivial widening of the QRS complex (up to 0.11 s). It is known as incomplete bundle branch block.

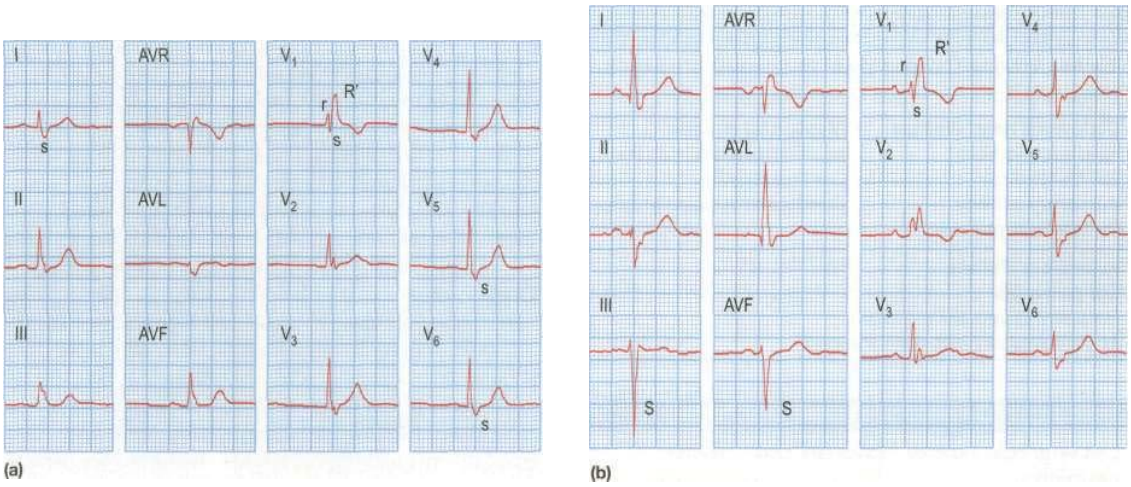

Fig. 13.43 **Right bundle branch block versus bifascicular block, (a)** A 12-lead ECG showing right bundle branch block. Note an rsR pattern with the tall R in lead V.|-V_2 and the broad S waves in leads I and V_5-V_6. (b) Compare with an ECG showing bifascicular block. In addition to right bundle branch block, note left axis deviation and deep S waves in leads III and AVF typical for left anterior hemiblock.

Complete block of a bundle branch. This is associated with a wider QRS complex (0.12 s or more). The shape of the QRS depends on whether the right or the left bundle is blocked.

Right bundle branch block (Fig. 13.43a) produces late activation of the right ventricle. This is seen as deep S waves in leads I and V_6 and as a tall late R wave in lead V] (late activation moving towards right- and away from left-sided leads).

Left bundle branch block (Fig. 13.44) produces the opposite - a deep S wave in lead Vj and a tall late R wave in leads I and V_{fi}. Because left bundle branch conduction is normally responsible for the initial ventricular activation, left bundle branch block also produces abnormal Q waves.

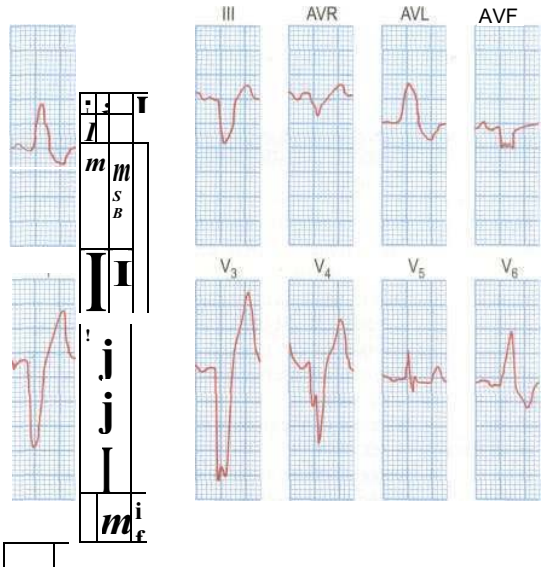

Fig. 13.44 **A 12-lead ECG showing left bundle branch block.** The QRS duration is greater than 0.12 s. Note the broad notched R waves with ST depression in leads I, AVL, and V_6, and the broad QS waves in V,-V_3.

Hemiblock. Delay or block in the divisions of the left bundle branch produces a swing in the direction of depolarization (electrical axis) of the heart. When the anterior division is blocked (left anterior hemiblock), the left ventricle is activated from inferior to superior. This produces a superior and leftwards movement of the axis (left axis deviation). Delay or block in the postero-inferior division swings the QRS axis inferiorly to the right (right axis deviation).

Bifascicular block (Fig. 13.43b). This is a combination of a block of any two of the following: the right bundle branch, the left antero-superior division and the left postero-inferior division. Block of the remaining fascicle will result in complete AV block.

Clinical features

Bundle branch blocks are usually asymptomatic. Right bundle branch block causes wide but physiological splitting of the second heart sound. Left bundle branch block may cause reverse splitting of the second sound. Patients with intraventricular conduction disturbances may complain of syncope. This is due to intermittent complete heart block or to ventricular tachyarrhythmias. ECG monitoring and electrophysiological studies are needed to determine the cause of syncope in these patients.

Causes

Right bundle branch block occurs as an isolated congenital anomaly or is associated with cardiac or pulmonary conditions (Table 13.9). Right bundle branch block alone does not alter the electrical axis of the heart.

Table 13.9 **Causes of right b**

It is also a normal finding in 1 % elderly adults

Congenital heart disease
Atrial septal defect
Fallot's tetralogy
Pulmonary stenosis
Ventricular septal defect

Pulmonary disease
Cor pulmonale

Acute pulmonary embolism (transient)

Myocardial disease
Acute myocardial infarction
Cardiomyopathy
Conduction system fibrosis

Table 13.10 **Causes of left bundle branch block**

Left ventricular outflow obstruction	**Coronary artery disease**
Aortic stenosis	Acute myocardial infarction Severe coronary disease (two- to three-vessel disease)
Hypertension	

Axis deviations signify right ventricular hypertrophy (RV overload) or coexistent fascicular block. The combination of right bundle branch block with left axis deviation is associated with ostium primum atrial septal defects. Complete left bundle branch block is often associated with extensive left ventricular disease. The most common causes are listed in Table 13.10 and are similar to those of complete heart block.

SUPRAVENTRICULAR TACHYCARDIAS

Supraventricular tachycardias (SVTs) arise from the atrium or the atrioventricular junction. Conduction is via the His-Purkinje system; therefore the QRS shape during tachycardia is usually similar to that seen in the same patient during baseline rhythm. A classification of supraventricular tachycardia is listed in Table 13.11. Some of these are discussed in more detail below.

Inappropriate sinus tachycardia

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated to or out of proportion with the level of physical or emotional stress. It is found predominantly in women and is not uncommon in health professionals. Sinus tachycardia due to intrinsic sinus node abnormalities such as enhanced automaticity, or abnormal autonomic regulation of the heart with excess sympathetic and reduced parasympathetic input, is extremely rare.

In general, sinus tachycardia is a secondary phenomenon and the underlying causes need to be actively investigated. Depending on the clinical setting, acute causes include exercise, emotion, pain, fever, infection, acute heart failure, acute pulmonary embolism and hypovolaemia. Chronic causes include pregnancy, anaemia, hyperthyroidism and catecholamine excess. The underlying cause should be found and treated, rather than treating the compensatory physiological response. If necessary, beta-blockers may be used to slow the sinus rate, e.g. in hyperthyroidism (p. 1073).

Atrioventricular junctional tachycardias

AV nodal re-entry and AV re-entry tachycardias are usually referred to as paroxysmal SVTs and are often seen in young patients with no or little structural heart disease, although congenital heart abnormalities (e.g. Ebstein's anomaly, atrial septal defect, Fallot's tetralogy) can coexist in a small proportion of patients with these arrhythmias. The first presentation is common between ages 12 and 30, and the prevalence is approximately 2.5 per 1000.

In these tachycardias the AV node is an essential component of the re-entry circuit.

Atrioventricular nodal re-entry tachycardia (AVNRT)

This tachycardia is twice as common in women. Clinically, the tachycardia often strikes suddenly without

Table 13.11 **Causes of supraventricular tachycardia (SVT)**

Tachycardia	ECG features	Comment
Sinus tachycardia	P wave morphology similar to sinus rhythm No visible P wave, or inverted P wave immediately before or after QRS complex P wave visible between QRS and T wave complexes	Need to determine underlying cause
AV nodal re-entry tachycardia (AVNRT) AV reciprocating tachycardia (AVRT)		Commonest cause of palpitations in patients with normal hearts Due to an accessory pathway. If pathway conducts in both directions, ECG during sinus rhythm may be pre-excited
Atrial fibrillation Atrial flutter	Irregularly irregular RR intervals and absence of organized atrial activity Visible flutter waves at 300/min (saw-tooth appearance) usually with 2 : 1 AV conduction	Commonest tachycardia in patients over 65 years Suspect in any patient with regular SVT at 150/min Usually occurs in patients with structural heart disease Rare arrhythmia; most commonly associated with significant chronic lung disease
Atrial tachycardia Multifocal atrial tachycardia	Organized atrial activity with P wave morphology different from sinus rhythm Multiple P wave morphologies (> 3) and irregular RR intervals	
Accelerated junctional tachycardia	ECG similar to AVNRT	Rare in adults

obvious provocation, but exertion, coffee, tea and alcohol may aggravate or induce the arrhythmia. An attack may stop spontaneously or may continue indefinitely until medical intervention.

In AVNRT, there are two functionally and anatomically different pathways within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and conducts faster. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g. an atrial premature beat) occurs early when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles. It then travels back through the fast pathway which has already recovered its excitability, thus initiating the most common 'slow-fast', or typical, AVNRT.

The rhythm is recognized on ECG by normal regular QRS complexes, usually at a rate of 140-240 per minute (Fig. 13.45a). Sometimes the QRS complexes will show typical bundle branch block. P waves are either not visible or are seen immediately before or after the QRS complex because of simultaneous atrial and ventricular activation. Less commonly observed (5-10%) is tachycardia when the atrial impulse conducts anterogradely through the fast pathway and returns through the slow pathway, producing a long RP' interval ('fast-slow', or long RP' tachycardia).

Atrioventricular reciprocating tachycardia (AVRT)

In AVRT there is a large circuit comprising the AV node, the His bundle, the ventricle and an abnormal connection from the ventricle back to the atrium. This abnormal connection consists of myocardial fibres that span the atrioventricular groove; it is called an accessory pathway or bypass tract. Bypass tracts result from incomplete separation of the atria and the ventricles during fetal development.

In contrast to AVNRT, this tachycardia is due to a macro-reentry circuit and each part of the circuit is activated sequentially. As a result atrial activation occurs after ventricular activation and the P wave is usually clearly seen between the QRS and T complexes (Fig. 13.45b).

Accessory pathways are most commonly situated on the left but may occur anywhere around the AV groove. The most common accessory pathways known as *Kent bundles* are in the free wall or septum. In about 10% of cases multiple pathways occur. *Mahaim fibres* are atriofascicular or nodo-fascicular fibres entering the ventricular myocardium in the region of the right bundle branch. Accessory pathways that conduct from the ventricles to the atria only are not visible on the surface ECG during sinus rhythm and are therefore 'concealed'. Accessory pathways that conduct bidirectionally usually are manifest on the surface ECG. If the accessory pathway conducts from the atrium to the ventricle during sinus rhythm, the electrical impulse can conduct quickly over this abnormal connection to depolarize part of the ventricles abnormally (pre-excitation). A pre-excited ECG is characterized by a short PR interval and a wide QRS complex that begins as a slurred part known as the δ wave (Fig. 13.45c). Patients with a history of palpitations and a pre-excited ECG have a syndrome known as Wolff-Parkinson-White (WPW) syndrome.

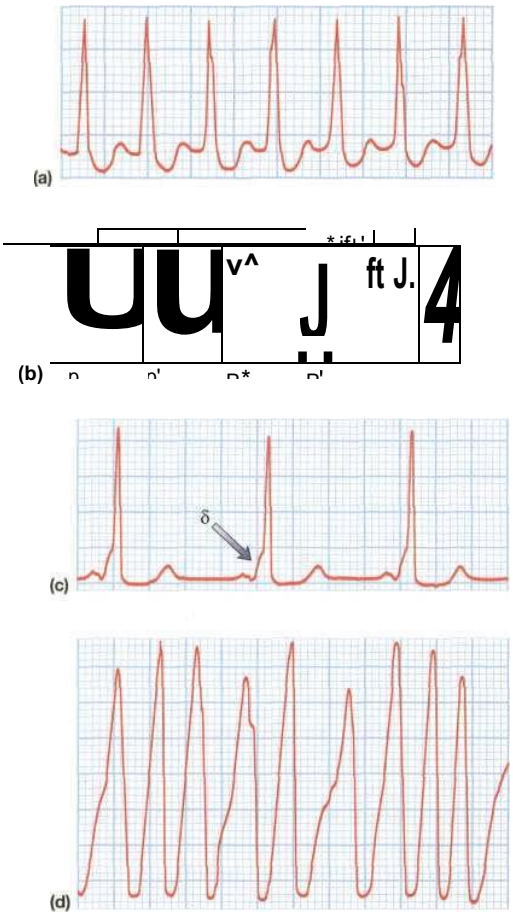

Fig. 13.45 **Atrioventricular junctional tachycardia.**
(a) Atrioventricular *nodal re-entry* tachycardia. The QRS complexes are narrow and the P waves cannot be seen.
(b) *Atrioventricular re-entry* tachycardia (Wolff-Parkinson-White syndrome). The tachycardia P waves are clearly seen after narrow QRS complexes.
(c) An electrocardiogram taken in a patient with Wolff-Parkinson-White syndrome during sinus rhythm. Note the short PR interval and the δ wave (arrow).
(d) Atrial fibrillation in the Wolff-Parkinson-White syndrome. Note tachycardia with broad QRS complexes with fast and irregular ventricular rate.

During AVRT the AV node and ventricles are activated normally (orthodromically), resulting usually in a narrow QRS complex. Less commonly, the tachycardia circuit can be reversed, with activation of the ventricles via the accessory pathway and atrial activation via retrograde conduction through the AV node (antidromic AVRT). This results in a broad complex tachycardia. These patients are also prone to atrial fibrillation.

During atrial fibrillation, the ventricles may be depolarized by impulses travelling over both the abnormal and the normal pathways. This results in pre-excited atrial fibrillation, a characteristic tachycardia that is characterized by irregularly irregular broad QRS complexes (Fig. 13.45d). If an accessory pathway has a short antegrade effective refractory period (< 250 ms), it may conduct to the ventricles at an extremely high rate and may cause ventricular fibrillation. The incidence of sudden death is 0.15-0.39% per patient-year and it may be a first manifestation of the disease in younger individuals. Verapamil and digoxin may allow a higher rate of conduction over the abnormal pathway and precipitate ventricular fibrillation. Therefore, neither verapamil nor digoxin should be used to treat atrial fibrillation associated with the WPW syndrome.

Symptoms

The leading symptom of most SVTs, in particular AV node re-entry and AV re-entry tachycardias, is rapid regular palpitations, usually with abrupt onset, which can occur spontaneously or be precipitated by simple movements. A common feature is termination by Valsalva manoeuvres. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathological finding.

Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation or multifocal atrial tachycardia. In patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and cause hypotension and congestive heart failure.

Other symptoms may include anxiety, dizziness, dyspnoea, neck pulsation, central chest pain, and weakness. Polyuria may occur because of release of atrial natriuretic peptide in response to increased atrial pressures during the tachycardia. Prominent jugular venous pulsations due to atrial contractions against closed atrioventricular valves may be observed during AVNRT or AVRT.

Syncope has been reported in 10-15% patients, usually just after initiation of the arrhythmia or in association with a prolonged pause following its termination. However, in older patients with concomitant heart disease, such as aortic stenosis, hypertrophic cardiomyopathy, and cerebrovascular disease, significant hypotension and syncope may result from moderately fast ventricular rates.

Acute management

In emergency, distinguishing between AVNRT and AVRT may be difficult, but it is usually not critical as both tachycardias respond to the same treatment. Patients presenting with SVTs and haemodynamic instability (e.g. hypotension, pulmonary oedema) require emergency cardioversion. If the patient is haemodynamically stable, vagal manoeuvres, including right carotid massage (Practical box 13.4), Valsalva manoeuvre (Practical box 13.5) and facial immersion in cold water can be successfully employed.

Practical Box 13.4
Carotid sinus massage

Ensure there is no significant carotid artery disease (carotid bruits).
Provide continuous electrocardiographic monitoring.
Patient is in supine position with the head slightly extended.
Start with right carotid sinus massage.
Apply firm rotary pressure to the carotid artery at the level of the third cervical vertebra for 5 seconds.
Alternatively, steady pressure can be applied.
If no response, massage left carotid sinus.
Generally, right carotid sinus massage decreases the sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.
Do not massage both carotid sinuses at the same time.
Single application of carotid sinus pressure may be effective in about 20-30% of patients with paroxysmal supraventricular tachycardias; multiple applications can terminate tachycardia in about 50% of patients.
Asystole is a potential but rare complication.

mfm **PracBcaTBoxrens**
Valsalva manoeuvre
^^*F* **Valsalva manoeuvr**

Valsalva manoeuvre is an abrupt voluntary increase in intrathoracic and intra-abdominal pressures by straining.
Provide continuous electrocardiographic monitoring.
Patient is in supine position.
Patient should not take deep inspiration before straining.
Ideally, the patient blows into the mouthpiece of a manometer against a pressure of 30-40 mmHg for 15 seconds.
Alternatively, the patient strains for 15 seconds while breath-holding.
Transient acceleration of tachycardia usually occurs during the strain phase as a result of sympathetic excess.
On release of strain, the rate of tachycardia slows because of the compensatory increase in vagal tone (baroreceptor reflex) and it may be terminated in about 50% of patients.
Termination of tachycardia may be followed by pauses and transient ventricular ectopics.

u

Of these techniques, the Valsalva manoeuvre is the best and often easier for the patient to perform successfully. It should be undertaken when the patient is resting in the supine position (thus avoiding elevated background sympathetic tone). Several seconds after the release of strain, the resulting intense vagal effect may terminate AVNRT or AVRT or may produce sufficient AV block to reveal an underlying atrial tachyarrhythmia.

If physical manoeuvres have not been successful, intravenous adenosine (up to 0.25 mg/kg) should be tried. This is a very short-acting (half-life < 10 s) naturally occurring purine nucleoside that causes complete heart block for a fraction of a second following i.v. adminis-

tration. It is highly effective at terminating AVNRT and AVRT or unmasking underlying atrial activity. It rarely affects ventricular tachycardia. The side-effects of adenosine are very brief but include:

- bronchospasm
- flushing
- chest pain
- heaviness of the limbs.

It is contraindicated in patients with a history of asthma. In some patients, adenosine can induce atrial fibrillation. An alternative treatment is verapamil 5-10 mg i.v. over 5-10 minutes, i.v. diltiazem, or beta-blockers (esmolol, propranolol, metoprolol). Verapamil (or diltiazem) must not be given after beta-blockers *or* if the tachycardia presents with broad (> 0.12 s) QRS complexes.

Long-term management

Patients with suspected cardiac arrhythmias should always be referred to the cardiologist for electrophysiological evaluation and long-term management, as both pharmacological and non-pharmacological alternatives, including ablation of an accessory pathway, are readily available. Verapamil, diltiazem, and beta-blockers have proven effective in 60-80% of patients. Sodium-channel blockers (flecainide and propafenone), potassium repolarization current blockers (sotalol, dofetilide, azimilide), and the multichannel blocker amiodarone may also prevent the occurrence of tachycardia.

Refinement of catheter ablation techniques has rendered many AV junctional tachycardias entirely curable. Modification of the slow pathway is successful in 96% of patients with AVNRT, although a 1% risk of AV block is present. In AVRT, the target for catheter ablation is the accessory pathway(s). The success rate for ablation of a single accessory pathway is approximately 95%, with a recurrence rate of 5%, requiring a repeat procedure.

Atrial tachyarrhythmias

Atrial tachyarrhythmias including atrial fibrillation, atrial flutter, atrial tachycardia and atrial ectopic beats all arise from the atrial myocardium. They share common aetiologies, which are listed in Table 13.12.

Table 13.12 Causes of atrial tachyarrhythmias

Cardiac	Non-cardiac
Hypertension Congestive heart failure Coronary artery disease and myocardial infarction Valvular heart disease Cardiomyopathy: dilated, hypertrophic Myocarditis and pericarditis Wolff-Parkinson-White syndrome Sick sinus syndrome Cardiac tumours Cardiac surgery Familial tachyarrhythmia (e.g. lone atrial fibrillation)	Thyrotoxicosis Phaeochromocytoma Acute and chronic pulmonary disease (pneumonia, chronic obstructive pulmonary disease) Pulmonary vascular disease (pulmonary embolism) Electrolyte disturbances (hypokalaemia) Increased sympathetic tone (exercise, adrenergically mediated arrhythmia) Increased parasympathetic tone (vagally induced and postprandial arrhythmia) Alcohol abuse ('holiday heart' and long-term use) Caffeine, smoking, recreational drug use

Atrial fibrillation

This is a common arrhythmia, occurring in 5-10% of patients over 65 years of age. It also occurs, particularly in a paroxysmal form, in younger patients. Any condition resulting in raised atrial pressure, increased atrial muscle mass, atrial fibrosis, or inflammation and infiltration of the atrium, may cause atrial fibrillation. There are also many systemic causes of atrial fibrillation (Table 13.12).

Hypertension and heart failure are most often associated with non-rheumatic atrial fibrillation. Hyperthyroidism may provoke atrial fibrillation, sometimes as virtually the only feature of the disease, and thyroid function tests are mandatory in any patient with unaccounted atrial fibrillation. Atrial fibrillation occurs in one-third of patients after coronary bypass surgery and in more than half of those undergoing valvular surgery. It usually manifests during the first 4 days and is associated with increased morbidity and mortality, largely due to stroke and circulatory failure, and longer hospital stay.

In some patients no cause can be found, and this group are labelled as Tone' atrial fibrillation. The pathogenesis of Tone', or 'idiopathic', atrial fibrillation is unknown but genetic predisposition or even specific genetically predetermined forms of the arrhythmia have been proposed. Recently, a gene defect linked to chromosome 10q22-q24 has been identified in three Catalonian families, half the members of which presented with atrial fibrillation at a relatively young age. The mutated genes responsible for atrial fibrillation have been mapped to other chromosomes but have not yet been identified.

Atrial fibrillation is maintained by continuous, rapid (300-600 per minute) activation of the atria by multiple meandering re-entry wavelets, often driven by rapidly depolarizing automatic foci. The atria respond electrically at this rate but there is no coordinated mechanical action and only a proportion of the impulses are conducted to the ventricles. The ventricular response depends on the rate and regularity of atrial activity, particularly at the entry to the AV node, the refractory properties of the AV node itself, and the balance between sympathetic and parasympathetic tone.

Symptoms and signs

Symptoms attributable to atrial fibrillation are highly variable. In some patients (about 30%) it is an incidental finding, whilst others attend hospital as an emergency following the onset of atrial fibrillation. Most patients experience some deterioration of exercise capacity or well-being, but this may only be appreciated once sinus rhythm is restored. When caused by rheumatic mitral stenosis, the onset of atrial fibrillation results in considerable worsening of cardiac failure.

The patient has a very irregular pulse, as opposed to a basically regular pulse with an occasional irregularity (e.g. extrasystoles) or recurring irregular patterns (e.g. Wenckebach block). The irregular nature of the pulse in atrial fibrillation is maintained during exercise.

The ECG shows fine oscillations of the baseline (so-called fibrillation or f waves) and no clear P waves. The QRS rhythm is rapid and irregular. Untreated, the ventricular rate is usually 120-180 per minute, but it slows with treatment.

The clinical classification of atrial fibrillation includes first detected, paroxysmal, persistent, and permanent forms of the arrhythmia and is essential for the decision-making between rhythm restoration and rate control. For example, atrial fibrillation may be asymptomatic and the 'first detected episode' should not be regarded as necessarily the true onset.

Management

When atrial fibrillation is due to an acute precipitating event such as alcohol toxicity, chest infection or hyperthyroidism, the provoking cause should be treated. Strategies for the acute management of AF are ventricular rate control or cardioversion (± anticoagulation). Ventricular rate control is achieved by drugs which block the AV node (see below), while the cardioversion is achieved electrically by DC shock (p. 761) or medically either by intravenous infusion of an anti-arrhythmic drug such as a class Ic or a class III agent or by taking an oral agent previously tested in hospital and found to be safe in a particular patient ('pill-in-pocket' approach). The choice depends upon:

- how well the arrhythmia is tolerated (is cardioversion urgent?)
- whether anticoagulation is required before considering elective cardioversion
- whether spontaneous cardioversion is likely (previous history? reversible cause?).

Conversion to sinus rhythm can be achieved by electrical DC cardioversion 200 J, then 2 x 360 J (p. 761) in about 80% of patients. Biphasic waveform defibrillation is more effective than conventional (monophasic) defibrillation, and biphasic defibrillators are becoming available. In some cases, internal transvenous low-energy (4 J) cardioversion is capable of restoring sinus rhythm where conventional transthoracic cardioversion has failed. Patients are anticoagulated with warfarin for 4 weeks before cardioversion. Anticoagulants are used to minimize the risk of thromboembolism associated with cardioversion unless atrial fibrillation is of less than 1-2 days' duration. Transoesophageal echocardiography is being used to document the presence or absence of atrial thrombus as a guide to the necessity for long-term anticoagulation.

Two strategies are available for the long-term management of atrial fibrillation:

- 'rhythm control' (antiarrhythmic drugs plus DC cardioversion *plus warfarin)*
- *m* 'rate control' (AV nodal slowing agents *plus warfarin).*

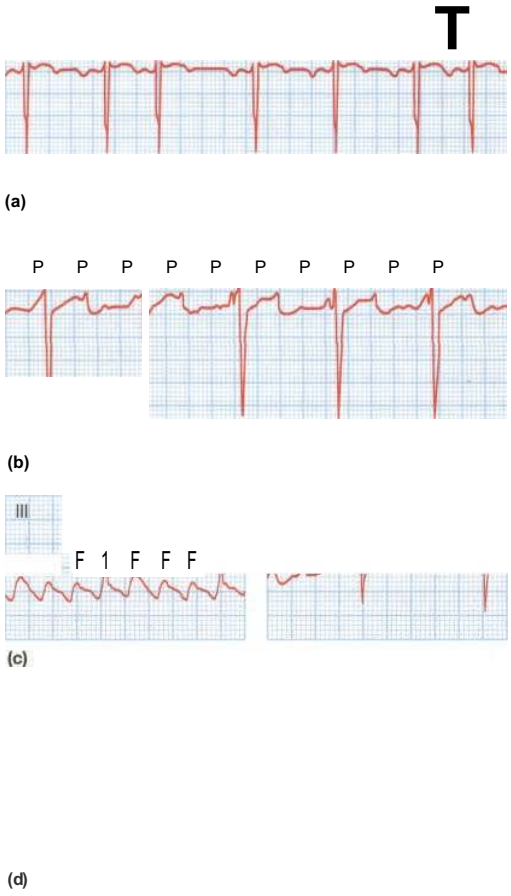

Fig. 13.46 **ECGs of a variety of atrial arrhythmias.**
(a) Atrial premature beats (arrows). The premature P wave is different from the sinus P wave and conducts to the ventricle with a slightly prolonged PR interval.
(b) Atrial tachycardia with second-degree atrioventricular block. Note the fast atrial (P wave) rate of 150/min and the slower ventricular (R wave) rate of 75/min.
(c) Atrial flutter. Some flutter waves are marked with an F. In this case the flutter frequency is 240/min. Every fourth flutter wave is transmitted to the ventricles and the ventricular rate is therefore 60/min.
(d) Atrial fibrillation. Note absolute rhythm irregularity and baseline undulations (f waves).

Which strategy to adopt needs to be assessed for each individual patient. Factors to consider include the likelihood of maintaining sinus rhythm and the safety/tolerability of antiarrhythmic drugs in a particular patient. Recurrent paroxysms may be prevented by oral medication. In general, class Ic agents are employed in patients with no significant heart disease and class III agents are preferred in patients with significant structural heart disease.

Rate control as a primary strategy may be appropriate in patients who:

- have the permanent form of the arrhythmia associated with mild symptoms which can be further improved by slowing heart rate

- are older than 65 years with recurrent atrial tachyarrhythmias (primary 'accepted' atrial fibrillation)
- have persistent tachyarrhythmias and have failed cardioversion(s) and serial prophylactic antiarrhythmic drug therapy and in whom the risk/benefit ratio from using specific antiarrhythmic agents is shifted towards increased risk
- do not have heart failure or left ventricular dysfunction that can be improved by restoring sinus rhythm.

Rate control is usually achieved by a combination of *digoxin, beta-blockers* or *calcium-channel blockers (verapamil* or *diltiazem).* The ventricular rate response is generally considered controlled if the heart rate is between 60 and 80 beats per minute at rest and 90 and 115 beats per minute during moderate exercise. To assess the adequacy of rate control, an ECG rhythm strip may be sufficient in an elderly patient but ambulatory 24-hour Holter monitoring and an exercise stress test (treadmill) are needed in younger individuals. Patients with poor rate control despite optimal medical therapy should be considered for AV node ablation and pacemaker implantation *(^ablate and pace' strategy).* These patients usually experience a marked symptomatic improvement but because of the ongoing risk of thromboembolism require life-long *anticoagulation.*

Anticoagulation (target INR 2.0-3.0)

This is indicated in patients with atrial fibrillation and one of the following major or two of the moderate risk factors:

Major risk factors

Prosthetic heart valve
Rheumatic mitral valve disease
Prior history of CVA/TIA
Age > 75 years
Hypertension
Coronary artery disease with poor LV function.

Moderate risk factors

m Age 65-75 years
- Coronary artery disease but normal LV function
- Diabetes mellitus.

In addition, other features, e.g. left atrial enlargement, LV dysfunction of any cause, evidence of atrial thrombus or a reduced atrial appendage emptying velocity, also encourage anticoagulation with warfarin.

In most other patients, aspirin is prescribed. Young patients (< 65 years) with no heart disease (lone atrial fibrillation) usually require no thromboembolic prophylaxis but should be treated with *aspirin* 300 mg. A new oral anticoagulant, ximelagatran, which is effective and easier to use, is currently under trials.

Younger patients with lone paroxysmal atrial fibrillation should be carefully assessed to rule out a single atrial ectopic focus triggering atrial fibrillation. Such foci are usually located in the pulmonary veins. This form of atrial fibrillation can be effectively cured by catheter ablation *(pulmonary vein isolation).*

Atrial flutter

Atrial flutter is often associated with atrial fibrillation and often shares clinical presentation requiring a similar initial therapeutic approach. Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 beats per minute. Typical, or isthmus-dependent, atrial flutter involves a macro re-entrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the Eustachian ridge between the tricuspid annulus and the inferior vena cava, and up the inter-atrial septum, giving rise to the most frequent pattern, referred to as counterclockwise flutter. Re-entry can also occur in the opposite direction (clockwise or reverse flutter).

The ECG shows regular sawtooth-like atrial flutter waves (F waves) between QRS complexes (Fig. 13.46c). In typical counterclockwise atrial flutter, the F waves are negative in the inferior leads and positive in leads V_x and V_2. In clockwise atrial flutter, the deflection of the F waves is the opposite. If F waves are not clearly visible, it is worth accentuating them by slowing AV conduction by carotid sinus massage or by the administration of AV nodal blocking drugs such as adenosine or verapamil.

Symptoms are largely related to the degree of AV block. Most often, every second flutter beat conducts, giving a ventricular rate of 150 b.p.m.. Occasionally, every beat conducts, producing a heart rate of 300 b.p.m. More often, especially when patients are receiving treatment, AV conduction block reduces the heart rate to approximately 75 b.p.m.

Management

Treatment of a symptomatic acute paroxysm is electrical *cardioversion.* Patients who have been in atrial flutter more than 1-2 days should be treated in a similar manner to patients with atrial fibrillation and *anticoagulated* for 4 weeks prior to cardioversion.

Recurrent paroxysms may be prevented by oral medication. In general, *class Ic* agents are employed in patients with no significant heart disease and *class III* agents are preferred in patients with significant structural heart disease. *AV nodal blocking agents* may be used to control the ventricular rate if the arrhythmia persists. However, the treatment of choice for patients with recurrent atrial flutter is radiofrequency catheter *ablation* (p. 782). This technique offers patients whose only arrhythmia is typical atrial flutter an almost certain chance of a cure.

Atrial tachycardia

This is an uncommon arrhythmia. Its prevalence is believed to be less than 1 % in patients with arrhythmias It is usually associated with structural heart disease but in many cases it is referred to as idiopathic. Macro re-entrant tachycardia often occurs after surgery for congenital heart disease Atrial tachycardia with block is often a result of digitalis poisoning.

The mechanisms of atrial tachycardia are attributed to enhanced automaticity, triggered activity or intra-atrial re-entry. Atrial re-entry tachycardia is usually relatively slow (125-150 b.p.m.) and can be initiated and terminated

by atrial premature beats. The P'P' intervals are regular. The PR interval depends on the rate of tachycardia and is longer than in sinus rhythm at the same rate.

Automatic tachycardia usually presents with higher rates (125-250 b.p.m.) and is often characterized by a progressive increase in the atrial rate with onset of the tachycardia ('warm-up') and progressive decrease prior to termination ('cool-down'). Atrial tachycardia is typically caused by a focus which is frequently located along the crista terminalis in the right atrium, adjacent to a pulmonary vein in the left atrium, or around one of the atrial appendages. Automatic atrial tachycardia may also present as an incessant variety leading to tachycardia-induced cardiomyopathy.

Figure 13.46b demonstrates an atrial tachycardia at an atrial rate of 150 per minute. The P waves are abnormally shaped and occur in front of the QRS complexes. Carotid sinus massage may increase AV block during tachycardia, thereby facilitating the diagnosis, but does not usually terminate the arrhythmia. Treatment options include *cardioversion, antiarrhythmic drug therapy* to maintain sinus rhythm, *AV nodal slowing agents* to control rate and, in selected cases, radiofrequency catheter *ablation*.

Atrial ectopic beats

These often cause no symptoms, although they may be sensed as an irregularity or heaviness of the heartbeat. On the ECG they appear as early and abnormal P waves, and are usually, but not always, followed by normal QRS complexes (Fig. 13.46a). Treatment is not normally required unless the ectopic beats provoke more significant arrhythmias, when *beta-blockers* may be effective.

VENTRICULAR TACHYARRHYTHMIAS

Ventricular tachyarrhythmias can be considered under the following headings:

life-threatening ventricular tachyarrhythmias
torsades de pointes normal heart ventricular
tachycardia non-sustained ventricular
tachycardia ventricular premature beats

Life-threatening ventricular tachyarrhythmias

Sustained ventricular tachycardia and ventricular fibrillation with haemodynamic instability (e.g. syncope, hypotension) are life-threatening ventricular tachyarrhythmias.

Sustained ventricular tachycardia

Sustained ventricular tachycardia (> 30 s) often results in *presyncope* (dizziness), *syncope, hypotension* and *cardiac arrest,* although it may be remarkably well tolerated in some patients. Examination reveals a pulse rate typically between 120 and 220 b.p.m. Usually there are clinical signs of atrioventricular dissociation (i.e. intermittent cannon 'a' waves in the neck, p. 738) and variable intensity of the first heart sound).

Table 13.13 **ECG distinction between supraventricular tachycardia (SVT) with bundle branch block and ventricular tachycardia (VT)**

VT is more likely than SVT with bundle branch block where there is:

a very broad QRS (> 0.14 s)
atrioventricular dissociation
a bifid, upright QRS with a taller first peak in V-,
a deep S wave in V_6
a concordant (same polarity) QRS direction in all chest leads (VVe)

The ECG shows a rapid ventricular rhythm with broad (often 0.14 s or more), abnormal QRS complexes. AV dissociation may result in visible P waves which appear to march through the tachycardia, capture beats (intermittent narrow QRS complex owing to normal ventricular activation via the AV node and conducting system) and fusion beats (intermediate between ventricular tachycardia beat and capture beat).

Supraventricular tachycardia with bundle branch block may resemble ventricular tachycardia on the ECG. However, if a broad complex tachycardia is due to SVT with either right or left bundle branch block, then the QRS morphology should resemble a typical RBBB or LBBB pattern (Figs 13.43 and 13.44). Other ECG criteria to differentiate VT from SVT with aberrancy are indicated in Table 13.13. Eighty per cent of all broad complex tachycardias are due to ventricular tachycardia, and the proportion is even higher in patients with structural heart disease. Therefore, in all cases of doubt, ventricular tachycardia should be diagnosed.

Treatment may be urgent, depending on the haemodynamic situation. If the patient is haemodynamically compromised (e.g. hypotensive or pulmonary oedema) emergency DC cardioversion may be required. On the other hand, if the blood pressure and cardiac output are well maintained, intravenous therapy with class I drugs or amiodarone is usually used. First-line drug treatment consists of lidocaine (50-100 mg i.v. over 5 minutes) followed by a lidocaine infusion (2-4 mg i.v. per minute). DC cardioversion is necessary if medical therapy is unsuccessful.

Ventricular fibrillation

This is very rapid and irregular ventricular activation with no mechanical effect. The patient is pulseless and becomes rapidly unconscious, and respiration ceases (cardiac arrest). The ECG shows shapeless, rapid oscillations and there is no hint of organized complexes (Fig. 13.47). It is usually provoked by a ventricular ectopic beat. Ventricular fibrillation rarely reverses spontaneously. The only effective treatment is electrical defibrillation. Basic and advanced cardiac life support is needed (p. 759).

If the attack of ventricular fibrillation occurs during the first day or two of an acute myocardial infarction, it is

***Fig. 13.47* Ventricular fibrillation.** Four beats of sinus rhythm followed by a ventricular ectopic beat that initiates ventricular fibrillation. The ST segment during sinus rhythm is elevated owing to acute myocardial infarction in this case.

probable that prophylactic therapy will be unnecessary. If the ventricular fibrillation was not related to an acute infarction, the long-term risk of recurrent cardiac arrest and sudden death is high.

Survivors of these ventricular tachyarrhythmias are, in the absence of an identifiable reversible cause (e.g. acute myocardial infarction, severe metabolic disturbance), at high risk of sudden death. Implantable cardioverter-defibrillators (ICDs) are first-line therapy in the management of these patients (p. 782).

The Brugada syndrome

This inheritable condition accounts for part of a group of patients with idiopathic ventricular fibrillation who have no evidence of causative structural cardiac disease. It is more common in young male adults and in South East Asia. The diagnosis is made by identifying the classic ECG changes that may be present spontaneously or provoked by the administration of a class I anti-arrhythmic (flecainide or ajmaline): right bundle branch block with coved ST elevation in leads V_1-V_3 (Fig. 13.48). In 20% of cases it is a monogenic inheritable condition associated with cardiac sodium channel *(SCN5A)* mutations. It can present with sudden death during sleep, resuscitated cardiac arrest and syncope, or the patient may be asymptomatic and diagnosed incidentally or during familial assessment. There is a high risk of sudden death, particularly in the symptomatic patient or those with spontaneous ECG changes. The only successful treatment is an ICD. Beta-blockade is not helpful and may be harmful in this syndrome.

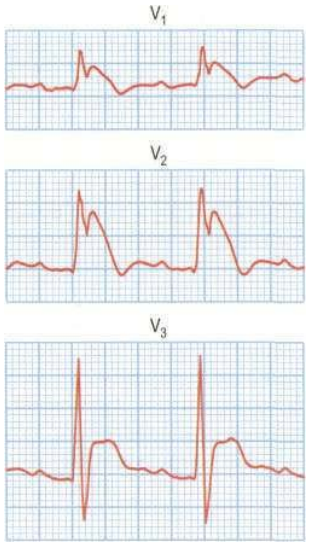

***Fig. 13.48* The Brugada ECG.** ST elevation in V^ with right bundle branch block.

Torsades de pointes

Torsades de pointes arises when ventricular repolarization (QT interval) is greatly prolonged (long QT syndrome). The causes of long QT syndrome and torsades de pointes are listed in Table 13.14.

Congenital long QT syndrome may (Jervell-Lange-Nielsen syndrome) or may not (Romano-Ward syndrome) be associated with congenital deafness. QT prolongation and torsades de pointes can be precipitated by increased adrenergic drive (exertion or emotion), sudden arousal (e.g. being woken from sleep by an alarm) or it can occur even when asleep. In acquired long QT syndrome, QT prolongation and torsades de pointes are usually provoked by bradycardia.

Torsades de pointes causes palpitations and syncope but usually terminates spontaneously. It may, however,

***Table 13.14* Causes of long QT syndrome and torsades de pointes tachycardia**

Congenital syndromes
Jervell-Lange-Nielsen (autosomal recessive)
Romano-Ward (autosomal dominant)

Electrolyte abnormalities
Hypokalaemia
Hypomagnesaemia
Hypocalcaemia

Drugs
Quinidine, disopyramide
Sotalol, amiodarone
Amitriptyline (and other tricyclic antidepressants)
Chlorpromazine (and other phenothiazine drugs)
Erythromycin, other macrolides and fluoroquinolones

Poisons
Organophosphate insecticides

Miscellaneous
Bradycardia Mitral valve prolapse Acute myocardial infarction
Prolonged fasting and liquid protein diets (long term)
Central nervous system diseases, e.g. dystrophia myotonica

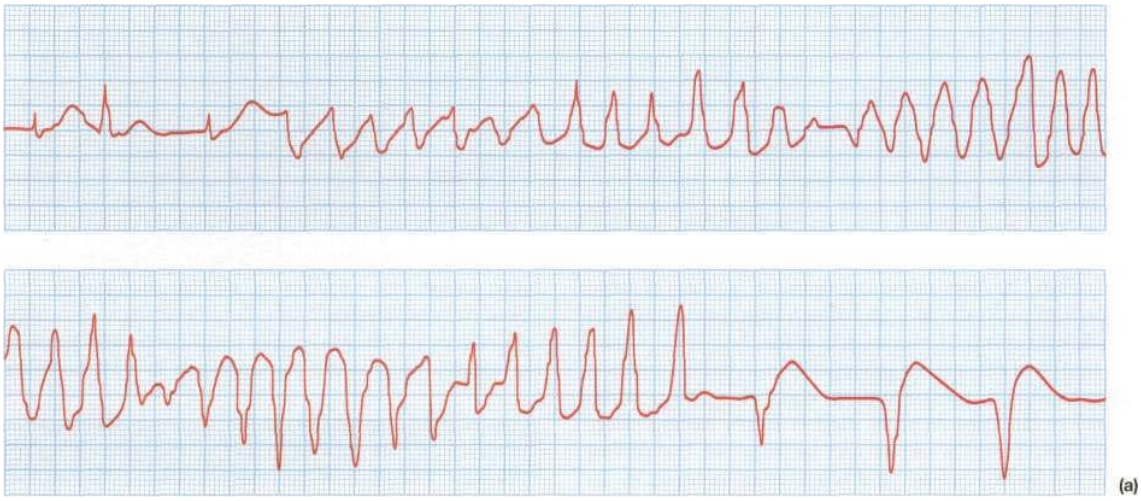
degenerate to ventricular fibrillation resulting in sudden death. It is characterized on the ECG by rapid, irregular, sharp complexes that continuously change from an upright to an inverted position (Fig. 13.49a).

Between spells of tachycardia or immediately preceding the onset of tachycardia the ECG shows a prolonged QT interval; the corrected QT (Table 13.5, p. 746) is equal to or greater than 0.44 s. Figure 13.49b shows examples of three forms of long QT interval prolongation. Acute management is as follows:

- Any electrolyte disturbance is corrected.
- Causative drugs are stopped.
- The heart rate is maintained with atrial or ventricular pacing.
- Magnesium sulphate 8 mmol (mg^{2+}) over 10-15 min for acquired long QT.
- Intravenous isoprenaline may be effective when QT prolongation is acquired (isoprenaline is contraindicated for congenital long QT syndrome).

Long-term management of acquired long QT syndrome involves avoidance of all drugs known to prolong the QT interval. Congenital long QT syndrome is generally treated by beta-blockade, left cardiac sympathetic denervation, and pacemaker therapy. Patients who remain symptomatic despite conventional therapy and those with a strong family history of sudden death usually need ICD therapy.

The molecular biology of the congenital long QT syndromes has been shown to be heterogeneous. It is usually a monogenic disorder and has been associated with mutations in cardiac potassium and sodium channel genes (Table 13.15). The different genes involved appear to correlate with different phenotypes (Fig. 13.49b) that



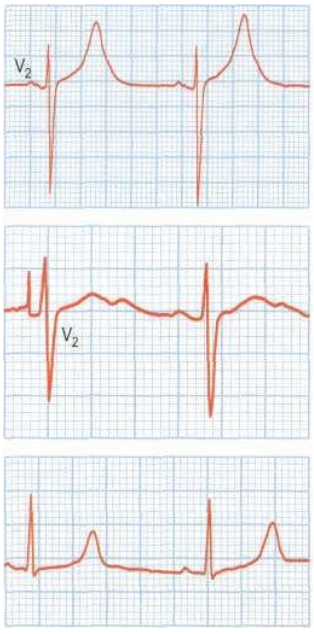


Fig. 13.49 **Prolonged QT. (a)** An ECG demonstrating a supraventricular rhythm with a long QT (LQT) interval giving way to atypical ventricular tachycardia (torsades de pointes). The tachycardia is short-lived and is followed by a brief period of idioventricular rhythm.

(b) Further examples of a prolonged QT interval corresponding to three different types of LQT.

Table 13.15 Single gene mutations responsible for congenital long QT syndrome

Subtype	Chromosome	Product	Channel
LQT1	11	KCNQ1	I_{ks} a subunit
LQT2	7	HERG	I_{kr} a subunit
LQT3	3	SCN5A	I_{Na} a subunit
LQT4	4	Ankyrin B	Unknown
LQT5	21	KCNE1	I_{ks} p subunit
LQT6	21	KCNE2	I_{kr}p subunit

can exhibit such variable penetrance that carriers may have completely normal ECGs. It is likely that identification of the mutation involved will not only improve diagnostic accuracy but also guide future therapy for the congenital long QT syndrome.

Normal heart ventricular tachycardia

Monomorphic ventricular tachycardia in patients with structurally normal hearts (idiopathic VT) is usually a benign condition with an excellent long-term prognosis. Occasionally, it is incessant (so called Galavardin's tachycardia) and if untreated may lead to cardiomyopathy. Normal heart VT either arises from a focus in the right ventricular outflow tract or in the left ventricular septum. Treatment of symptoms is usually with beta-blockers. There is a special form of verapamil-sensitive tachycardia that responds well to non-dihydropyridine calcium antagonists. In symptomatic patients, radiofrequency catheter ablation is highly effective, resulting in a cure in > 90% cases.

Non-sustained ventricular tachycardia

Non-sustained ventricular tachycardia (NSVT) is defined as ventricular tachycardia that is > 5 consecutive beats but lasts < 30 s (Fig. 13.50d). NSVT can be found in 6% of patients with normal hearts and usually does not require treatment. NSVT is documented in up to 60-80% of patients with heart disease. There is insufficient evidence on prognosis, but an ICD has been shown to improve survival of patients with particularly poor left ventricular function (ejection fraction 30% or less) by preventing arrhythmic death. Antiarrhythmic suppression of NSVT is not usually advocated but beta-blockers may improve quality of life in symptomatic individuals.

Ventricular premature beats

These may be uncomfortable, especially when frequent. The patient complains of extra beats, missed beats or heavy beats because it may be the premature beat, the post-ectopic pause or the next sinus beat that is noticed by the patient. The pulse is irregular owing to the premature beats. Some early beats may not be felt at the wrist. When a premature beat occurs regularly after every normal beat, 'pulsus bigeminus' may occur.

These premature beats (Fig. 13.50a-c) have a broad (> 0.12 s) and bizarre QRS complex because they arise from an abnormal (ectopic) site in the ventricular myocardium. Following a premature beat there is usually a complete compensatory pause because the AV node or ventricle is refractory to the next sinus impulse. Early 'R-on-T' ventricular premature beats (occurring simultaneously with the upstroke or peak of the T wave of the previous beat) may induce ventricular fibrillation in patients with heart disease, particularly in patients following myocardial infarction.

Ventricular premature beats are usually treated only if symptomatic. Usually simple measures such as reassurance and beta-blocker therapy are all that is required.

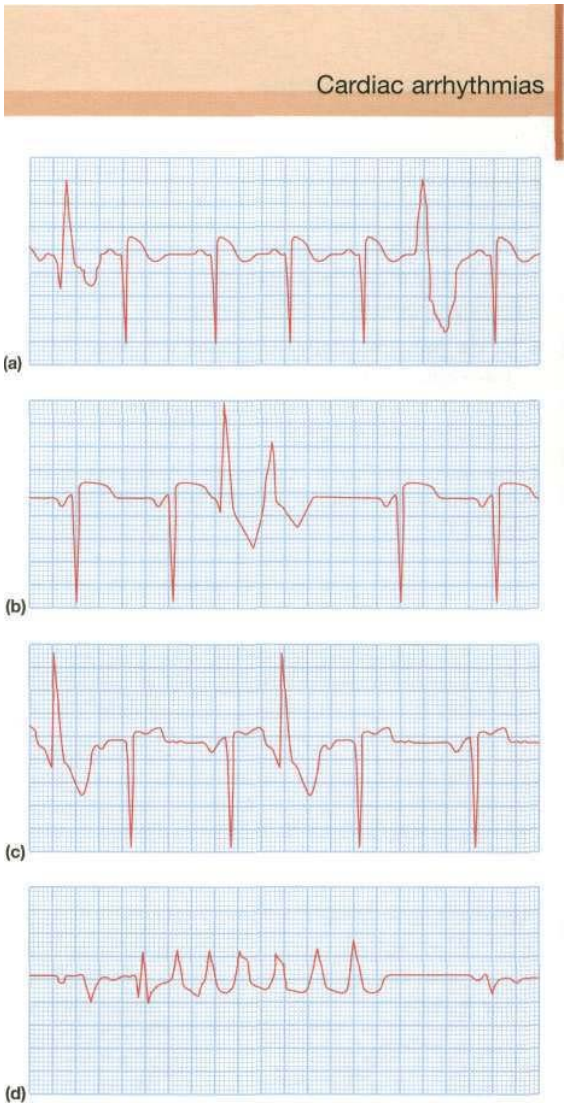

Fig. 13.50 **Varieties of ventricular ectopic activity.**
(a) Two ventricular ectopic beats of different morphology (multimorphological).
(b) Two ventricular premature beats (VPBs) occurring one after the other (a pair or couplet of VPBs).
(c) Frequently repetitive ventricular ectopic activity of a single morphology.
(d) Brief run of ventricular tachycardia (non-sustained ventricular tachycardia) that follows previous ectopic activity.

LONG-TERM MANAGEMENT OF CARDIAC TACHYARRHYTHMIAS

Options for the long-term management of cardiac tachyarrhythmias include:

- antiarrhythmic drug therapy
- ablation therapy
- device therapy. :

To determine the optimal strategy for a given patient the following questions must be addressed:

- Is the principal aim of treatment symptom relief or prevention of sudden death?
- Is maintaining sinus rhythm or controlling ventricular rates the treatment goal?

Commonly employed treatment strategies for the management of specific tachyarrhythmias are outlined in Table 13.16.

Antiarrhythmic drugs

Drugs that modify the rhythm and conduction of the heart are used to treat cardiac arrhythmias. Antiarrhythmic drugs may aggravate or produce arrhythmias (proarrhythmia) and they may also depress ventricular contractility and must therefore be used with caution. They are classified according to their effect on the action potential (Vaughan Williams' classification; Table 13.17 and Fig. 13.51).

Class I drugs

These are membrane-depressant drugs that reduce the rate of entry of sodium into the cell (sodium-channel

Table 13.16 **Long-term management of tachyarrhythmias**

Tachycardia	Management aims	Management strategies
AV node re-entry tachycardia (AVNRT)	Relieve symptoms	AV-node-blocking agents Class Ic or class III Catheter ablation
AV reciprocating tachycardia (AVRT)	Relieve symptoms	AV-node-blocking agents Class Ic or class III Catheter ablation
Wolff-Parkinson-White (WPW) syndrome	Relieve symptoms Prevent sudden death (esp. if documented pre-excited atrial fibrillation)	Class Ic or class III Catheter ablation
Atrial fibrillation	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Maintenance of sinus rhythm: class Ic or class III ± cardioversion catheter ablation of ectopic focus Rate control: AV-node-slowing agents AV node ablation plus pacemaker Anticoagulation
Atrial flutter	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Class Ic or class III Catheter ablation AV-node-blocking agents Anticoagulation
Atrial tachycardia	Relieve symptoms Prevent worsening heart failure due to poor rate control Prevent thromboembolic complications	Class Ic or class III Catheter ablation AV-node-blocking agents Anticoagulation
Life-threatening ventricular tachyarrhythmias	Prevent sudden death	Implantable cardioverter-defibrillator (ICD) Beta-blockers
Congenital long QT	Prevent sudden death	Beta-blockers ± pacemaker ICD Correct bradycardia Correct electrolytes
Acquired long QT	Prevent sudden death	Avoidance of all QT-prolonging drugs
Normal heart ventricular tachycardias	Relieve symptoms	Beta-blockers, calcium-channel blockers Catheter ablation
Non-sustained VT (NSVT)	Relieve symptoms Prevent sudden death in certain situations	Beta-blockers Class Ic or class III ICD in clearly defined subgroups

Table 13.17 **Vaughan Williams' classification of antiarrhythmic drugs**

Class I	Membrane-depressant drugs (sodium-channel blockers)
Ia	Disopyramide, procainamide, quinidine
Ib	Lidocaine (lignocaine), mexiletine
Ic	Flecainide, propafenone
Class II	p-Adrenoceptor blocking drugs, e.g. atenolol, propranolol, esmolol Class III Prolong action potential, e.g. amiodarone, sotalol Class IV Calcium-channel blockers, e.g. verapamil, diltiazem (Other Adenosine, digoxin)

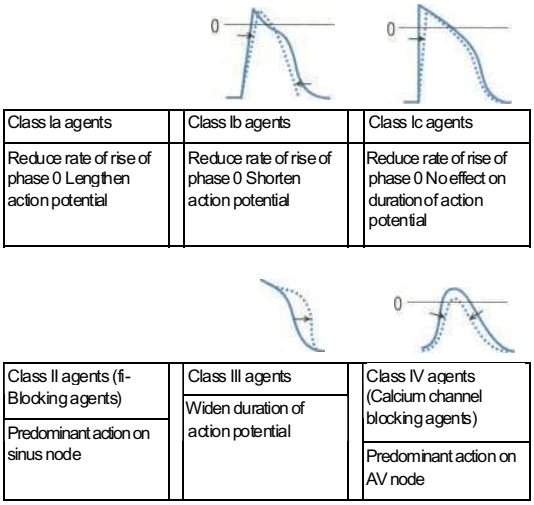

Fig. 13.51 **Vaughan Williams' classification of antiarrhythmic drugs** based on their effect on cardiac action potentials. 0, 0 mV. The dotted curves indicate the effects of the drugs.

blockers). They may slow conduction, delay recovery or reduce the spontaneous discharge rate of myocardial cells. Class Ia drugs (e.g. disopyramide) lengthen the action potential, class Ib drugs (e.g. lidocaine) shorten the action potential, and class Ic (flecainide, propafenone) do not affect the duration of the action potential. Class I agents have been found to increase mortality compared to placebo in post-myocardial infarction patients with ventricular ectopy (Cardiac Arrhythmia Suppression Trial (CAST) trials - class Ic agents) and in patients treated for atrial fibrillation (class Ia agent, quinidine). In view of this, class Ic agents such as flecainide and indeed all other class I drugs should be reserved for patients who do not have significant coronary artery disease, left ventricular dysfunction, or other forms of significant structural hearts disease.

Class II drugs (see Table 13.49)
These antisympathetic drugs prevent the effects of catecholamines on the action potential. Most are (3-adrenoceptor antagonists. Cardioselective beta-blockers ({}) include metoprolol, atenolol and acebutalol. Beta-blockers suppress AV node conduction, which may be effective in preventing attacks of junctional tachycardia, and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation). In general beta-blockers are anti-ischaemic, and anti-adrenergic and have proven beneficial effects in patients post-myocardial infarction (by preventing ventricular fibrillation) and in patients with congestive heart failure. It is therefore advisable to consider beta-blocker therapy either alone or in combination with other antiarrhythmic drugs in patients with symptomatic tachyarrhythmias, particularly in patients with coronary artery disease.

Class III drugs
These prolong the action potential and do not affect sodium transport through the membrane. The drugs in this class are amiodarone and sotalol. Sotalol is also a beta-blocker.

Some drugs, such as ibutilide and dofetilide, are only available in some countries. Sotalol may result in acquired long QT syndrome and torsades de pointes. The risk of torsades is increased in the setting of hypokalaemia, and particular care should be taken in patients taking diuretic therapy. Amiodarone therapy in contrast to most other antiarrhythmic drugs carries a low risk of pro-arrhythmia in patients with significant structural heart disease. Because it has many toxic and potentially serious side-effects, patients need to be counselled prior to commencing amiodarone and monitored carefully at regular follow-up intervals. Dofetilide has been used to treat atrial fibrillation and flutter in patients with recent myocardial infarction and poor LV function.

Class IV drugs (see also Table 13.28) The non-dihydropyridine calcium antagonists that reduce the plateau phase of the action potential are particularly effective at slowing conduction in nodal tissue. Verapamil and diltiazem are two drugs in this group. These drugs can prevent attacks of junctional tachycardia (AVNRT and AVRT) and may help to control ventricular rates during paroxysms of other forms of SVT (e.g. atrial fibrillation).

Drug therapy is commonly used for symptomatic relief in patients who do not have life-threatening tachy-arrhythmias. Patient safety is the main factor determining the choice of antiarrhythmic therapy and proarrhythmic risks need to be carefully assessed prior to initiating therapy. As a generalization, class Ic agents are employed in patients with structurally normal hearts and class **III** agents are used in patients with structural heart disease.

In order to administer antiarrhythmic agents as safely as possible it is helpful to be familiar with the different proarrhythmia mechanisms and their main predisposing risk factors (Table 13.18).

Patients with structurally normal hearts and normal QT intervals, or with implantable defibrillators, are either at very low risk of proarrhythmia or are protected from any life-threatening consequences, and in these patients it

Table 13.18 **Proarrhythmia mechanisms and the predisposing risk factors**

Prearrhythmia mechanism	Drug	Predisposing risk factors
Torsades de pointes	Class Ia (disopyramide, procainamide, quinidine) Sotalol 'Pure' class III (ibutilide)	Baseline QT prolongation Female gender Hypokalaemia/diuretic use Clinical heart failure Advanced structural heart disease Conversion of AF to sinus rhythm
Atrial flutter with 1 : 1 AV conduction and wide QRS complexes	Class I_a (disopyramide, quinidine) Class I_c (flecainide, propafenone) Class I_c (flecainide)	Risk reduced by adding an AV-nodal-slowing agent Myocardial ischaemia
'Late' sudden death (arrhythmic mechanism not clearly defined)	Quinidine	

is possible to persevere with drug therapy until an efficacious, well-tolerated agent is identified.

Catheter ablation

Radiofrequency catheter ablation is frequently employed in the management of symptomatic tachyarrhythmias. Ablations are performed by placing three or four electrode catheters into the heart chambers in order to record and pace from various sites. Pacing the atria or the ventricles is used to trigger the tachycardia and to study the tachycardia mechanism. Successful ablation depends on accurate identification of either the site of origin of a focal tachycardia or of a critical component of a macro-reentry tachycardia. The following tachyarrhythmias can be readily ablated:

- AV node re-entry tachycardia (AVNRT)
- AV re-entry tachycardia (AVRT) with an accessory pathway, including WPW syndrome
- normal heart VT
- atrial flutter
- atrial tachycardia.

Symptomatic patients with a pre-excited ECG because of accessory pathway conduction (WPW syndrome) are advised to undergo catheter ablation as first-line therapy, owing to the risk of sudden death associated with this condition. This is especially the case in patients with pre-excited atrial fibrillation. Patients with accessory pathways that only conduct retrogradely from the ventricles to the atrium are not at increased risk of sudden death but experience symptoms due to AVRT. These patients are commonly offered an ablation procedure if simple measures such as AV nodal slowing agents fail to suppress tachycardia. The main risk associated with accessory pathway ablation is thromboembolism in patients with left-sided accessory pathways. The success rate for catheter ablation of AVNRT and accessory pathways is greater than 95%.

Patients with normal hearts and documented ventricular tachycardia should be referred for specialist evaluation. Unlike VT in patients with structural heart disease, normal heart VT is not associated with increased risk of sudden death and is easily cured by catheter ablation.

Catheter ablation is recommended in patients with atrial flutter that is not easily managed medically. Ablation of typical flutter is effective in 90-95% cases. In the direct comparison of catheter ablation and anti-arrhythmic therapy, the rate of recurrence was significantly lower following ablation. Atrial tachycardia, especially in patients with structurally normal hearts, may also be cured by catheter ablation. In atrial fibrillation, adequate control of ventricular rates is sometimes not possible despite optimal medical therapy. These patients experience a marked symptomatic improvement following AV node ablation and pacemaker implantation. Unlike other forms of catheter ablation this does not cure the arrhythmia; atrial fibrillation continues and anticoagulation is still required following ablation.

In younger patients with structurally normal hearts, atrial ectopic beats, which commonly arise from a focus situated in the pulmonary veins, may trigger atrial fibrillation. Catheter ablation of this ectopic focus includes the application of radiofrequency energy in or around the pulmonary veins in order to abolish the connection between the sleeves of arrhythmogenic atrial myocardium surrounding or extending into the veins from the remaining atrium (pulmonary vein isolation). The trigger is therefore eliminated and the arrhythmia does not recur. The complications of the procedure involve pulmonary vein stenosis, thrombosis and stroke. The complication rate is small and the success rate is 60-80% in patients with paroxysmal atrial fibrillation and 20-40% in those with a persistent form of the arrhythmia.

Implantable cardioverter-defibrillator (ICD)

Life-threatening ventricular arrhythmias (ventricular fibrillation or rapid ventricular tachycardia with hypotension) result in death in up to 40% within 1 year of diagnosis. Large multicentre prospective trials such as the Antiarrhythmics (amiodarone) Versus Implantable Defibrillator (AVID) trial have proven that implantable defibrillators improve overall survival in patients who have experienced an episode of life-threatening ventricular tachyarrhythmia (Fig. 13.52).

The ICD recognizes ventricular tachycardia or fibrillation and automatically delivers pacing or a shock to the

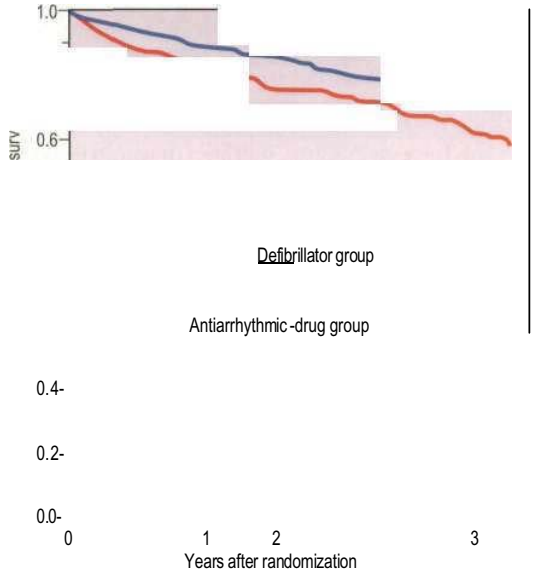

Fig. 13.52 **Survival curves of the Multicentre Automatic Defibrillator Implantation Trial (MADIT)** following myocardial infarction. Patients with left ventricular ejection fractions of < 0.35 and documented asymptomatic non-sustained ventricular tachycardia and inducible ventricular tachycardia were randomized to receive an ICD or conventional therapy.

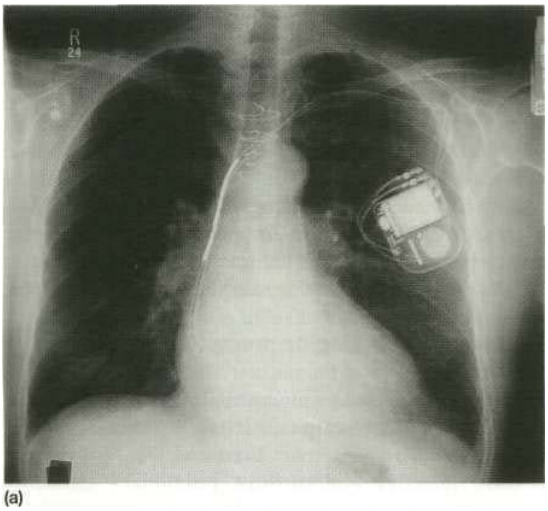
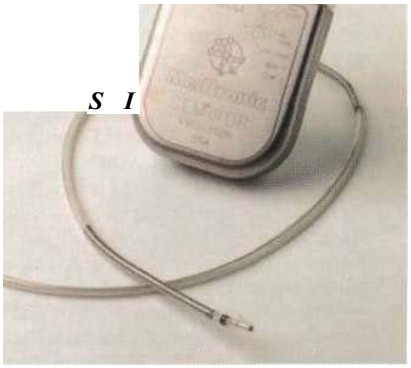
heart to cause cardioversion to sinus rhythm. Modern ICDs are only a little larger than a pacemaker and are implanted in a pectoral position (Fig. 13.53). The device may have leads to sense and pace both the right atrium and ventricle, and the lithium batteries employed are able to provide energy for over 100 shocks each of around 30 J. ICD discharges are painful if the patient is conscious. However, ventricular tachycardia may often be terminated by overdrive pacing the heart, which is painless. The ICD is superior to all other treatment options at preventing sudden cardiac death. The use of this device has cut the sudden death rate in patients with a history of serious ventricular arrhythmias to approximately 2% per year. However, the majority of these patients have significant structural heart disease and overall cardiac mortality due to progressive heart failure remains high. As a result ICDs are now first-line therapy in the secondary prevention of sudden death.

Implantable cardioverter-defibrillators are also employed in the primary prevention of sudden cardiac death. The chances of surviving an out of hospital cardiac arrest are as low as 10%. Therefore selected patients who have never experienced a spontaneous episode of life-





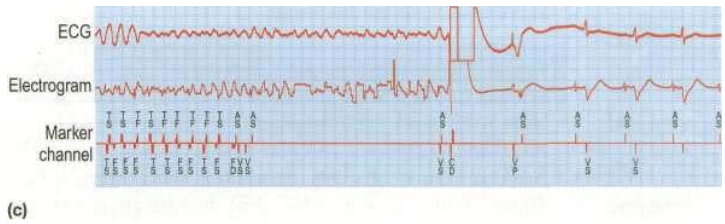


Fig. 13.53 **Implantable cardioverter-defibrillator. (a) X-ray of a 'dual-chamber' ICD** in a left pectoral position with atrial and ventricular leads, **(b) An implantable dual-chamber cardioverter-defibrillator** (GEM III **DR). (c) Termination of ventricular fibrillation** by the direct current shock at 20 J. Electrogram recorded internally from the ventricular lead of an ICD reveals chaotic ventricular activity consistent with ventricular fibrillation. This is confirmed by an electrocardiogram (lead V_2). The marker channel demonstrates that the device detects ventricular fibrillation correctly (FS, fibrillation sensing, lower line) and delivers an appropriate shock (CD) that terminates the arrhythmia and restores normal sinus rhythm (VS, ventricular sensing, lower line). Incidentally, atrial fibrillation is also detected before shock delivery (upper line on the marker channel).

threatening ventricular tachyarrhythmia but who are assessed to be at high risk of sudden death are advised to undergo ICD implantation. In two large primary prevention ICD trials, Multicenter Automated Defibrillator Implantation Trial (MADITII) and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), therapy with an ICD reduced mortality by 23-31% on top of conventional treatment, which included revascularization, beta-blockers, and angiotensin-converting enzyme inhibitors. The following groups of patients may merit prophylactic ICD placement:

- patients with coronary artery disease; significant impairment of left ventricular function (LVEF < 35-40%), spontaneous non-sustained ventricular tachycardia in whom sustained ventricular tachycardia was induced by pacing the heart during an electrophysiological study
- patients with very poor LV function post-MI (LVEF < 30%); however a recent study has shown no overall reduction in mortality
- patients with dilated and particularly hypertrophic cardiomyopathy, long QT syndrome and Brugada syndrome who have a strong family history of sudden cardiac death.

HEART FAILURE

Heart failure is a complex syndrome that can result from any structural or functional cardiac disorder that impairs the ability of the heart to function as a pump to support a physiological circulation.

The incidence of heart failure increases with advancing age. The average annual incidence is 2-4% between 35 and 64 years, and 10% in patients over 65 years. The prognosis of heart failure has improved over the past 10 years, but the mortality rate is still high with approximately 50% of patients dead at 5 years. Heart failure accounts for 5% of admissions to hospital medical wards. The cost of managing heart failure in the UK exceeds £1 billion per year. Coronary artery disease is the commonest cause of heart failure in western countries.

The causes of heart failure are shown in Table 13.19.

Factors aggravating or precipitating heart failure

Any factor that increases myocardial work may aggravate existing heart failure or initiate failure. The most common are arrhythmias, anaemia, thyrotoxicosis, pregnancy, obesity, infective endocarditis, pulmonary infection, change of heart failure therapy including poor compliance. Readmission rates range from 29% and 47% within 3-6 months of hospital discharge.

PATHOPHYSIOLOGY

When the heart fails, considerable changes occur to the heart and peripheral vascular system in response to the haemodynamic changes associated with heart failure (Table 13.20). These physiological changes are compensatory and maintain cardiac output and peripheral perfusion. However, as heart failure progresses, these mechanisms are overwhelmed and become pathophysiological. The development of pathological peripheral vasoconstriction and sodium retention in heart failure by activation of the renin—angiotensin—aldosterone system, is a loss of beneficial compensatory mechanisms and

Table 13.19 Causes of heart failure

Main causes
Ischaemic heart disease (35-40%)
Cardiomyopathy (dilated) (30-34%)
Hypertension (15-20%)

Other causes
Cardiomyopathy (undilated): hypertrophic/obstructive, restrictive (amyloidosis, sarcoidosis) Valvular heart disease (mitral, aortic, tricuspid) Congenital heart disease (ASD, VSD) Alcohol and drugs (chemotherapy) Hyperdynamic circulation (anaemia, thyrotoxicosis, haemochromatosis, Paget's disease) Right heart failure (RV infarct, pulmonary hypertension, pulmonary embolism, cor pulmonale (COPD)) Tricuspid incompetence Arrhythmias (atrial fibrillation, bradycardia (complete heart block, the sick sinus syndrome)) Pericardial disease (constrictive pericarditis, pericardial effusion)

Table 13.20 Pathophysiological changes in heart failure

Ventricular dilatation
Myocyte hypertrophy
Increased collagen synthesis
Altered myosin gene expression
Altered sarcoplasmic Ca^{2+}-ATPase density
Increased ANP secretion
Salt and water retention
Sympathetic stimulation
Peripheral vasoconstriction

represents cardiac decompensation. Factors involved are venous return, outflow resistance, contractility of the myocardium, and salt and water retention.

Venous return (preload)

In the intact heart, myocardial failure leads to a reduction of the volume of blood ejected with each heartbeat and an increase in the volume of blood remaining after systole. This increased diastolic volume stretches the myocardial fibres and, as Starling's law of the heart would suggest, myocardial contraction is restored. However, the failing myocardium results in depression of the ventricular function curve (cardiac output plotted against the ventricular diastolic volume) (Fig. 13.5, p. 728).

Mild myocardial depression is not associated with a reduction in cardiac output because it is maintained by an increase in venous pressure (and hence diastolic volume). However, the proportion of blood ejected with each heartbeat (ejection fraction) is reduced early in heart failure. Sinus tachycardia also ensures that any reduction of stroke volume is compensated for by the increase in heart rate; cardiac output (stroke volume x heart rate) is therefore maintained.

When there is more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and/or marked sinus tachycardia. The increased venous pressure contributes to the development of dyspnoea, owing to the accumulation of interstitial and alveolar fluid, and to the occurrence of hepatic enlargement, ascites and dependent oedema, due to increased systemic venous pressure. However, the cardiac output at rest may not be much depressed, but myocardial and haemodynamic reserve is so compromised that a normal increase in cardiac output cannot be produced by exercise.

In very severe heart failure the cardiac output at rest is depressed, despite high venous pressures. The inadequate cardiac output is redistributed to maintain perfusion of vital organs, such as the heart, brain and kidneys, at the expense of the skin and muscle.

Outflow resistance (afterload) (see Figs 15.3 and 15.4)

This is the load or resistance against which the ventricle contracts. It is formed by:

- pulmonary and systemic resistance
- physical characteristics of the vessel walls
- the volume of blood that is ejected.

An increase in afterload decreases the cardiac output. This results in a further increase of end-diastolic volume and dilatation of the ventricle itself, which further exacerbates the problem of afterload. This is expressed by Laplace's law: the tension of the myocardium (T) is proportional to the intraventricular pressure (P) multiplied by the radius of the ventricular chamber *(R):* i.e. $T \propto PR$.

Myocardial contractility (inotropic state)

The state of the myocardium also influences performance. The sympathetic nervous system is activated in heart failure via baroreceptors as an early compensatory mechanism, which provides inotropic support and maintains cardiac output. Chronic sympathetic activation, however, has deleterious effects by further increasing neurohormonal activation and myocyte apoptosis. This is compensated by a downregulation of P-receptors. Increased contractility (positive inotropism) can result from increased sympathetic drive, and this is a normal part of the Frank-Starling relationship (Fig. 13.5, p. 728). Conversely, myocardial depressants (e.g. hypoxia) decrease myocardial contractility (negative inotropism).

Neurohormonal and sympathetic system activation: salt and water retention

The increase in venous pressure that occurs when the ventricles fail leads to retention of salt and water and their accumulation in the interstitium, producing many of the physical signs of heart failure. Reduced cardiac output also leads to diminished renal perfusion, activating the renin-angiotensin system and enhancing salt and water retention (Fig. 12.3, p. 691), which further increases venous pressure (Fig. 13.54). The retention of sodium is in part compensated by the action of circulating atrial natriuretic peptides and anridiuretic hormone (see p. 691 and below).

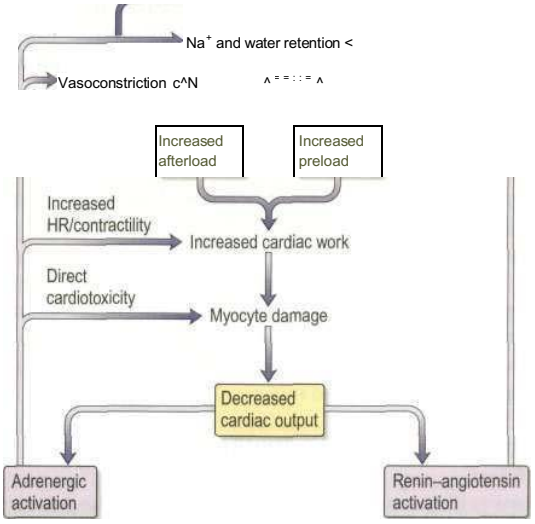

Fig. 13.54 **The compensatory physiological response to heart failure.** Chronic activation of the renin-angiotensin and adrenergic systems results in a 'vicious cycle' of cardiac deterioration that further exacerbates the physiological response.

The interaction of haemodynamic and neurohumoral factors in the progression of heart failure remains unclear. Increased ventricular wall stress promotes ventricular dilatation and further worsens contractile efficiency. In addition, prolonged activation of the sympathetic nervous and renin-angiotensin-aldosterone systems exerts direct toxic effects on myocardial cells.

Myocardial remodelling in heart failure

Left ventricular remodelling is a process of progressive alteration of ventricular size, shape, and function owing to the influence of mechanical, neurohormonal, and possibly genetic factors in several clinical conditions, including myocardial infarction, cardiomyopathy, hypertension, and valvular heart disease. Its hallmarks include hypertrophy, loss of myocytes, and increased interstitial fibrosis. Remodelling continues for months after the initial insult, and the eventual change in the shape of the ventricle becomes responsible for significant impairment of overall function of the heart as a pump (Fig. 13.55a). In cardiomyopathy, the process of progressive ventricular dilatation or hypertrophy occurs without ischaemic myocardial injury or infarction (Fig. 13.55b).

Changes in myocardial gene expression

Haemodynamic overload of the ventricle stimulates changes in cardiac contractile protein gene expression. The overall effect is to increase protein synthesis, but many proteins also switch to fetal and neonatal isoforms. Human myosin is composed of a pair of heavy chains and two pairs of light chains. Myosin heavy chains (MHC) exist in two isoforms, *a* and (3, that have different contractile properties and ATPase activity. ceoe-MHC predominates in the atria and pfJ-MHC in the ventricles. In animal models, pressure overload results in a shift from oca- to PfS-MHC in the atria, in parallel with atrial size. This results in reduction in atrial contractility but reduced energy demands. This shift is less significant in the human ventricle, as the pSp-MHC isoform already predominates. Other genes affected in heart failure include those encoding Na^+/K^+-ATPase, Ca^{2+}-ATPase and (3_1-adrenoceptors.

Abnormal calcium homeostasis

Calcium ion flux within myocytes plays a pivotal role in the regulation of contractile function. Excitation of the myocyte cell membrane causes the rapid entry of calcium

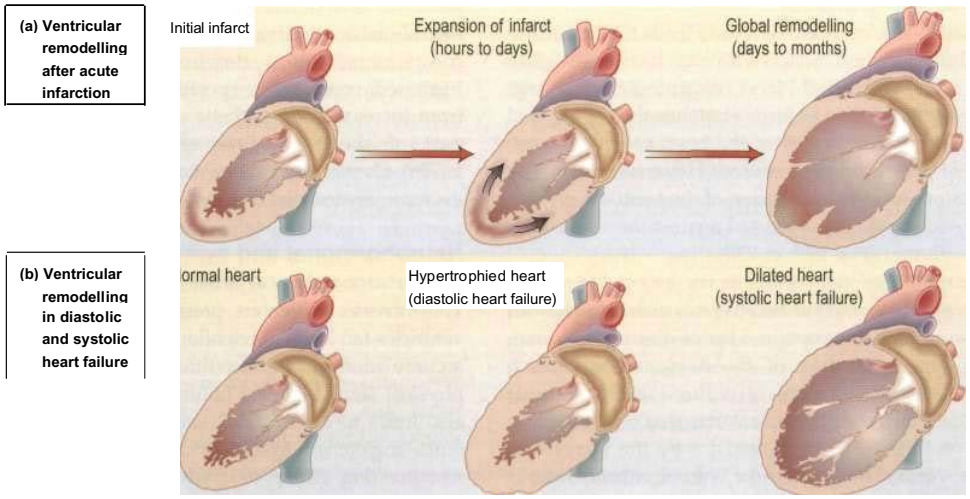

Fig. 13.55 **Ventricular remodelling in (a) ischaemic (MI) and (b) non-ischaemic heart failure, e.g. in cardiomyopathy.** From Jessop M, Brozana S (2003) *New England Journal of Medicine* **348:** 2011, with permission. Copyright © 2003 Massachusetts Medical Society. All rights reserved.

into myocytes from the extracellular space via calcium channels. This triggers the release of intracellular calcium from the sarcoplasmic reticulum and initiates contraction (see Fig. 13.3). Relaxation results from the uptake and storage of calcium by the sarcoplasmic reticulum (see Fig. 13.9) controlled by changes in nitric oxide. In heart failure, there is a prolongation of the calcium current in association with prolongation of contraction and relaxation.

ApoptOSis (see also p. 162)

Apoptosis (or 'programmed cell death') of myocytes has been demonstrated in animal models of ischaemic reperfusion, rapid ventricular pacing, mechanical stretch, and pressure overload. Apoptosis is associated with irreversible congestive heart failure, and the spiral of ventricular dysfunction, characteristic of heart failure, results from the initiation of apoptosis by cytokines, free radicals and other triggers.

Natriuretic peptides (ANP, BNP and C-type)

Atrial natriuretic peptide (ANP) is released from atrial myocytes in response to stretch. ANP induces diuresis, natriuresis, vasodilatation and suppression of the renin-angiotensin system. Levels of circulating ANP are increased in congestive cardiac failure and correlate with functional class, prognosis and haemodynamic state. The renal response to ANP is attenuated in heart failure, probably secondarily to reduced renal perfusion, receptor downregulation, increased peptide breakdown, renal sympathetic activation, and excessive renin—angiotensin activity. *Brain natriuretic peptide (BNP)* (so called because it was first discovered in brain) is predominantly secreted by the ventricles and has an action similar to that of ANP but it has greater diagnostic and prognostic value (p. 789). *C-type peptide,* which is limited to vascular endothelium and the central nervous system, has similar effects to those of ANP and BNP. The therapeutic benefits of the natriuretic peptides have been investigated by administration of ANP and by the inhibition of the enzyme responsible for breakdown of the peptides (neutral endopeptidase - NEP).

Endothelial function in heart failure

The endothelium has a central role in the regulation of vasomotor tone. In patients with heart failure, endothelium-dependent vasodilatation in peripheral blood vessels is impaired and may be one mechanism of exercise limitation. The cause of abnormal endothelial responsiveness relates to abnormal release of both nitric oxide and vasoconstrictor substances, such as endothelin (ET). The activity of nitric oxide, a potent vasodilator, is blunted in heart failure. ET secretion from a variety of tissues is stimulated by many factors, including hypoxia, catecholamines and angiotensin II. The plasma concentration of ET is elevated in patients with heart failure, and levels correlate with the severity of haemodynamic disturbance. The major source of circulating ET in heart failure is the pulmonary vascular bed.

ET has many actions that potentially contribute to the pathophysiology of heart failure: vasoconstriction, sympathetic stimulation, renin-angiotensin system activation and left ventricular hypertrophy. Acute intravenous administration of endothelin antagonists improves haemodynamic abnormalities in patients with congestive cardiac failure, and oral endothelin antagonists are being developed. Plasma concentrations of some cytokines, in particular TNF, are increased in patients with heart failure.

Antidiuretic hormone (vasopressin)

Antidiuretic hormone (ADH) is raised in severe chronic heart failure, particularly in patients on diuretic treatment. High ADH concentration precipitates hyponatraemia which is an ominous prognostic indicator.

CLINICAL SYNDROMES OF HEART FAILURE

Various terms are used in clinical practice to mean 'heart failure' without following any guideline definition of heart failure or diagnostic criteria.

The terms 'biventricular' or 'congestive' heart failure are used variously but are best restricted to cases where right heart failure results from pre-existing left heart failure.

Biventricular cardiac failure is the most common manifestation of heart failure. It is clinically useful to divide heart failure into the syndromes of left and right cardiac failure, but it is rare for any part of the heart to fail in isolation.

Chronic heart failure can be 'compensated' or 'decompensated'. In *compensated heart failure,* symptoms are stable and overt features of fluid retention are absent. *Decompensated heart failure* refers to an acute or continuing deterioration. Causes, such as ischaemia, arrhythmia, infection and electrolyte disturbance, should be identified and reversed. The natural history of moderate heart failure involves increasingly frequent hospital admissions due to symptom exacerbation.

Left heart failure

Causes include:

- ischaemic heart disease (the most common cause)
- systemic hypertension (chronic or 'malignant')
- mitral and aortic valve disease
- cardiomyopathies.

Mitral stenosis causes left atrial hypertension and signs of left heart failure but does not itself cause failure of the left ventricle.

Clinical features

Symptoms are predominantly fatigue, exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea.

Physical sigr\s are few and not prominent until a late stage or if ventricular failure is acute. Cardiomegaly is demonstrable with a displaced and often sustained apical impulse. Auscultation reveals a left ventricular third or fourth heart sound that, with tachycardia, is described as a gallop rhythm. Dilatation of the mitral anulus results in functional mitral regurgitation. Crackles are heard at the lung bases. In severe left heart failure the patient has pulmonary oedema (see p. 797).

Right heart failure

This syndrome occurs **in** association **with:**

- left heart failure
- chronic lung disease (cor pulmonale)
- pulmonary embolism or pulmonary hypertension
- tricuspid valve disease
- pulmonary valve disease
- left-to-right shunts (e.g. atrial or ventricular septal defects)
- isolated right ventricular cardiomyopathy
- mitral valve disease with pulmonary hypertension.

Clinical features

Symptoms (fatigue, breathlessness, anorexia and nausea) relate to distension and fluid accumulation in areas drained by the systemic veins. *Physical signs* are usually more prominent than the symptoms, with:

- jugular venous distension (± *v* waves of tricuspid regurgitation)
- tender smooth hepatic enlargement
- dependent pitting oedema
- development of free abdominal fluid (ascites)
- pleural transudates (commonly right-sided).

Dilatation of the right ventricle produces cardiomegaly and may give rise to functional tricuspid regurgitation. Tachycardia and a right ventricular third heart sound are usual.

Right heart failure cannot be diagnosed from symptoms and signs alone. Objective evidence of cardiac dysfunction, for example from echocardiography, is needed.

Systolic versus diastolic heart failure

Systolic and diastolic dysfunction usually coexist.

Systolic ventricular dysfunction is most commonly due to coronary artery disease, usually following myocardial infarction. The left ventricle is usually dilated and fails to contract normally.

Diastolic ventricular dysfunction results from impaired myocardial relaxation, with increased stiffness in the ventricular wall and decreased left ventricular compliance leading to impairment of diastolic ventricular filling and hence decreased cardiac output. Coronary artery disease, hypertension and hypertrophic cardiomyopathy are common causes, although infiltrative disease such as amyloid may lead to pure diastolic dysfunction. The incidence remains unclear, although up to 30% of patients with heart failure may have normal systolic contraction. Management is similar to systolic heart failure but there may be an additional place for calcium-channel blockers. Diastolic dysfunction appears to carry a better prognosis.

High-output heart failure

The heart may not be able to meet the demands placed on it in conditions such as anaemia, thyrotoxicosis, beriberi and Gram-negative septicaemia. This form of heart failure presents in much the same manner as low-output states but is associated with tachycardia and a gallop rhythm. Patients are often warm with distended superficial veins. Unlike low-output failure, the oxygen content of systemic venous blood is high owing to the delivery of large amounts of arterial blood to non-metabolizing tissues.

Acute heart failure

The term 'acute heart failure' is often used exclusively to mean acute (cardiogenic) dyspnoea characterized by signs of pulmonary congestion. It is preferable to use **the** term 'acute pulmonary oedema' or where applicable 'cardiogenic shock'.

Acute failure of the heart most commonly occurs in the setting of acute myocardial infarction when there is extensive loss of ventricular muscle. The condition may also occur with rupture of the interventricular septum producing a ventricular septal defect, or be due to acute valvular regurgitation. Common examples of valvular regurgitation are papillary or chordal rupture producing mitral regurgitation, or sudden aortic valve regurgitation in infective endocarditis. Other causes of acute heart failure include obstruction of the circulation by acute pulmonary embolus and cardiac tamponade. In each case severe cardiac failure can occur with a relatively normal heart size.

Chronic heart failure

Chronic heart failure is often punctuated by acute exacerbations where an abnormality of cardiac function is responsible for the failure of the heart to maintain a physiological circulation. At present no simple objective definition of heart failure is available, since there is no cut-off value or cardiac or ventricular dysfunction or change in flow, pressure, dimension or volume that can be used reliably to identify patients with heart failure.

Cardiac cachexia

The term cardiac cachexia describes the loss of lean (non-oedematous) body mass that occurs in some patients with moderate or severe heart failure. Most patients with cachexia are over 40 years of age, have had heart failure for at least 5 years and are in NYHA (see p. 732) functional class 3/4. Its presence is associated with increased morbidity and mortality.

Several mechanisms are thought to contribute to wasting in heart failure, including malabsorption, anorexia caused by intestinal oedema and drugs, and loss of nutrients through the gastrointestinal and renal tracts. Patients with heart failure also have an increased metabolic rate secondary to increased sympathetic activity in association with reduced anabolic metabolism. Tumour necrosis factor alpha (TNF-oc) is increased in patients with cardiac cachexia and contributes to the phenomenon. Possible stimuli to TNF-a release include reduced peripheral blood flow, failing myocardium and

prostaglandin release. Natriuretic C-type peptide is also elevated in cachectic patients.

Diagnosis of heart failure

The diagnosis of heart failure should not be based on history and clinical findings; it requires evidence of cardiac dysfunction with appropriate investigation using objective measures of left ventricular structure and function (usually echocardiography). Similarly, the underlying cause of heart failure should be established in all patients (Table 13.21 and Fig. 13.56).

INVESTIGATIONS

Diagnostic

- **Blood tests** - full blood count, liver biochemistry, urea and electrolytes, cardiac enzymes in acute heart failure to diagnose myocardial infarction, thyroid function.
- **Chest X-ray** - cardiac size and evidence of pulmonary congestion, initially upper lobe diversion, then fluid in fissures and Kerley B lines (pulmonary venous pressure > 20 mmHg), then frank pulmonary oedema (pulmonary venous pressure > 25 mmHg).
- **Electrocardiogram** - evidence of ischaemia, hyper tension or arrhythmia.
- **Natriuretic peptide** (B-type NP (BNP) or N terminal (NTproBNP)). A normal plasma level excludes heart failure and is a useful screening test in the investiga tion of patients with breathlessness.
- **Echocardiography.** Two-dimensional and Doppler echocardiography establish the presence of systolic and/ or diastolic impairment of the left or right ventricle. They may also reveal the aetiology (valve disease, regional wall motion abnormalities in ischaemic heart disease, cardiomyopathy, amyloid), and may detect intracardiac thrombus. An ejection fraction of < 0.45 is generally accepted as evidence for systolic dysfunction.
- **Stress echocardiography.** Exercise or pharmacological stress echocardiography has no radiation hazard and is a reliable technique for detecting ischaemia as a cause of persistent but reversible cardiac dysfunction and in determining the viability of akinetic myo cardium in patients with heart failure. *Dobutamine* sfress-induced sustained contractile improvement is observed when flow reserve is appropriate, in the presence of stunning or non-transmural infarction.
- **Nuclear cardiology.** Radionuclide angiography (RNA) provides accurate measurements of left, and to a lesser extent, right ventricular ejection fractions, cardiac volumes and regional wall motion. Left ventri cular filling dynamics (diastolic function) can also be analysed. These measurements are not reliable in the presence of atrial fibrillation. Single-photon-emission computed tomography (SPECT) can be performed at rest or during stress, e.g. dobutamine infusion using different radionuclides, e.g. thallium-201 or technetium-99m, to detect the presence and extent of ischaemia (p. 755).

Table 13.21 **Diagnosis of heart failure (European Society of Cardiology guidelines)**

Essential features (criteria 1 and 2)

1. Symptoms and signs of heart failure (e.g. breathlessness, fatique, ankle swelling)
2. Objective evidence of cardiac dysfunction (at rest)

Non-essential features

3. Response to treatment directed towards heart failure (in cases where the diagnosis is in doubt)

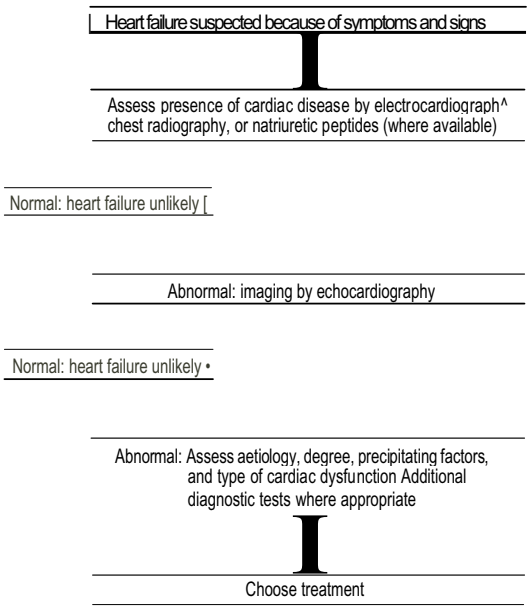

Fig. 13.56 **Algorithm for the diagnosis of heart failure.** Based on the recent European Society of Cardiology and NICE guidelines.

Cardiac MRI. At present, MRI is only recommended in selected patients with heart failure where other investigations do not provide satisfactory diagnosis. Advanced techniques with high-resolution image quality accurately measure cardiac volumes, wall thicknesses and left ventricular mass. MRI also reliably detects thickened pericardium and quantitates myocardial necrosis, perfusion and function. Quantitative biochemical information and metabolic function can also be obtained.

Positron emission tomography (PET). When other tests (e.g. stress echocardiography, SPECT) cannot provide satisfactory results, PET scanning can be used, especially to identify potentially viable muscle that is hibernating. The importance of identifying the pathology is that appropriate treatment (surgical or medical) may restore the function. The technique can determine myocardial blood flow and cellular metabolism very precisely.

Cardiac catheterization (see p. 757). **Cardiac biopsy** for infiltrative disease, e.g. amyloid.

Functional/prognostic

- **Cardiopulmonary exercise testing.** Peak oxygen consumption (Vo_2) is a strong independent predictor of hospital admission and death in patients with heart failure but is not widely available. A 6-minute exercise walk may be used instead.
- **Ambulatory (24-48 hours) ECG monitoring** - if arrhythmia is suspected.
- **Resting and stress radionuclide angiography (MUGA)** - for estimation of ejection fraction, regional wall motion abnormality.

TREATMENT OF HEART FAILURE

Treatment is aimed at relieving symptoms, prevention and control of disease leading to cardiac dysfunction and heart failure, retarding disease progression and improving quality and length of life.

Measures to prevent heart failure include cessation of smoking, alcohol and illicit drugs, effective treatment of hypertension, diabetes and hypercholesterolaemia, and pharmacological therapy following myocardial infarction.

The management of heart failure requires that any factor aggravating the failure should be identified and treated. Similarly the cause of heart failure must be elucidated and where possible corrected. Community nursing programmes to help with drug compliance and to detect early deterioration may prevent acute hospitalization.

General lifestyle advice

Education

Effective counselling of patients and family emphasizing weight monitoring and dose adjustment of diuretics may prevent hospitalization.

Obesity control

Maintain desired weight and body mass index.

Dietary modification

Large meals should be avoided and if necessary weight reduction instituted. Salt restriction is necessary and foods rich in salt or added salt in cooking and at the table should be avoided. A low-sodium diet is unpalatable and of questionable value. In severe heart failure fluid restriction is necessary. Alcohol has a negative inotropic effect and heart failure patients should moderate consumption.

Smoking

Smoking should be stopped, with help from anti-smoking clinics (p. 893) if necessary.

Physical activity, exercise training and rehabilitation

For patients with exacerbations of congestive cardiac failure, bed rest reduces the demands on the heart and is useful for a few days. Migration of fluid from the interstitium promotes a diuresis, reducing heart failure. Prolonged bed rest may lead to development of deep vein thrombosis; this canbe avoided by daily legexercises, low-dose subcutaneous heparin and elastic support stockings. Low-level endurance exercise (e.g. 20-30 minutes walking three or five times per week, or 20 minutes cycling at 70-80% of peak heart rate five times per week) is actively encouraged in patients with compensated heart failure in order to reverse 'deconditioning' of peripheral muscle metabolism. Strenuous isometric activity should be avoided.

Vaccination

While prospective clinical trials are lacking, it is recommended that patients with heart failure be vaccinated against pneumococcal disease and influenza.

Air travel

This is possible for most patients, subject to clinical circumstances. Check with the airline - most have guidelines on who should travel.

Sexual activity

Tell patients on nitrates not to take phosphodiesterase type 5 inhibitors (e.g. sildenafil) as it may induce profound hypotension.

Driving **(UK)**

DVLA guidance (DVLA Guide to the Current Medical Standards of Fitness to Drive, August 2003) should be followed. Driving motor cars and motorcycles may continue provided there are no symptoms that distract the driver's attention. The DVLA need not be notified. Symptomatic heart failure disqualifies patients from driving large lorries and buses. Re/ licensing may be permitted provided that the LV ejection fraction is good (i.e. LVEF is > 0.4), the exercise test requirements can be met and there is no other disqualifying condition.

Monitoring of heart failure patients

The clinical condition of a person with heart failure may fluctuate, and repeated admission to hospital is common. Monitoring of clinical status is necessary and this responsibility should be shared between primary and secondary care health professionals.

Essential monitoring includes assessment of:

- functional capacity (e.g. Vo_2 max, exercise tolerance test, echocardiography)
- fluid status (body weight, U&Es, clinical)
- cardiac rhythm (ECG, 24-hour tape).

Multidisciplinary team approach

Heart failure care should be delivered by a multidisciplinary team with an integrated approach across the healthcare community. The multidisciplinary team should involve specialist healthcare professionals: heart failure nurse, dietitian, pharmacist, occupational therapist, physiotherapist, palliative care adviser.

Understanding the information needs of patients and carers is vital. Good communication is essential for best clinical management, which should include advice on anxiety, depression and 'end of life' issues.

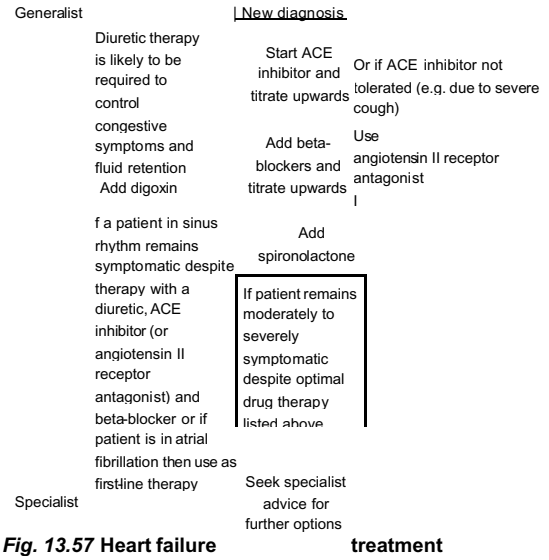

***Fig. 13.57* Heart failure treatment guidelines** (NICE (2003) Chronic heart failure. Clinical Guideline No. 5. Available from www.nice.org.uk)

Drug f ^ £ ^ ^ ^ ^ ^ ^

The recommendations for pharmacological treatment of heart failure are based on consensus guidelines produced by the European Society of Cardiology and NICE (UK) (Figs 13.57 and 13.58). A summary of treatment is on page 794.

Diuretics

These act by promoting the renal excretion of salt and water by blocking tubular reabsorption of sodium and chloride. The resulting loss of fluid reduces ventricular filling pressures (~~preload), pro~~duces consistent haemodynamic and symptomatic benefits in patients with heart failure, and rapidly improves dyspnoea and peripheral oedema. The intravenous administration of loop diuretics such as furosemide relieves pulmonary oedema rapidly by means of arteriolar vasodilatation reducing afterload, an action that is independent of its diuretic effect. Diuretics act in various ways.

Loop diuretic (see p. 697)
Loop diuretics such as furosemide and bumetanide have a rapid onset of action (i.v. - 5 min; oral - 1-2 h) and generally short-lived (4-6 h) diuresis as the concentrating power of the kidney is reduced. These agents also produce marked potassium loss and promote hyperuricaemia, and renal function should be monitored.

Thiazide diuretics (see p. 698)
Thiazide diuretics such as bendroflumethiazide have a mild diuretic effect. Potassium excretion is enhanced. Thiazides are less effective in patients with reduced glomerular filtration rates. In some patients with severe congestive heart failure, oedema may persist despite high doses of loop diuretic. Thiazide diuretics in combination with loop diuretics have a synergistic action and greater diuretic effect. Associated metabolic abnormalities are more likely and close supervision is needed. Metolazone is a powerful thiazide, producing profound diuresis acting synergistically with loop diuretics. This combina-

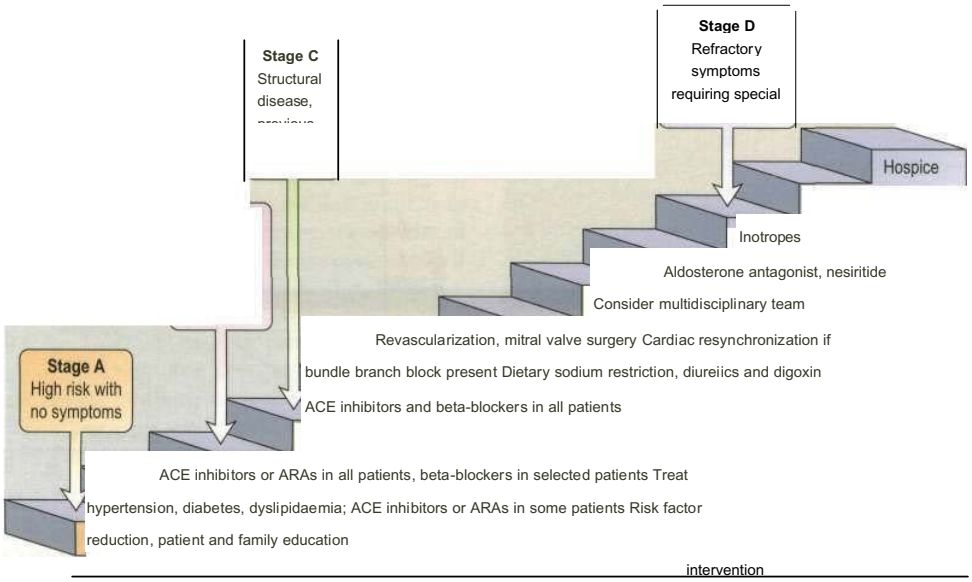

***Fig. 13.58* Stages of heart failure and treatment options for systolic heart failure.** ARA, angiotensin II receptor antagonist; ACE, angiotensin-converting enzyme; VAD, ventricular assisted device. From Jessop M, Brozana S (2003) *New England Journal of Medicine* **348:** 2013, with permission. Copyright © 2003 Massachusetts Medical Society. All rights reserved.

tion is only used for the treatment of severe and resistant heart failure.

Although heart failure symptoms are improved by thiazides and loop diuretic treatment, loop diuretics are not proven to have any survival benefit. In addition, their use may be complicated by overdiuresis and electrolyte depletion (potassium and magnesium), which may predispose to the development of lethal ventricular arrhythmias, hyperkalaemia (potassium-sparing diuretics) and other metabolic disturbances (hyperuricaemia and dyslipidaemia).

Potassium-sparing diuretics (see Table 12.3) *Spironolactone* is a specific competitive antagonist to aldosterone, producing a weak diuresis but with a potassium-sparing action. A randomized placebo-controlled study, the Randomized Aldactone Evaluation Study (RALES) showed a 30% reduction in all-cause mortality when spironolactone (up to 25 mg) was added to conventional treatment in patients with moderate to severe heart failure. These results have now been confirmed with another aldosterone antagonist - eplerenone - that has less hormonal side-effects. The risk of hyperkalaemia was low in the trial. Risk factors for developing hyperkalaemia include spironolactone dose > 50 mg/day, high-dose angiotensin-converting enzyme inhibitor (ACEI) and renal impairment. Potassium should be measured 5 days after the initiation of spironolactone until levels are stable and then every 1-3 months, and the dose of spironolactone should not be increased (p. 1000).

Amiloride and *triamterene* act at the distal tubule preventing potassium secretion in exchange for sodium. These drugs are weak diuretics but are useful in combination with more powerful loop diuretics. They should be avoided in the presence of renal failure and in patients taking ACE inhibitors unless there is persistent hypokalaemia. There is no evidence as yet that these two potassium-sparing diuretics have any prognostic effect.

Vasodilator therapy (see Table 13.22) Diuretics and sodium restriction serve to activate the renin-angiotensin system, promoting formation of angiotensin (a potent vasoconstrictor) and an increase in afterload. A variety of other neural and hormonal reactions also serve to increase preload and afterload. These compensatory mechanisms are initially beneficial in maintaining blood pressure and redistributing blood flow, but in the later stages of heart failure they are deleterious and reduce cardiac output. The high venous pressures found in heart failure are also related to the activation of the sympathetic nervous system and the presence of circulating vasoconstrictors, thus shifting the Starling curve to the right.

Table 13.22 **Effects of vasodilator drugs used in heart failure**

	R Preload duction in:	Afterload
Nitroprusside Glyceryl trinitrate Isosorbide di/mononitrate P- Adrenoceptor blockers ACE inhibitors/antagonists Hydralazine Calcium-channel blockers		

ACE, angiotensin-converting enzyme

Angiotensin-converting enzyme inhibitors ACEI (Fig. 18.27, p. 1096)

Several large controlled trials (e.g. CONSENSUS and SOLVD), have established the benefit of ACEI in heart failure (Fig. 13.59). The trials have shown that in addition to producing considerable symptomatic improvement in patients with symptomatic heart failure, prognosis is markedly improved and development of heart failure is slowed. The SAVE study confirmed the benefit of ACEI in patients with asymptomatic heart failure following myocardial infarction, in whom the development of overt heart failure was reduced.

ACEI lower systemic vascular resistance and venous pressure, and reduce levels of circulating catecholamines, thus improving myocardial performance. The beneficial haemodynamic effect of these drugs appears to be independent of their inhibition of ACE as they are equally effective when plasma renin activity is normal.

These drugs should be carefully introduced in patients with heart failure because of the risk of first-dose hypotension. This is a particular risk in patients who are receiving large doses of diuretics and who have hyponatraemia (< 130 mmol/L). In such cases a test dose of ACEI should be commenced and the preceding diuretic doses omitted. Some of these agents are pro-drugs (e.g. enalapril) and require conversion to the active metabolite (enalaprilat) by liver enzymes; these drugs have a delayed onset of action and first-dose hypotension may not occur for several hours. Pro-drugs are best avoided if

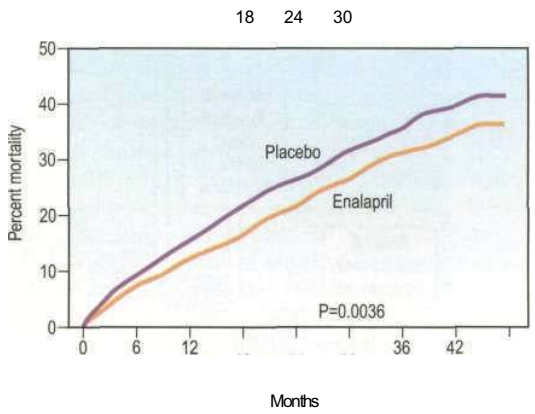

Fig. 13.59 **Survival in patients with symptomatic heart failure taking placebo and enalapril (the SOLVD treatment trial).** Adapted with permission from *New England Journal of Medicine* (1991) 325: 293-302. © 1991 Massachusetts Medical Society, all rights reserved.

heart failure results in significantly altered hepatic function. Serious hypotension may result in acute renal failure. Concomitant potassium-sparing diuretics should be discontinued, as ACEI tend to promote potassium retention. Creatinine levels rise by approximately 10-15% during ACE therapy. ACEI are contraindicated in patients with bilateral renal artery stenosis. Between 10% and 15% of patients develop a cough, owing to the inhibition of bradykinin metabolism. A prospective trial looking at dose and survival (ATLAS study) showed no significant mortality difference, although high-dose treatment was associated with a significant reduction in all-cause mortality and hospitalization.

Angiotensin receptor antagonists

Angiotensin II receptor antagonists (ARA) (e.g. losartan, ibersartan, candesartan and valsartan) have similar haemodynamic effects to ACEI, but as they do not affect bradykinin metabolism, they do not produce a cough. A trial comparing losartan with the ACEI enalapril in patients with heart failure (ELITE 2) showed no difference between the AII receptor antagonist and the ACEI.

The combination of ACEI and AII receptor antagonists may confer additional benefit compared to ACEI therapy alone. The Val HeFT study of valsartan and captopril in combination showed that the use of valsartan resulted in a significant reduction in hospitalization but no difference in mortality. However, in a small number of patients (7%) valsartan alone resulted in significant reduction in mortality. The CHARM study showed the value of candesartan in heart failure with an overall 12% reduction in death and hospital admission.

Arteriolar vasodilators (Fig. 13.60) Drugs such as ce-adrenergic blockers (e.g. prazosin) and direct smooth-muscle relaxants (e.g. hydralazine) are potent arteriolar vasodilators but are not very effective in heart failure. Calcium-channel blockers also reduce after-

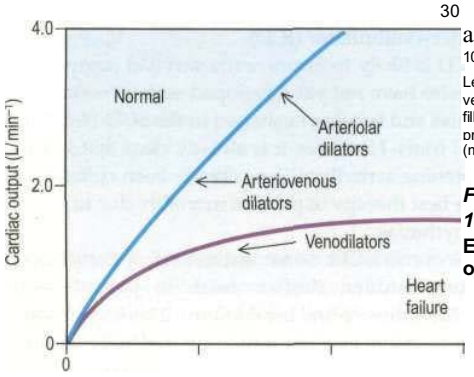

***Fig. 13.60* Effect of vasodilators on cardiac output and left ventricular filling pressure in heart failure.** Agents with arteriolar and arteriovenous dilating properties reduce the afterload and increase cardiac output. Venodilators reduce the left ventricular filling pressure (and pulmonary oedema) but do not increase cardiac output.

load, but first-generation calcium antagonists (diltiazem, nifedipine) may have a detrimental effect on left ventricular function in patients with heart failure. The PRAISE 2 trial showed that the second-generation calcium antagonist amlodipine showed no prognostic benefit in patients with heart failure.

Venodilators (Fig. 13.60)
Short- and long-acting nitrates (e.g. glyceryl trinitrate and isosorbide mononitrate) act by reducing preload and lowering venous pressure, with resulting reduction in pulmonary and dependent oedema. Reduction of filling pressure does not significantly enhance cardiac output because the heart is operating on the flat portion of the ventricular filling curve. With chronic use, tolerance develops with loss of efficacy and consequent worsening of heart failure. Only combination therapy of nitrate with hydralazine (Veterans Heart Failure Trials, VHeFT) has been shown to improve mortality and exercise performance, and may be useful when ACEI are contraindicated. The benefit of vasodilators is not as great as with ACEI (VHeFT2).

fl-Adrenoceptor blocking agents

There is considerable evidence to support the use of beta-blockers in patients with chronic stable heart failure. The studies MERIT and CIBIS 2 using the beta-blockers metoprolol and bisoprolol respectively have shown improved symptomatic class, exercise tolerance, left ventricular function and mortality in patients with heart failure of any cause. The US Carvedilol Studies using carvedilol, a non-selective vasodilator beta-blocker with additional vasodilator and antioxidant properties, has also demonstrated a significant improvement in mortality. The current guidelines recommend that beta-blockers licensed for use (bisoprolol and carvedilol) in heart failure should be initiated in patients with confirmed heart failure due to left ventricular systolic dysfunction after diuretics and ACE inhibitor therapy, regardless of whether or not symptoms persist. Following the administration of beta-blockers, the ejection fraction may decline, but usually returns to baseline within a month and then increases after 3 months. Thus, initial doses should be low, e.g. carvedilol 3.125 mg twice daily and should be titrated slowly over a period of months rather than days. Patients who are in heart failure and already on treatment with a beta-blocker for a coexisting condition, such as coronary artery disease or hypertension, should continue with their current beta-blocker initially.

Inotropic agents

Intravenous inotropes are frequently used to support myocardial function in patients with acute left ventricular failure and following cardiac surgery.

Epinephrine (adrenaline), dobutamine, dopexamine and dopamine are intravenous adrenergic agonists. *Dobutamine* predominantly acts on the (Vadrenoceptor, increasing intracellular cyclic AMP, which in turn increases calcium availability for myocardial contraction. Dobutamine also causes peripheral vasodilatation by an

anti-a-adrenergic effect. *Dopexamine* is a selective p_2 agonist with an additional action on peripheral dopamine receptors that theoretically results in improved renal perfusion. *Dopamine* is a less selective inotrope that is often used in a low dose to improve renal perfusion (via dopaminergic receptors) although this renal effect has been questioned (see p. 976).

(3-Adrenergic agonists are used in patients with acute left ventricular failure and in patients with end-stage heart failure as a bridge to transplantation. Intermittent intravenous infusions of dobutamine may produce long-lasting improvements in symptoms and exercise performance at the cost of increased mortality.

Several orally active agents have been tested in patients with chronic congestive cardiac failure, but all apart from digoxin have been associated with increased mortality and are not generally used.

Digitalis glycosides

Digitalis glycosides have been used for many years in patients with heart failure and atrial fibrillation. A large prospective trial (Digoxin Investigation Group (DIG) trial) showed that digoxin combined with ACE inhibitors and diuretics, reduced death and hospitalization resulting from progressive heart failure in patients in sinus rhythm. A small significant increase in deaths presumed to be secondary to myocardial infarction and/or arrhythmia meant that the effect on overall mortality was neutral. Therefore patients who are hospitalized or present with severe heart failure in spite of therapy with vasodilators, beta-blockers, diuretics (and also patients with rapid AF), should have digoxin added to their therapeutic regimen.

The half-life of digoxin is approximately 36 hours. It is partly protein-bound, making it liable to drug interaction. As 90% is excreted unchanged in urine, accumulation can occur in renal failure. Digoxin acts as a positive inotrope by competitive inhibition of Na^+/K^+-ATPase, producing high levels of intracellular sodium. This is then exchanged for extracellular calcium. High levels of intracellular calcium result in enhanced actin-myosin interaction and increased contractility (Fig. 13.3). Digoxin also improves baroreceptor responsiveness, and reduces sympathetic activity and circulating renin.

Digoxin is administered orally (1 mg loading and 0.125-0.25 mg daily according to body mass and renal function). Trough serum levels should be monitored (1.3-2.6 nmol/L) and hypokalaemia should be avoided. The elderly and patients with hyperthyroidism are more prone to digoxin toxicity. In patients with fluctuating renal function, digitoxin, which is metabolized by the liver, is preferable.

With improvement in formulation, digoxin toxicity has become less problematic. The most common features of digoxin toxicity are:

- anorexia, nausea, altered vision
- arrhythmia (e.g. ventricular premature beats especially bigeminy, ventricular tachycardia and AV block)
- digoxin levels > 2.5 nmol/L.

Digoxin toxicity is treated by stopping the drug, restoration of serum potassium and management of arrhythmias. Digoxin antibody (FAB fragments) is a specific antidote that is useful for life-threatening toxicity (p. 1012).

^-*Adrenergic agonists*

Based on the demonstration that the inotropic state of the failing myocardium is impaired and that the myocardial response to adrenergic stimulation is reduced, several adrenergic agonists have been tested in heart failure. All of these agents consistently increase mortality in the longer term and are therefore restricted in use.

Anticoagulants

Heart failure is associated with a fourfold increase in the risk of a stroke. Oral anticoagulants are recommended in patients with atrial fibrillation and in sinus rhythm with a history of thromboembolism, endocardial thrombus or LV aneurysm. Large-scale prospective randomized controlled trials of antithrombotic treatment in heart failure are in progress.

Antiarrhythmic agents

Precipitating factors should be treated, in particular electrolyte disturbance. Atrial fibrillation is common in heart failure and leads to a deterioration in symptoms. Restoration of sinus rhythm, either by electrical cardioversion or drugs, is desirable but less successful in the presence of structural heart disease and decompensated heart failure. Rate control with digoxin is often preferred.

Arrhythmias are frequent in heart failure and are implicated in sudden death. Although treatment of complex ventricular arrhythmias might be expected to improve survival, there is conflicting evidence that this is so. This may be related to the diverse mechanisms of death in patients with heart failure, death commonly being associated with bradyarrhythmias, particularly in patients with non-ischaemic heart failure. Patients with sustained episodes of ventricular tachycardia should receive empirical treatment, usually with an implantable cardioverter-defibrillator (ICD).

The ICD is likely to improve the survival prospects of patients who have not yet developed serious ventricular arrhythmias and is being evaluated in the SCD-HeFT and MADIT II trials. However, it is already clear that when a life-threatening arrhythmia has already been suffered, an ICD is the best therapy to prevent mortality due to ventricular arrhythmias.

Beta-blockers, ACEI, some statins and spironolactone may reduce sudden cardiac death in patients with coronary heart disease and heart failure. It should be noted that ACEI probably exert an indirect antiarrhythmic effect by reducing high circulating levels of norepinephrine (noradrenaline) and improving cardiac function.

Summary of treatment (see Table 13.23) All patients with clinical heart failure should receive treatment with diuretics and an ACEI followed by beta-blocker therapy. Spironolactone should be added for severe heart failure. Patients in atrial fibrillation should

Table 13.23 **Summary of drug treatment for heart failure**

Spironolactone	4	44	444	44

ACEI, angiotensin-converting enzyme inhibitor; AURA, angiotensin-II receptor antagonists; SCD, sudden cardiac death; 4, reduce; o, no change

be digitalized but patients in sinus rhythm may also be improved by the addition of digoxin or a beta-blocker. Patients with asymptomatic left ventricular dysfunction are at risk of progressive deterioration and should be treated with prophylactic ACEI therapy. Patients with ischaemic heart failure and ongoing ischaemia, and patients intolerant of ACEI or in whom they are contraindicated (hypotension, renal insufficiency or hyperkalaemia) may benefit from nitrate/hydralazine therapy.

The results of the CHARM study show benefits of candesartan (angiotensin II receptor antagonist), which may be used for heart failure treatment as an alternative to ACEI, when ACE inhibitors are ineffective or not tolerated, in patients with systolic or diastolic dysfunction. Heart failure medication must be up-titrated to the maxi mum dose, particularly of ACEI and beta-blocker, to obtain maximum benefit. Patients with diastolic heart failure have similar prognostic implications to those with systolic heart failure and should be treated in a similar way.

Non-pharmacological treatment of heart failure

Revascularization

While coronary artery disease is the most common cause of heart failure, the role of revascularization in patients with heart failure is unclear. Patients with angina and left ventricular dysfunction have a higher mortality from surgery (10-20%), but have the most to gain in terms of improved symptoms and prognosis. Factors that must be considered before recommending surgery include age, symptoms and evidence for reversible myocardial ischaemia.

Hibernating myocardium and myocardial stunning

'Hibernating' myocardium can be defined as reversible left ventricular dysfunction due to chronic coronary artery disease that responds positively to inotropic stress and indicates the presence of viable heart muscle that may recover after revascularization. It is due to reduced myocardial perfusion, which is just sufficient to maintain viability of the heart muscle. Myocardial hibernation results from repetitive episodes of cardiac stunning that occur, for example, with repeated exercise in a patient with coronary artery disease.

Myocardial stunning is reversible ventricular dysfunction that persists following an episode of ischaemia when the blood flow has returned to normal, i.e. there is a mismatch between flow and function.

The prevalence of hibernating myocardium in patients with coronary artery disease can be estimated from the frequency of improvement in regional abnormalities in wall motion after revascularization and is estimated to be 33% of such patients. Techniques to try to identify hibernating myocardium include stress echocardiography, nuclear imaging techniques and positron emission tomography.

The clinical relevance of the hibernating and stunned myocardium is that ventricular dysfunction due to these mechanisms may be wrongly ascribed to myocardial necrosis and scarring which seems untreatable, whereas reversible hibernating and stunning respond to coronary revascularization.

Biventricular pacemaker or implantable cardioverter-defibrillator (p. 783) (Fig. 13.61)

Pacemakers are indicated in patients with sinoatrial disease and atrioventricular conduction block. Pacemakers are also valuable in patients without AV block but with prolonged PR intervals, left bundle branch block and severe mitral regurgitation. In patients with heart failure and left bundle branch block and NYHA 3 heart failure (MUSTIC study) biventricular pacing is more beneficial than conventional right ventricular pacing. The

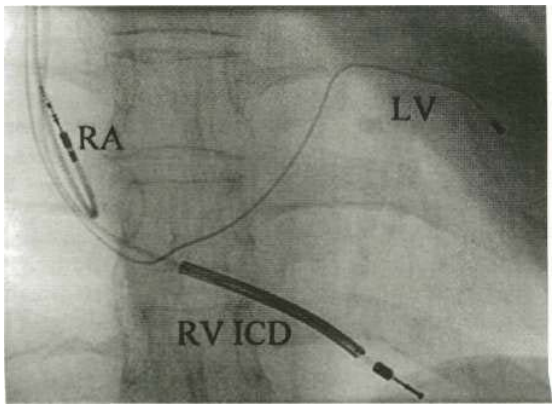

Fig. 13.61 **Implanted biventricular pacing with ICD device.**

results showed an improvement in symptoms and exercise tolerance. The effect on prognosis is being addressed by an ongoing trial (CARE HF).

Biventricular pacing should also be considered in patients not responding to therapy in the following situations:

- systolic heart failure
- non-reversible cause
- highly symptomatic (New York Heart Association grade 3/4)
- optimal medical therapy
- ventricular dys-synchrony: left bundle branch block QRS > 120 ms
- sinus rhythm, and possibly atrial fibrillation
- significant mitral regurgitation.

New guidelines recommend advanced pacing technologies should be used for cardiac resynchronization therapy (CRT) in selected patients with heart failure. Atrio-biventricular pacing has been shown to improve symptoms and reduce admission to hospital in patients with left bundle branch block and heart failure with poor LV function. The use of combined implantable defibrillators and atrio-biventricular pacemakers for patients with heart failure is likely to increase. One large trial (COMPANION) shows 21% reduction in all-cause mortality and all-cause admissions to hospital in the groups receiving biventricular pacing. ICD therapy in patients with NYHA (Grade 1 and 2, see Table 13.2) has shown a reduction in mortality compared with placebo and amiodarone.

Cardiac transplantation

Cardiac transplantation has become the treatment of choice for younger patients with severe intractable heart failure, whose life expectancy is less than 6 months. With careful recipient selection, the expected 1-year survival for patients following transplantation is over 90%, and is 75% at 5 years. Irrespective of survival, quality of life is dramatically improved for the majority of patients. The availability of heart transplantation is limited.

Heart allografts do not function normally. Cardiac denervation results in a high resting heart rate, loss of diurnal blood pressure variation and impaired renin-angiotensin-aldosterone regulation. Some patients develop 'stiff heart' syndrome, caused by rejection, denervation and ischaemic injury during organ harvest and implantation. Transplantation of an inappropriately small donor heart can also result in elevated right and left heart pressure.

The complications of heart transplantation are summarized in Table 13.24. Many (infection, malignancy, hypertension and hyperlipidaemia) are related to immunosuppression. Allograft coronary atherosclerosis is the major cause of long-term graft failure and is present in 30-50% of patients at 5 years. It is due to a 'vascular' rejection process in conjunction with hypertension and hyperlipidaemia.

There are specific contraindications to cardiac transplantation (Table 13.25); notably, high pulmonary vascular resistance is an absolute contraindication. Several alternatives to transplantation are available: cardiomyoplasty (augmentation of left ventricular contraction by wrapping a latissimus dorsi muscle flap around the ventricle), and the Batista procedure (surgical ventricular size reduction and remodelling the geometry of the left ventricle). Both procedures have a high mortality and limited evidence of substantial benefit in the medium term.

Table 13.24 Complications of cardiac transplantation

Allograft rejection 'Humoral' 'Vascular' 'Cell-mediated'	**Allograft vascular disease**
	Hypertension
	Hypercholesterolaemia
Infections Early: nosocomial organisms - staphylococci, Gram-negatives Late (2-6 months): opportunistic (toxoplasmosis, cytomegalovirus, fungi, *Pneumocystis)*	**Malignancy**

Table 13.25 Contraindications for cardiac transplantation

Age > 60 years (some variations between centres)
Alcohol/drug abuse
Uncontrolled psychiatric illness
Uncontrolled infection
Severe renal/liver failure
High pulmonary vascular resistance
Systemic disease with multiorgan involvement
Treated cancer in remission but with < 5 years' follow-up
Recent thromboembolism
Other disease with a poor prognosis

LVAD (left ventricular assist device) and artificial heart

Artificial hearts and left ventricular assist devices are used as bridges to transplantation or corrective surgery. Mechanical devices are also indicated if there is a possibility of spontaneous recovery; for example, acute myocarditis.

The available ventricular assist devices include extracorporeal membrane oxygenation, univentricular and biventricular extracorporeal non-pulsatile devices, extracorporeal and implantable pulsatile devices, and the total artificial heart. A recent study using a total artificial heart improved the rate of survival to cardiac transplantation and survival after transplantation in patients with irreversible biventricular failure. Although most of these devices require the patient to be connected to cumbersome extracorporeal drive systems, miniaturization of control and power-supply components has resulted in the development of wearable left ventricular assist devices.

PULMONARY OEDEMA

This is a very frightening, life-threatening emergency characterized by extreme breathlessness. The dyspnoea may first occur at night in the form of paroxysmal dyspnoea due to pulmonary congestion. This occurs because of reabsorption of dependent oedema when lying flat, and the relative insensitivity of the respiratory centre at night allows pulmonary congestion to develop.

Pathophysiology

A pressure above 20 mmHg causes increased filtration of fluid out of the capillaries into the interstitial space (interstitial oedema). Further accumulation of fluid disrupts intercellular membranes, leading to the collection of fluid in the alveolar spaces (alveolar oedema). Alveolar oedema occurs when the capillary pressure exceeds the total oncotic pressures (approximately 25 mmHg).

Clinical features

Patients with alveolar oedema are acutely breathless, wheezing, anxious and perspiring profusely. In addition, they have a cough productive of frothy, blood-tinged (pink) sputum, which can be copious. The patient is tachypnoeic with peripheral circulatory shutdown. There is a tachycardia, a raised venous pressure and a gallop rhythm. Crackles and wheezes are heard throughout the chest. The arterial Po_2 falls and initially the P_aco_2 also falls, owing to overbreathing. Later, however, the P_aco_2 increases because of impaired gas exchange. The chest X-ray shows diffuse haziness, owing to alveolar fluid, and the Kerley B lines of interstitial oedema (Fig. 13.18). The abnormality can be unilateral, giving the appearance of a tumour that disappears on treatment (a pseudotumour).

Treatment

The patient must be placed in a sitting position. High-concentration oxygen (60% via a variable performance mask) is given. In severe cases it may be necessary to ventilate (non-invasively initially) the patient (see p. 985).

Intravenous diuretic treatment with furosemide or bumetanide is given. These diuretics induce an acute venodilatory response with a reduction in preload that helps to relieve pulmonary congestion in addition to the more delayed diuretic response.

Morphine (10-20 mg i.v. depending on the size of the patient) together with an antiemetic such as metoclopramide (10 mg i.v.) is given. Morphine sedates the patient and causes systemic vasodilatation; it must be avoided if the systolic arterial pressure is less than 90 mmHg. Respiratory depression occurs with large doses of morphine.

Venous vasodilators, such as glyceryl trinitrate, may produce prompt relief by reducing the preload. Cardiac output may be increased by using arterial vasodilatation, such as occurs with hydralazine (Table 13.22 and Fig.13.60).

Aminophylline (250-500 mg or 5 mg/kg i.v.) is infused over 10 minutes. Aminophylline is a phosphodiesterase inhibitor that causes bronchodilatation, vasodilatation and increased cardiac contractility. It must be given slowly because of the risk of precipitating ventricular arrhythmias. It is usually used when bronchospasm is present.

Venesection and mechanical methods of reducing venous return (e.g. sphygmomanometer cuffs inflated to 10 mmHg below diastolic blood pressure and placed around the thighs) are inefficient and rarely used.

In a severe case, after the acute emergency is controlled, a pulmonary artery balloon catheter may be inserted to monitor progress and treatment. Any factor that precipitated the heart failure, such as cardiac arrhythmias or chest infection, should be corrected. The underlying cardiac problem should be diagnosed and treated.

CARDIOGENIC SHOCK

Shock is a severe failure of tissue perfusion, characterized by hypotension, a low cardiac output and signs of poor tissue perfusion such as oliguria, cold extremities and poor cerebral function. Cardiogenic shock (pump failure) is commonly due to myocardial infarction (10% of Mis). Other causes are acute massive pulmonary embolus, pericardial tamponade and sudden-onset valvular regurgitation. . , .

Diagnosis

Cardiogenic shock is diagnosed when critical impairment of tissue perfusion occurs despite an adequate or elevated pulmonary capillary wedge pressure and in the absence of mechanical circulatory obstruction. An essential element in this diagnosis is the measurement of the pulmonary capillary wedge pressure (see p. 971). In situations where the vascular capacity has expanded or the circulatory fluid volume has decreased, the wedge pressure will be low. In cardiogenic shock the wedge pressure is normal or elevated.

The mortality rate in cardiogenic shock is high, estimated at 90%, because of the vicious downward spiral that occurs: hypotension due to pump failure results in a reduction of coronary flow, which results in further impairment of pump function, and so on.

Treatment

Patients require intensive care, as described in Chapter 15. General measures such as complete rest, continuous 60% oxygen administration and pain and anxiety relief are essential.

The infusion of fluid is necessary if the pulmonary capillary wedge pressure is below 18 mmHg, which is probably the optimal 'filling pressure' with which to prime a failing heart.

Short-acting venous dilators such as glyceryl trinitrate or sodium nitroprusside should be administered intravenously if the wedge pressure is 25 mmHg or more.

Cardiac inotropes such as epinephrine (adrenaline), dobutamine and dopamine may be used to increase aortic diastolic pressure (coronary perfusion pressure). Emergency revascularization of occluded arteries for cardiogenic shock adds benefit compared with medical therapy

(including intra-aortic balloon counterpulsation and thrombolytic therapy).

These lead to a temporary improvement; long-term prognosis is not improved unless there is a surgically correctable cause, such as a ruptured interventricular septum or acute mitral regurgitation.

ISCHAEMIC HEART DISEASE

Myocardial ischaemia occurs when there is an imbalance between the supply of oxygen (and other essential myocardial nutrients) and the myocardial demand for these substances. The causes are as follows:

Coronary blood flow to a region of the myocardium may be reduced by a mechanical obstruction that is due to:

atheroma
thrombosis
spasm
embolus
coronary ostial stenosis
coronary arteritis (e.g. in SLE).

There can be a decrease in the flow of oxygenated blood to the myocardium that is due to:

- anaemia
- carboxyhaemoglobulinaemia
- hypotension causing decreased coronary perfusion pressure.

An increased demand for oxygen may occur owing to an increase in cardiac output (e.g. thyrotoxicosis) or myocardial hypertrophy (e.g. from aortic stenosis or hypertension).

Myocardial ischaemia most commonly occurs as a result of obstructive coronary artery disease (CAD) in the form of coronary atherosclerosis. In addition to this fixed obstruction, variations in the tone of smooth muscle in the wall of a coronary artery may add another element of dynamic or variable obstruction.

CAD is the largest single cause of death in the UK and many parts of the world. However, over the last decade, the mortality rate in the UK has fallen considerably. Each year there are approximately 60 deaths per 100 000 (giving a standardized mortality rate of about 200 per 100 000). Sudden cardiac death is a prominent feature of CAD. One in every six coronary attacks was found to present with sudden death as the first, last, and only symptom.

The process of coronary atherosclerosis

Coronary atherosclerosis is a complex inflammatory process characterized by the accumulation of lipid, macrophages and smooth muscle cells in intimal plaques in the large and medium-sized epicardial coronary arteries. The vascular endothelium plays a critical role in maintaining vascular integrity and homeostasis. Mechanical shear stresses (e.g. from morbid hypertension), biochemical abnormalities (e.g. elevated and modified LDL, diabetes mellitus, elevated plasma homocysteine), immunological factors (e.g. free radicals from smoking), inflammation (e.g. infection such as *Chlamydia pneumoniae* and *Helicobactor pylori)* and genetic alteration may contribute to the initial endothelial 'injury' or dysfunction, which is believed to trigger atherogenesis. The development of atherosclerosis follows the endothelial dysfunction, with increased permeability to and accumulation of oxidized lipoproteins, which are taken up by macrophages at focal sites within the endothelium to produce lipid-laden foam cells. Macroscopically, these lesions are seen as flat yellow dots or lines on the endothelium of the artery and are known as *'fatty streaks'.* The 'fatty streak' progresses with the appearance of extracellular lipid within the endothelium *('transitional plaque').* Release of cytokines such as platelet-derived growth factor and transforming growth factor-(5 (TGF-P) by monocytes, macrophages or the damaged endothelium promotes further accumulation of macrophages as well as smooth muscle cell migration and proliferation. The proliferation of smooth muscle with the formation of a layer of cells covering the extracellular lipid separates it from the adaptive smooth muscle thickening in the endothelium. Collagen is produced in larger and larger quantities by the smooth muscle and the whole sequence of events cumulates as an *'advanced* or *raised fibrolipid plaque'.* The 'advanced plaque' may grow slowly and encroach on the lumen or become unstable, undergo thrombosis and produce an obstruction *{^complicated plaque').*

Two different mechanisms are responsible for thrombosis on the plaques (Fig. 13.62). *The first process* is superficial endothelial injury, which involves denudation of the endothelial covering over the plaque. Subendocardial connective tissue matrix is then exposed and platelet adhesion occurs because of reaction with

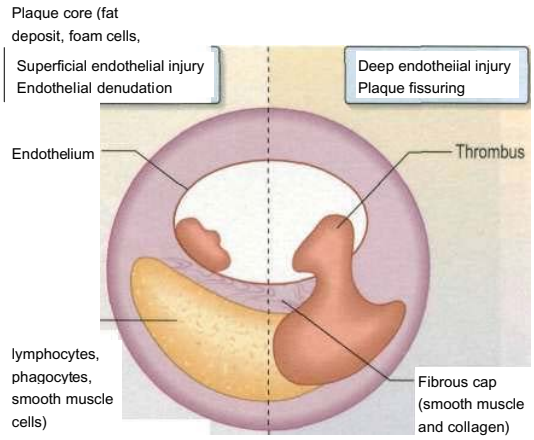

Fig. 13.62 **The mechanisms for the development of thrombosis on plaques.**

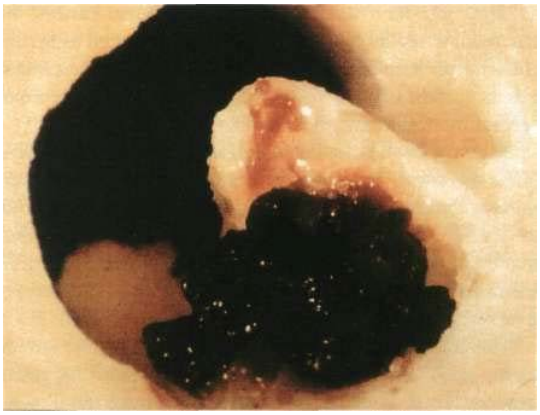

Fig. 13.64 **Acute coronary thrombus.** Cross-section (x30) of the epicardial coronary artery, demonstrating a rupture of the shoulder region of the plaque with a luminal thrombus.

collagen. The thrombus is adherent to the surface of the plaque. The *second process* is deep endothelial fissuring, which involves an advanced plaque with a lipid core. The plaque cap tears (ulcerates, fissures or ruptures), allowing blood from the lumen to enter the inside of the plaque itself. The core with lamellar lipid surfaces, tissue factor (which triggers platelet adhesion and activation) produced by macrophages and exposed collagen, is highly thrombogenic. Thrombus forms within the plaque, expanding its volume and distorting its shape. Thrombosis may then extend into the lumen.

A 50% reduction in luminal diameter (producing a reduction in luminal cross-sectional area of approximately 70%) causes a haemodynamically significant stenosis. At this point the smaller distal intramyocardial arteries and arterioles are maximally dilated (coronary flow reserve is near zero), and any increase in myocardial oxygen demand provokes ischaemia.

CAD gives rise to a wide variety of clinical presentations, ranging from relatively stable angina through to the acute coronary syndromes of unstable angina and myocardial infarction (Fig. 13.63). Figure 13.64 shows an actual plaque rupture.

(a) Stable angina pectoris. (b) and (c) Acute coronary syndromes.

Risk factors for coronary artery disease - primary and secondary prevention

CAD is an atherosclerotic disease that is multifactorial in origin, giving rise to the risk-factor concept. Certain living habits promote atherogenic traits in genetically susceptible persons. A number of 'risk' factors are known to predispose to the condition (Table 13.26). Some of these, such

Table 13.26 **Risk factors for coronary disease**

Fixed
Age
Male sex
Positive family history

Homocysteinaemia
Personality
Obesity
Gout
Soft water
Contraceptive pill
Heavy alcohol consumption

ACE, angiotensin-converting enzyme

as age, gender, race and family history, cannot be changed, whereas other major risk factors, such as serum cholesterol, smoking habits, diabetes and hypertension, can be modified. However, not all patients with myocardial infarction are identified by these risk factors.

Atherosclerotic disease manifest in one vascular bed is often advanced in other territories. Patients with intermittent claudication have a two- to fourfold increased risk of CAD, stroke, or heart failure. Following initial myocardial infarction (MI), there is a three- to sixfold increase in the risk of heart failure and stroke. After stroke, the risk of heart failure and MI is increased twofold.

The disease can be asymptomatic in its most severe form, with one in three myocardial infarctions going unrecognized. Thirty to forty per cent of individuals who present with an acute coronary syndrome have had no prior warning symptom to suggest the presence of underlying disease.

Prevention is now feasible because epidemiological research has identified a number of modifiable predisposing lifestyles and personal attributes that, when corrected, have been shown to reduce the likelihood of the development of clinical atherosclerotic cardiovascular disease (CVD). Atherosclerotic disease begins early in life but those at high risk of CAD cannot be identified at an early age, and therefore prevention must be aimed at the whole population.

Primary prevention can be defined as the prevention of the atherosclerotic disease process and *secondary prevention* as the treatment of the atherosclerotic disease process (i.e. treatment of the disease or its complications). The objective of prevention is to reduce the incidence of first or recurrent clinical events due to CAD, ischaemic stroke and peripheral artery disease.

Traditional risk factors

Age

CAD rates increase with age. Atherosclerosis is rare in childhood, except in familial hyperlipidaemia, but is often detectable in young men between 20 and 30 years of age. It is almost universal in the elderly in the West. Atheromatous lesions in the elderly are often complicated by calcification (Fig. 13.65).

Gender

Men have a higher incidence of coronary artery disease than premenopausal women. However, after the menopause, the incidence of atheroma in women approaches that in men. The reasons for this gender difference are not clearly understood, but probably relate to the loss of the protective effect of oestrogen.

Family history

CAD is often found in several members of the same family. Because the disease is so prevalent and because other risk factors are familial, it is uncertain whether family history, per se, is an independent risk factor. A positive family history is generally accepted to refer to those in whom a first-degree relative has developed ischaemic heart disease before the age of 50 years.

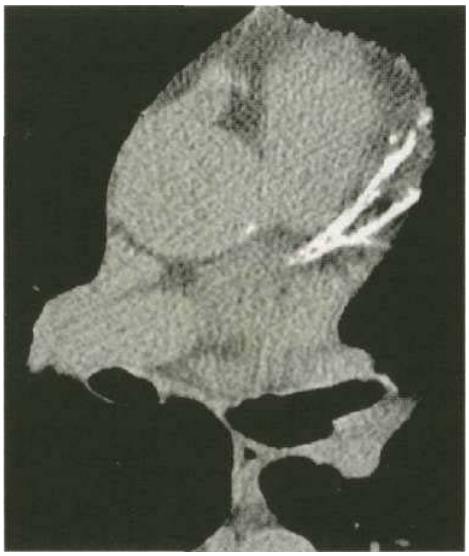

Fig. 13.65 Electron beam CT scan showing extensive calcification in left anterior descending artery and diagonal branch. Courtesy of Dr M Rubens, Royal Brompton Hospital, London.

Smoking (see p. 893)

In men, the risk of developing CAD is directly related to the number of cigarettes smoked. It is estimated that about 20% of deaths from CAD in men and 17% of deaths from CAD in women are due to smoking. Evidence suggests that each person stopping smoking will reduce his/her own risk by 25%. The risk from smoking declines to almost normal after 10 years of abstention.

Diet and obesity **(see p. 252)**

Diets high in fats are associated with ischaemic heart disease, as are those with low intakes of antioxidants (i.e. fruit and vegetables). Supplementation with antioxidants has been shown to be unhelpful in RCTs (p. 247).

It is estimated that up to 30% of deaths from CAD are due to unhealthy diets. The dietary changes which would help to reduce rates of CAD include a reduction in fat, particularly saturated fat intake, a reduction in salt intake and an increase in carbohydrate intake. The consumption of fruit and vegetables should be increased by 50% to about 400 g per day, which is equivalent to at least five daily portions (see Box 5.2).

There is overwhelming evidence from clinical trials that modification of the diet has a significant impact on the risk of CVD in both the primary and secondary prevention settings.

Patients who are overweight and those who are obese have an increased risk of CAD. It is estimated that about 5% of deaths from CAD in men and that 6% of such deaths in women are due to obesity (a body mass index (BMI) of greater than 30 kg/m^2).

The adverse effect of excess weight is more pronounced when the fat is concentrated mainly in the

abdomen. This is known as central obesity (visceral fat) and can be identified by a high waist to hip ratio.

Reduction in weight by diet and exercise not only lowers the incidence of CVD but also diabetes/insulin resistance. It is estimated that about 36% of deaths from CAD in men and 38% of deaths from CAD in women are due to lack of physical activity. To produce the maximum benefit the activity needs to be regular and aerobic. Aerobic activity involves using the large muscle groups in the arms, legs and back steadily and rhythmically so that breathing and heart rate are significantly increased.

It is recommended that adults should participate in a minimum of 30 minutes of at least moderate intensity activity (such as brisk walking, cycling or climbing the stairs) on 5 or more days of the week.

Hypertension

Both systolic and diastolic hypertension are associated with an increased risk of CAD. Both drug treatment and lifestyle changes - particularly weight loss, an increase in physical activity, and a reduction in salt and alcohol intake - can effectively lower blood pressure.

It is estimated that 14% of deaths from CAD in men and 12% of deaths from CAD in women are due to a raised blood pressure (defined as a systolic blood pressure of 140 mmHg or over, or a diastolic blood pressure of 90 mmHg or over) and that 6% of deaths from CAD in the UK could be avoided if the numbers of people who have high blood pressure were to be reduced by 50%.

Hyperlipidaemia (seep. 1137)

High serum cholesterol, especially when associated with a low value of high-density lipoproteins (HDL), is strongly associated with coronary atheroma. There is increasing evidence that high serum triglyceride (TG) is also independently linked with coronary atheroma.

Familial hypercholesterolaemia combined with hypertriglyceridaemia and remnant hyperlipidaemia are also associated with increased risk of coronary atherosclerosis.

Measurement of the fasting lipid profile (total cholesterol, low- and high-density lipoproteins and triglycerides) should be performed on all patients.

The risk of CAD is directly related to serum cholesterol levels. Serum cholesterol levels can be reduced by drugs, physical activity and by dietary changes, in particular a reduction in the consumption of saturated fat. It is estimated that 45% of deaths from CAD in men and 47% of deaths from CAD in women are due to a raised serum cholesterol level (in this case greater than 5.2 mmol/L) and that 10% of deaths from CAD in the UK could be avoided if everyone in the population had a serum cholesterol level of less than 6.5 mmol/L.

Different guidelines give slightly different advice for managing high levels of serum cholesterol (hyperlipidaemia). The National Service Framework for coronary heart disease in England includes guidelines on the prevention of CAD in clinical practice and suggests a cholesterol target of less than 5.0 mmol/L for both primary and secondary prevention.

High-density lipoprotein cholesterol (HDL-cholesterol) is the fraction of cholesterol that removes cholesterol (via the liver) from the blood. Low levels of HDL-cholesterol are associated with an increased risk of CAD and a worse prognosis after a heart attack. Guidelines on HDL-cholesterol generally recommend treatment for those with concentrations below 1.0 mmol/L. HDL increases with exercise, alcohol in moderation, not smoking and when TG is lowered.

A 1% reduction in cholesterol levels reduces risks of CAD by 2-3%. Hyperlipidaemia can be treated as follows:

- Statins: 24-30% reduction in mortality in primary and secondary prevention will be achieved if a flat dose of statin (pravastatin or simvastatin) is given. Up to 50% reduction is achieved if the dose of statin (atorvastatin) is titrated to achieve a target LDL of < 2.6 mmol/L.
- Fibrates result in a significant reduction in CAD events in diabetics and patients with high TG and low HDL.
- Diet: the so-called Mediterranean diet (p. 233) has resulted in a 75% reduction in CAD events in post-myocardial infarction patients.

Angiographic studies have shown that lowering the serum cholesterol can slow the progression of coronary atherosclerosis, and can cause regression of disease. Large clinical trials have shown that lipid lowering, usually with a statin, can decrease total mortality and new coronary events, and reduce the need for revascularization. Management of hypercholesterolaemia is described in detail on page 1141.

Diabetes mellitus

Diabetes, an abnormal glucose tolerance or raised fasting glucose is strongly associated with vascular disease.

Diabetes substantially increases the risk of CAD. Men with type 2 diabetes have a two- to fourfold greater annual risk of CAD, with an even higher (three- to fivefold) risk in women with type 2 diabetes.

Diabetes not only increases the risk of CAD but also magnifies the effect of other risk factors for CAD such as raised cholesterol levels, raised blood pressure, smoking and obesity.

Newer risk factors

Although there is general agreement on established cardiovascular risk factors, epidemiological research continues to identify or evaluate additional risk factors that contribute to the occurrence of atherosclerotic CVD and warrant further clarification.

Sedentary lifestyle

Lack of exercise is an independent risk factor for CAD equal to hypertension, hyperlipidaemia and smoking. Regular exercise probably protects against its development (see above).

Psychosocial well-being

Four different types of psychosocial factor have been found to be most consistently associated with an

increased risk of CAD: work stress, lack of social support, depression (including anxiety) and personality (particularly hostility).

Alcohol

Moderate alcohol consumption (one or two drinks per day) is associated with a reduced risk of CAD. At high levels of intake - particularly in 'binges' - the risk of CAD is increased. It is currently advised that 'regular consumption of between three and four units a day by men' and 'between two and three units a day by women of all ages will not lead to any significant health risk'.

Genetic factors

A number of genetic factors have been linked with coronary artery disease. The angiotensin-converting enzyme (ACE) gene contains an insertion/deletion (I/D) polymorphism, the DD genotype of which has been associated with a predisposition to coronary artery disease and myocardial infarction.

Lipoprotein (a)

High plasma Lp(a) concentrations are associated with CAD and, although probably not an independent risk factor, elevated plasma Lp(a) increases the CAD risk associated with more traditional risk factors.

Coagulation factors

Serum fibrinogen is strongly, consistently, and independently related to CAD risk. The pathophysiological mechanism by which fibrinogen levels mediate coronary disease risk is related to its effect on the coagulation cascade, platelet aggregation, endothelial function and smooth muscle cell proliferation and migration.

High levels of *coagulation factor VII* are also a risk factor. Polymorphisms of the factor VII gene may increase the risk of myocardial infarction.

Homocysteine, an amino acid regulated by vitamins B_{12}, B_6 and folate, is another factor that has been associated with CAD and atherosclerosis (see p. 248). Homocysteinaemia is a major risk factor in the pathogenesis of CAD and a strong predictor of mortality in this group. Plasma levels of homocysteine are influenced by a variety of genetic and non-genetic factors. The mechanism associating hyperhomocysteinaemia with atherosclerosis is its adverse effect on vascular endothelium. Folic acid in low doses may ameliorate this process.

C-reactive protein (CRP)

CRP is linked with future risk of coronary events independently of the traditional risk factors but its use as a marker for subclinical atherosclerosis and cardiovascular risk has recently been questioned.

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs that are specific inhibitors against cyclo-oxygenase-2 (COX-2) have been shown to increase cardiovascular risk and mortality. Rofecoxib has already , been withdrawn.

Prevention policy

The priorities for CVD prevention in clinical practice are:

- Patients with established CAD, PVD and cerebrovascular atherosclerotic disease.
- Asymptomatic individuals who are at high risk of developing atherosclerotic disease because of multiple risk factors resulting in a 10-year risk of > 5% now (or if extrapolated to age 60) for developing a fatal event, i.e. those with markedly raised levels of single risk factors:
  - cholesterol > 8 mmol/L
  - LDL cholesterol > 6 mmol/L
  - BP > 180/110 mmHg.
- All patients with diabetes.
- Close relatives of:
  - patients with early-onset atherosclerotic cardio vascular disease
  - asymptomatic individuals at a particular high risk.
- Other individuals encountered in routine clinical practice.

How to estimate total cardiovascular risk in asymptomatic people as a guide to prevention strategies

Patients with established CVD have declared themselves to be at high total risk of further vascular events. Therefore they require the most intense lifestyle intervention, and where appropriate drug therapies.

However, in the majority of asymptomatic, apparently healthy people, preventative actions should be guided in accordance with the total CVD risk level. Indeed, risk factor management decisions should usually not be based on considerations of a single modestly raised factor.

To evaluate candidates for the major cardiovascular events cost-effectively, multivariate risk profiles have been formulated; these facilitate targeting those at high risk for preventative measures.

The Joint British Societies, the European Society of Cardiology and the American Heart Association recently emphasized the importance of these risk profiles for motivating as well as reassuring patients and in assisting in selecting therapy. They concluded that these scores direct healthcare professionals to look at the whole patient and to recognize the cumulative nature of risk factors (Fig. 13.66). However, not all practitioners agree with this approach (see pp. 803 and 804).

National Service Framework (NSF)

Plans to reduce CAD-related death in the under-75-year age group by 40% by the year 2010 by the implementation of set standards have been published in the UK by the Department of Health. The NSF includes a nurse-led audited approach to reduce CAD by lowering saturated fat intake, increasing exercise and, most relevant, decreasing/stopping smoking. The hypertension treatment targets are 140/85 mmHg in patients at risk of or with established coronary artery disease and 130/80 mmHg in diabetics. The cholesterol target is either total cholesterol of < 5.0 mmol/L (LDL-cholesterol < 3 mmol/L) or a reduction of 30% (whichever is greater).

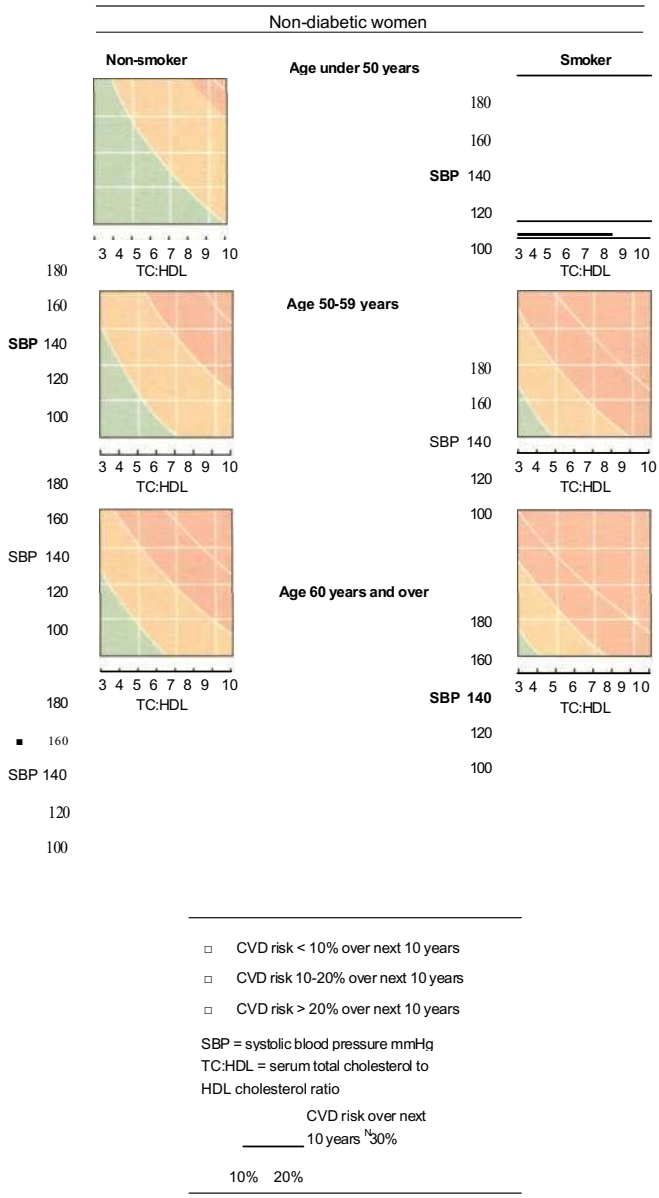

Fig. 13.66 (a) Cardiovascular risk prediction charts for women. Reproduced with permission from The University of Manchester.

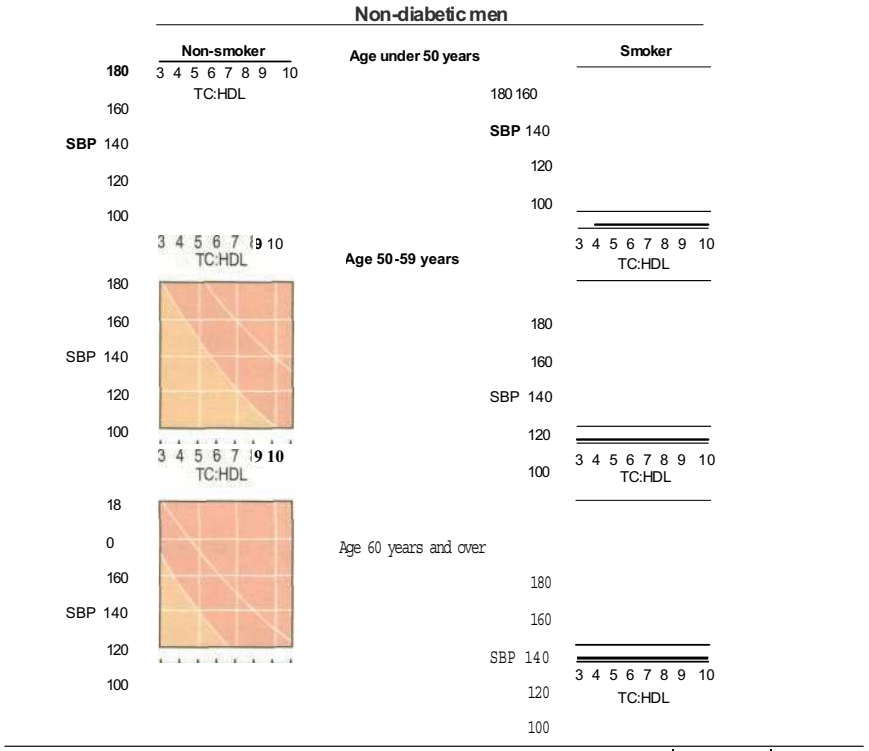
Coronary artery disease in women

Until the age of 65, the prevalence of CAD is much less in women than in men and the incidence of MI in women aged 60-70 increases dramatically, corresponding to that in men. Women have a generally poorer survival post-MI than men and have 2-3% higher in-hospital mortality independent of age and other risk factors.

ANGINA (see also p. 732)

The diagnosis of angina is largely based on the clinical history. The chest pain is generally described as 'heavy', 'tight' or 'gripping'. Typically, the pain is central/ retrosternal and may radiate to the jaw and/or arms. *Angina* can range from a mild ache to a most severe pain that provokes sweating and fear. There may be associated breathlessness. CAD is common, fatal and largely preventable. More than 1.4 million people in the UK surfer from angina. CAD accounts for about 3% of all hospital admissions in England. The prevalence of angina is approximately 2% with an incidence of new cases each year approximately 1 per 1000.

Classical or exertional angina pectoris is provoked by physical exertion, especially after meals and in cold,



- To estimate an individualis absolute 10-year risk of developing CVD, choose the panel for the gender, smoking status and age. Within this, define the level of risk from the point where the co-ordinates for SBP and ratio of the total to HDL-cholesterol cross. If no HDL cholesterol result is available, assume it is 1.00mmol/l and use the lipid scale as total serum cholesterol.
- Highest risk individuals (red areas) are those whose 10-year CVD risk exceeds 20%, which is approximately equivalent to a 10-year CHD risk of >15% (indicated by the 1998 charts). As a minimum, those with CVD risk >30% (shown by the line within the red area) should be targeted and treated now. When resources allow, others with a CVD risk >20% should be targeted progressively.
- The chart also assists in identification of individuals with a moderately high 10-year CVD risk — in the range of 10-20% (orange area) and those in whom it is lower than 10% (green area).
- Smoking status should reflect lifetime exposure to tobacco.

For further information, see
http://www.bhf.org.uk/professionals/uploaded/aug_2004%20v2.pdf

Fig. 13.66 **(b) Cardiovascular risk prediction charts for men.** Reproduced with permission from The University of Manchester.

windy weather, and is commonly aggravated by anger or excitement. The pain fades quickly (usually within minutes) with rest. Occasionally it disappears with continued exertion ('walking through the pain'). Whilst in some patients the pain occurs predictably at a certain level of exertion, in most patients the threshold for developing pain is variable.

DecubitUS angina is that occurring on lying down. It usually occurs in association with impaired left ventricular function, as a result of severe coronary artery disease.

Nocturnal angina occurs at night and may wake the patient from sleep. It can be provoked by vivid dreams. It tends to occur in patients with critical coronary artery disease and may be the result of vasospasm.

Variant (Prinzmetal's) angina refers to an angina that occurs without provocation, usually at rest, as a result of coronary artery spasm. It occurs more frequently in women. Characteristically, there is ST segment elevation on the ECG during the pain. Specialist investigation using provocation tests (e.g. hyperventilation, cold-pressor testing or ergometrine challenge) may be required to establish the

diagnosis. Arrhythmias, both ventricular tachyarrhythmias and heart block, can occur during the ischaemic episode.

Cardiac syndrome X refers to those patients with a good history of angina, a positive exercise test and angiographically normal coronary arteries. They form a heterogeneous group, and the syndrome is much more common in women than in men. Whilst they have a good prognosis, they are often highly symptomatic and can be difficult to treat. In women with this syndrome the myocardium shows an abnormal metabolic response to stress, consistent with the suggestion that the myocardial ischaemia results from abnormal dilator responses of the coronary microvasculature to stress. The prognostic and therapeutic implications are not known.

Unstable angina refers to angina of recent onset (less than 1 month), worsening angina or angina at rest, and will be described in more detail as Acute coronary syndrome on page 808. . ,

Examination and diagnosis

There are usually no abnormal findings in angina, although occasionally a fourth heart sound may be heard. Signs to suggest anaemia, thyrotoxicosis or hyperlipidaemia (e.g. lipid arcus, xanthelasma, tendon xanthoma) should be sought. It is essential to exclude aortic stenosis (i.e. slow-rising carotid impulse and ejection systolic murmur radiating to the neck) as a possible cause for the angina. The blood pressure should be taken to identify coexistent hypertension. , ,

Investigations for angina

Resting ECG

This is usually normal between attacks. Evidence of old myocardial infarction (e.g. pathological Q waves), left ventricular hypertrophy or left bundle branch block may be present. During an attack, transient ST depression, T-wave inversion or other changes of the shape of the T wave may appear.

Exercise ECG

Exercise testing can be very useful both in confirming the diagnosis of angina and in giving some indication as to the severity of the CAD. ST segment depression of > 1 mm suggests myocardial ischaemia, particularly if typical chest pain occurs at the same time (Fig. 13.23).

The test has a specificity of 80% and a sensitivity of about 70% for CAD. A strongly positive test (within 6 minutes of starting the Bruce protocol) suggests 'prognostic' disease (see Surgical management below) and helps to identify patients who should be offered coronary angiography. Exercise testing, however, can be misleading:

- A normal test does not exclude CAD (so-called false-negative test) although these patients, as a group, have a good prognosis.
- Up to 20% of patients with positive exercise tests are subsequently found to have no evidence of coronary *t artery disease (so-called false-positive test).

Cardiac scintigraphy

Myocardial perfusion scans (see p. 755), both at rest and after stress (i.e. exercise or dobutamine), are helpful. Redistribution of the contrast agent is a sensitive indicator of ischaemia and can be particularly useful in deciding if a stenosis seen at angiography is giving rise to ischaemia. A normal perfusion scan makes significant CAD unlikely.

Echocardiography

This can be used to assess ventricular wall involvement and ventricular function. Regional wall motion abnormalities at rest reflect previous ventricular damage. Stress echocardiography, although technically difficult, is useful especially in women with coronary artery disease.

Coronary angiography

This is occasionally useful in patients with chest pain where the diagnosis is unclear. More often, the test is performed to delineate the exact coronary anatomy (Fig. 13.67) in patients being considered for revascularization (i.e. coronary artery bypass grafting or coronary angioplasty). Coronary angiography should be performed only when the benefit in terms of diagnosis and potential treatment outweighs the small risk of the procedure (a mortality rate of less than 1 in 1000 cases). The indications for coronary angiography are outlined in Table 13.27.

Lesions with complex morphology (irregular borders, overhanging edges, thrombus or ulceration) appear to identify a subgroup of stenoses associated with disease progression and adverse clinical outcomes. .. , . . .

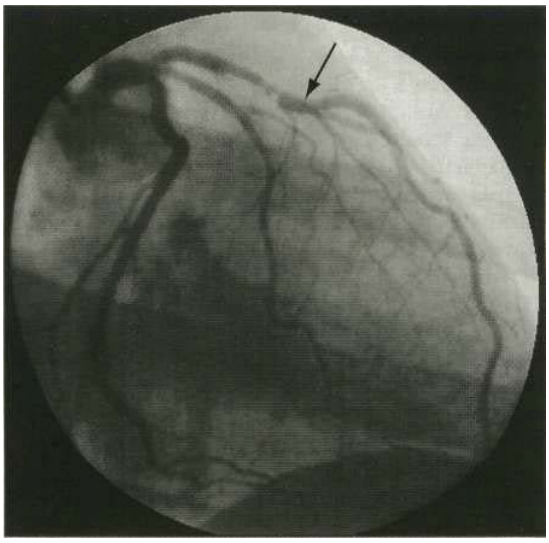


Fig. 13.67 **Left coronary angiogram.** X-ray contrast material is injected into the ostium of the left main coronary artery. In this example, the left main artery divides into three vessels: left anterior descending (top), diagonal and circumflex (bottom) vessels. In the proximal part of the left anterior descending artery is a severe narrowing due to an :. ; : atherosclerotic plaque (arrow).

Treatment of angina

General management

Patients should be informed as to the nature of their condition and reassured that the prognosis is good (annual mortality less than 2%). Underlying problems, such as anaemia or hyperthyroidism, should be treated. Management of coexistent conditions, such as diabetes and hypertension, should be optimized. Risk factors should be evaluated and steps made to correct them where possible; for example, smoking must be stopped, hypercholesterolaemia should be identified and treated (see below), weight loss, where appropriate, and regular exercise should be encouraged.

Choosing between medical therapy and revascularization (coronary artery bypass grafting and angioplasty) can be difficult and will depend on a number of factors including symptoms, angiographic anatomy and patient/physician preference. The various treatment options are not mutually exclusive and should be considered as complementary.

Medical treatment

Prognostic therapies

Aspirin reduces the risk of coronary events in patients with coronary artery disease. All patients with angina, therefore, should take aspirin (75 mg daily is probably adequate) unless contraindicated.

Lipid-lowering therapy (see p. 1141) should be used in patients with total cholesterol above 4.8 mmol/L (particularly if the LDL is > 3.3 mmol/L and the HDL is < 1.0 mmol/L), despite a low fat diet. If the triglycerides (TGs) are under 3.5 mmol/L, then one of the statins (HMG-CoA reductase inhibitors) should be used. If the TGs are above 3.5 mmol/L, a fibrate is indicated. If simple therapy fails to reduce the LDL adequately, then the patient should be referred to a lipidologist. Lipid-lowering therapy can be expected to prevent 20-30 deaths or myocardial infarcts per 1000 patient-years.

Hormone replacement therapy (HRT) is of no value in prevention of CAD.

Symptomatic treatment

Glyceryl trinitmte (GTN) used sublingually, either as a tablet or as a spray, gives prompt relief (peak action 4—8 minutes and lasts 20—30 minutes). It can be used prior to performing activities that the patient knows will provoke angina. Transdermal GTN preparations last up to 24 hours.

All but the most mildly affected patients will probably require regular prophylactic therapy. The choice of drugs is between beta-blockers, nitrates and calcium-channel blockers. There is no commonly accepted algorithm and treatment needs to be tailored to the individual patient. Some patients will require combination therapy, but there is little evidence that adding a third drug is of benefit. Patients not controlled adequately on medical therapy should be considered for revascularization (see below).

Beta-blockers reduce the heart rate (negative chronotropic effect) and the force of ventricular contraction (negative inotropic effect), both of which reduce myocardial oxygen demand, especially on exertion. They are the drugs of choice in patients with previous myocardial infarction because of their proven benefit in secondary prevention. Atenolol, 50-100 mg daily, is the most commonly prescribed. Metoprolol, 25—50 mg twice daily, is often used if renal function is impaired. Beta-blockers may aggravate coronary artery spasm.

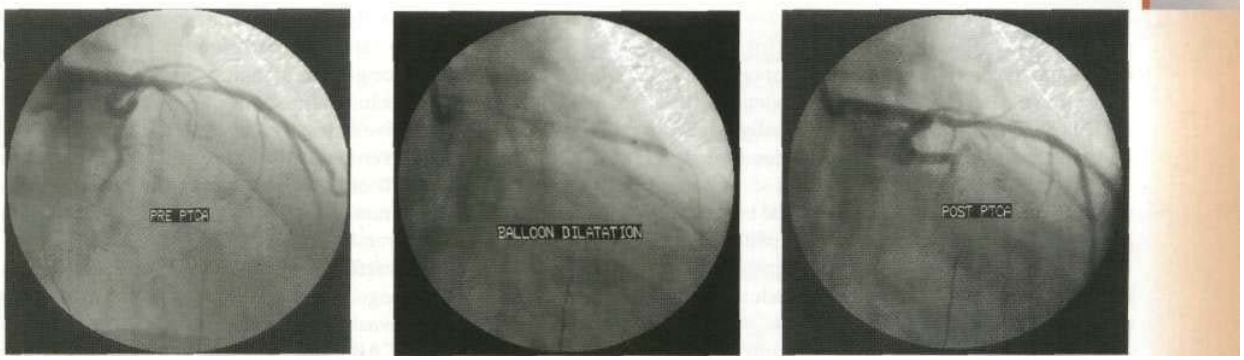
Long-acting nitrates (e.g. isosorbide mononitrate) are particularly useful in patients who gain relief from sublingual GTN. They reduce venous return and hence intracardiac diastolic pressures, reduce the impedance to the emptying of the left ventricle and relax the tone of the coronary arteries. Once-daily preparations are available which have a smooth pharmacokinetic profile and avoid the problem of tolerance. Nitrates should be given with care to patients on other hypotensive agents. Sildenafil (or other PDE_5 inhibitors) should not be given to patients taking nitrates.

Calcium-channel blockers block calcium flux into the cell and the utilization of calcium within the cell (Table 13.28). They relax coronary arteries, cause peripheral vasodilatation and reduce the force of left ventricular contraction, thereby reducing the oxygen demand of the myocardium. The non-dihydropyridine calcium antagonists (e.g. diltiazem and verapamil) also reduce the heart rate and are particularly useful anti-anginal agents, but should be used with caution in combination with beta-blockers. Short-acting dihydropyridines (e.g. nifedipine) can cause reflex tachycardia when used alone. Case-control studies have suggested that high-dose nifedipine is associated with adverse outcome. Slow-release formulations and the third-generation agents (e.g. amlodipine) can be used once daily and have a smooth profile of action with no significant effect on the heart rate and no significant negative inotropic effect.

Nicorandil is a potassium-channel activator with a nitrate component; it has both arterial and venous vasodilating properties. Whilst not used as a first-line drug, it is used when there are contraindications to the above agents and in refractory unstable angina.

Coronary angioplasty

Percutaneous transluminal coronary angioplasty (PTCA) refers to the technique of dilating coronary atheromatous obstructions by inflating a balloon within the obstruction (Fig. 13.68). The balloon, which is mounted on the tip of a very thin catheter, is inserted through the obstruction



(a) (b) (c)

Fig. 13.68 **Percutaneous transluminal coronary angioplasty (PTCA).**
(a) Coronary angiography demonstrates a severe stenosis in the proximal left anterior descending artery (arrow).
(b) During PTCA a soft guidewire is passed across the stenosis and then a balloon is expanded that dilates the stenosis.
(c) Post-PTCA.

using X-ray fluoroscopy and is then inflated with dilute contrast material. Multiple inflations of the balloon using a pressure of several atmospheres usually relieve the obstruction. A number of different mechanisms have been postulated, including fracturing and compression of the plaque, and stretching of the artery. Endothelial denudation, local dissection and distal embolization also occur and may account for some of the complications of the procedure. Whilst PTCA is ideally suited to single, discrete stenoses, multiple lesions may be treated and repeat procedures can be undertaken.

Acute coronary occlusion occurs in a small proportion of cases (2-4%), and local dissection of the coronary artery is frequently observed. PTCA improves symptoms of angina, but confers no significant prognostic benefit. The risks associated with PTCA are often understated and comprise mortality (1%), acute myocardial infarction (2%), and the need for urgent coronary artery bypass grafting (CABG) (2%).

A number of trials have compared PTCA with medical therapy for stable angina. PTCA may provide more complete relief from angina, but is associated with higher rates of myocardial infarction or bypass surgery (as a result of this procedure).

Intra-coronary stents

An increasing number of intracoronary stents (Fig. 13.69) are being used both to 'bale out' in cases of dissection and for the primary treatment of stenoses in large vessels (> 3 mm; for example, proximal lesions in big left anterior descending arteries and dominant right coronary arteries), in coronary vein grafts, and in restenotic lesions following PTCA.

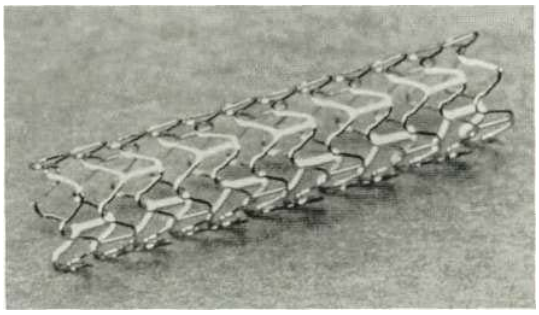

Fig. 13.69 **An intracoronary stent.**

Primary stenting or PTCA plus stent implantation is superior to PTCA alone for reducing cardiovascular events and the need for repeat intervention (BENESTENT). Stents have a lower incidence of restenosis, which still complicates up to 30% of PTCA (usually within the first 6 months post-procedure), but are more expensive.

Aspirin plus clopidogrel or ticlopidine are routinely prescribed following stent insertion. The use of monoclonal antibodies to the glycoprotein lib/IIia platelet receptor (the final common pathway of platelet aggregation) in selected high-risk cases may reduce peri-procedural complications and reduce the need for re-intervention.

Ongoing studies of new drug-eluting stents (that are coated with agents, e.g. sirolimus, paclitaxel, that reduce in-stent restenosis) and optimal antithrombotic therapies are being carried out. Intracoronary radiation therapy (on the stent) has been used to prevent and treat coronary restenosis.

Surgical management (Fig. 13.70)

There are two principal indications for coronary artery bypass grafting (CABG):

- *Symptom control* in patients who remain symptomatic despite optimal medical therapy and whose disease is not suitable for PTCA. Surgery provides dramatic relief from angina in about 90% of cases.
- *Improved survival* in patients with severe three-vessel CAD (significant proximal stenoses in all three main coronary vessels), particularly those with impaired left ventricular function, and in those with left main stem artery disease. These patients obtain prognostic benefit from CABG, irrespective of symptoms.

Where possible, the left internal mammary artery (LIMA) is used to bypass proximal stenoses in the left anterior descending artery. Similarly, the right internal mammary artery is increasingly being used to bypass stenoses in the right coronary artery. Reverse saphenous vein grafts are still commonly used in addition to arterial grafts, although the long-term patency is less good, with atheromatous occlusion occurring in up to 10% of cases per year. Operative mortality is well below 1% in patients with normal left ventricular function. Perioperative strokes occur in up to 2% of cases, and more subtle neurological deficits are common.

Off-pump coronary surgery is now performed; results show that it is as safe as on-pump surgery and causes less myocardial damage, but the graft patency rate is lower.

Minimally invasive operative procedures for bypass grafting ('MIDCAB') are being developed, including laparoscopic approaches, and may be of use in certain subgroups of patients (e.g. previous CABG and those with coexistent medical conditions which would increase the operative risks of 'full' CABG).

Aggressive lowering of LDL (to less than 2.5 mmol/L) has been shown to be beneficial in patients who have had coronary artery bypass surgery.

PTCA versus bypass surgery

Several studies have compared PTCA with bypass surgery. Both techniques provide excellent symptomatic relief with a similar incidence of major ischaemic complications. The major short-term advantage of PTCA is the avoidance of major open-heart surgery (and a shorter hospital stay). However, up to 50% of patients will require a repeat revascularization procedure within the next 2 years. There is some evidence that diabetic patients have a better 5-year survival after treatment with bypass surgery than with PTCA.

Patients with intractable angina

Some patients remain symptomatic despite medication and are not suitable for (further) revascularization. Transmyocardial laser revascularization (TMR), whereby a laser is used to form channels in the myocardium to allow direct perfusion of the myocardium from blood within the ventricular cavity has been used in some centres but in controlled trials it has not been beneficial.

Spinal cord stimulation (SCS) is accomplished using a flexible electrode in the epidural space at the midthoracic level. Stimulation via a pacemaker-like generator reduces angina and has been shown to reduce indices of ischaemia. Similarly, transcutaneous electrical nerve stimulation has been shown to reduce angina and increase exercise capacity in selected patients.

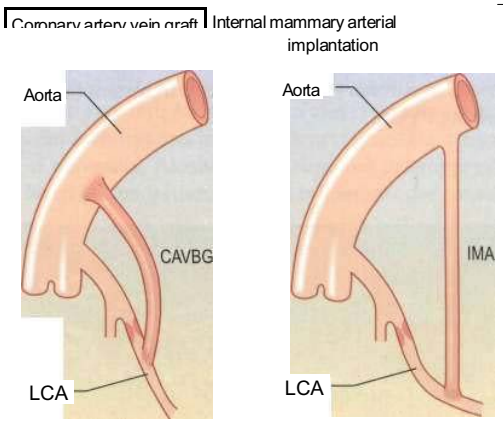

***Fig. 13.70* Relief of coronary obstruction by surgical techniques:** coronary artery vein bypass grafting (CAVBG) or internal mammary arterial implantation (IMA). In both of these examples, the graft bypasses a coronary obstruction in the left coronary artery (LCA).

ACUTE CORONARY SYNDROMES

Acute coronary syndromes (ACS) include ST-elevation myocardial infarction (STEMI), non-ST-elevation myocardial infarction (NSTEMI), and unstable angina. Myocardial infarction occurs when cardiac myocytes die due to myocardial ischaemia, and can be diagnosed on the basis of appropriate clinical history, 12-lead ECG and elevated biochemical markers — troponin I and T, creatinine-kinase-MB (CK-MB). STEMI will be covered in the next section (p. 812).

Pathophysiology

The common mechanism to all ACS is rupture or erosion of the fibrous cap of a coronary artery plaque. This leads to platelet aggregation and adhesion, localized thrombosis, vasoconstriction, and distal thrombus embolization. The presence of a rich lipid pool within the plaque and a thin fibrous cap, are associated with an increased risk of rupture. Thrombus formation and the vasoconstriction produced by platelet release of serotonin and thromboxane A_2, results in myocardial ischaemia due to reduction of coronary blood flow.

Diagnosis

Clinical presentation

Patients with an ACS may complain of a new onset of *chest pain,* chest pain *at rest,* or a deterioration of pre-existing angina. However, some patients present with *atypical features* including indigestion, pleuritic chest pain or dyspnoea. Physical examination will help to detect alternative diagnoses such as aortic dissection, pulmonary embolism or peptic ulceration and adverse clinical signs such as hypotension, basal crackles, fourth heart sound and cardiac murmurs.

Electrocardiogram

Although the 12-lead ECG may be normal in patients with an ACS, ST depression and T-wave inversion are highly suggestive of an ACS, particularly if associated with anginal chest pain. The ECG should be repeated when the patient is in pain, and continuous ST-segment monitoring is recommended. With STEMI, complete occlusion of a coronary vessel will result in persistent ST-elevation or LBBB pattern, although transient ST elevation is seen with coronary vasospasm (Prinzmetal's angina).

Biochemical markers

The measurement of the *creatinine-kinase-MB* level was until recently the standard marker for myocyte death used in ACS. However, the presence of low levels of CK-MB in the serum of normal individuals and in patients with significant skeletal muscle damage, has limited its accuracy. It can be used to determine re-infarction as levels drop back to normal after 36-72 hours.

The cardiac *troponin* complex is made up of three distinct proteins (I, T and C) that are situated with tropomyosin on the thin actin filament that forms the skeleton of the cardiac myofilament. *Troponin T* attaches the complex to tropomyosin, troponin C binds calcium during excitation-contraction coupling, and troponin I inhibits the myosin binding site on the actin.

The cardiac troponins are not detectable in normal people and so monoclonal antibody tests for cardiac-specific troponin I and cardiac-specific troponin T are highly sensitive markers of myocyte necrosis. If the initial troponin assay is negative, then it should be repeated 9-12 hours after admission. The troponin assay has prognostic information that can determine mortality risk in ACS and define which patients may benefit from aggressive medical therapy and early coronary revascularization (Fig. 13.71).

Myoglobin may be useful for a rapid diagnosis of ACS, as the levels become elevated very early in the time course of an MI, but because of the presence of myoglobin in skeletal muscle the test has poor specificity for ACS. New markers are becoming available, e.g. myeloperoxidase or glutathione peroxidase 1.

Risk stratification

Initial risk in ACS is determined by complications of the acute thrombosis. This may produce recurrent myocardial ischaemia, marked ST depression, dynamic ST changes, a raised troponin level, and be demonstrated with coronary angiography. Long-term risk is defined by clinical risk factors: age, prior myocardial infarction or bypass surgery, diabetes or heart failure. Biological markers such as C-reactive protein, fibrinogen, brain-natriuretic peptide, modified albumin and serum

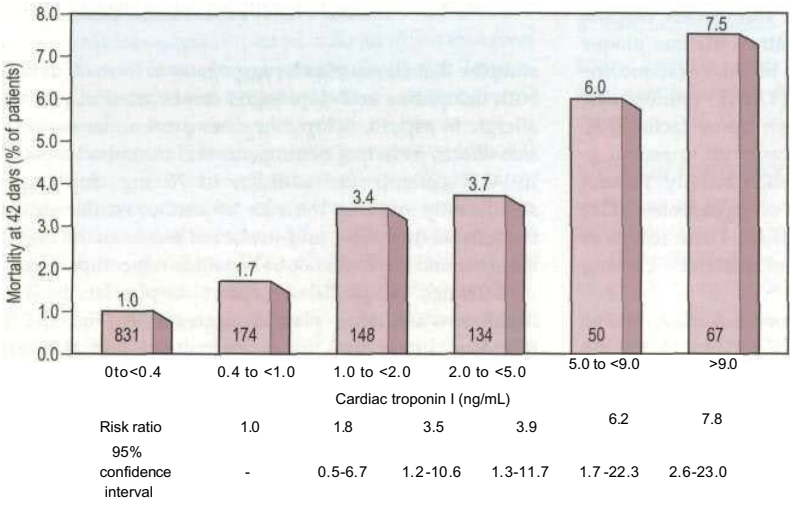

Fig. 13.71 **Relationship between cardiac troponin I levels and risk of death in patients with the acute coronary syndrome (ACS).** From Antman EM (1996) *New England Journal of Medicine* **335:** 1342-1349.

Table 13.29 **The TIMI risk score in ACS**

Risk factor	Score
Age > 65	1
More than three coronary artery disease risk factors - hypertension, hyperlipidaemia, family history, diabetes, smoking	1
Known coronary artery disease (coronary angiography stenosis > 50%)	1
Aspirin use in the last 7 days	1
Severe angina (more than two episodes of rest pain in 24 hours)	1
ST deviation on ECG (horizontal ST depression or transient ST elevation > 1 mm)	1
Elevated cardiac markers (CK-MB or troponin)	1

Total score	Rate of death/MI in 14 days	Rate of death/MI/urgent revascularization
0-1	3%	4.75
2	3%	8.3%
3	5%	13.2%
4	7%	19.9%
5	12%	26.2%
6-7	19%	40.9%

creatinine, can be used to further stratify patient risk. Left ventricular dysfunction and the presence of left main or triple vessel disease, significantly increase the future cardiovascular risk. The TIMI score can be used in patients with ACS to define risk (Table 13.29).

Investigation and treatment (Table 13.30)

Urgent coronary angiography is indicated for diagnosis and treatment in patients at high risk for progression to myocardial infarction or death.

Low-risk patients (no recurrence of chest pain during observation, normal ECG or minor T wave changes only, normal troponin on the initial assay and at 6-12 hours post-admission) can be managed with oral aspirin and/or clopidogrel, beta-blockers, and nitrates. An exercise test should be performed - a negative result has good prognosis, and an early positive test should direct the patient to an invasive strategy. If the patient is unable to exercise satisfactorily, or if the baseline ECG is abnormal (e.g. LVH or LBBB), then dobutamine stress echocardiography or myocardial perfusion scintigraphy is recommended.

Antiplatelet agents

The platelet is a key part of the thrombosis cascade involved in ACS. Rupture of the atheromatous plaque exposes the circulating platelets to ADP (adenosine diphosphate), thromboxane A_2 (TXA_2), epinephrine (adrenaline), thrombin, and collagen tissue factor (Fig. 13.72). This causes platelet activation, with thrombin as an especially potent stimulant of such activity. Platelet activation produces the expression of glycoprotein (GP) IIb/IIIa receptors on the platelet surface. These receptors bridge fibrinogen between adjacent platelets, causing platelet aggregates.

Aspirin blocks the formation of thromboxane A_2 and so prevents platelet aggregation. In ACS patients 75-150 mg aspirin reduces the relative risk of death or myocardial infarction by about 35-50% and should be given to all patients unless contra-indicated.

Ticlopidine and *clopidogrel* are thienopyridines that inhibit ADP-dependent activation of the GP lib/ Ilia

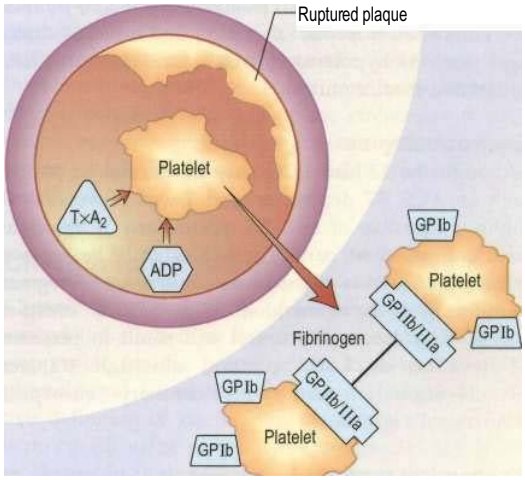

Fig. 13.72 **Platelet aggregation.** Rupture of the atheromatous plaque releases adenosine diphosphate (ADP) and thromboxane A_2 (TXA_2), which activate platelets causing expression of glycoprotein (GP) IIb/IIIa receptors on their surface. These receptors link with fibrinogen causing platelet aggregation.

complex that allows platelet aggregates to form. Although both ticlopidine and clopidogrel can be used in patients allergic to aspirin, ticlopidine does cause more systemic side-effects, including neutropenia and thrombocytopenia. In ACS patients the addition of 75 mg clopidogrel significantly reduces the risk of cardiovascular death, myocardial infarction, and stroke but increases the risk of bleeding and the evidence of benefit is not compelling.

Activated GP IIb/IIIa receptors on platelets bind to fibrinogen, initiating platelet aggregation (Fig. 13.72). Receptor antagonists have been developed that are powerful inhibitors of platelet aggregation. *Abcixitnab* is a monoclonal antibody that binds tightly and has a long half-life. *Eptifibatide* is a cyclic peptide that selectively inhibits GP IIb/IIIa receptors, but has a short half-life and wears off in 2-4 hours. *Tirofiban* is a small non-peptide

Table 13.30 **Pharmacological therapy in acute coronary syndromes**

Drug	Dose	Notes
	General myocardial oxygenation	
Oxygen	35-50%	Check ABG in severe COPD Give
Antiplatelet		
Aspirin	150-300 mg chewable or soluble aspirin, then 75-100 mg p.o. daily	PPI with dyspepsia history
Clopidogrel	300 mg p.o, loading dose, then 75 mg p.o. daily	Caution - increased risk of bleeding, avoid if CABG planned
Analgesia		
Diamorphine	2.5-5.0 mg i.v.	Prescribe with antiemetic, metoclopramide 10 mg i.v.
Myocardial energy consumption		
P blockers	e.g. Atenolol 5 mg i.v. repeated after 15 min, then 25-50 mg p.o. daily or Metoprolol 5 mg i.v. repeated to a maximum of 15 mg, then 25-50 mg p.o. twice daily	Avoid in asthma, heart failure, hypotension, bradyarrhythmias Avoid in asthma, heart failure, hypotension, bradyarrhythmias
Coronary vasodilatation		Maintain systolic BP above 90 mmHg
Glyceryl trinitrate	2-10 mg/h i.v./buccal/or sublingual	
Plaque stabilization/ventricular remodelling		Combine with dietary advice and modification
HMG-CoA reductase inhibitors (statins)	e.g. Simvastatin 20-40 mg p.o. daily Pravastatin 20-40 mg p.o. daily Atorvastatin 80 mg p.o. daily	Monitor renal function
ACE inhibitors	e.g. Ramipril 2.5-10 mg p.o. daily Lisinopril 5-10 mg p.o. daily	
Plus for non-ST-elevation myocardial infarction (NSTEMI)		
Antithrombin		
Low-molecular-weight heparins	Enoxaparin 1 mg/kg s.c. twice daily	
Glycoprotein IIB/IIIA inhibitors		
Abciximab	0.25 mg/kg i.v. bolus, then 0.125 mg/kg/min up to 10 mg/min i.v. for 12 h	If coronary intervention likely within 24 h
Eptifibatide	180 mg/kg i.v. bolus, then 2 mg/kg/min i.v. for 72 h	Indicated in high-risk patients managed without coronary intervention or during PCI
Tirofiban	0.4 mg/kg/min i.v. for 30 min, then 0.1 mg/kg/min for 48-108 h	Indicated in high-risk patients managed without coronary intervention or during PCI
Plus for ST-elevation myocardial infarction (STEMI)		
Thrombolysis		
Streptokinase or	1 500 000 units i.v. over 60 min	Antibodies appear after 4 days, which reduces effectiveness
Alteplase (rt-PA) or	15 mg i.v. bolus, then 50 mg over 30 min and 35 mg over 60 min	Dose modification if < 65 kg or 6-12 h post-MI Prescribe LMW heparin i.v. for 48 h Prescribe LMW heparin i.v. for 48 h or enoxaparin 1 mg/kg twice daily Prescribe LMW heparin i.v. for 48 h
Tenecteplase (TNKase) or	30-50 mg i.v. bolus according to weight	
Reteplase	10 units i.v. bolus repeated after 30 min	

ABG, arterial blood gases; CABG, coronary artery bypass grafting; COPD, chronic obstructive pulmonary disease; PCI, percutaneous coronary intervention; PPI, proton pump inhibitor

that rapidly blocks the GP lib/Ilia receptors, and is reversible in 4-6 hours.

In ACS patients tirofiban reduces the 30-day death or myocardial infarction rate from 7.1% (placebo) to 5.8%.

Troponin-positive patients with diabetes scheduled to have coronary intervention benefit most from GP lib/Ilia receptor antagonists.

Antithrombins

In ACS patients off aspirin, *low-molecular-weight heparins* (and in particular enoxaparin) can be given subcutaneously twice daily and have replaced unfractionated heparin. They produce a lower rate of refractory angina/myocardial infarction and death than placebo, and when used with aspirin reduce death from myocardial infarction from 10.3% to *7.9%*.

Anti-ischaemia agents

In patients with no contraindications (asthma, AV-block, acute pulmonary oedema), beta-blockers are administered intravenously or orally, to reduce myocardial ischaemia by blocking circulating catecholamines. This will reduce the heart rate and blood-pressure, reducing myocardial oxygen consumption. The dose can be titrated to produce a resting heart rate of 50-60 b.p.m.

In patients with ongoing angina, nitrates should be given by either the sublingual, buccal, or intravenous route. They effectively reduce preload and produce coronary vasodilatation. However, tolerance can become a problem, and intravenous administration should be gradually stopped if the patient's symptoms resolve.

Plaque stabilization/remodelling

HMG-CoA reductase inhibitor drugs (statins) and ACE-inhibitors are routinely administered to patients with ACS. These agents may produce plaque stabilization, improve vascular and myocardial remodelling, and reduce future cardiovascular events. Starting the drugs whilst the patient is still in hospital increases the likelihood of patients receiving secondary drug therapy.

Coronary intervention

Coronary revascularization is recommended in high-risk patients with ACS. Coronary stenting may stabilize the disrupted coronary plaque and reduces angiographic restenosis rates compared to PTCA alone.

Pre-procedure clopidogrel and the peri-procedure GP lib/IIia inhibitors significantly reduce the complication rate of coronary intervention.

The current rate of CABG in ACS is low (5.4%). The mortality rates with CABG are greater in the high-risk group patients, particularly with a recent myocardial infarction.

Single vessel lesions are usually treated with percutaneous coronary intervention (PCI), unless the anatomy is unfavourable. Conversely, patients with left main stem or triple vessel disease with impaired left ventricular function are best managed with surgery.

Comparing a conservative strategy (coronary intervention only for severe and recurrent angina) versus an interventional strategy (early coronary angiography and intervention) in patients with ACS, the interventional approach significantly reduces the mortality rate, as well as reducing the rate of myocardial infarction, recurrent angina, and hospital readmission. Patients with an increased level of troponin obtain most benefit.

Post-ACS

After the initial management of the ACS (diagnosis, treatment, investigation, revascularization), risk factor modification is necessary to reduce future cardiovascular events.

- Patients should be encouraged to stop cigarette smoking and should be referred to a smoking cessation clinic.
- The patient should maintain optimal weight, exercise daily for 30 minutes, and have a healthy diet.
- Hypertension should be treated to a level < 130/85.
- In patients with diabetes, glycaemic control should be very tight (HbA_{1c} < 7%, p. 1117).
- Low-fat diets should be combined with HMG-CoA reductase inhibitors to reduce LDL cholesterol.

Medication on discharge should include aspirin (clopidogrel), statin, beta-blocker, and an ACE-inhibitor, with a GTN spray for symptomatic relief of angina.

ST ELEVATION MYOCARDIAL INFARCTION (STEMI)

Myocardial infarction occurs when cardiac myocytes die due to prolonged myocardial ischaemia. The diagnosis can be made in patients with an appropriate clinical history together with findings from repeated 12-lead ECGs and elevated biochemical markers - troponin I and T,CK-MB.

Pathophysiology

Rupture or erosion of a vulnerable coronary artery plaque can produce prolonged occlusion of a coronary artery leading to myocardial necrosis within 15-30 minutes. The subendocardial myocardium is initially affected but with continued ischaemia the infarct zone extends through to the subepicardial myocardium, producing a transmural Q-wave myocardial infarction. Early reperfusion may salvage regions of the myocardium, reducing future mortality and morbidity.

The 1-month mortality in patients with a myocardial infarction may be as high as 50% in the community, with 50% of deaths occurring in the first 2 hours of the event. In the pre-thrombolytic era the in-hospital mortality rate was nearly 20% but with modern therapy may be as low as 6-7% at 1 month. Several risk factors can be identified that predict death rate at 30 days (TIMI STEMI score - Table 13.31).

Diagnosis

Symptoms and signs

Any patient presenting with *severe chest pain* lasting more than 20 minutes may be suffering from a myocardial infarction. The pain may not respond to sublingual GTN, and opiate analgesia may be required. The pain may radiate to the left arm, neck or jaw. However, in some patients, particularly with elderly or diabetic patients, the symptoms may be atypical and include *dyspnoea, fatigue,* pre-syncope or *syncope.* Autonomic symptoms are common and on examination the patient may be pale and clammy, with marked sweating. In addition, the pulse may be thready with significant hypotension, bradycardia or tachycardia.

Electrocardiograph)?

An ECG in patients with chest pain should be performed on admission to A&E. The baseline ECG is rarely normal, but if so should be repeated every 15 minutes while the

Table 13.31 TIMI risk score in ST elevation myocardial infarction (STEMI)

7	23.4%
8	26.8%
9-16	**35.9%**

patient remains in pain. Continuous cardiac monitoring is required because of the high likelihood of significant cardiac arrhythmias. ECG changes (Table 13.32) are usually confined to the ECG leads that 'face' the infarction. The presence of new ST elevation > 0.2 mV at the J-point in leads V_1-V_3, and > 0.1 mV in other leads, suggests anterior MI (Fig. 13.73). An inferior wall MI is diagnosed when ST elevation is seen in leads II, III and AVF (Fig. 13.74). Lateral MI produces changes in leads I, AVL and V_5/V_6. In patients with a posterior MI, there may be ST depression in leads V_1-V_3 with a dominant R wave, and ST elevation in lead V_5/V_6. New LBBB or presumed new LBBB is compatible with coronary artery occlusion requiring urgent reperfusion therapy. The evolution of the ECG during the course of STEMI is illustrated in Figure 13.75.

Investigations

Blood samples should be taken for cardiac troponin I or T levels or CK-MB level according to local hospital protocol, although treatment should not be deferred until the results are available. Full blood count, serum electrolytes, glucose, and lipid profile should be obtained. Transthoracic echocardiography (TTE) may be helpful to confirm a myocardial infarction, as wall-motion abnormalities are detectable early in STEMI. TTE may detect alternative diagnoses such as aortic dissection, pericarditis, or pulmonary embolism.

Table 13.32 Typical ECG changes in myocardial infarction (STEMI)

Infarct site	Leads showing ST elements
Anterior:	
Small	V_3-V_4
Extensive	V_2-V_5
Anteroseptal	V1-V3
Anterolateral	V_4-V_6, 1, AVL
Lateral	I.AVL
Inferior	II, III, AVF
Posterior	V-,, V_2 (reciprocal)
Subendocardial	Any lead
Right ventricle	VR_4

Early medical management (Table 13.30)

Accident and emergency

Rapid triage for chest pain (N.B. Time is muscle)

- aspirin 150-300 mg chewed
- sublingual glyceryl trinitrate 0.3-1 mg. Repeat
- oxygen - nasal cannula 2-4 L/min (Fig. 15.22)
- brief history/risk factors. Examination
- intravenous access + blood for markers (plus FBC, biochemistry, lipids, glucose)
- 12 lead ECG
- intravenous opiate, e.g. diamorphine 2.5-5 mg + anti-emetic, e.g. metoclopramide 10 mg
- beta-blocker (if no contra-indication) for ongoing chest pain, hypertension, tachycardia
- if primary PCI available (see p. 815) give GP Ilb/IIIa inhibitor. Alternatively give thrombolysis (see below).

Pre-hospital treatment, including thrombolysis, can be given by trained healthcare professions under strict guidelines.

Fibrinolysis

Fibrinolytic agents enhance the breakdown of occlusive thromboses by the activation of plasminogen to form plasmin. The initial thrombolytic agent used in clinical trials was streptokinase. This agent is derived from bacteria, which can lead to the development of neutralizing antibodies that limit its repeated use. In the ISIS 2 study of acute myocardial infarction, patients were randomized to receive a 1-hour intravenous infusion of 1.5 million units of streptokinase, or 1 month of 160 mg/day enteric-coated aspirin, both active treatments, or neither. Both streptokinase and aspirin were significantly better than placebo in reducing vascular mortality at 5 weeks (9.2% versus 12.0%, and 9.4% versus 11.8% respectively). The combination of streptokinase and aspirin was significantly better than either agent alone.

The GISSI 2 and ISIS 3 studies showed no significant difference in the effectiveness of streptokinase and tissue plasminogen activator (t-PA) or anistreplase. In addition there was no mortality benefit from subcutaneous unfractionated heparin versus no heparin.

In the GUSTO trial, accelerated t-PA over 90 minutes with intravenous heparin reduced death by 10/1000 patients versus streptokinase, although there were three more strokes in the t-PA group versus streptokinase and subcutaneous heparin.

In the meta-analysis of fibrinolytics (FTT), fibrinolysis within 6-hours of STEMI *or* LBBB MI, prevented 30 deaths/1000 patients treated. Between 7 and 12 hours 20/1000 deaths were prevented. After 12 hours the benefits are limited, and there is evidence to suggest less

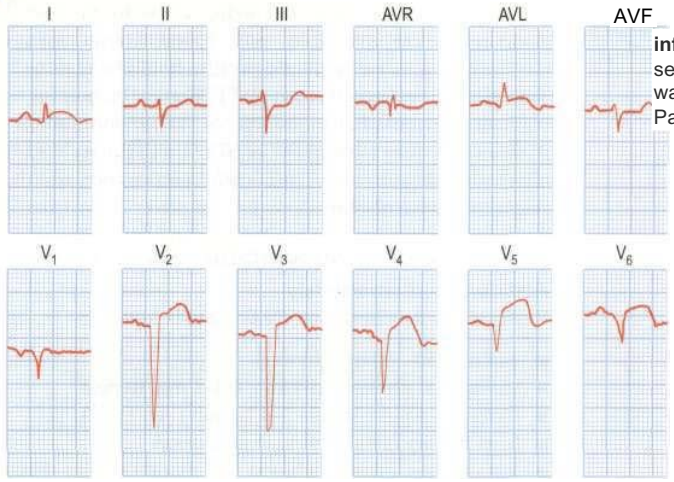

Fig. 13.73 **An acute anterolateral myocardial infarction** shown by a 12-lead ECG. Note the ST segment elevation in leads I, AVL, and V_2-V_6. The T wave is inverted in leads I, AVL and V_3-V_6. ~ Pathological Q waves are seen in leads V_2-V_6.

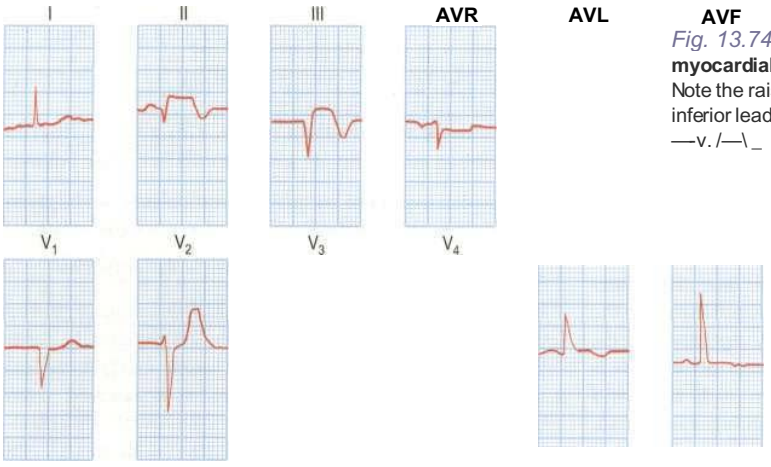

Fig. 13.74 An acute inferior wall [i ; i; !:; I **myocardial infarction** shown by a 12-lead ECG. Note the raised ST segment and Q waves in the inferior leads (II, III and AVF). The additional T wave —v. /—\ _ inversion in V_4 and V_5 probably represents anterior wall ischaemia.

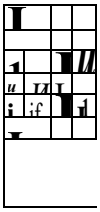

benefit for older patients, possibly because of the increased risk of strokes.

Prompt reperfusion therapy (door to needle time < 30 min) will reduce the death rate following myocardial infarction. Double bolus r-PA (reteplase) and single bolus TNK-t-PA (tenecteplase) facilitate rapid administration of fibrinolytic therapy and can be used for pre-hospital thrombolysis. In patients that fail to reperfuse by 60-90 minutes as demonstrated by 50% resolution of the ST segment elevation, re-thrombolysis or referral for rescue coronary angioplasty is recommended.

Aspirin therapy should be prescribed with fibrinolysis, but there is little additional benefit in combining clopidogrel or abciximab therapy in patients with STEMI/new LBBB. Heparin is recommended with t-PA or tenecteplase, but not with streptokinase. Enoxaparin (low molecular weight heparin) appears to be superior to unfractionated i.v. heparin in patients receiving TNK-t-PA, with less reocclusion and better late patency (ASSENT 3).

The contraindications to thrombolysis are provided in Table 13.33.

Percutaneous coronary intervention (PCI)

PCI performed within 90 minutes is the preferred reperfusion therapy in interventional cardiology centres

Table 13.33 **Contraindications to thrombolysis**

Absolute contraindications
Haemorrhagic stroke or stroke of unknown origin at any time
Ischaemic stroke in preceding 6 months
Central nervous system damage or neoplasms Recent major trauma/ surgery/head injury (within preceding 3 weeks)
Gastrointestinal bleeding

within the last month Known bleeding disorder Aortic dissection

Relative contraindications

Transient ischaemic attack in preceding 6 months Oral anticoagulant therapy
Pregnancy or within 1 week postpartum
Non-compressible punctures
Traumatic resuscitation
Refractory hypertension (systolic blood pressure > 180 mmHg
Advanced liver disease
Infective endocarditis

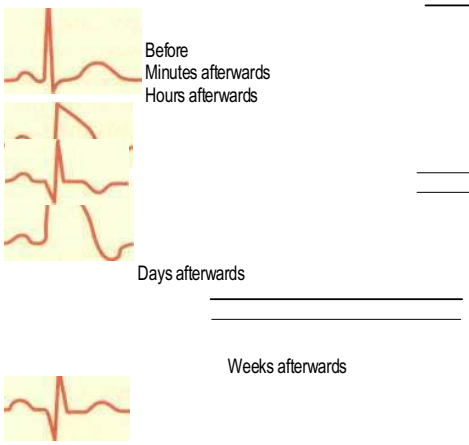

Fig. 13.75 **Electrocardiographic evolution of myocardial infarction (STEMI).** After the first few minutes the T waves become tall, pointed and upright and there is ST segment elevation. After the first few hours the T waves invert, the R wave voltage is decreased and Q waves develop. After a few days the ST segment returns to normal. After weeks or months the T wave may return to upright but the Q wave remains.

that have the expertise available. In the PAMI (Primary Angioplasty in Myocardial Infarction) trial, patients with a myocardial infarction who presented within 12 hours of the onset of STEMI were randomized to primary PTCA or tissue-type plasminogen activator (t-PA) followed by conservative care. At 2-year follow-up the primary PTCA group had less recurrent ischaemia, lower re-intervention rates and reduced hospital readmission rates. Primary PTCA produced a combined end-point of death or re-infarction of 14.9% compared to 23% for t-PA.

The DANAMI 2 study investigated if rapid transfer of patients with STEMI for primary angioplasty in an interventional centre was superior to thrombolysis. Patients within 12 hours of a high-risk STEMI (> 4 mm elevation) received front-loaded t-PA, primary angioplasty at a local centre, or primary angioplasty at an interventional centre after transfer. Primary PCI significantly reduced the death rate in both local and transferred patients as compared to thrombolytic therapy (8.0% versus 13.7%). The majority of the benefits with primary PCI are obtained by a reduction in recurrent myocardial infarction.

Coronary stenting in primary PCI reduces the need for repeat target vessel revascularization but does not appear to reduce mortality rates.

The use of abciximab in STEMI patients undergoing primary angioplasty reduces immediate outcome (death, myocardial infarction, urgent revascularization), but this benefit is minimal by 6-months.

PCI following thrombolysis was discouraged but a recent trial suggests it is safe and improves the 1-year clinical outcome.

Coronary artery bypass surgery

Cardiac surgery is usually reserved for the complications of myocardial infarction such as ventricular septal defect or mitral regurgitation.

Complications of myocardial infarction

Heart failure

Cardiac failure post-STEMI is a poor prognostic feature that necessitates medical and invasive therapy to reduce the death rate. The Killip classification is used to assess patients with heart failure post-MI:

- Killip I - no crackles and no third heart sound
- Killip II - crackles in < 50% of the lung fields or a third heart sound
- Killip III - crackles in > 50% of the lung fields
- Killip IV - cardiogenic shock.

Mild heart failure may respond to intravenous furosemide 40-80 mg i.v., with GTN administration if the blood pressure is satisfactory. Oxygen is required, with regular oxygen monitoring. ACE-inhibitors can be given in < 24-48 hours if the blood pressure is satisfactory. Patients with severe heart failure may require Swan-Ganz catheterization to determine the pulmonary wedge pressure. Intravenous inotropes such as dopamine or dobutamine are used in patients with severe heart failure. If the patient is in cardiogenic shock, then revascularization ± intra-aortic balloon pump insertion, may be required.

Myocardial rupture and aneurysmal dilatation

Rupture of the free wall of the left ventricle is usually an early, catastrophic and fatal event. The patient will have a haemodynamic collapse, then an electromechanical cardiac arrest. A subacute rupture may allow for pericardiocentesis followed by the surgical repair of the rupture. Aneurysmal dilatation of the infarcted myocardium (Figs 13.76 and 13.17) is a late complication that may require surgical repair.

Ventricular septal defect (VSD)

A VSD may occur in 1-2.0% of patients with STEMI, and may be associated with delayed or failed fibrinolysis. However, mortality is very high with a 12-month unoperative mortality of 92%. An intra-aortic balloon pump (IABP) and coronary angiography may allow for patient optimization prior to surgery.

Mitral regurgitation

Severe mitral regurgitation can occur early in the course

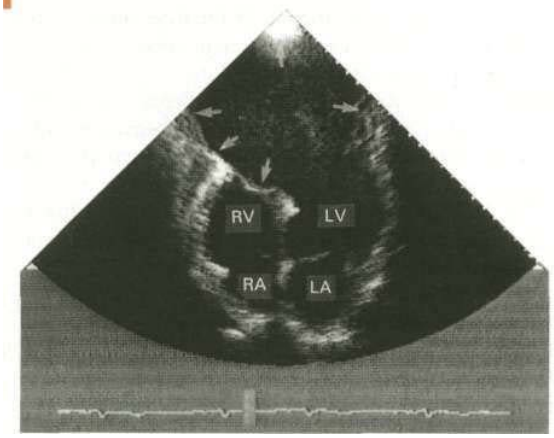

Fig. 13.76 **Two-dimensional echocardiogram (apical four-chamber view) showing a very large apical left ventricular aneurysm** (arrowed).The relatively static blood in the aneurysm produces a swirling 'smoke' effect. This aneurysm was successfully resected surgically. LV, left ventricle; LA, left atrium; RV, right ventricle; RA, right atrium.

of STEMI. Three mechanisms may be responsible for the mitral regurgitation, and a transoesophageal echocardiogram (TOE) may be necessary to confirm the aetiology:

- severe left ventricular dysfunction and dilatation, causing annular dilatation of the valve and subsequent regurgitation
- myocardial infarction of the inferior wall, producing dysfunction of the papillary muscle that may respond to coronary intervention
- myocardial infarction of the papillary muscles, producing sudden severe pulmonary oedema and cardiogenic shock (IABP, coronary angiography, and early surgery may improve patient survival).

Cardiac arrhythmias

Ventricular tachycardia and ventricular fibrillation are common in STEMI, particularly with reperfusion. Cardiac arrest requires defibrillation. Ventricular tachycardia should be treated with intravenous beta-blockers (metoprolol 5 mg, esmolol 25-200 ug/kg/min), lidocaine 50-100 mg, or amiodarone 900-1200 mg per 24 hours. If the patient is hypotensive, synchronized cardioversion may be performed. Ensure that the serum potassium is above 4.5 mmol/L. Refractory ventricular tachycardia or fibrillation may respond to magnesium 8 mmol/L over 15 minutes i.v.

Atrial fibrillation occurs frequently and treatment with beta-blockers and digoxin may be required. Cardioversion is possible but relapse is frequent.

Bradyarrhythmias can be treated initially with i.v. atropine 0.5 mg repeated up to six times in 4 hours. Temporary transcutaneous or transvenous pacemaker insertion may be required in patients with symptomatic heart block.

Conduction disturbances

These are common following MI. AV block may occur during acute MI, especially of the inferior wall (the right coronary artery usually supplies the SA and AV nodes). Heart block, when associated with haemodynamic compromise, may need treatment with atropine or a temporary pacemaker. Such blocks may last for only a few minutes, but frequently continue for several days. Permanent pacing may need to be considered if heart block persists for over 2 weeks.

Post-MI pericarditis and Dressler's syndrome

See Pericardial disease, page 854.

Post-MI drug therapy

Extensive clinical trial evidence has been gathered in post-myocardial infarction patients demonstrating that a range of pharmaceuticals are advantageous in reducing mortality over the following years. Therefore, post-MI most patients should be taking the following medications:

- aspirin 75-100 mg/day
- beta-blocker to maintain heart rate < 60 b.p.m., e.g. metoprolol 50 mg twice daily
- oral nitrates if there is angina, e.g. isosorbide mononitrate 20 mg twice daily
- ACE-inhibitors, e.g. ramipril 2.5 mg twice daily
- statins, e.g. simvastatin 20-80 mg twice daily.

Post-STEMI assessment and risk factor modification

Post-MI, most patients need to modify their lifestyle to reduce the likelihood of future cardiac events, with the same recommendations as for ACS.

If primary angioplasty has not been performed, then it is necessary to identify residual ischaemia and viability, to determine the need for coronary angiography. Uncomplicated patients with no angina during the hospital stay should have a low-level exercise test prior to discharge followed by a formal ETT 6 weeks later. A positive test usually suggests diagnostic/therapeutic coronary angiography/stenting. Alternatively, nuclear scintigraphy or dobutamine stress echocardiography can be used at 5 days to determine the amount of viable myocardium and the extent of myocardial ischaemia. Echocardiography should be performed to guide therapy and to determine baseline ejection fraction. In a patient with an ejection fraction < 30%, ventricular tachycardia on a Holter monitor may warrant an ICD.

SUDDEN CARDIAC DEATH

(see also Table 13.7)

Sudden cardiac death is generally defined as death due to cardiac causes which occurs within 6 hours of the onset of symptoms. The causes of sudden cardiac death tend to mirror, in risk factors and prevalence, the predominant cardiac causes of death in a given population. In developed countries, the majority (80%) are estimated to

be due to coronary artery disease, a further 10-15% to cardiomyopathies and 5% to valvular heart disease. Post-mortem studies have revealed that coronary atheroma is present in 80-90% of cases. Forty per cent of all deaths due to coronary atherosclerosis occur suddenly in this way, although up to 50% of patients dying suddenly because of coronary atheroma have no preceding history of coronary disease. The majority of cases of sudden death due to atheroma appear to be due to fatal ventricular arrhythmia, sometimes triggered by acute myocardial ischaemia. Other less common causes of sudden cardiac death are listed in Table 13.34. Patients presenting with a cardiac arrest require immediate cardiopulmonary resuscitation as outlined in Figure 13.35. In those patients that survive a cardiac arrest, an implantable cardioverter-defibrillator is often required, to prevent further cardiac arrest. Antiarrhythmic drugs such as amiodarone may be used as an alternative to an implantable cardioverter-defibrillator but are less effective.

Table 13.34 **Causes of sudden cardiac death**

Coronary artery disease
Acute myocardial infarction - STEMI Chronic ischaemic heart disease Following coronary artery bypass surgery After successful resuscitation for cardiac arrest Congenital anomaly of coronary arteries Coronary artery embolism Coronary arteritis
Non-coronary artery disease
Hypertrophic cardiomyopathy
Dilated cardiomyopathy (ischaemic or idiopathic)
Arrhythmogenic right ventricular cardiomyopathy
Congenital long QT syndrome
Brugada's syndrome
Valvular heart disease (aortic stenosis, mitral valve prolapse) ± infective endocarditis Cyanotic heart disease (tetralogy of Fallot, transposition) Acyanotic heart disease (ventricular septal defect, patent ductus arteriosus)

VALVULAR HEART DISEASE

MITRAL STENOSIS

Almost all mitral stenosis is due to rheumatic heart disease.

At least 50% of sufferers have a history of rheumatic fever or chorea. The single most common valve lesion due to rheumatic fever is pure mitral stenosis (50%) (Table 13.35). The mitral valve is affected in over 90% of those with rheumatic valvular heart disease. Rheumatic mitral stenosis is much more common in women. The pathological process results after some years in valve thickening, cusp fusion, calcium deposition, a narrowed (stenotic) valve orifice and progressive immobility of the valve cusps.

Other causes include:

- Lutembacher's syndrome, which is the combination of acquired mitral stenosis and an atrial septal defect
- a rare form of congenital mitral stenosis
- in the elderly, a syndrome similar to mitral stenosis, which develops because of calcification and fibrosis of the valve, valve ring and subvalvular apparatus (chordae tendineae)
- carcinoid tumours metastasizing to the lung, or primary bronchial carcinoid.

Pathophysiology

When the normal valve orifice area of 5 cm^2 is reduced to approximately 1 cm^2, severe mitral stenosis is present. In order that sufficient cardiac output will be maintained, the left atrial pressure increases and left atrial hypertrophy and dilatation occur. Consequently, pulmonary venous, pulmonary arterial and right heart pressures also increase. The increase in pulmonary capillary pressure is

Table 13.35 **Rheumatic valvular lesions**

Valves involved	Percentage of cases
Mitral valve alone	50
Mitral and aortic valves	40
Mitral, aortic and tricuspid	5
Aortic valve alone	2
All other combinations	3

Table 13.36 Complications of mitral stenosis

Atrial fibrillation	Systemic embolization
Pulmonary hypertension	Pulmonary infarction
Chest infections	Infective endocarditis (rare)
Tricuspid regurgitation	Right ventricular failure

followed by the development of pulmonary oedema. This is partially prevented by alveolar and capillary thickening and pulmonary arterial vasoconstriction (reactive pulmonary hypertension). Pulmonary hypertension leads to right ventricular hypertrophy, dilatation and failure. Right ventricular dilatation results in tricuspid regurgitation. Mitral stenosis is frequently associated with complications (Table 13.36).

Symptoms

Usually there are no symptoms until the valve orifice is moderately stenosed (i.e. has an area of 2 cm^2). In Europe this does not usually occur until several decades after the first attack of rheumatic fever, but children of 10-20 years of age in the Middle or Far East may have severe calcific mitral stenosis.

Because of *pulmonary venous hypertension* and recurrent bronchitis, progressively *severe dyspnoea* develops. A cough productive of blood-tinged, frothy sputum is quite common, and occasionally frank haemoptysis may occur. The development of pulmonary hypertension eventually leads to *right heart failure* and its symptoms of weakness, *fatigue* and abdominal or lower limb swelling.

The large left atrium favours *atrial fibrillation,* giving rise to symptoms such as palpitations. Atrial fibrillation may result in *systemic emboli,* most commonly to the cerebral vessels resulting in neurological sequelae, but mesenteric, renal and peripheral emboli are also seen. Clinical pulmonary embolism as a result of mitral stenosis associated with atrial fibrillation is less commonly seen, but it is likely that subclinical pulmonary emboli occur.

Signs (see Clinical memo in Fig. 13.77)

Face

Severe mitral stenosis with pulmonary hypertension is associated with the so-called mitral fades or malar flush. This is a bilateral, cyanotic or dusky pink discoloration over the upper cheeks that is due to arteriovenous anastomoses and vascular stasis.

Pulse

Mitral stenosis may be associated with a small-volume pulse which is usually regular early on in the disease process when most patients are in sinus rhythm. However, as the severity of the disease progresses, many patients develop atrial fibrillation resulting in an irregularly irregular pulse. The development of atrial fibrillation in these patients often causes a dramatic clinical deterioration.

Jugular veins

If right heart failure develops, there is obvious distension of the jugular veins. If pulmonary hypertension or tricuspid stenosis is present, the *a* wave will be prominent provided that atrial fibrillation has not supervened.

Palpation

There is a tapping impulse felt parasternally on the left side. This is the result of a palpable first heart sound combined with left ventricular backward displacement produced by an enlarging right ventricle. A sustained parasternal impulse due to right ventricular hypertrophy may also be felt.

Auscultation

Auscultation (Fig. 13.77) reveals a loud first heart sound if the mitral valve is pliable, but it will not occur in calcific mitral stenosis. As the valve suddenly opens with the force of the increased left atrial pressure, an 'opening snap' will be heard. This is followed by a low-pitched 'rumbling' mid-diastolic murmur best heard with the bell of the stethoscope held lightly at the apex with the patient lying on the left side. If the patient is in sinus rhythm, the murmur becomes louder at the end of diastole as a result of atrial contraction (presystolic accentuation).

The severity of mitral stenosis is judged clinically on the basis of several criteria:

- The presence of pulmonary hypertension implies that mitral stenosis is severe. Pulmonary hypertension is recognized by a right ventricular heave, a loud pulmonary component of the second heart sound, with eventually signs of right-sided heart failure, such as oedema and hepatomegaly. Pulmonary hypertension results in pulmonary valvular regurgitation that causes an early diastolic murmur in the pulmonary area known as a Graham Steell murmur.
- The closeness of the opening snap to the second heart sound is proportional to the severity of mitral stenosis.
- The length of the mid-diastolic murmur is proportional to the severity.
- As the valve cusps become immobile, the loud first heart sound softens and the opening snap disappears. When pulmonary hypertension occurs, the pulmonary component of the second sound is increased in intensity and the mitral diastolic murmur may become quieter because of the reduction of cardiac output.

Investigations

Chest X-ray

The chest X-ray usually shows a generally small heart with an enlarged left atrium (Fig. 13.16, p. 742). Pulmonary venous hypertension is usually also present. Late in the course of the disease a calcified mitral valve may be seen on a penetrated or lateral view. The signs of pulmonary oedema or pulmonary hypertension may also be apparent when the disease is severe.

Electrocardiogram

In sinus rhythm the ECG shows a bifid P wave owing to

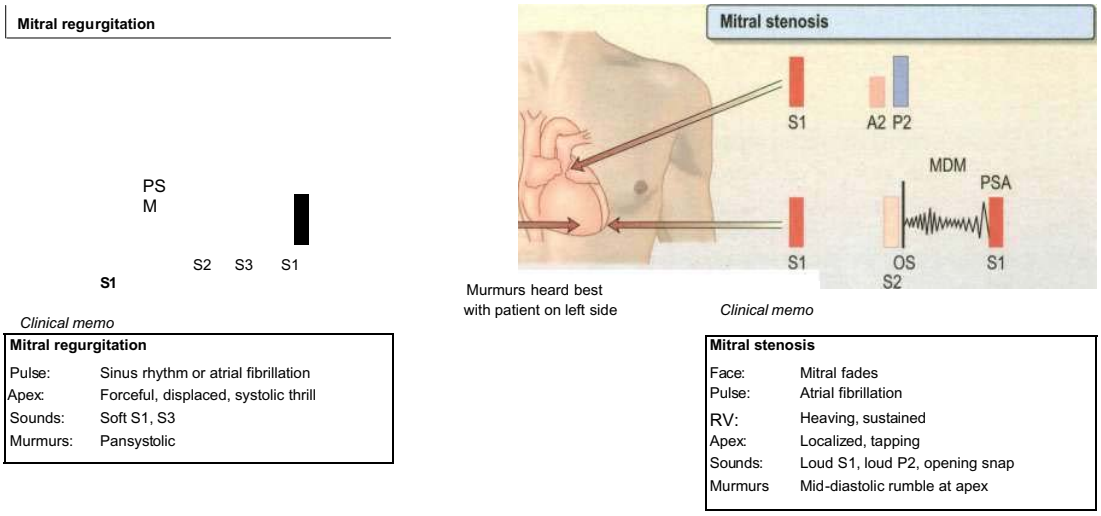

Fig. 13.77 **Features associated with mitral regurgitation and mitral stenosis.** A2, aortic component of the second heart sound; MDM, mid-diastolic murmur; OS, opening snap; P2, pulmonary component of the second heart sound; PSA, presystolic accentuation; PSM, pansystolic murmur; S1, first heart sound; S2, second heart sound; S3, third heart sound.

delayed left atrial activation (Fig. 13.78). However, atrial fibrillation is frequently present. As the disease progresses, the ECG features of right ventricular hypertrophy (right axis deviation and perhaps tall R waves in lead Vj) may develop (Fig. 13.79).

Echocardiogram (Fig. 13.29)

Two-dimensional echocardiography allows assessment of the mitral valve apparatus and calculation of mitral valve area, thus providing a useful guide in determining whether balloon valvotomy or valve replacement is the treatment of choice in patients symptomatic on medical therapy. Two-dimensional echocardiography also determines left atrial and right ventricular size and function. Continuous wave (CW) Doppler may also be used to measure mitral valve area and provides an estimate of pulmonary artery pressure through measurement of the degree of tricuspid regurgitation. In most cases, echocardiography alone is sufficient to judge the severity of mitral stenosis such that decisions regarding surgery can be made.

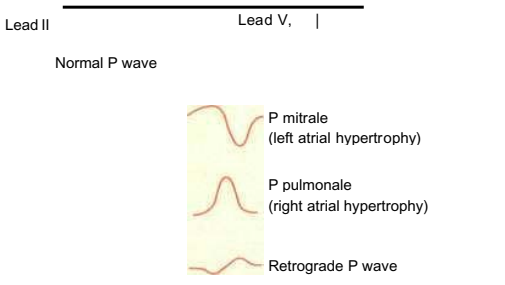

Fig. 13.78 **A bifid P wave as seen on the ECG in mitral stenosis** (P mitrale). Also shown for comparison are other P wave abnormalities.

Cardiac catheterization

This is required only if an adequate echocardiogram (transthoracic or transoesophageal) is impossible to obtain or if coexisting cardiac problems (e.g. mitral regurgitation or coronary artery disease) are suspected. The typical findings in mitral stenosis are a diastolic pressure that is higher in the left atrium than in the left ventricle (Fig. 13.80). This gradient of pressure is usually proportional to the degree of the stenosis.

Treatment

Mild mitral stenosis may need no treatment other than prompt therapy of attacks of bronchitis. Although

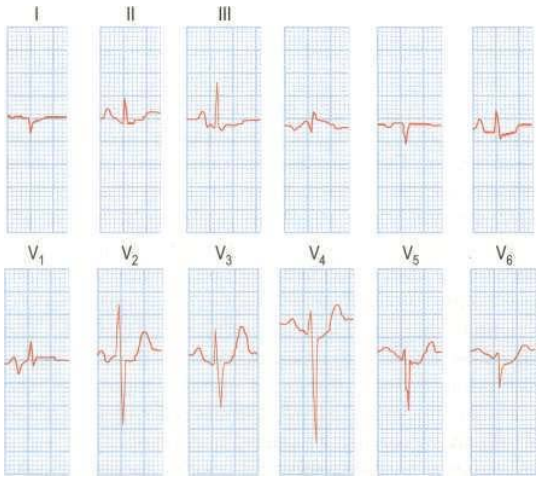

Fig. 13.79 **Severe mitral stenosis** shown by a 12-lead ECG. Note the right axis deviation (frontal plane axis = + 120°), the left atrial conduction abnormality (large terminal negative component of the P wave in V,) and the right ventricular hypertrophy (R wave in V, and right axis deviation).

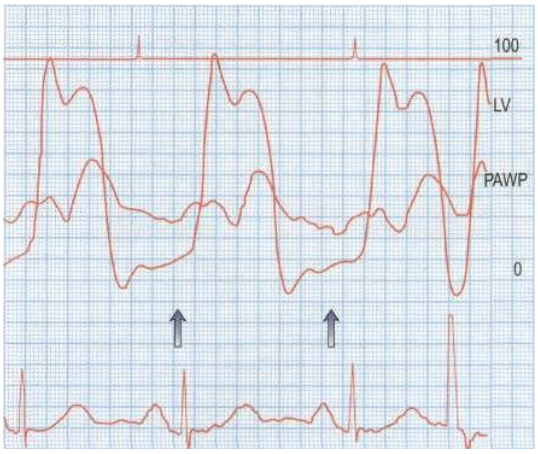

Fig. 13.80 **Simultaneous recordings of the ECG, the left ventricular (LV) and the pulmonary arterial wedge pressure (PAWP).** The PAWP is almost equivalent to the left atrial pressure. Thus at end-diastole (the onset of the QRS complex) the PAWP is significantly higher than the LV pressure (arrows). The pressure gradient is due to mitral valve stenosis. PAWP is also known as PAOP (occlusion pressure).

infective endocarditis in pure mitral stenosis is uncommon, antibiotic prophylaxis is advised (see p. 31). Early symptoms of mitral stenosis such as mild dyspnoea can usually be treated with low doses of diuretics. The onset of atrial fibrillation requires treatment with digoxin and anticoagulation to prevent atrial thrombus and systemic embolization. If pulmonary hypertension develops or the symptoms of pulmonary congestion persist despite therapy, surgical relief of the mitral stenosis is advised. There are four operative measures.

Trans-septal balloon valvotomy

A catheter is introduced into the right atrium via the femoral vein. The inter-atrial septum is then punctured and the catheter advanced into the left atrium and across the mitral valve. A balloon is passed over the catheter to lie across the valve, and then inflated briefly to split the valve commissures. The procedure is performed under local anaesthesia in the cardiac catheter laboratory. As with other valvotomy techniques, significant regurgitation may result, necessitating valve replacement (see below). This procedure is ideal for patients with pliable valves in whom there is little involvement of the subvalvular apparatus and in whom there is minimal mitral regurgitation. The procedure cannot be performed when there is heavy calcification or more than mild mitral regurgitation. The presence of thrombus in the left atrium is a contraindication to balloon valvotomy; therefore, transoesophageal echocardiography must be performed prior to this technique in order that left atrial thrombus can be excluded.

Closed valvotomy

This operation is advised for patients with mobile, non-calcified and non-regurgitant mitral valves. The fused cusps are forced apart by a dilator introduced through the apex of the left ventricle and guided into position by the surgeon's finger inserted via the left atrial appendage. Cardiopulmonary bypass is not needed for this operation. Closed valvotomy may produce a good result for 10 years or more. The valve cusps often re-fuse and eventually another operation may be necessary.

Open valvotomy

This operation is often preferred to closed valvotomy. The cusps are carefully dissected apart under direct vision. Cardiopulmonary bypass is required. Open dissection reduces the likelihood of causing traumatic mitral regurgitation.

Mitral valve replacement

Replacement of the mitral valve is necessary if:

- mitral regurgitation is also present
- there is a badly diseased or badly calcified stenotic valve that cannot be reopened without producing significant regurgitation
- there is moderate or severe mitral stenosis and thrombus in the left atrium despite anticoagulation.

Artificial valves (see p. 827) may work successfully for more than 20 years. Anticoagulants are generally necessary to prevent the formation of thrombus, which might obstruct the valve or embolize.

MITRAL REGURGITATION

Of the many causes of mitral valve regurgitation, rheumatic heart disease (50%) and a prolapsing mitral valve are the most common. There are many other causes, which include:

aortic valve disease
acute rheumatic fever
myocarditis
dilated cardiomyopathy
hypertensive heart disease
ischaemic heart disease
infective endocarditis - mitral regurgitation may result from destruction of the mitral valve leaflets

- hypertrophic cardiomyopathy - left ventricular contraction is disorganized and mitral regurgitation often results
- connective tissue disorders — systemic lupus erythematosus (SLE) may cause mitral regurgitation
- collagen abnormalities - Marfan's syndrome and Ehlers-Danlos syndrome cause mitral regurgitation
- degeneration of the valve cusps or mitral annular calcification - results in mitral regurgitation
- rupture of the chordae tendineae (due to myocardial infarction, infective endocarditis or trauma) - results in acute and very severe mitral regurgitation
- drugs, e.g. fenfluramine is associated with mitral regurgitation.

Pathophysiology

Regurgitation into the left atrium produces left atrial

dilatation but little increase in left atrial pressure if the regurgitation is long-standing, as the regurgitant flow is accommodated by the large left atrium. With acute mitral regurgitation the normal compliance of the left atrium does not allow much dilatation and the left atrial pressure rises. Thus, in acute mitral regurgitation the left atrial *v* wave is greatly increased and pulmonary venous pressure rises to produce pulmonary oedema. Since a proportion of the stroke volume is regurgitated, the stroke volume increases to maintain the forward cardiac output and the left ventricle therefore enlarges.

Symptoms

Mitral regurgitation can be present for many years and the cardiac dimensions greatly increased before any symptoms occur. The increased stroke volume is sensed as a 'palpitation'. *Dyspnoea and orthopnoea* develop owing to pulmonary venous hypertension occurring as a direct result of the mitral regurgitation and secondarily to left ventricular failure. *Fatigue and lethargy* develop because of the reduced cardiac output. In the late stages of the disease the *symptoms of right heart failure* also occur and eventually lead to congestive cardiac failure. *Cardiac cachexia* may develop. Thromboembolism is less common than in mitral stenosis, but *subacute infective endocarditis* is much more common.

Signs (see Clinical memo in Fig. 13.77)

The physical signs of uncomplicated mitral regurgitation are:

- laterally displaced (forceful) diffuse apex beat and a systolic thrill (if severe)
- soft first heart sound, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins
- pansystolic murmur, owing to the occurrence of regurgitation throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla
- prominent third heart sound, owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension, and left and right heart failure develop later in the disease. The onset of atrial fibrillation has a much less dramatic effect on symptoms than in mitral stenosis.

Investigations

Chest X-ray

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the CTR, and valve calcification is seen.

Electrocardiogram

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (Fig. 13.81) as manifested by tall R waves in the left lateral leads (e.g. leads I and V_6) and deep S waves in the right-sided precordial leads, (e.g. leads Vj and V_2). (Note that SVj plus RV_5 or RV_6 > 35 mm indicates left ventricular hypertrophy.) Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.

Echocardiogram

The echocardiogram shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. CW Doppler can determine the velocity of the regurgitant jet.

The echocardiogram is not as definitive in mitral regurgitation as in mitral stenosis. However, useful information regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. Transoesophageal echocardiography (TOE) helps to identify structural valve abnormalities before surgery. Intraoperative TOE can also aid assessment of the efficacy of valve repair.

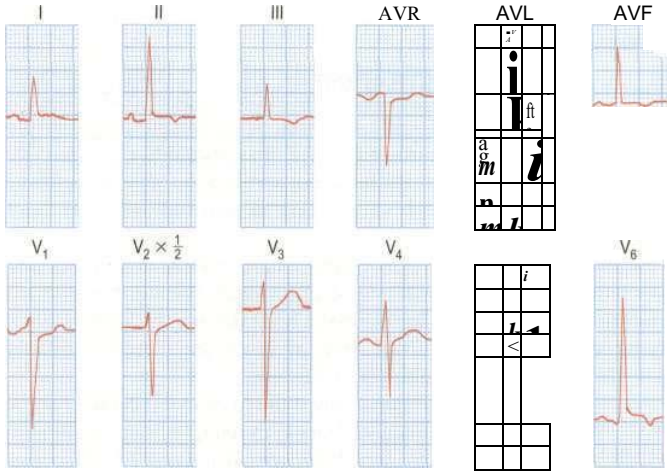

Fig. 13.81 **Left ventricular hypertrophy** shown in a 12-lead ECG. Note the size of the S wave seen in V, (21 mm); S in V, + R in V_6 = > 35 mm.

Cardiac catheterization

This demonstrates a prominent left atrial systolic pressure wave, and when contrast is injected into the left ventricle it is seen regurgitating into an enlarged left atrium during systole.

Treatment

Mild mitral regurgitation in the absence of symptoms can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is required (see p. 31). Any evidence of progressive cardiac enlargement generally warrants early surgical intervention by either mitral valve repair or replacement. The advantages of surgical intervention are diminished in more advanced disease. In patients who are not considered appropriate for surgical intervention, or in whom surgery will be considered at a later date, management usually involves treatment with ACE inhibitors, diuretics and possibly anticoagulants. Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or infective endocarditis, necessitates emergency mitral valve replacement.

Prolapsing (billowing) mitral valve

This is also known as Barlow's syndrome or floppy mitral valve. It is due to excessively large mitral valve leaflets, an enlarged mitral annulus, abnormally long chordae or disordered papillary muscle contraction. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. It is more commonly seen in young women than in men or older women and it has a familial incidence. Its cause is unknown but it is associated with Marfan's syndrome, thyrotoxicosis, rheumatic or ischaemic heart disease. It also occurs in association with atrial septal defect and as part of hypertrophic cardiomyopathy. Mild mitral valve prolapse is so common that it should be regarded as a normal variant.

Pathophysiology

During ventricular systole, a mitral valve leaflet (most commonly the posterior leaflet) prolapses into the left atrium. This may result in abnormal ventricular contraction, papillary muscle strain and some mitral regurgitation. Usually the syndrome is not haemodynamically serious. Thromboembolism occurs.

Symptoms

Atypical chest pain is the most common symptom. Usually the pain is left submammary and stabbing in quality. Sometimes it is substernal, aching and severe. Rarely it is similar to typical angina pectoris. *Palpitations* may be experienced because of the abnormal ventricular contraction or because of the atrial and ventricular arrhythmias that are commonly associated with mitral valve prolapse. Sudden cardiac death due to fatal *ventricular arrhythmias* is a very rare but recognized complication.

Signs

The most common sign is a mid-systolic click, which is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation. With more regurgitation, the murmur becomes pansystolic mitral regurgitation.

Investigations

Chest X-ray

The chest X-ray is usually normal unless significant mitral regurgitation is present.

Electrocardiogram

Non-specific ST/T wave changes have been described in 15-30% of cases, but there is no evidence that this is more than in the general population.

Echocardiogram

The diagnosis is confirmed on two-dimensional echocardiography, which typically shows posterior movement of one or both mitral valve cusps into the left atrium during systole.

Cardiac catheterization

Contrast angiograms performed during cardiac catheterization reveal the systolic prolapse of the mitral valve into the left atrium, and mitral regurgitation, if present, is seen. This investigation is not normally required.

Treatment

Usually, beta-blockade is effective for the treatment of the atypical chest pain and palpitations. Sometimes more specific antiarrhythmic drug treatment is necessary. When a prolapsing mitral valve is associated with significant mitral regurgitation and atrial fibrillation, anticoagulation is advised to prevent thromboembolism. Mitral valve prolapse associated with severe mitral regurgitation has a risk of sudden cardiac death. Mitral valve repair is indicated in all such cases. Very occasionally, mitral valve replacement rather than repair may be necessary for severe regurgitation when there is severe prolapse of both leaflets. Prophylaxis against endocarditis (see p. 31) is advised if there is significant mitral valve regurgitation.

AORTIC STENOSIS

Congenital aortic valve stenosis develops progressively because of turbulent blood flow through a congenitally abnormal (usually bicuspid) aortic valve. Most congenitally abnormal aortic valves occur in men and will calcify later in life.

Rheumatic fever results in progressive fusion, thickening and calcification of a previously normal three-cusped aortic valve. In rheumatic heart disease the aortic valve is affected in about 40% of cases and there is usually associated mitral valve disease.

Calcific valvular disease is the commonest cause of aortic stenosis and mainly occurs in the elderly. This is an inflammatory process involving macrophages and T lymphocytes

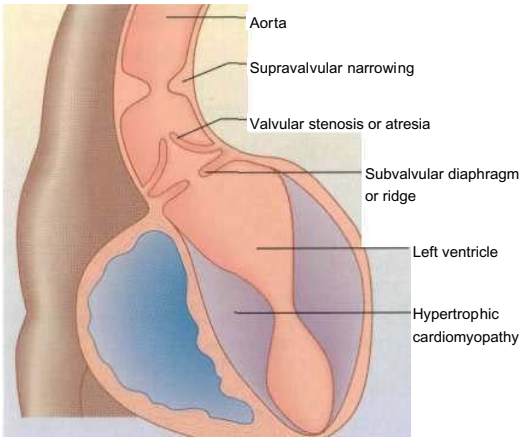

Fig. 13.82 Several forms of left ventricular outflow tract obstruction.

with initially thickening of the subendothelium with adjacent fibrosis. The lesions contain lipoproteins which calcify, increasing leaflet stiffness and reducing systolic opening.

Valvular aortic stenosis should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 13.82), which include:

- supravalvular obstruction - a congenital fibrous diaphragm above the aortic valve often associated with mental retardation and hypercalcaemia (William's syndrome)
- hypertrophic cardiomyopathy - septal muscle hyper trophy obstructing left ventricular outflow
- subvalvular aortic stenosis - a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve.

Pathophysiology

Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium, and consequent angina, arrhythmias and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails and cardiac arrhythmias develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis (cf. aortic regurgitation).

Symptoms

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, *exercise-induced syncope, angina* and *dyspnoea* develop. When symptoms occur, the prognosis is poor - on average, death occurs within 2-3 years if there has been no surgical intervention.

Signs (see Clinical memo in Fig. 13.83)

Pulse

The carotid pulse is of small volume and is slow-rising or plateau in nature (see p. 736).

Precordial palpation

The apex beat is not usually displaced because hypertrophy (as opposed to dilatation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction ('kick') may be palpable. A systolic thrill may be felt in the aortic area.

Auscultation

The most obvious auscultatory finding in aortic stenosis is an ejection systolic murmur that is usually 'diamond-shaped' (crescendo-decrescendo). The murmur is usually longer when the disease is more severe, as a longer ejection time is needed. The murmur is usually rough in quality and best heard in the aortic area. It radiates into the carotid arteries and also the precordium. The intensity of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases, the murmur may be inaudible. Other findings include:

- systolic ejection click (see p. 739), unless the valve has become immobile and calcified
- soft or inaudible aortic second heart sound when the aortic valve becomes immobile
- reversed splitting of the second heart sound (splitting on expiration) (see p. 740)
- prominent fourth heart sound (see p. 739), unless coexisting mitral stenosis prevents this.

Investigations

Chest X-ray

The chest X-ray usually reveals a relatively small heart with a prominent, dilated, ascending aorta. This occurs because turbulent blood flow above the stenosed aortic valve produces so-called 'post-stenotic dilatation'. The aortic valve may be calcified. The CTR increases when heart failure occurs.

Electrocardiogram

The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular 'strain' pattern due to 'pressure overload' (depressed ST segments and T wave inversion in leads orientated towards the left ventricle, i.e. leads I, AVL, V_5 and V_6) is common when the disease is severe. Usually, sinus rhythm is present, but ventricular arrhythmias may be recorded.

Echocardiogram

The echocardiogram readily demonstrates the thickened, calcified and immobile aortic valve cusps. Left ventricular

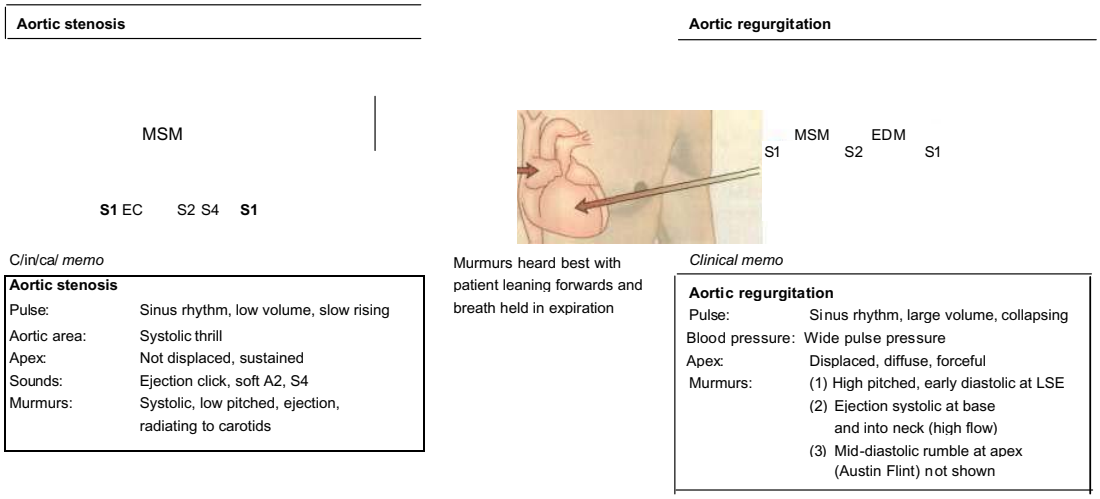

Fig. 13.83 **Features of aortic stenosis and aortic regurgitation.** EC, ejection click; EDM, early diastolic murmur; MSM, mid-systolic murmur; S1, first heart sound.

hypertrophy may also be seen. The gradient across the valve can be estimated by CW Doppler, provided the left ventricular function is reasonable (Fig. 13.28, p. 752).

Cardiac catheterization

Cardiac catheterization can be used to document the systolic pressure difference (gradient) between the aorta and the left ventricle (Fig. 13.84) and assess left ventricular function. This is rarely necessary since all of this information can be gained non-invasively with echocardiography. Coronary angiography is necessary before recommending surgery.

Treatment

In patients with aortic stenosis, symptoms are a good index of severity and all symptomatic patients should have aortic valve replacement. Asymptomatic patients should be under regular review for assessment of symptoms and echocardiography. Antibiotic prophylaxis against infective endocarditis is essential (see p. 31).

Provided that the valve is not severely deformed or heavily calcified, critical aortic stenosis in childhood or adolescence can be treated by valvotomy (performed under direct vision by the surgeon or by balloon dilatation using X-ray visualization). This produces temporary relief from the obstruction. Aortic valve replacement will usually be needed a few years later. Balloon dilatation (valvuloplasty) has been tried in adults, especially in the elderly, as an alternative to surgery. Generally results are poor and such treatment is reserved for patients unfit for surgery or as a 'bridge' to surgery (as systolic function will often improve).

AORTIC REGURGITATION

The most common causes of aortic regurgitation are rheumatic fever and infective endocarditis complicating a previously damaged valve. This can be a congenitally abnormal valve (e.g. a bicuspid valve) or one damaged by rheumatic fever. There are numerous other causes and associations (Table 13.37). The majority of patients with

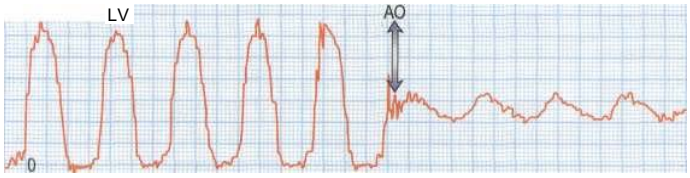

Fig. 13.84 **ECG and pressure trace as a cardiac catheter is withdrawn** from the left ventricle (LV) to the aorta (AO). Note that the peak systolic pressure changes from 250 to 130 mmHg (arrow). The 120 mmHg peak-to-peak systolic gradient indicates severe aortic valvular stenosis.

Table 13.37 Causes and associations of aortic regurgitation

Acute aortic regurgitation	Chronic aortic regurgitation
Acute rheumatic fever	Rheumatic heart disease
Infective endocarditis	Syphilis
Dissection of the aorta	Arthritides:
Ruptured sinus of Valsalva aneurysm	Reiter's syndrome
Failure of prosthetic heart valve	Ankylosing spondylitis
	Rheumatoid arthritis
	Hypertension (severe)
	Bicuspid aortic valve
	Aortic endocarditis
	Marian's syndrome
	Osteogenesis imperfecta

aortic regurgitation are men (75%), but rheumatic aortic regurgitation occurs more commonly in women.

Pathophysiology

Aortic regurgitation is reflux of blood from the aorta through the aortic valve into the left ventricle during diastole. If net cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase, and consequently the left ventricular size must enlarge. Because of the aortic run-off during diastole, diastolic blood pressure falls and coronary perfusion is decreased. In addition, the larger left ventricular size is mechanically less efficient so that the demand for oxygen is greater and cardiac ischaemia develops.

Symptoms

In aortic regurgitation, significant symptoms occur late and do not develop until *left ventricular failure* occurs. As with mitral regurgitation, a common symptom is *'pounding of the heart'* because of the increased left ventricular size and its vigorous pulsation. *Angina pectoris* is a frequent complaint. Varying grades of *dyspnoea* occur depending on the extent of left ventricular dilatation and dysfunction. *Arrhythmias* are relatively uncommon.

Signs (see Clinical memo in Fig. 13.83) The signs of aortic regurgitation are many and are due to the hyperdynamic circulation, reflux of blood into the left ventricle and the increased left ventricular size.

The pulse is bounding or collapsing (see p. 736). The following signs, which are rare, also indicate a hyperdynamic circulation:

- Quincke's sign - capillary pulsation in the nail beds
- De Musset's sign - head nodding with each heartbeat
- Duroziez's sign - a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)
- pistol shot femorals - a sharp bang heard on auscultation over the femoral arteries in time with each heartbeat.

The apex beat is displaced laterally and downwards and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space with the patient leaning forward and the breath held in expiration. Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can impinge on the anterior mitral valve cusp, causing a mid-diastolic murmur (Austin Flint).

Investigations

Chest X-ray

The chest X-ray features are those of left ventricular enlargement and possibly of dilatation of the ascending aorta. The ascending aortic wall may be calcified in syphilis, and the aortic valve may be calcified if valvular disease is responsible for the regurgitation.

Electrocardiogram

The ECG appearances are those of left ventricular hypertrophy due to 'volume overload' - tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

Echocardiogram

The echocardiogram demonstrates vigorous cardiac contraction and a dilated left ventricle. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint murmur, see p. 741). The regurgitant jet can be detected by CW Doppler. :■ •

Cardiac catheterization

During cardiac catheterization, injection of contrast medium into the aorta (aortography) will outline aortic valvular abnormalities and allow assessment of the degree of regurgitation.

Treatment

The underlying cause of aortic regurgitation (e.g. syphilitic aortitis or infective endocarditis) may require specific treatment. The treatment of aortic regurgitation usually requires aortic valve replacement but the timing of surgery is critical.

Because symptoms do not develop until the myocardium fails and because the myocardium does not recover fully after surgery, operation is performed before significant symptoms occur. The timing of the operation is best determined according to haemodynamic, echocardiographic or angiographic criteria.

Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and when anticoagulants must be avoided, but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves.

Antibiotic prophylaxis against infective endocarditis (see p. 31) is necessary even if a prosthetic valve replacement has been performed.

TRICUSPID STENOSIS

This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in the carcinoid syndrome.

Pathophysiology

Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion produces hepatomegaly, ascites and dependent oedema.

Symptoms

Usually, patients with tricuspid stenosis complain of symptoms due to associated left-sided rheumatic valve lesions. The *abdominal pain* (due to hepatomegaly) and swelling (due to ascites) and *peripheral oedema* that occur are relatively severe when compared with the degree of *dyspnoea.*

Signs

If the patient remains in sinus rhythm, which is unusual, there is a prominent jugular venous *a* wave. This presystolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of coexisting mitral stenosis. A tricuspid opening snap may occasionally be heard.

Hepatomegaly, abdominal ascites and dependent oedema may be present.

Investigations

Chest X-ray

On the chest X-ray there may be a prominent right atrial bulge.

Electrocardiogram

The enlarged right atrium may be manifested on the ECG by peaked, tall P waves (> 3 mm) in lead II.

Echocardiogram

The echocardiogram may show a thickened and immobile tricuspid valve, but this is not so clearly seen as an abnormal mitral valve.

Cardiac catheterization

This demonstrates a diastolic pressure gradient between the right atrium and the right ventricle. Contrast injection will demonstrate a large right atrium.

Treatment

Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible, but tricuspid valve replacement is often necessary. Other valves usually also need replacement because tricuspid valve stenosis is rarely an isolated lesion.

TRICUSPID REGURGITATION

Functional tricuspid regurgitation may occur whenever the right ventricle dilates, e.g. in cor pulmonale, myocardial infarction or pulmonary hypertension.

Organic tricuspid regurgitation may occur with rheumatic heart disease, infective endocarditis, carcinoid syndrome, Ebstein's anomaly (a congenitally malpositioned tricuspid valve) and other congenital abnormalities of the atrioventricular valves.

Symptoms and signs

The valvular regurgitation gives rise to high right atrial and systemic venous pressure. Patients may complain of the symptoms of *right heart failure* (see p. 788).

Physical signs include a large jugular venous *cv* wave and a palpable liver that pulsates in systole. Usually a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common.

Treatment

Functional tricuspid regurgitation usually disappears with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or plication). Very occasionally, tricuspid valve replacement may be necessary. In drug addicts with infective endocarditis of the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is considered on page 827.

PULMONARY STENOSIS

This is usually a congenital lesion, but it may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with an intact ventricular septum or with a ventricular septal defect (Fallot's tetralogy).

Pulmonary stenosis may be valvular, subvalvular or supravalvular. Multiple congenital pulmonary arterial stenoses are usually due to infection with rubella during pregnancy.

Symptoms and signs

The obstruction to right ventricular emptying results in *right ventricular hypertrophy* which in turn leads to right atrial hypertrophy. Severe *pulmonary obstruction* may be incompatible with life, but lesser degrees of obstruction give rise to fatigue, syncope and the symptoms of *right heart failure.* Mild pulmonary stenosis may be asymptomatic.

The physical signs are characterized by a harsh midsystolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular.

A right ventricular fourth sound and a prominent jugular venous *a* wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

Investigations

Chest X-ray

The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilatation.

Electrocardiogram

The ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal even in severe pulmonary stenosis,

Echocardiogram

Doppler is the investigation of choice.

Cardiac catheterization

The passage of a catheter through the right heart allows the level and degree of the stenosis to be established by measuring the systolic pressure gradient.

Treatment

Treatment of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

PULMONARY REGURGITATION

This is the most common acquired lesion of the pulmonary valve. It results from dilatation of the pulmonary valve ring, which occurs with pulmonary hypertension. It is characterized by a decrescendo diastolic murmur, beginning with the pulmonary component of the second sound, that is difficult to distinguish from the murmur of aortic regurgitation. Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

PROSTHETIC VALVES

There is no ideal replacement for our own normally functioning, native heart valves. There are two alternatives for valve prostheses: mechanical or tissue (bioprosthetic) (Fig. 13.85). The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial concluders: a ball and cage (Starr-Edwards), tilting disc (Bjork-Shiley) or double tilting disc (St Jude). Tissue prostheses are derived from human (homograft), or from porcine or bovine (xenograft) origin. A valve replacement from within the same patient (i.e. pulmonary to aortic valve position) is termed an autograft.

Mechanical vs tissue valves

Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. Tissue valves only require anticoagulation for a limited post-operative period whilst the suture lines endothelialize; it can then be discontinued unless another risk factor for thromboembolism (e.g. atrial fibrillation) persists. The potential lifetime of the prosthetic valve and the patient's tolerance of long-term anticoagulation can inform the choice of valve to be implanted. On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder and both opening and closing sounds can be heard.

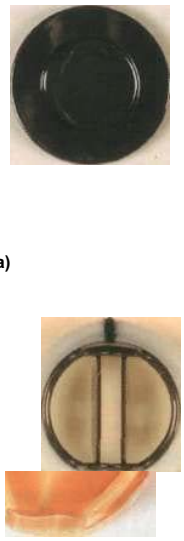

Fig. 13.85 Prosthetic valves, (a) Bjork-Shiley mechanical prosthetic valve.
(b) St Jude double tilting disc.
(c) Aortic valve tissue prosthesis (aortic view).

Complications

All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality; prevention is the cornerstone of management. Patient education about antibiotic prophylaxis is vital and this should be reinforced at clinic visits. Any procedure which results in a breach of the body's innate defences (i.e. dental treatment, catheter insertion) increases the risk of exposing the prosthesis to a bacteraemia. This must be borne in mind when managing a patient with a prosthetic heart valve and steps taken to minimize the risk involved. The prosthetic valve occluding mechanism can be interrupted by vegetations, but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthesis can become detached from the valve ring resulting in a para-prosthetic leak. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. Transthoracic echocardiography is non-invasive, but

scattering of echoes by mechanical valves makes their assessment difficult. Transoesophageal echocardiography provides alternative views and higher image resolution, making it the investigation of choice when prosthetic valve endocarditis is suspected.

INFECTIVE ENDOCARDITIS

Infective endocarditis is an infection of the endocardial surface of the heart. The disease may occur as an acute, fulminating infection, but more commonly runs an insidious course and is known as subacute bacterial endocarditis (SBE.) The term 'infective endocarditis' is preferred because not all the infecting organisms are bacteria, and fungi can be responsible. The annual incidence in the UK is 6-7 per 100 000, but it is more common in developing countries. Without treatment the mortality approaches 100% and even with treatment there is a significant morbidity and mortality.

Aetiology

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream and abnormal cardiac endothelium facilitating their adherence and growth.

Factors causing a bacteraemia

Anything that results in a breach of the body's innate defences can potentially cause a bacteraemia. In some cases the cause of the bacteraemia is unknown; more often; there is an obvious factor that facilitated the entry of organisms into the bloodstream. This may be patient orientated: poor dental hygiene, intravenous drug use, soft tissue infections; or iatrogenic: dental treatment, intravascular cannulae (especially central), cardiac surgery, or permanent pacemakers.

Local cardiac factors

Damaged vascular endothelium will promote platelet and fibrin deposition. It is these small thrombi that allow organisms to adhere and grow. As they grow, more fibrin and platelets are deposited, forming the characteristic infected vegetation. Abnormal vascular endothelium can be the result of valvular lesions, which create areas of non-laminar blood flow, or jet lesions resulting from ventricular septal defects or a patent ductus arteriosus. Infective endocarditis is less likely to develop where the haemodynamic disturbance is minimal (i.e. low-pressure systems). Hence it is more common in ventricular septal defects than atrial septal defects, and rare in mitral valve prolapse without significant regurgitation. Aortic and mitral valves are the commonest valves to be affected. Right-sided endocarditis is typically related to intravenous drug use, although the exact pathological mechanisms that underlie this association are not fully known. It may be that damage to right-sided valves results from the injected particulate matter used to cut the drugs. Instrumentation of the right heart (central venous catheter and temporary pacemaker insertion) is also a common cause of right-sided endocarditis.

Virulent pathogens such as *Staphylococcus aureus* and *Streptococcus pneumoniae* may adhere and multiply on previously normal valves.

Organisms responsible

Common organisms and the sources of infections are shown in Figure 13.86. ,

Rare causes

These include the HACEK group of organisms *(Haemophilus* species *(H. parainfluenzae, H. aphrophilus,* and *H. paraphrophilus,* though not *H. influenzae), Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae)* and tend towards a more insidious course.

Culture-negative endocarditis

This accounts for 5-10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history taking is vital) but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include *Coxiella bumetii* (the cause of Q fever), *Chlamydia* spp., *Bartonella* spp. (organisms that cause trench fever and cat scratch disease) and *Legionella*.

Clinical presentation

Patients can present with an acute illness and the classic features of a new or changing heart murmur and a fever. However, they may present with a subacute insidious illness. A high index of suspicion for the possibility of endocarditis is therefore required; otherwise the diagnosis can easily be delayed with potentially catastrophic consequences.

Clinical signs tend to arise from the following pathological processes: systemic features of infection; cardiac lesions; embolization, and immune complex deposition (Table 13.38).

Distal embolization may result in infarction of the distal organ, and/ or spread of infection. The signs and symptoms will depend on the organ involved. For example, cerebral abscess can present with seizures, loss of consciousness or focal neurological signs. Clubbing occurs in 10% (p. 884).

Diagnostic criteria

Criteria for the diagnosis of infective endocarditis have been established. They have subsequently been refined

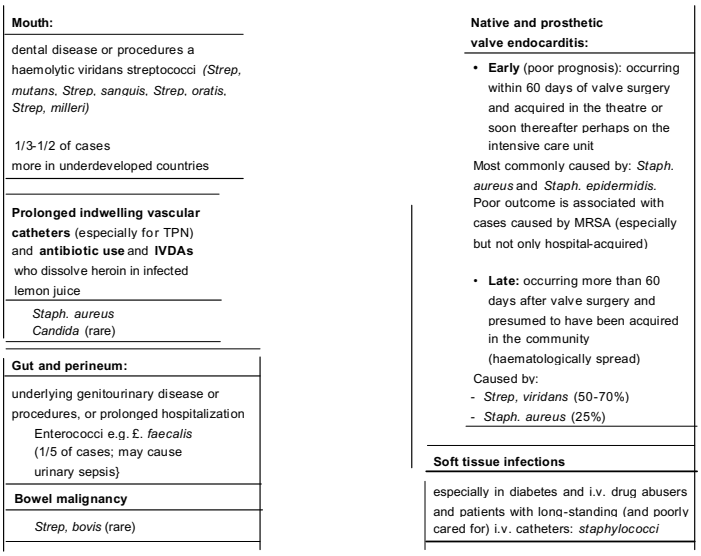

Fig. 13.86 **Aetiology and sources of infection in infective endocarditis.**

and are now commonly known as the Duke criteria (Box 13.1).

Investigations

The purpose of these investigations is threefold: *first* to confirm the diagnosis of infective endocarditis; *second,* to identify the causative organism to ensure appropriate therapy; *third,* to monitor the patient's response to therapy.

Microbiology

Blood cultures are the *key diagnostic investigation* in infective endocarditis. At least three sets of samples (i.e. six bottles) should be taken and there should be liaison with the microbiology department. The yield of any test is increased by the amount of information about the subject given. Serological tests can be sent when the diagnosis is suspected and the blood cultures are negative. They aid diagnosis in cases where the organisms will not grow in standard blood cultures (i.e. *Coxiella, Bartonella, Legionella* and *Chlamydia).*

Table 13.38 **Clinical features of infective endocarditis**

	Approximate %
General	
Malaise	95
Clubbing	10
Cardiac	
Murmurs	90
Cardiac failure	50
Arthralgia	25
Pyrexia	90
Skin lesions	
Osier's nodes	15
Splinter haemorrhages	10
Janeway lesions	5
Petechiae	50
Eyes	
Roth spots	5
Conjunctival splinter haemorrhages	Rare
Splenomegaly	40
Neurological	
Cerebral emboli	20
Mycotic aneurysm	10
Renal	
Haematuria	70

Other laboratory tests

These are useful to confirm sepsis and monitor response to therapy, though they are non-specific.

- **Full blood count.** A normochromic normocytic anaemia and polymorphonuclear leucocytosis are com mon. Thrombocytopenia or thrombocytosis can occur.
- **Urea and electrolytes.** Renal dysfunction is a complication of sepsis. Electrolyte disturbance should be identified and corrected primarily in any patient prone to arrhythmias.
- **Liver biochemistry** is often mildly deranged with, in particular, an increased serum alkaline phosphatase.
- **Inflammatory markers.** C-reactive protein and erythrocyte sedimentation rate are non-specific markers of inflammation and are increased in any infection. CRP tends to respond more acutely than ESR.
- **Immunoglobulins and complement.** Serum immunoglobulins are increased, but total complement and C3 complement are decreased owing to immune complex formation. Circulating immune complexes are present in more than 70% of cases, but are not routinely measured.
- **Urine.** Proteinuria may occur and microscopic haematuria is nearly always present.
- **Polymerase chain reaction (PCR)** is used to recover specific DNA or RNA from blood, urine, or surgically excised tissue. It has specific application when the

Box 13.1 **Duke criteria for the diagnosis of infective endocarditis (IE)**

A diagnosis of IE can be made if two major criteria, one major and three minor, or five minor criteria are present.

Major criteria

Positive blood culture for infective endocarditis

Expected microorganisms for infective endocarditis from two separate blood cultures - viridans streptococci,* HACEK* groups, Streptococcus bovis, or community-acquired Staphylococcus aureus or enterococci, without known primary focus, or

M Persistently positive blood culture, defined as growth and identification of a microorganism consistent with IE originating from:

- blood cultures that are obtained more than 12 hours apart, or
- 3/3 or 3/4 or more separate blood cultures, with the first and last blood cultures obtained at least 60 minutes apart

Evidence of endocardial involvement supporting the diagnosis of IE

« Echocardiogram findings

(a) Oscillating intracardiac mass present:

- on valve or supporting structures, or
- in the path of regurgitant bloodstream flow, or
- on implanted material, in the absence of an alternative anatomical explanation, or

(b) Abscess, or

(c) Newly identified partial dehiscence of prosthetic valve, or

81 New valvular regurgitation (increase or change in pre-existing murmur does not count as a criterion)

Minor criteria

Fever: = or > 38°C (100.4°F)

m Predisposition to IE: heart condition predisposing to IE, or intravenous drug abuse (IVDA) **a** Echocardiogram: findings may be consistent with IE, but major criteria as stated above are not met *m* Immunological phenomena present: Roth spots, Osier's nodes, glomerulonephritis, rheumatoid factor via laboratory analysis

Microbiological evidence of IE: blood cultures are positive but major criteria are not met as previously described,* or serological studies support an infection that is consistent with the diagnosis of IE

Vascular phenomena present: major arterial emboli, mycotic aneurysm, septic pulmonary infarcts, conjunctival haemorrhages, intracranial haemorrhage, Janeway lesions

* Including nutritional variant strains

[f] HACEK, *Haemophilus aphrophilus, Haemophilus paraphrophilus, Haemophilus parainfluenzae, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella*

* Excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis

potential pathogen is slow growing or non-culturable by conventional methods and when phenotypic characterization is essential after two or more organisms are isolated in separate cultures. The latter happens most commonly after contamination with skin commensals during sampling or in case of polymicrobial infection in injecting drug users.

PCR and other novel diagnostic techniques, such as specific fluorescent labelled antibody staining and electron microscopy, should be considered in all cases where cultures have tested negative for infective endocarditis.

Electrocardiogram

This may show evidence of myocardial infarction (emboli) or conduction defects. New atrioventricular block is suggestive of abscess formation. Patients with suspected infective endocarditis therefore should have an ECG on presentation and repeated regularly during their admission depending on their clinical course.

Chest X-ray

This may show evidence of heart failure or, in right-sided endocarditis, multiple pulmonary emboli and/or abscesses. The combination of sepsis and pulmonary infiltrates on chest X-ray should alert the clinician to the possibility of right-sided endocarditis.

Echocardiography

Transthoracic echocardiography (TTE) is rapid, non-invasive and has high specificity for visualizing vegetations (Fig. 13.87) although sensitivity is 60-75%. It is also useful in documenting valvular dysfunction and other local complications, such as aortic root abscesses.

Transoesophageal echocardiography (TOE) has a higher sensitivity and specificity for abscess formation because of the close physical proximity of the transducer to the aortic root. TOE also enhances the visualization of prosthetic valves and is recommended for all cases of suspected prosthetic valve endocarditis.

Echocardiography is an extremely useful tool if used appropriately. A negative echocardiogram does not exclude a diagnosis of endocarditis and it is not an appropriate screening test for patients with a fever or an isolated positive blood culture, where there is a low pre-test probability of endocarditis. However, echocardio-

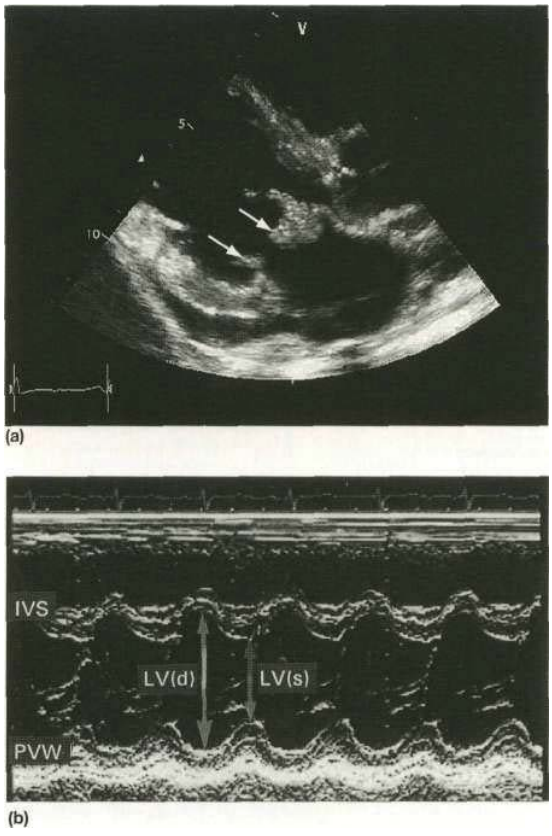

Fig. 13.87 **(a) Two-dimensional echocardiogram (long-axis view) showing vegetations** (arrowed) attached to both the anterior and posterior leaflets of the mitral valve in a patient with infective endocarditis, **(b) M-mode echocardiogram of the left ventricle** demonstrating hyperdynamic contraction associated with volume overloading from severe mitral regurgitation in a patient with endocarditis. IVS, interventricular septum; LV(d) and LV(s), diastolic and systolic left ventricular dimensions; PVW, posterior ventricular wall.

graphy is indicated for all patients suspected of having infective endocarditis.

Principles of therapy

Therapy of endocarditis is difficult because organisms reside within a protected site within the vegetation. High concentrations of intravenous antibiotic are required for prolonged periods to achieve successful treatment. Where possible, synergistic combinations of antibiotics are used, in order to maximize the microbiocidal effect. Given that infective endocarditis carries a substantial morbidity and mortality, a rapid diagnosis and initiation of appropriate antimicrobial therapy is essential. This is best achieved by a multidisciplinary approach consisting of clinicians, cardiologists, cardiothoracic surgeons and microbiologists.

Drug therapy

Empirical antibiotic treatment is started only after cultures are taken. The regimen is then adjusted according to culture results. The only exception to this is in those patients who have recently received antibiotics. A delay of 48-72 hours to await culture results prevents further antibiotics confounding the picture and increases the likelihood of identifying the causative organism. This delay is only possible in haemodynamically stable patients. The treatment should continue for 4-6 weeks, although studies of 2-week, short-course therapy have shown that it is highly effective in uncomplicated penicillin-sensitive *Strep. viridans* endocarditis. Typical therapeutic regimens are shown in Table 13.39. The UK guidelines devised by the working party on endocarditis are available from the British Society for Antimicrobial Chemotherapy (BSAC).

Serum levels of gentamicin and vancomycin need to be monitored. In patients with penicillin allergy one of the glycopeptide antibiotics, vancomycin or teicoplanin, can be used. Penicillins, however, are fundamental to the therapy of bacterial endocarditis; allergies therefore seriously compromise the choice of antibiotics. It is essential to confirm the nature of a patient's allergy to ensure that the appropriate treatment is not withheld needlessly. Anaphylaxis would be much more influential in antibiotic choice than a simple gastrointestinal disturbance.

Persistent fever

Most patients with infective endocarditis should respond within 48 hours of initiation of appropriate antibiotic therapy. This is evidenced by a resolution of fever, reduction in serum markers of infection (CRP tends to be the most sensitive) and relief of systemic symptoms of infection. Failure of this to occur needs to be taken very seriously. The following should be considered:

- perivalvular extension of infection and possible abscess formation
- drug reaction (the fever should promptly resolve after drug withdrawal)
- nosocomial infection (i.e. venous access site, UTI)
- pulmonary embolism (as a consequence of right-sided endocarditis or prolonged hospitalization).

In such cases, samples for culture should be taken from all possible sites and evidence sought for the above causes. Changing antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is suspected. Emergence of bacterial resistance is uncommon. Close liaison with microbiology is recommended and a cardiothoracic surgical opinion should be sought.

Surgery

Surgical intervention should be considered in the following cases:

- extensive damage to a valve
- prosthetic valve endocarditis (valve replacement is usually required)
- persistent infection despite therapy
- large vegetations
- serious embolization

Table 13.39 **Antibiotics in endocarditis (adapted from BSAC guidelines)**

Clinical situation	Suggested antibiotic regimen to start (all given i.v.)
Clinical endocarditis, culture results awaited, no suspicion of staphylococci Suspected staphylococcal endocarditis (IVDA, recent intravascular devices or cardiac surgery, acute infection)	Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly Vancomycin 1 g 12-hourly, gentamicin 80-120 mg 8-hourly
Streptococcal endocarditis (penicillin sensitive) Enterococcal endocarditis (no high-level gentamicin resistance) Staphylococcal endocarditis	Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly Ampicillin/amoxicillin 2 g 4-hourly, gentamicin 80 mg 12-hourly Vancomycin 1 g 12-hourly, OR Flucloxacillin 2 g 4-hourly, OR Benzylpenicillin 1.2 g 4-hourly, PLUS gentamicin 80-120 mg 8-hourly

Note:
1. Monitor vancomycin and gentamicin levels, and adjust if necessary
2. Choice of antibiotic for staphylococci depends on sensitivities
3. Optimum choice of therapy needs close liaison with Microbiology/Infectious Diseases

All antibiotics given i.v.
IVDA, intravenous drug abuse; BSAC, British Society for Antimicrobial Chemotherapy

- myocardial abscess
- fungal endocarditis (this is usually refractory to antimicrobial therapy)
- progressive cardiac failure.

Early liaison with a cardiothoracic surgeon is essential. It is desirable to eradicate active infection before any surgical intervention, but if antibiotic therapy is failing, with progressive cardiac failure, uncontrolled sepsis or severe emboli, it will not be possible to wait. In general, early surgery is preferable.

Antibiotic prophylaxis (see Table 2.9)

Where rheumatic fever is still common, control and prevention will prevent rheumatic heart disease and thus associated endocarditis. In developed countries the focus is on antibiotic prophylaxis. People with valvular lesions who are at moderate to high risk of developing endocarditis are recommended to receive antibiotic therapy before undergoing a procedure likely to result in a bacteraemia, such as dental treatment, endoscopy or surgical instrumentation. There are no randomized placebo-controlled trials to assess the efficacy of such antibiotic prophylaxis, and hence its value has been questioned. It is argued that with uncertain benefits, there is a greater risk of an anaphylactic reaction from widespread penicillin use. Meticulous oral and skin hygiene is probably also significant in preventing endocarditis. Many cases of hospital-acquired endocarditis can be prevented by better care during insertion and handling of intravascular catheters, and prompt removal if they become infected. However, there is enough evidence to recommend the selected use of antibiotic prophylaxis, e.g. with prosthetic valves in those patients who are at a significantly increased risk of developing endocarditis whilst undergoing certain procedures known to cause a bacteraemia.

CONGENITAL HEART DISEASE

A congenital cardiac malformation occurs in about 1 % of live births. There is an overall male predominance, although some individual lesions (e.g. atrial septal defect and persistent ductus arteriosus) occur more commonly in females. As a result of improved medical and surgical management, more children with congenital cardiac disease are surviving into adolescence and adulthood. Thus there is a need for an increased awareness amongst general physicians and cardiologists of the problems posed by these individuals.

Aetiology

The aetiology of congenital cardiac disease is often unknown, but recognized associations include:

- maternal prenatal rubella infection (persistent ductus arteriosus, and pulmonary valvular and arterial stenosis)
- maternal alcohol abuse (septal defects)
- maternal drug treatment and radiation
- genetic abnormalities (e.g. the familial form of atrial septal defect and congenital heart block)
- chromosomal abnormalities (e.g. septal defects and mitral and tricuspid valve defects are associated with Down's syndrome (trisomy 21) or coarctation of the aorta in Turner's syndrome (45, XO)).

Table 13.40 Classification of congenital heart disease

Without shunts	**Without shunts**
Coarctation of the aorta Congenital aortic stenosis	Severe pulmonary stenosis Tricuspid atresia Pulmonary atresia Hypoplastic left heart

Classification (see Table 13.40)

Symptoms and signs

Congenital heart disease should be recognized as early as possible, as the response is usually better the earlier treatment is initiated. Some symptoms, signs and clinical problems are common in congenital heart disease:

- *Central cyanosis* occurs because of right-to-left shunting of blood or because of complete mixing of systemic and pulmonary blood flow. In the latter case, e.g. Fallot's tetralogy, the abnormality is described as cyanotic congenital heart disease.
- *Pulmonary hypertension* results from large left-to-right shunts. The persistently raised pulmonary flow leads to the development of increased pulmonary artery vascular resistance and consequent pulmonary hypertension. This is known as the Eisenmenger reaction (or the Eisenmenger complex when due specifically to a ventricular septal defect). The development of pulmonary hypertension significantly worsens the prognosis.
- *Clubbing of the fingers* occurs in congenital cardiac conditions associated with prolonged cyanosis.
- *Paradoxical embolism* of thrombus from the systemic veins to the systemic arterial system may occur when a communication exists between the right and left heart. There is therefore an increased risk of cerebrovascular accidents and also abscesses (as with endocarditis).
- *Polycythaemia* can develop secondary to chronic hypoxaemia, leading to a hyperviscosify syndrome and an increased thrombotic risk, e.g. strokes.
- *Growth retardation* is common in children with cyanotic heart disease.
- *Syncope* is common when severe right or left ventricular outflow tract obstruction is present. Exertional syncope, associated with deepening central cyanosis, may occur in Fallot's tetralogy. Exercise increases resistance to pulmonary blood flow but reduces systemic vascular resistance. Thus, the right-to-left shunt increases and cerebral oxygenation falls.
- *Squatting* is the posture adopted by children with Fallot's tetralogy. It results in obstruction of venous return of desaturated blood and an increase in the peripheral systemic vascular resistance. This leads to a reduced right-to-left shunt and improved cerebral oxygenation.

Presentation

Adolescents and adults with congenital heart disease present with specific common problems related to the long-standing structural nature of these conditions and any surgical treatment:

- endocarditis (particularly in association with otherwise innocuous lesions such as small VSDs or bicuspid aortic valve that can give up to 10% lifetime risk)
- progression of valvular lesions (calcification and stenosis of congenitally deformed valves, e.g. bicuspid aortic valve)
- atrial and ventricular arrhythmias (often quite resistant to treatment)
- sudden cardiac death
- right heart failure (especially when surgical palliation results in the right ventricle providing the systemic supply)
- end-stage heart failure (rarely managed by heart or heart-lung transplantation).

Genetic counselling

These conditions necessitate active follow-up of adult patients. Pregnancy is normally safe except if pulmonary hypertension or vascular disease is present when the prognosis for both mother and fetus is poor.

Table 13.41 lists the most common congenital lesions and their occurrence in first-degree relatives.

Genetic factors should be considered in all patients presenting with congenital heart disease. For example, parents with a child suffering from Fallot's tetralogy stand a 4% chance of conceiving another child with the disease, and so fetal ultrasound screening of the mother during pregnancy is essential. Parents with congenital heart disease are also more likely to have affected offspring. Fathers have a 2% risk while mothers have a higher risk (around 5%). Individual families can exhibit even higher risks of recurrence.

Table 13.41 Common congenital lesions

	Percentage of congenital lesions	Occurrence in first-degree relatives (%)
Ventricular septal	39	4
Atrial septal defect	10	2
Persistent ductus arteriosus	10	4
Pulmonary stenosis	7	
Coarctation of the aorta	7	2
Aortic stenosis	6	4
Fallot's tetralogy	6	4
Others	15	

Ventricular septal defect (VSD)

VSD is the most common congenital cardiac malformation (1 in 500 live births). It may occur as an isolated abnormality or in association with other anomalies. Left ventricular pressure is higher than right ventricular pressure; blood therefore moves from left to right and pulmonary blood flow increases. When pulmonary blood flow is very large, progressive obliteration of the pulmonary vasculature eventually causes the pulmonary arterial pressure to equal the systemic pressure (Eisenmenger complex). Consequently, the shunt is reduced or reversed (becoming right-to-left) and central cyanosis may develop.

Clinical features (Fig. 13.88)

Small VSDs ('maladie de Roger') are asymptomatic and usually close spontaneously, with 90% no longer patent by 10 years of age. Unfortunately there is a future risk of the development of aortic regurgitation or endocarditis even after spontaneous closure. A *moderate VSD* produces fatigue and dyspnoea with cardiac enlargement and a prominent apex beat. There is often a palpable systolic thrill at the lower left sternal edge. A loud 'tearing' pansystolic murmur is heard at the same position. A *large VSD* eventually causes pulmonary hypertension.

Investigations

A small VSD produces no abnormal X-ray or ECG findings.

Chest X-ray shows a prominent pulmonary artery owing to increased pulmonary blood flow in larger defects. In Eisenmenger's complex the radiological signs of pulmonary hypertension (i.e. 'pruned' pulmonary arteries) can be seen. Cardiomegaly occurs when a moderate or a large VSD is present. ECG shows features of both left and right ventricular hypertrophy.

2-D echocardiography and CW Doppler (Fig. 13.89) can assess the size and location of the VSD, and its haemodynamic consequences

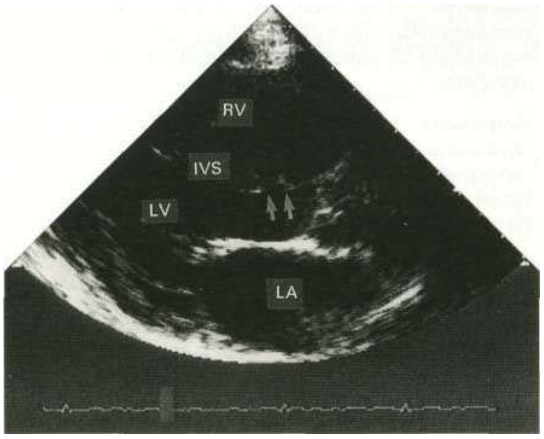

Fig. 13.89 Two-dimensional echocardiogram (long-axis view) showing a ventricular septal defect (arrowed). Colour Doppler would provide graphic demonstration of the left-to-right shunt. RV, right ventricle; IVS, interventricular septum; LV, left ventricle; LA, left atrium.

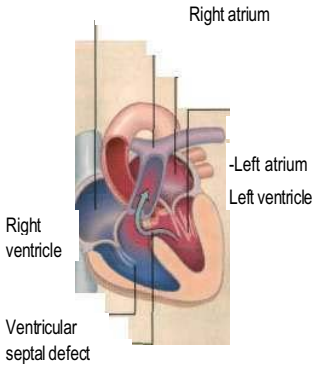
Treatment

Moderate and large VSDs should be surgically repaired before the development of severe pulmonary hyper tension. Infective endocarditis prophylaxis (p. 31) should be advised in all cases.

Atrial septal defect (ASD)

Clinical features

This condition is often first diagnosed in adults and represents one-third of all adult congenital heart disease. It is two to three times more common in women than in men. There are two main types of ASD, *ostium secundum* and *ostium primum*. The common form is the ostium secundum defect, which involves the fossa ovalis in the atrial mid-septum. This should not be confused with the



Heart sounds and murmurs

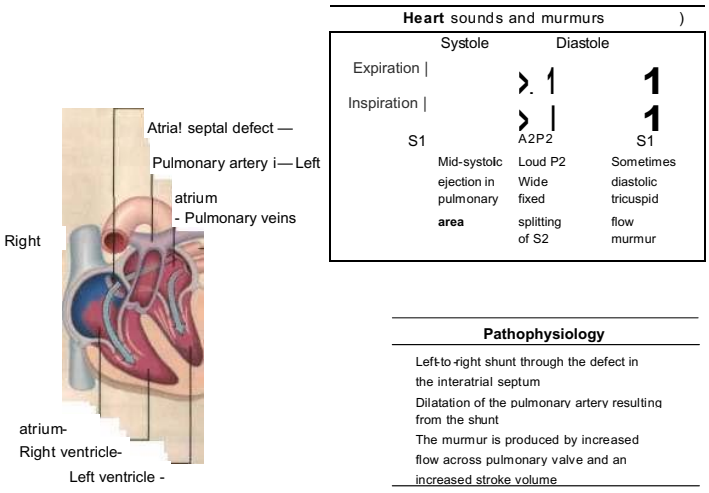

Fig. 13.90 Atrial septal defect: Pathophysiology and auscultatory findings.

patent foramen ovale (PFO) which is a normal variant and not a true septal defect. PFO is usually asymptomatic but is associated with paradoxical emboli and an increased incidence of embolic stroke. Communication at the level of the atria allows left-to-right shunting of blood. Because the pulmonary vascular resistance is low and the right ventricle is easily distended (i.e. it is compliant), there is a considerable increase in right heart output. Above the age of 30 years there may be an increase in pulmonary vascular resistance, which gives rise to *pulmonary hypertension.* Atrial arrhythmias, particularly *atrial fibrillation,* are common at this stage.

Most children with ASD are asymptomatic, although they are prone to *pulmonary infection.* Some complain of *dyspnoea* and *weakness.* Palpitations due to atrial arrhythmias are not uncommon. Right heart failure and atrial fibrillation may develop to become the initial presentation in adult life.

The physical signs of ASD reflect the volume overloading of the right ventricle (Fig. 13.90). A right ventricular heave can usually be felt.

Investigations

- **Chest X-ray** reveals a prominent pulmonary artery and pulmonary plethora. There may be noticeable right ventricular enlargement.
- **ECG** usually shows some degree of right bundle branch block (because of dilatation of the right ventricle) and right axis deviation. Sometimes the ASD is part of a major developmental abnormality involving the ventricular septum and the mitral and tricuspid valves. In this case there is left axis deviation on the ECG.
- **Echocardiogram** is usually abnormal if a significant defect is present. Indirect evidence includes right ventricular hypertrophy and pulmonary arterial dilatation, and abnormal motion of the interventricular septum. Subcostal views may demonstrate the ASD (Fig. 13.91). Flow disturbance can be assessed by colour Doppler.

Treatment

A significant ASD (i.e. a pulmonary flow that is more than 50% increased when compared with systemic flow) should be repaired before the age of 10 years or as soon as possible if first diagnosed in adulthood. There is a dilemma with regard to whether less severe shunts should be closed when diagnosed in adulthood. Anecdotal evidence suggests that the shunt might be progressive and that low-risk closure would be appropriate.

There is a good result from surgery unless pulmonary hypertension has developed. Angiographic closure is

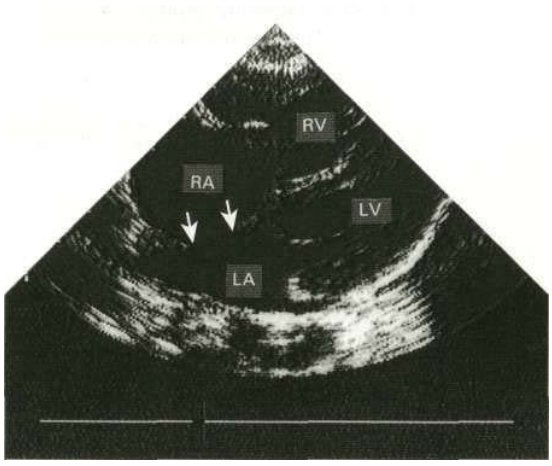

Fig. U.ifl **Ostium secundum atrial septal defect** (arrowed) in a young girl, shown by a two-dimensional echocardiogram subcostal four-chamber view (similar to Fig. 13.89, but rotated clockwise). Colour Doppler can demonstrate the left-to-right shunt. LA, left atrium; RA, right atrium; LV, left ventricle; RV, right ventricle.

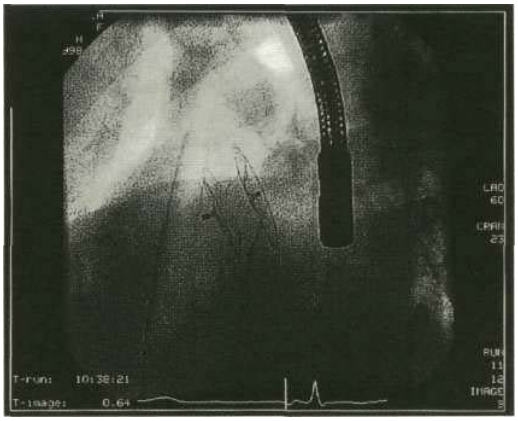

Fig. 13.92 The angiographic appearance of a fully deployed ASD closure device. The device bridges the ASD and wedges against the surfaces of the right and left atrial septa, occluding flow. The metal object in frame is the distal end of a transoesophageal echocardiography probe. Courtesy of Dr D Ward.

now possible with significantly lower risk using a transcatheter clamshell device (Fig. 13.92). A PFO discovered in a patient with an otherwise unexplained thrombotic stroke is now closed in this way to prevent paradoxical thromboembolism. In high-risk groups, for example deep-sea divers, such closures may be undertaken even though the patients are asymptomatic. Uncorrected ASDs do not usually require antibiotic prophylaxis for endocarditis. If there is an accompanying valvular lesion, however, prophylaxis is indicated.

Patent ductus arteriosus (PDA)

The ductus arteriosus connects the pulmonary artery at its bifurcation to the descending aorta immediately distal to the subclavian artery. In fetal life the ductus diverts blood away from the unexpanded, and hence high-resistance, pulmonary circulation into the systemic circulation, where the blood is reoxygenated as it passes through the placenta. At birth, the high oxygen in the lungs and the reduced pulmonary vascular resistance trigger closure of the duct. If the duct is malformed (i.e. it does not contain sufficient elastic tissue) it will not close. This is more common in females and is sometimes associated with maternal rubella. Premature babies are often born with persistent ducts that are anatomically normal but are immature in that they lack the mechanism to close. Other associations include continual prenatal hypoxaemia and high-altitude environments.

Because aortic pressure exceeds pulmonary artery pressure throughout the cardiac cycle, a persistent duct produces continuous aorta-to-pulmonary artery shunting. This leads to an increased pulmonary venous return to the left heart and an increased left ventricular volume load. If the shunt is large, this results in severe left heart failure and pulmonary hypertension. One-third of individuals with an unrepaired ductus die from heart failure, pulmonary hypertension or endocarditis by the age of 40; two-thirds by the age of 60.

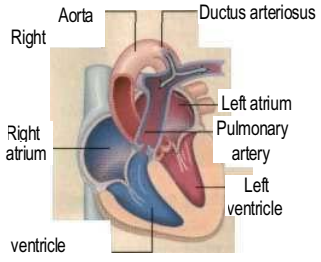
Clinical features

There are often no symptoms until later in life when heart failure or infective endocarditis develops.

The characteristic physical sign is a continuous 'machinery' murmur (Fig. 13.93). The peripheral pulse is large in volume ('bounding') because of the increased left heart blood flow and the decompression of the aorta into the pulmonary artery.

Investigations

The aorta and pulmonary arterial system are usually prominent on X-ray, although a small ductus shows no abnormality. There is both a left atrial abnormality and left ventricular hypertrophy on the ECG. With the



Systole

Heart sounds and murmurs

Diastole

S1 S2

Continuous 'machinery' murmur best heard below the left clavicle in the first interspace or over the first rib. A thrill can often be felt

Pathophysiology

Left-to-right shunt

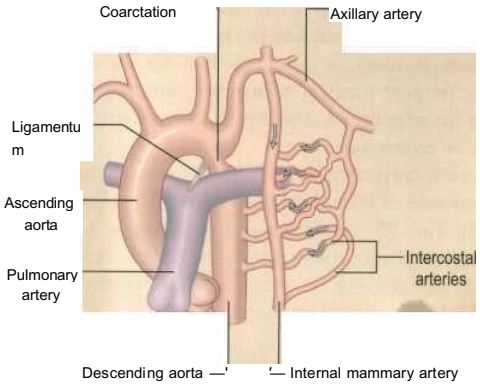
Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery

Murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole

Dilatation of the pulmonary artery, left atrium and left ventricle

As pulmonary hypertension (Eisenmenger's reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear causing central cyanosis

Fig. 13.93 Patent ductus arteriosus: Pathophysiology and auscultatory findings.



Heart sounds and murmurs

Pathophysiology	
Coarctation causes severe obstruction of blood flow in the descending thoracic aorta. The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries	

Fig. 13.94 **Coarctation of the aorta:** Pathophysiology and auscultatory findings.

development of Eisenmenger's reaction, right ventricular hypertrophy may be seen. The echocardiogram shows a dilated left atrium and left ventricle. Right heart changes are apparent in late disease.

Treatment

Premature infants with a persistent duct are treated medically with indometacin, which inhibits prostaglandin production and stimulates duct closure. In other cases the duct can be ligated surgically or angiographically with very little risk. Surgery should be performed as soon as possible and not later than the age of 5 years. Closure is inappropriate if pulmonary hypertension is severe.

Coarctation of aorta

A coarctation of the aorta is a narrowing of the aorta at, or just distal to, the insertion of the ductus arteriosus, i.e. distal to the left subclavian artery (Fig. 13.94). Rarely it can occur proximal to the left subclavian. It occurs twice as commonly in men as in women. It is also associated with Turner's syndrome (p. 1064). In 80% of cases the aortic valve is bicuspid (and potentially stenotic or endocarditic). Other associations include patent ductus arteriosus, ventricular septal defect, mitral stenosis or regurgitation and circle of Willis aneurysms.

Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the periscapular and intercostal arteries. Decreased renal perfusion can lead to the development of systemic hypertension that persists even after surgical correction.

Clinical features

Coarctation of the aorta is often asymptomatic for many years. *Headaches* and *nosebleeds* (due to hypertension) and *daudication* and cold legs (due to poor blood flow in the lower limbs) may be present.

Physical examination reveals hypertension in the upper limbs, and weak, delayed (radiofemoral delay) pulses in the legs.

For heart sounds and murmurs in coarctation of aorta, see Figure 13.94.

Investigations

Chest X-ray may reveal a dilated aorta indented at the site of the coarctation. This is manifested by an aorta (seen in the upper right mediastinum) shaped like a 'figure 3'. In adults, tortuous and dilated collateral intercostal arteries may erode the undersurfaces of the ribs ('rib notching') (Fig. 13.95).

ECG demonstrates left ventricular hypertrophy. Echocardiography sometimes shows the coarctation and other associated anomalies. Aortography will show the defect, and digital vascular imaging allows the coarctation

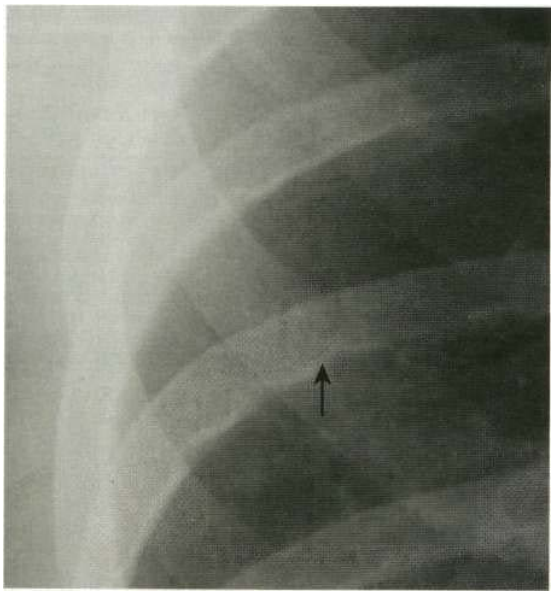

Fig. 13.95 **Chest X-ray close-up of right posterior ribs showing rib-notching** (arrow).

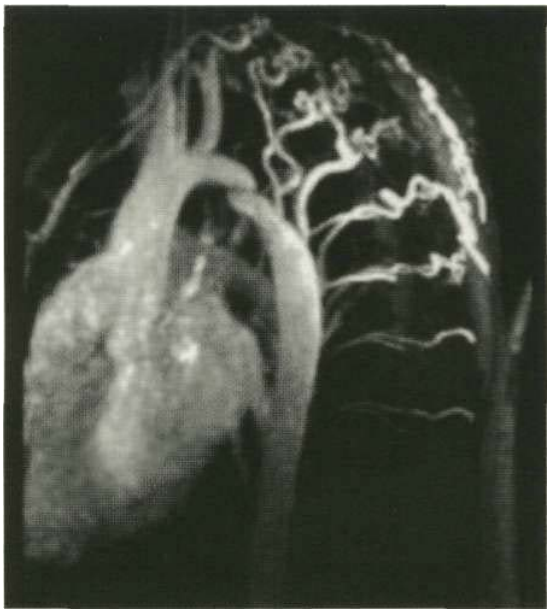

Fig. 13.96 **Magnetic resonance angiography image of severe aortic coarctation in an adult.**

to be visualized after the intravenous injection of contrast. CT and MRI (Fig. 13.96) scanning can accurately demonstrate the coarctation and quantify flow.

Treatment

Treatment is usually indicated if the pressure gradient across the coarctation is greater than 30 mmHg. This involves surgical excision of the coarctation and end-to-end anastomosis of the aorta. If the coarctation is extensive, prosthetic vascular grafts may be needed. When surgery is performed in early childhood, hypertension usually resolves completely. However, when the operation is performed on adolescents or adults the hypertension persists in 70% because of previous renal damage. There is also an increased risk of accelerated atherosclerosis and strokes in these individuals. Balloon dilatation is used in some centres for either primary disease or post-surgical recurrence, although there is a higher incidence of aneurysm formation and post-dilatation recurrence.

Surgical correction in childhood gives a good 25-year survival rate of 83%. If this is delayed until adulthood (20-40), the 25-year survival rate drops to 75%. If coarctation is left uncorrected, however, only 25% of patients are alive at 50, while cardiac failure ensues in two-thirds of surviving patients over 40.

Cyanotic congenital heart disease: Fallot's tetralogy

Most children with cyanotic congenital heart disease do not survive the neonatal period. Fallot's is the most common cyanotic anomaly in those who do survive and is commonest amongst adults. Transposition of the great vessels is more common in the neonatal period but more likely to be fatal. Other cyanotic congenital heart diseases are shown in Table 13.40.

Fallot's tetralogy consists of the four features shown in Figure 13.97.

The level of the right ventricular outflow obstruction may be subvalvular, valvular or supravalvular. The most common obstruction is subvalvular, either alone (50%) or in combination with valvular stenosis (25%).

This combination of lesions leads to a high right ventricular pressure and right-to-left shunting of blood through the VSD. Thus the patient is centrally cyanosed.

Clinical features

Children with this condition may present with *dyspnoea* or *fatigue,* or with hypoxic episodes on exertion (Fallot's spells) - *deep cyanosis* and possible *syncope*. These can

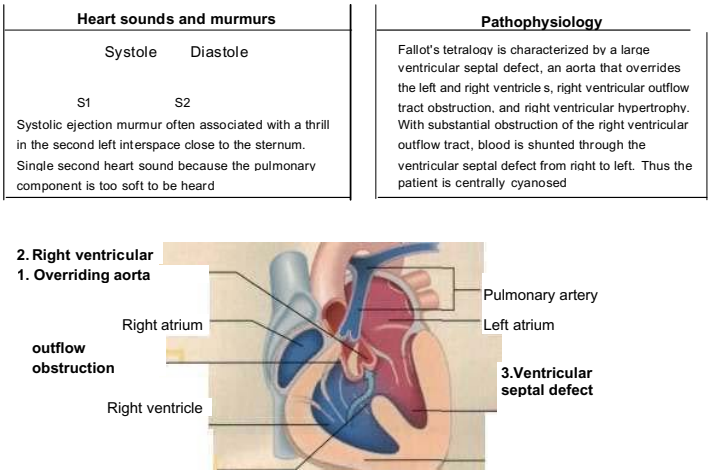

Fig. 13.97 **Fallot's tetralogy:** Pathophysiology and auscultatory findings.

Left ventricle

4. Right ventricular hypertrophy

even result in seizures, cerebrovascular events or sudden death. *Squatting* is common.

Adults tend not to suffer 'spells' but fatigue easily with dyspnoea on exertion. *Erythrocytosis* (polycythaemia) secondary to chronic hypoxaemia commonly results in *thrombotic strokes. Endocarditis* is common.

A parasternal sustained heave is evident. Central cyanosis is commonly present from birth, and *finger clubbing* and *polycythaemia* are obvious after about 12 months. Growth is usually retarded.

Investigations

- **Chest X-ray** shows a large right ventricle and a small pulmonary artery (classically described as 'boot-shaped').
- **ECG** reveals right ventricular hypertrophy, and the echocardiogram demonstrates discontinuity between the aorta and the anterior wall of the ventricular septum.
- **Cardiac catheterization** is performed to evaluate the size and degree of the right ventricular outflow obstruction.

Treatment

Complete surgical correction of this combination of lesions is possible even in infancy. As adults, however, these individuals are at increased risk of right ventricular failure and ventricular arrhythmias due to the trauma from past corrective surgery. Less-damaging procedures are used presently, the long-term results of which are unknown as yet.

Occasionally a palliative procedure - an anastomosis between a subclavian artery and a pulmonary artery (Blalock shunt) - is performed on very young infants or the premature, in order to increase blood supply to the lungs. Without intervention, 66% survive to 1 year, while only 11% survive to 20 years.

Fallot's spells may need treatment with beta-blockade or, when severe, with diamorphine to relax the right ventricular outflow obstruction. Antibiotic prophylaxis for endocarditis is indicated.

MARFAN'S SYNDROME (see also p 1356)

Clinical features

Marfan's syndrome (MFS) is one of the most common autosomal dominant inherited disorders of connective tissue, affecting the heart (aortic aneurysm and dissection, mitral valve prolapse) eye (dislocated lenses, retinal detachment) and skeleton (tall, thin body build with long arms, legs and fingers; scoliosis and pectus deformity) (Fig. 13.98a).

Clinically, two out of three major systems must be affected, to avoid overdiagnosing the condition. Diagnosis may be confirmed by studying family linkage to the causative gene, or by demonstrating a mutation in the Marfan's syndrome gene *(MFS1)* for fibrillin (FBN-1) on chromosome 15q21.

MFS affects approximately 1 in 5000 population worldwide and 25% of patients are affected as a result of a new mutation. This group includes many of the more severely affected patients, with high cardiovascular risk. Other known associations with early death due to aortic aneurysm and dissection are: family history of early cardiac involvement; family history of dissection with an aortic root diameter of < 5 cm; male sex; and extreme physical characteristics, including markedly excessive stature and widespread striae. Histological examination of aortas often shows widespread medial degeneration, described as 'cystic medial necrosis'.

Cardiac investigations

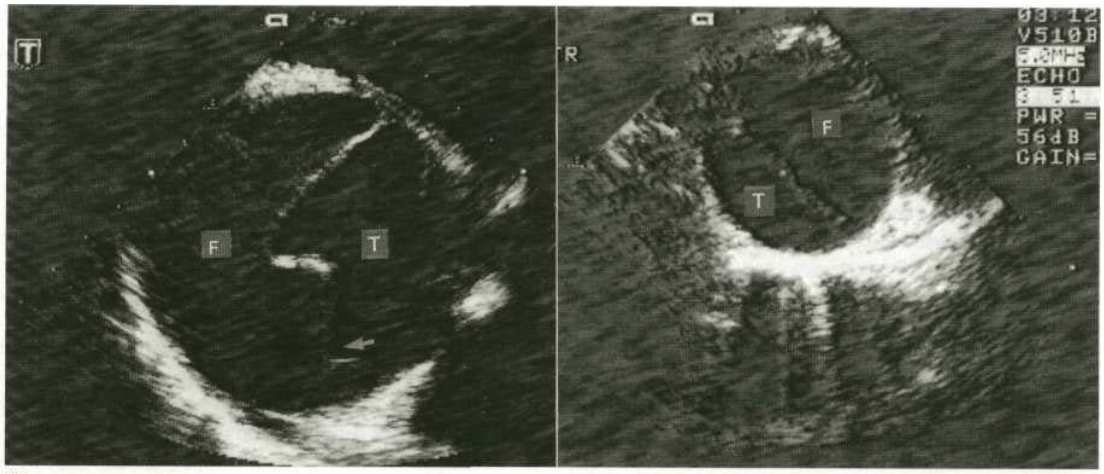
- **Chest X-ray** is often normal but may show signs of aortic aneurysm and unfolding, or of widened mediastinum. Pneumothorax affects 11% and scoliosis is present in 70% of patients.
- **ECG** may be misleadingly normal with an acute dissection. Usually, in conjunction with mitral valve prolapse 40% of patients have arrhythmia, with premature ventricular and atrial arrhythmias.
- **Echocardiography** shows mitral valve prolapse, and mitral regurgitation are seen in the majority of patients. High-quality serial echocardiogram measurements of aortic root diameter in the sinuses of Valsalva, at 90° to the direction of flow are the basis for medical and surgical management (Fig. 13.99b).

Management

Beta-blocker therapy slows the rate of dilatation of the aortic root. Lifestyle alterations, involving sports and career choice, may be indicated, because of ocular, cardiac or skeletal involvement. Sports that necessitate prolonged exertion at maximum cardiac output, such as cross-country running, are to be avoided. Sedentary occupations are usually best, as patients tend to suffer from easy fatiguability and hypermobile painful joints.

The patient should be monitored with yearly echocardiograms up to aortic root diameter 4.5 cm, 6-monthly from 4.5 to 5 cm, and then referred directly to a surgeon who is experienced in aortic root replacement in Marfan's syndrome for elective surgery.

(a)



(b)

Fig. 13.98

Marfan's syndrome, (a) Photograph of 63-year-old man. (b) Two-dimensional transoesophageal echocardiograms from a patient with Marfan's syndrome resulting in dissection of the aorta. From its position in the oesophagus, the transducer can be aimed forward to visualize the greatly enlarged ascending aorta (left), or backwards to show the descending thoracic aorta (right). In both views the dissected intima is seen within the aortic lumen. The main entry point to the false lumen is seen in the ascending aorta (arrowed), just above the aortic valve. T, true lumen; F, false lumen.

Pregnancy is generally well tolerated if no serious cardiac problems are present, but is preferably avoided if the aortic root diameter is over 4 cm, with aortic regurgitation. Echocardiography should be performed every 6-8 weeks throughout pregnancy and during the initial 6 months postpartum. Blood pressure should be regularly monitored and hypertension treated actively. Delivery should be by the least stressful method; ideally a vaginal delivery. Caesarean section should not be routinely performed. However, if the aortic root is over 4.5 cm, delivery at 39 weeks by induction or caesarean section should be considered. Beta-blocker therapy may be safely instituted or continued throughout pregnancy, to help prevent aortic dissection.

Careful medical and surgical management have increased the overall survival rate. On average, 13 years

of life is added, when surgical survival is compared to that reported in the natural history of MFS.

Genetic counselling

The condition is inherited in an autosomal dominant mode, with each child of one affected parent having a 50:50 chance of inheriting the condition. Males and females are equally often affected. In 25% of all cases, the condition arises as the result of a spontaneous mutation in the sperm or ovum of one of the parents. Fibrillin-1 gene mutations can be identified in 80% of those affected, confirming diagnosis and aiding prognosis. The mutation can also be used to screen at-risk family members, including postnatal or prenatal offspring.

PULMONARY HEART DISEASE

Introduction

The normal values for mean pulmonary artery pressure (mPAP), mean capillary wedge pressure (mPCWP) and cardiac output (CO) are 12 ± 2 mmHg, 6 + 2 mmHg and 5 L/min respectively. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The *pulmonary vascular resistance* (PVR) is calculated by the formula:

$$\frac{\text{mPAP - mPCWP}}{\text{CO}}$$

It is normally about 1.5 mmHg/L/min (1.5 Wood units). Approximately 60% of the body's endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the precapillary pulmonary arterioles is thin as compared with their more muscular systemic counterparts that have to respond constantly to postural changes under the influence of gravity. The fact that the lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.

Pulmonary hypertension

Definition

Pulmonary hypertension is defined as an mPAP of greater than 25 mmHg at rest or of greater than 30 mmHg during exercise. It may present spontaneously with no apparent underlying disease association (and is then known as primary pulmonary hypertension, PPH) or it can occur in association with other disease processes as listed in Table 13.42.

Causes of pulmonary hypertension

The most common cause of pulmonary hypertension is chronic obstructive pulmonary disease (COPD). In general, the causes of pulmonary hypertension (Table 13.42) can be subdivided depending on whether their effects on the lung circulation are precapillary, capillary or postcapillary.

Precapillary (i.e. in the pulmonary arteries and arterioles). The most severe elevations in PAP and in PVR occur with these disorders. Examples include *PPH, congenital heart disease with Eisenmenger's reaction* and *multiple pulmonary embolism.* In PPH the PCWP is usually normal.

Capillary disorders causing damage to the alveolar capillary mechanisms also cause pulmonary hyper tension and these usually fall under the umbrella of parenchymal lung diseases, e.g. emphysema and pul monary fibrosis. Pulmonary arterial hypoxaemia is a potent cause of vasoconstriction and hence of pulmonary hypertension. Any diseases which lead to low pul monary artery oxygen levels will give rise to pulmonary hypertension. ... . .

Postcapillary (passive) processes involve disease in structures distal to the pulmonary capillary bed. They

Table 13.42 **Causes of pulmonary hypertension**

Pulmonary vascular disorders
Acute pulmonary thromboembolism (rarely tumour emboli)
Primary pulmonary hypertension Multiple pulmonary artery stenoses Pulmonary veno-occlusive disease Chronic pulmonary thromboembolism
Parasitic infection, e.g. schistosomiasis

Diseases of the lung and parenchyma
COPD
Other chronic lung disorders (Ch. 14)

Musculoskeletal disorders (causing chronic underventilation)
Kyphoscoliosis
Poliomyelitis
Myasthenia gravis

Disturbance of respiratory control
Obstructive sleep apnoea Morbid obesity (Pickwickian syndrome) Cerebrovascular disease

Cardiac disorders
Mitral stenosis Left ventricular failure Left atrial myxoma
Congenital heart disease with Eisenmenger's reaction

Miscellaneous
Appetite-suppressant drugs, e.g. dexfenfluramine Type 1 glycogen storage diseases Lipid storage diseases, e.g. Gaucher's disease Connective tissue diseases, e.g. SLE Hepatic cirrhosis Sickle cell disease

cause pulmonary hypertension through elevated venous pressures. Examples include pulmonary veno-occlusive disease, chronic left ventricular failure and mitral valve disease.

A variety of *miscellaneous conditions* can also cause pulmonary hypertension, and these include a history of appetite suppressant drug ingestion and glycogen and lipid storage diseases.

Progressive elevation in PVR ultimately leads to right ventricular dilatation, right ventricular failure and death. When pulmonary hypertension occurs in association with other conditions such as lung disorders or chronic left ventricular failure the primary underlying cause may have the major influence on mortality and the secondary effects of pulmonary hypertension are additive.

Mechanisms of pulmonary hypertension

These depend on the cause and involve hypoxic vasoconstriction, e.g. COPD, decreased surface area of the pulmonary vascular bed, e.g. lung fibrosis, and increased right ventricular volume/pressure, e.g. congenital heart disease.

Following the rise in pulmonary arterial pressure, damage to the pulmonary endothelium leads to excessive release of endothelium-derived vasoconstrictors such as endothelin (ET, see p. 731) which contribute to an increase in PVR. Increased platelet and leukocyte adhesion, elevated serotonin, plasminogen activator inhibitor-1 (PAI-1) and fibrinopeptide A can produce inappropriate intravascular thrombus. ET, angiotensin II and thromboxane A_2 can act as growth factors, giving rise ultimately to vasoconstriction, cell proliferation, fibrosis and smooth muscle hypertrophy. Such vascular remodelling increases the PVR.

The symptoms, signs and investigations of pulmonary hypertension are discussed on page 842.

Management

Since pulmonary hypertension is a condition caused by a heterogeneous group of diseases, treatment is directed at the primary cause, e.g. chest physiotherapy, good nutrition and early antibiotics to treat infection in patients with cystic fibrosis and bronchiectasis.

Surgical or medical therapies to optimize cardiac and respiratory function, supplemental oxygen and anticoagulation are necessary together with newer specific therapies designed at modulating pulmonary vasomotor tone.

Patients who have symptoms resulting in marked limitation of physical activity or those who are symptomatic at rest have a poor median survival (32 and 6 months respectively). Adverse factors include right ventricular dysfunction and reduced 6-minute walk distance.

Primary pulmonary hypertension

Primary pulmonary hypertension is a condition of unknown cause characterized by clinical, radiological and electrocardiographic evidence of pulmonary hypertension and increased PAP and PVR with normal PCWP. It is estimated that one to two individuals per million per year are diagnosed with PPH compared to five to six individuals per million per year with pulmonary hypertension secondary to connective tissue diseases. There is an unexplained predominance of females (approximately a 3 to 1 ratio) with women mainly presenting in the third decade and men in the fourth. Approximately 6-12% of cases are believed to have a familial origin with inheritance in an autosomal dominant fashion.

Some patients with familial PPH have mutations in the gene encoding bone morphogenic protein receptor 2 (BMPR 2) on chromosome 2q33. This gene encodes TGF-(3, which acts as a growth suppressor and opposes cellular proliferation. Other gene mutations exist.

PPH has also been linked to certain *drugs:* aminorex fumarate, an amfetamine-like appetite suppressant, talc which is often inhaled with cocaine, fenfluramine and phenteramine in combination (a prescription weight-loss drug).

Plexogenic pulmonary arteriopathy, identical to that seen in PPH, has also been described in patients with connective tissue diseases (limited cutaneous scleroderma, p. 577). These may have a rapidly progressive and fatal disease associated with pulmonary hypertension.

Patients with *systemic lupus erythematosus* can also develop pulmonary hypertension secondary to vascular remodelling, with identical histopathological features to patients with PPH. Patients with *hepatic cirrhosis* and *Eisenmenger reaction* also have identical pathology to patients with PPH.

Clinical presentation

Patients with pulmonary hypertension have an insidious onset and indeed often their condition comes to the attention of the physician late in the course of their illness or when symptoms of right ventricular failure develop. Physical examination may reveal findings consistent with pulmonary hypertension and right ventricular overload (Table 13.43). Clinical signs of right ventricular dysfunction may be present.

Chest X-ray may demonstrate enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement. *ECG* may show right ventricular

Table 13.43 Clinical signs of pulmonary hypertension

Large 'a' wave in jugular venous waveform
Right ventricular (parasternal) heave
Pulmonary ejection sound and flow murmur
Loud pulmonary component to second heart sound
Right ventricular fourth heart sound
Right ventricular failure (hepatomegaly, ascites, peripheral oedema)
Prominent V wave in jugular venous waveform
Right ventricular third heart sound Tricuspid and pulmonary regurgitation murmurs

hypertrophy and right atrial enlargement (P pulmonale). *Echocardiography* demonstrates enlarged right ventricular dimensions. *Pulmonary function tests* are usually normal.

The *diagnosis* can be confirmed by CT pulmonary angiography.

The differential diagnoses for PPH are an exclusion of secondary causes as shown in Table 13.42. In particular, mitral stenosis, congenital heart disease with Eisenmenger's reaction, connective **tissue** disease and sickle cell disease should be excluded.

Treatment

Conventional therapy initially consists of warfarin and oxygen followed by oral calcium-channel blockers. A sustained response to this treatment is unlikely (occurring in less than 10% of patients) and advanced treatments include oral endothelin receptor antagonists (bosentan), prostanoid analogues (inhaled illoprost, treprostinil, beraprost) or intravenous epoprostenol.

Prognosis

Several studies have reported a mean survival of 2-3 years from the time of diagnosis. The cause of death is usually right ventricular failure or sudden death. Increased right atrial pressure above 15 mmHg and cardiac index below 2 L/min/m^2 are haemodynamic predictors of poor prognosis. Heart and lung transplantation is used (p. 796).

Chronic cor pulmonale

Cor pulmonale is enlargement of the right ventricle because of increase in afterload that is due to diseases of the thorax, lung and pulmonary circulation; the presence of right ventricular failure is not necessary for the diagnosis of cor pulmonale.

Pathophysiology

The precise mechanism varies according to the cause of cor pulmonale, but chronic obstructive pulmonary disease (COPD), which is discussed here, is illustrative. Pulmonary vascular resistance is increased because of loss of pulmonary vascular tissue and because of pulmonary vasoconstriction caused by hypoxia and acidosis. **The** increased pulmonary vascular resistance leads **to** pulmonary hypertension, which initially occurs only during an acute respiratory infection. Eventually, the pulmonary hypertension becomes persistent and progressively more severe. The pulmonary vascular bed is gradually obliterated by muscular hypertrophy of the arterioles and thrombus formation. Right ventricular function is progressively compromised because of the increased pressure load. Hypoxia further impairs right ventricular function and, as it develops, left ventricular function is also depressed.

Clinical features

Chest pain, exertional dyspnoea, syncope and *fatigue* are common symptoms, and *sudden death* occurs. Other symptoms are due to the cause of the pulmonary hypertension.

On *physical examination* (see Table 13.43), there is a prominent *'a'* wave in the jugular venous pulse, a right ventricular (parasternal) heave, and a loud pulmonary component to the second heart sound. Other findings include a right ventricular fourth heart sound, a systolic pulmonary ejection click, a mid-systolic ejection murmur, and an early diastolic murmur due to pulmonary regurgitation (Graham Steell murmur). If tricuspid regurgitation develops, there is a pansystolic murmur and a large jugular *cv* venous wave (see p. 741).

Investigations

- **Chest X-ray** may show right ventricular enlargement and right atrial dilatation. The pulmonary artery is usually prominent and the enlarged proximal pulmonary arteries taper rapidly. Peripheral lung fields are oligaemic.
- **ECG** demonstrates right ventricular hypertrophy (right axis deviation, possibly a dominant R wave in lead V_1, and inverted T waves in right precordial leads) and a right atrial abnormality (tall peaked P waves in lead II) (Fig. 13.99).
- **Echocardiography** will usually demonstrate right ventricular dilatation and/ or hypertrophy. It is often possible to measure the peak pulmonary artery pressure indirectly with Doppler echocardiography. The echocardiogram may also reveal the cause of pulmonary hypertension, such as an intracardiac shunt.

Other investigations may also be required to evaluate the cause of pulmonary hypertension and to look for treatable conditions, such as left-to-right shunts, mitral stenosis or left atrial tumours. With direct measurement of pulmonary artery pressure and pulmonary wedge pressure, *cardiac catheterization* is necessary in some

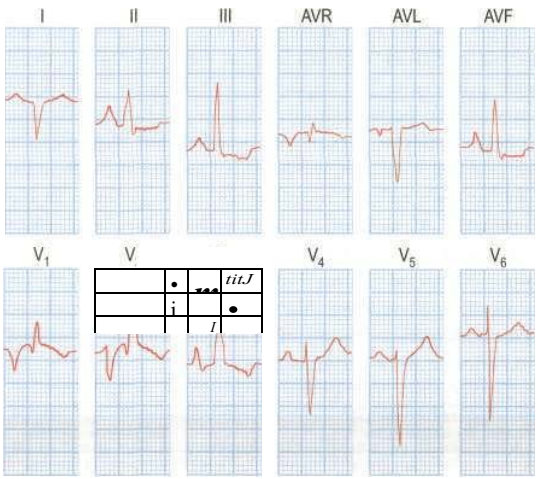

Fig. 13.99 **Pulmonary hypertension** shown by a 12-lead ECG. There is right axis deviation (+ 120°), right ventricular hypertrophy (dominant secondary R wave [R'] in V-,) and a combination of left and right atrial conduction abnormalities.

patients with severe pulmonary hypertension of unknown cause. *Pulmonary angiography* may be indicated if multiple pulmonary emboli are suspected, but is dangerous.

If no other cause is found, then a diagnosis of primary pulmonary hypertension is made (see p. 842).

Treatment

Treatment is determined by the condition underlying pulmonary hypertension. Diuretic treatment is used for right ventricular failure, but care should be taken to avoid excessive fluid depletion as this will result in reduced output from the impaired right ventricle. Hypoxia is avoided by the use of oxygen therapy when safe and necessary. In those with COPD and some others, long-term oxygen therapy improves symptoms and prognosis (p. 905). In contrast to their enormous value in those with left ventricular impairment, angiotensin-converting enzyme inhibitors are seldom useful and may make matters worse.

Pulmonary embolism

Thrombus, usually formed in the systemic veins or rarely in the right heart (less than 10% of cases), may dislodge and embolize into the pulmonary arterial system. Post-mortem studies indicate that this is a very common condition (microemboli are found in up to 60% of autopsies) but it is not usually diagnosed this frequently in life. Ten per cent of clinical pulmonary emboli are fatal.

Most clots which cause clinically relevant pulmonary emboli actually come from the pelvic and abdominal veins, but femoral deep venous thrombosis, and even occasionally axillary thrombosis, can be the origin of the clot. Clot forms as a result of a combination of sluggish blood flow, local injury or compression of the vein and a hypercoagulable state. Emboli can also occur from tumour, fat (long bone fractures), amniotic fluid and foreign material during i.v. drug abuse. Risk factors are shown in Table 8.27 and discussed on page 477.

After pulmonary embolism, lung tissue is ventilated but not perfused — producing an intrapulmonary dead space and resulting in impaired gas exchange. After some hours the non-perfused lung no longer produces surfactant. Alveolar collapse occurs and exacerbates hypoxaemia. The primary haemodynamic consequence of pulmonary embolism is a reduction in the cross-sectional area of the pulmonary arterial bed which results in an elevation of pulmonary arterial pressure and a reduction in cardiac output. The zone of lung that is no longer perfused by the pulmonary artery may infarct, but often does not do so because oxygen continues to be supplied by the bronchial circulation and the airways.

Clinical features

Sudden onset of *unexplained dyspnoea* is the most common, and often the only symptom of pulmonary embolism. *Pleuritic chest pain* and *haemoptysis* are present only when infarction has occurred. Many pulmonary emboli occur silently, but there are three typical clinical , presentations. A clinical deep venous thrombosis is not commonly observed, although detailed investigation of the lower limb and pelvic veins will reveal thrombosis in more than half of the cases.

Small/medium pulmonary embolism

In this situation an embolus has impacted in a terminal pulmonary vessel. Symptoms are pleuritic chest pain and breathlessness. Haemoptysis occurs in 30%, often 3 or more days after the initial event. On examination, the patient may be tachypnoeic with a localized pleural rub and often coarse crackles over the area involved. An exudative pleural effusion (occasionally blood-stained) can develop. The patient may have a fever, and cardiovascular examination is normal.

Massive pulmonary embolism

This is a much more rare condition where sudden collapse occurs because of an acute obstruction of the right ventricular outflow tract. The patient has severe central chest pain (cardiac ischaemia due to lack of coronary blood flow) and becomes shocked, pale and sweaty. Syncope may result if the cardiac output is transiently but dramatically reduced, and death may occur. On examination, the patient is tachypnoeic, has a tachycardia with hypotension and peripheral shutdown. The jugular venous pressure (JVP) is raised with a prominent *'a'* wave. There is a right ventricular heave, a gallop rhythm and a widely split second heart sound. There are usually no abnormal chest signs.

Multiple recurrent pulmonary emboli

This leads to increased breathlessness, often over weeks or months. It is accompanied by weakness, syncope on exertion and occasionally angina. The physical signs are due to the pulmonary hypertension that has developed from multiple occlusions of the pulmonary vasculature. On examination, there are signs of right ventricular overload with a right ventricular heave and loud pulmonary second sound.

Diagnosis

The symptoms and signs of small and medium-sized pulmonary emboli are often subtle and non-specific, so the diagnosis is often delayed or even completely missed. Pulmonary embolism should be considered if patients present with symptoms of unexplained cough, chest pain, haemoptysis, new-onset atrial fibrillation (or other tachycardia), or signs of pulmonary hypertension if no other cause can be found.

Investigations

Small/medium pulmonary emboli

- Chest X-ray is often normal, but linear atelectasis or blunting of a costophrenic angle (due to a small effusion) is not uncommon. These features develop only after some time. A raised hemidiaphragm is present in some patients. More rarely, a wedge-shaped pulmonary infarct, the abrupt cut-off of a pulmonary artery or a translucency of an underperfused distal zone is seen. Previous infarcts may be seen as opaque linear scars.

- **ECG** is usually normal, except for sinus tachycardia, but sometimes atrial fibrillation or another tachyarrhythmia occurs. There may be evidence of right ventricular strain.
- **Blood tests.** Pulmonary infarction results in a polymorphonuclear leucocytosis, an elevated ESR and increased lactate dehydrogenase levels in the serum. Immediately prior to commencing anticoagulants a thrombophilia screen should be checked.
- **Plasma D-dimer** (see p. 468) - if this is undetectable, it excludes a diagnosis of pulmonary embolism.
- **Radionuclide ventilation/perfusion scanning (*V/Q* scan)** is a good and widely available diagnostic investigation.

Pulmonary ^{99m}Tc scintigraphy demonstrates underperfused areas (Fig. 13.100a) which, if not accompanied by a ventilation defect on a ventilation scintigram performed after inhalation of radioactive xenon gas (see p. 888), is highly suggestive of a pulmonary embolus. There are limitations to the test, however. For example, a matched defect may arise with a pulmonary embolus which causes an infarct or from emphysematous bullae. This test is therefore conventionally reported as a probability (low, medium or high) of pulmonary embolus and should be interpreted in the context of the history, examination and other investigations.

- **Ultrasound scanning** can be performed for the detection of clots in pelvic or iliofemoral veins (see p. 870).
- **Spiral CT** scans with intravenous contrast (CT pulmonary angiography) show good sensitivity and specificity for medium-sized pulmonary emboli (Fig. 13.100b). They do not exclude pulmonary emboli in small arteries. New multislice CT machines have high sensitivities for even very small thrombi.
- MR **imaging** gives similar results and is used if CT angiography is contraindicated.

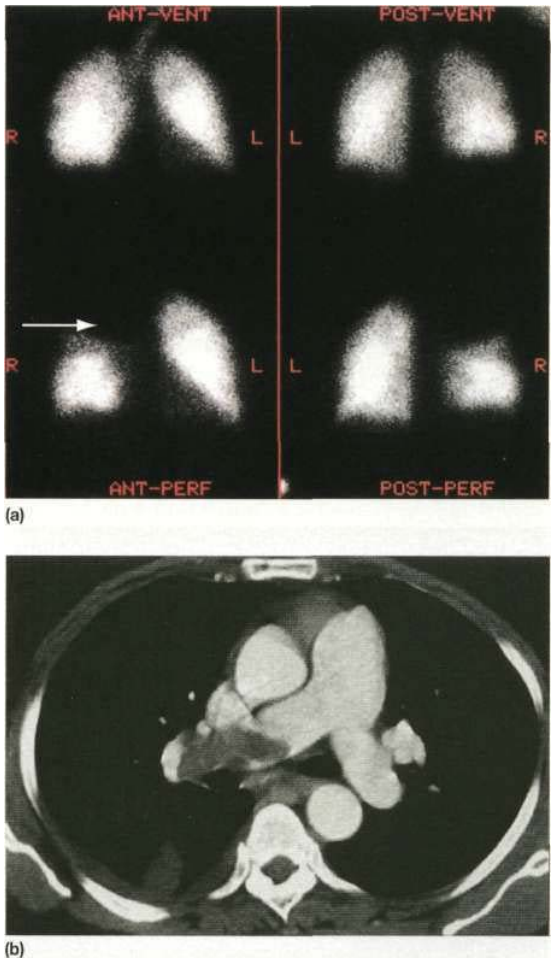

Fig. 13.100 **(a) Ventilation** (top) **and perfusion** (bottom) **lung scans** which demonstrate absence of perfusion but normal ventilation in the right upper lobe, i.e. probably pulmonary embolism, **(b) Spiral CT pulmonary angiographic image** at level of the main right and left pulmonary arteries showing a large thrombus in the right pulmonary artery.

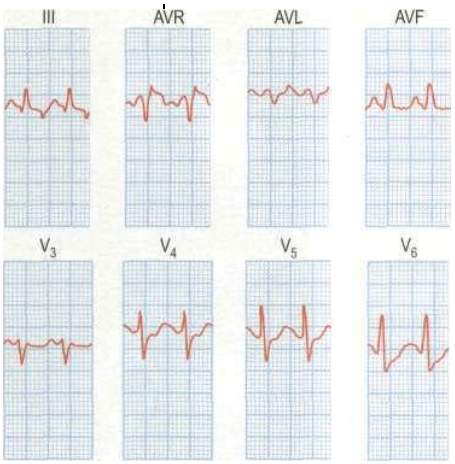
Massive pulmonary emboli

- **Chest X-ray** may show pulmonary oligaemia, sometimes with dilatation of the pulmonary artery in the hila. Often there are no changes.
- **ECG** shows right atrial dilatation with tall peaked P waves in lead II. Right ventricular strain and dilatation give rise to right axis deviation, some degree of right bundle branch block, and T wave inversion in the right precordial leads (Fig. 13.101). The 'classic' ECG pattern with an S wave in lead I, and a Q wave and inverted T waves in lead III (SI, Q3, T3), is rare.
- **Blood gases** show arterial hypoxaemia with a low arterial CO_2 level, i.e. type I respiratory failure pattern.
- **Echocardiography** shows a vigorously contracting left ventricle and occasionally a dilated right ventricle and a clot in the right ventricular outflow tract.
- **Pulmonary angiography** is sometimes undertaken if surgery is considered in acute massive embolism. The test is performed by injecting contrast material through a catheter inserted into the main pulmonary artery. Filling defects or obstructed vessels can be delineated (Fig. 13.102). Angiography is hazardous but the risk may be reduced if contrast is injected into each pulmonary artery separately. Although surgical removal of clot may be an option for selected patients it has no proven additional benefit above thrombolysis, and is therefore rarely preformed.

Multiple recurrent pulmonary emboli

- **Chest X-ray** may be normal. Enlarged pulmonary arterioles with oligaemic lung fields indicate advanced disease.
- **ECG** can be normal or show signs of pulmonary hypertension (Fig. 13.99).
- **Leg imaging** with ultrasound and venography may show thrombi.
- *V/Q* scan may show evidence of pulmonary infarcts.



F/ff. 13.101 Acute pulmonary embolism shown by a 12-lead ECG. There is an S wave in lead I, a Q wave in lead III and an inverted T wave in lead III (the S1, Q3, T3 pattern). There is sinus tachycardia (160 b.p.m.) and an incomplete right bundle branch block pattern (an R wave in AVR and V, and an S wave in V_6).

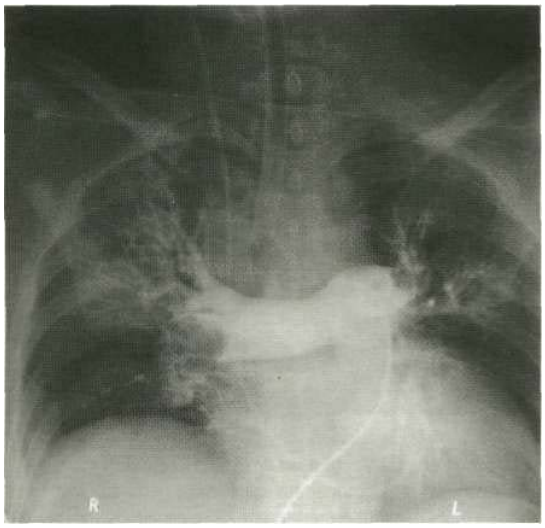


Fig. 13.102 **Pulmonary angiogram** (contrast injected directly into the main pulmonary artery) showing a large filling defect in the interlobar segment of the right pulmonary artery and extensive occlusion in the proximal left pulmonary artery.

Further tests looking for exercise-induced hypoxaemia and catheter studies to estimate pulmonary artery pressures are often required.

Treatment

Acute management

All patients should receive high-flow oxygen (60-100%) unless they have significant chronic lung disease. Patients with pulmonary infarcts require bed rest and analgesia. In severe cases, intravenous fluids and even inotropic agents to improve the pumping of the right heart are sometimes required, and very ill patients will require care on the intensive therapy unit (see p. 972).

Prevention of further emboli

A comparison of *low-molecular-weight heparin* (LMWH) with unfractionated heparin has shown no difference. As LMWHs simplify treatment (see p. 480) they are used exclusively if available, although they are more expensive. *Oral anticoagulants* are usually begun immediately and the heparin is tapered off as the oral anticoagulant becomes effective. Oral anticoagulants are continued for 6 weeks to 6 months, depending on the likelihood of recurrence of venous thrombosis or embolism. In some situations, such as after recurrent embolism, lifelong treatment is indicated.

Occasionally, physical methods are required to prevent further emboli. This is usually because recurrent emboli occur despite adequate anticoagulation, but is also indicated in high-risk patients in whom anticoagulation is absolutely contraindicated. The most common method by which pulmonary embolism is treated in this situation is by insertion of a *filter in the inferior vena cava* via the femoral vein to above the level of the renal veins.

Dissolution of the thrombus

Fibrinolytic therapy such as streptokinase (250 000 units by i.v. infusion over 30 minutes, followed by streptokinase 100 000 units i.v. hourly for up to 12-72 hours according to manufacturer's instructions) has been shown in control trials, to clear pulmonary emboli more rapidly and to confer a survival benefit in massive PE. It should be used more often.

Surgery

Surgical *embolectomy* is rarely necessary, but there may be no alternative when the haemodynamic circumstances are very severe.

MYOCARDIAL AND ENDOCARDIAL DISEAS

ATRIAL MYXOMA

This is the most common primary cardiac tumour. It occurs at all ages and shows no sex preference. Although most myxomas are sporadic, some are familial or are part of a multiple system syndrome. Histologically they are benign. The majority of myxomas are solitary, usually develop in the left atrium and are polypoid, gelatinous structures attached by a pedicle to the atrial septum. The tumour may obstruct the mitral valve or may be a site of thrombi that then embolize. It is also associated with constitutional symptoms: the patient may present with dyspnoea, syncope or a mild fever. The physical signs are a loud first heart sound, a tumour 'plop' (a loud third heart sound produced as the pedunculated tumour comes to an abrupt halt), a mid-diastolic murmur, and signs due to embolization. A raised ESR is usually present.

The diagnosis is easily made by echocardiography because the tumour is demonstrated as a dense space-occupying lesion (Fig. 13.103). Surgical removal usually results in a complete cure.

Myxomas may also occur in the right atrium or in the ventricles. Other primary cardiac tumours include rhabdomyomas and sarcomas.

MYOCARDIAL DISEASE

Myocardial disease that is not due to ischaemic, valvular or hypertensive heart disease or a known infiltrative, metabolic/toxic or neuromuscular disorder may be caused by:

- an acute or chronic inflammatory pathology (myocarditis)
- idiopathic myocardial disease (cardiomyopathy).

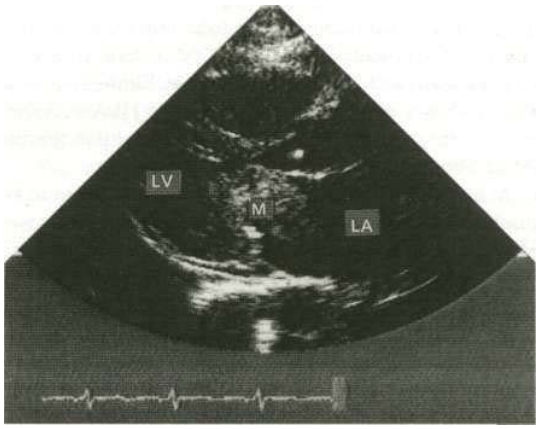

Fig. 13.103 Atrial myxoma shown by a two-**dimensional echocardiogram** (long-axis view). The myxoma is an echo-dense mass obstructing the mitral valve orifice. It was removed surgically. LV, left ventricle; LA, left atrium; M, mass.

Table 13.44 **Causes of myocarditis**

Idiopathic
Infective Viral: Coxsackievirus, adenovirus, CMV, echovirus, influenza, polio, hepatitis, HIV **Parasitic:** *Trypanosoma cruzi, Toxoplasma gondii* (a cause of myocarditis in the newborn or immunocompromised) **Bacterial:** Streptococcus (most commonly rheumatic carditis), diphtheria (toxin-mediated heart block common) **Spirochaetal:** Lyme disease (heart block common), leptospirosis **Fungal Rickettsial**
Toxic
Drugs Causing hypersensitivity reactions, e.g. methyldopa, penicillin, sulphonamides, antituberculous
Radiation May cause myocarditis but pericarditis more common
Autoimmune An autoimmune form with autoactivated T cells and organ-specific antibodies may occur

Myocarditis

Acute inflammation of the myocardium has many causes (Table 13.44). Establishment of a definitive aetiology with isolation of viruses or bacteria is difficult in routine clinical practice.

In western societies, the commonest causes of infective myocarditis are Coxsackie or adenoviral infection. Myocarditis in association with HIV infection is seen at post-mortem in up to 20% of cases but causes clinical problems in < 10% of cases. Chagas' disease, due to *Trypanosoma cruzi,* which is endemic in South America, is one of the commonest causes of myocarditis world-wide. Additionally toxins (including prescribed drugs), physical agents, hypersensitivity reactions and autoimmune conditions may also cause myocardial inflammation.

Pathology

In the acute phase myocarditic hearts are flabby with focal haemorrhages; in chronic cases they are enlarged and hypertrophied. Histologically an inflammatory infiltrate is present - lymphocytes predominating in viral causes; polymorphonuclear cells in bacterial causes; eosinophils in allergic and hypersensitivity causes (Fig. 13.104).

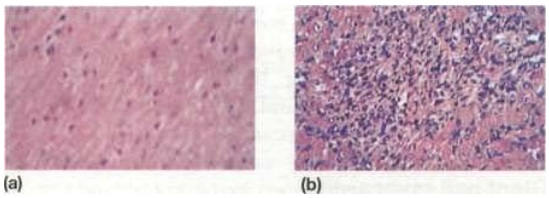

Fig. 13.104 **Biopsies showing (a) normal myocardium and (b) myocarditis, with increased interstitial inflammatory cells.**

i

Clinical features

Myocarditis may be an acute or chronic process; its clinical presentations range from an asymptomatic state associated with limited and focal inflammation to *fatigue, palpitations, chest pain, dyspnoea* and *fulminant congestive cardiac failure* due to diffuse myocardial involvement. An episode of viral myocarditis, perhaps unrecognized and forgotten, may be the initial event that eventually culminates in an 'idiopathic' dilated cardiomyopathy. Physical examination includes soft heart sounds, a prominent third sound and often a tachycardia. A pericardial friction rub may be heard.

Investigations

- **Chest X-ray** may show some cardiac enlargement, depending on the stage and virulence of the disease.
- **ECG** demonstrates ST and T wave abnormalities and arrhythmias. Heart block may be seen with diphtheritic myocarditis, Lyme disease and Chagas' disease (see below).
- **Cardiac** enzymes are elevated.
- **Viral antibody titres** may be increased. However, since enteroviral infection is common in the general population, the diagnosis depends on the demonstration of acutely rising titres.
- **Endomyocardial biopsy** may show acute inflammation but false negatives are common by conventional criteria. Biopsy is of limited value outside specialized units.
- **Viral RNA** can be measured from biopsy material using polymerase chain reaction (PCR). Specific diagnosis requires demonstration of active viral replication within myocardial tissue. ■

Treatment

The underlying cause must be identified, treated, eliminated or avoided. Bed rest is recommended in the acute phase of the illness and athletic activities should be avoided for 6 months. Heart failure should be treated conventionally with the use of diuretics, ACE inhibitors/All receptor antagonists, beta-blockers, spironolactone + digoxin. *Antibiotics* should be administered immediately where appropriate. *NSAIDs* are contraindicated in the acute phase of the illness but may be used in the late phase. The use of *corticosteroids* is controversial and no studies have demonstrated an improvement in left ventricular ejection fraction or survival following their use. The administration of high-dose intravenous *immunoglobulin* on the other hand appears to be associated with a more rapid resolution of the left ventricular dysfunction and improved survival. Novel and effective antiviral, immunosuppressive (e.g. gamma-interferon) and *intmunomodulating* (e.g. IL-10) agents are currently undergoing animal trials and may become available in the future to treat viral myocarditis.

Giant cell myocarditis

This is a severe form of myocarditis characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas and autoimmune disease. It has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

Chagas' disease

Chagas' disease is caused by the protozoan *Trypanosoma cruzi* and is endemic in South America where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a dilated cardiomyopathy with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed on page 780. Amiodarone is helpful for the control of ventricular arrhythmias; heart failure is treated in the usual way (p. 790).

CARDIOMYOPATHY

Cardiomyopathy is a general term indicating disease of the cardiac muscle. Diseases are classified on predominant clinical presentations:

- dilated cardiomyopathy - ventricular dilatation
- hypertrophic cardiomyopathy - myocardial hypertrophy
- restrictive cardiomyopathy - impaired ventricular filling
- arrhythmogenic right ventricular cardiomyopathy - prominent right ventricular involvement with a high frequency of ventricular arrhythmias
- other rare cardiomyopathies.

Dilated cardiomyopathy (DCM)

DCM is characterized by dilatation and impaired systolic function of the left and/or right ventricle, in the absence of abnormal loading conditions (e.g. hypertension, valve disease) and coronary disease. The aetiology in the majority of cases is unknown and in most patients no cause is found ('idiopathic').

A large number of cardiac and systemic diseases can cause cardiac dilatation and systolic impairment (Table 13.45). Other potential causes of DCM include persistent viral infection and autoimmune disease. Evidence for the latter includes associations with specific HLA subtypes and the frequent finding of circulating cardiac-specific autoantibodies.

At least 25% of the 'idiopathic' cases are known to be familial (Fig. 13.105). In the majority of familial cases inheritance is autosomal dominant, but X-linked and recessive cases occur. In a limited number of cases the responsible genes have been identified. Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, beta myosin heavy chain, sarcoglycans, vinculin and lamin a/c in autosomal dominant DCM) (Fig. 13.106). Many of these have prominent associated features such as skeletal myopathy or conduction system disease and therefore differ from the majority of cases of DCM. The aetiology in the majority of cases remains unknown.

Table 13.45 Causes of dilated cardiomyopathy (DCM)

Genetic	e.g. autosomal dominant DCM, X-linked cardiomyopathy
Inflammatory	Post-infective, autoimmune, connective tissue diseases (systemic lupus erythematosus, systemic sclerosis)
Metabolic	e.g. glycogen storage diseases
Nutritional	Thiamin, selenium deficiency
Endocrine	Acromegaly, thyrotoxicosis, myxoedema, diabetes mellitus
Infiltrative	Hereditary haemochromatosis
Neuromuscular	e.g. muscular dystrophy, Friedreich's ataxia, mitochondrial myopathies
Toxic	Alcohol, cocaine, doxorubicin, cyclophosphamide, cobalt
Haematological	Sickle cell anaemia, thrombotic thrombocytopenic purpura

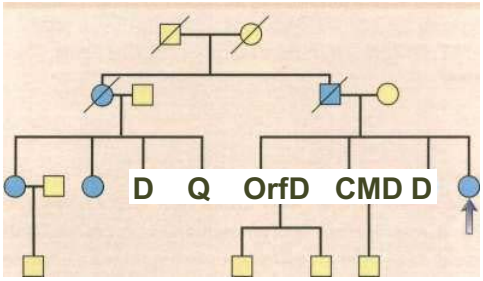

Fig. 13.105 **Pedigree of a family with dilated cardiomyopathy.** Blue symbols are affected family members. The arrow indicates the index case.

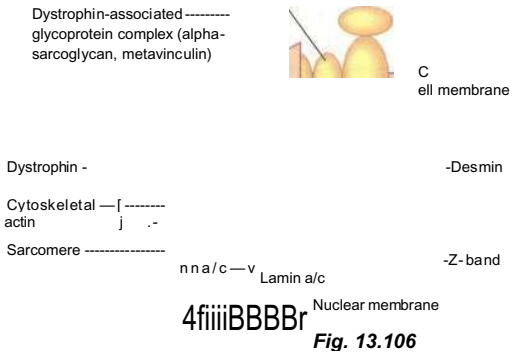

Fig. 13.106

Schematic representation of myocyte proteins implicated in dilated cardiomyopathy (DCM). See also Fig. 13.4.

Clinical features

Presentation is generally with congestive heart failure and therefore symptoms and signs are those of left and/or right *heart failure*. Additionally, patients may present with *syncope* due to ventricular arrhythmia or conduction disease or with pulmonary or systemic *embolism*. Occasionally, initial presentation is with *sudden cardiac death*. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include careful family history and construction of a pedigree where appropriate.

Investigations

- **Chest X-ray** demonstrates generalized cardiac enlargement.
- **ECG** shows diffuse non-specific ST segment and T wave changes. Sinus tachycardia, conduction abnormalities and arrhythmias (i.e. atrial fibrillation, ventricular premature contractions or ventricular tachycardia) are also seen.
- **Echocardiogram** reveals dilatation of the left and/or right ventricle with poor global contraction function (Fig. 13.107).
- **Angiography** should be performed to exclude coronary artery disease in all individuals at risk (generally patients > 40 years or younger if symptoms or risk factors are present).
- **Biopsy** is generally not indicated outside specialist

Treatment

The goals of management are to relieve symptoms, retard disease progression and prevent complications. Treatment involves conventional management of heart failure (see p. 790). Diuretics are highly effective for the relief of congestive symptoms but should not be used in isolation since they exacerbate activation of neurohormones that may contribute to disease progression. Disease progression is retarded by the use of ACE-inhibitors, angiotensin II receptor antagonists and spironolactone to antagonize activation of the renin-angiotensin-aldosterone system (RAAS), while beta-blockers act similarly on the sympathetic nervous system. These are indicated in most cases. Beta-blockers may also help prevent arrhythmias. In specific cases, permanent pacing, anti-arrhythmic therapy or implantable cardioverter—defibrillators may be indicated. Severe ventricular dilatation and dysfunction, documented atrial fibrillation or a history of embolization are indications for anticoagulant treatment. Cardiac transplantation remains the principal option for advanced disease refractory to medical therapy. Potential alternatives to transplantation are discussed in the section on heart failure (see p. 796). There is currently no specific treatment for idiopathic DCM although preliminary studies have investigated the role of growth hormone, immunoadsorption and anti-cytokine therapy.

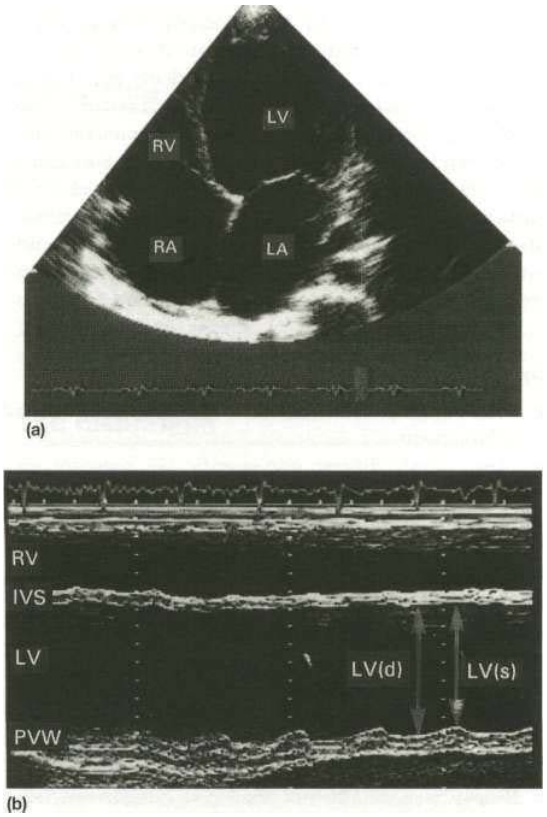

Fig. 13.107 **Dilated cardiomyopathy** shown in two-dimensional (apical four-chamber view) and M-mode echocardiograms. The heart has a 'globular' appearance with all four chambers dilated. The extremely impaired left ventricular function can be appreciated from the M-mode recording. Compare the systolic shortening fraction with that of Figures 13.26 and 13.29. LA, left atrium; RA, right atrium; LV, left ventricle; LV(d) and LV(s), diastolic and systolic left ventricular dimensions; IVS, interventricular septum; PVW, posterior ventricular wall.

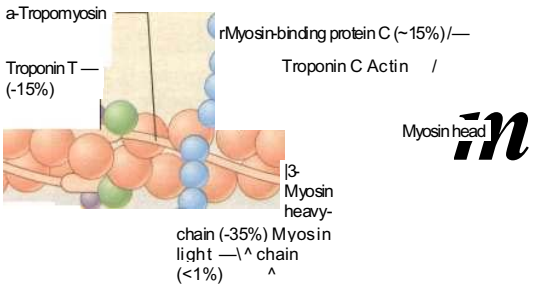

Fig. 13.108 **Sarcomeric proteins implicated in hypertrophic cardiomyopathy.** Reproduced with permission from Spirito P et al. (1997) The management of hypertrophic cardiomyopathy. *New England Journal of Medicine* **336:** 775-785. © Massachusetts Medical Society, all rights reserved.

Hypertrophic cardiomyopathy (HCM)

Hypertrophic cardiomyopathy is characterized by variable myocardial hypertrophy, most commonly involving the interventricular septum, and disorganization ('disarray') of cardiac myocytes and myofibrils (Fig. 13.108). Twenty-five per cent of patients have dynamic left ventricular outflow tract obstruction due to the combined effects of hypertrophy, systolic anterior motion (SAM) of the anterior mitral valve leaflet and rapid ventricular ejection.

The majority of cases are familial, autosomal dominant, and due to mutations in the genes encoding sarcomeric proteins.

The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with beta-myosin heavy chain mutations whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. Modifying genetic factors may also influence the phenotype in HCM. These include polymorphisms of components of the renin-angiotensin-aldosterone system which influence myocyte growth.

The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis in children difficult. HCM due to myosin-binding protein C may not manifest until the sixth decade of life or later. Sporadic cases of HCM occur, but the aetiology is unknown. HCM may also be associated with Noonan's syndrome, Friedreich's ataxia, glycogen storage disease, and mitochondrial myopathies.

Clinical features

Patients with HCM present with *chest pain, dyspnoea, syncope* or *presyncope* (typically with exertion), *cardiac arrhythmias* and *sudden death*. Sudden death may occur at any age but the highest rates (up to 6% per annum) occur in adolescents or young adults. Risk factors for sudden death are discussed below. Dyspnoea is common and is due to impaired relaxation of the heart muscle. Left ventricular filling - and therefore left ventricular emptying - is impaired, compounded by outflow obstruction in about one-third of cases. Systolic ventricular function remains good until the very late stages of disease when progressive dilatation may occur. Atrial fibrillation occurs (the prevalence increasing with increasing duration of disease) and is associated with worsening symptoms due to reduction in ventricular filling and an increased risk of stroke.

The classic physical findings are:

- double apical pulsation (forceful atrial contraction producing a fourth heart sound)
- jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole
- ejection systolic murmur due to left ventricular outflow obstruction late in systole - it can be increased by manoeuvres that decrease afterload, e.g. standing or Valsalva, and decreased by manoeuvres that increase afterload and venous return, e.g. squatting
- pansystolic murmur due to mitral regurgitation (secondary to SAM)
- fourth heart sound (if not in AF).

Investigations

- **Chest X-ray** is usually unremarkable.
- **ECG** demonstrates left ventricular hypertrophy (Fig. 13.81) and ST and T wave changes. Abnormal Q waves, most commonly in the inferolateral leads occur in 25-50% of patients.
- **Echocardiogram** is usually diagnostic and in the most typical cases shows asymmetric left ventricular hypertrophy (involving septum more than posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (Fig. 13.109). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy. Certain mutations, e.g. involving the troponin gene, are associated with minimal or even no hypertrophy.
- **Pedigree analysis** generally reveals autosomal dominant inheritance and may provide prognostic information (e.g. history of sudden death). Genetic analysis where available confirms the diagnosis, may provide prognostic information and facilitates evaluation of relatives.
- **Exercise testing** and ambulatory ECG recording also provide prognostic information.

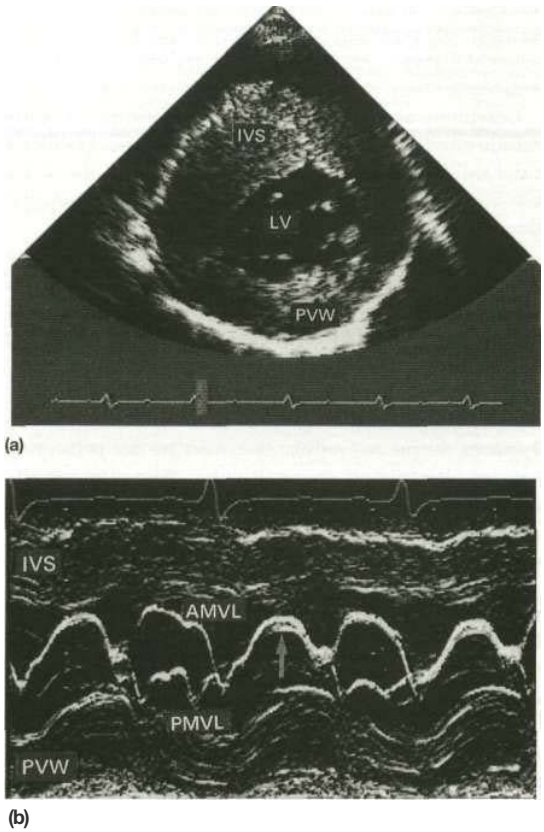

Fig. 13.109 **Hypertrophic cardiomyopathy** shown by (a) a two-dimensional echocardiogram (short-axis view) and (b) M-mode recording. The grossly thickened interventricular septum is shown, resulting in a small left ventricular cavity. This condition is associated with an abnormal anterior motion of the mitral valve during systole (arrowed). IVS, interventricular septum; LV, left ventricle; PVW, posterior ventricular wall; AMVL, PMVL, anterior and posterior mitral valve leaflets.

Treatment

The overriding concern in the management of HCM is the prevention of sudden death. Several risk factors for sudden death have been identified. Massive left ventricular hypertrophy (> 30 mm) is a recognized risk factor but the majority of sudden deaths do not occur in individuals with massive hypertrophy, and other risk factors must be considered. These include genotype, family history of sudden cardiac death, abnormal blood pressure response during exercise, non-sustained ventricular tachycardia on Holter monitoring and recurrent syncope. The presence of two or more of these risk factors is associated with a substantial risk of sudden death. Implantable defibrillators effectively prevent sudden death in high-risk cases. In patients in whom the risk is less high, amiodarone is an appropriate alternative. Recent research has suggested that microvascular dysfunction as assessed by PET scanning may be an independent risk factor for sudden death but this requires further validation.

Chest pain and dyspnoea are treated with beta-blockers and verapamil, either alone or in combination. If these are ineffective, disopyramide is a useful second-line therapy for patients with obstruction. In selected cases only (e.g. elderly patients) with significant left outflow obstruction and recalcitrant symptoms, dual-chamber pacing may be of use. Alcohol (non-surgical) ablation of the septum has been investigated and appears to give good results in reduction of outflow tract obstruction and subsequent improvement in exercise capacity. There are, however, significant risks, including the development of complete heart block and massive myocardial infarction. Occasionally, surgical resection of septal myocardium may be indicated. Vasodilators should be avoided because they may aggravate left ventricular outflow obstruction or cause refractory hypotension.

Restrictive cardiomyopathy

Some cardiomyopathies do not present with muscular hypertrophy or ventricular dilatation. Instead, the

ventricular filling is restricted (as with constrictive pericarditis), resulting in symptoms and signs of heart failure. Dilatation of the atria and thrombus formation commonly occur.

Conditions associated with this form of cardiomyopathy include amyloidosis (commonest), sarcoidosis, Loeffler's endocarditis and endomyocardial fibrosis; in the latter two conditions there is myocardial and endocardial fibrosis associated with eosinophilia.

The idiopathic form of restrictive cardiomyopathy may be familial and has been associated with mutations in the sarcomeric protein troponin I, suggesting that this form may be part of the spectrum of hypertrophic cardiomyopathy.

Clinical features

Dyspnoea, fatigue and embolic symptoms are the presenting features. Restriction to ventricular filling (especially right) results in persistently elevated venous pressures, consequent hepatic enlargement, ascites, and dependent oedema.

Physical signs are similar to those of constrictive pericarditis - a high jugular venous pressure with diastolic collapse (Friedreich's sign) and elevation of venous pressure with inspiration (Kussmaul's sign). A fourth heart sound is common in early disease and cardiac enlargement, and a third heart sound may be present in advanced disease. In idiopathic restrictive cardiomyopathy, however, cardiac size may remain normal.

Investigations

- **Chest X-ray** may show pulmonary venous congestion. The cardiac silhouette can be normal or show cardiomegaly and/or atrial enlargement.
- **ECG** usually has low-voltage and ST segment and T wave abnormalities.
- **Echocardiogram** shows symmetrical myocardial thickening and often a normal systolic ejection fraction, but impaired ventricular filling.
- **Cardiac catheterization** and haemodynamic studies help distinction from constrictive pericarditis.
- **Endomyocardial biopsy** in contrast with other cardiomyopathies is often useful in this condition and may permit a specific diagnosis such as amyloidosis to be made.

Treatment

There is no specific treatment. Cardiac failure and embolic manifestations should be treated. Cardiac transplantation should be considered in some severe cases, especially the idiopathic variety. In primary amyloidosis, combination therapy with melphalan plus prednisolone with or without colchicine may improve survival. However, patients with cardiac amyloidosis have a worse prognosis than those with other forms of the disease, and the disease often recurs after transplantation. Liver transplantation may be effective in familial amyloidosis (due to production of mutant prealbumin) and may lead to reversal of the cardiac abnormalities.

Fig. 13.110 **Gross pathological specimen demonstrating thinning and fibrofatty replacement of RV free wall.** From Basso et al. (1996) *Circulation* 94: 983-991, with permission.

Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is characterized by progressive fibrofatty replacement of the right ventricular myocardium (Fig. 13.110). This leads to ventricular arrhythmia and risk of sudden death in its early stages and right ventricular or biventricular failure in its later stages. It is familial in at least 50% of cases, most commonly with an autosomal dominant pattern of inheritance. A rare form of ARVC which is associated with dermatological abnormalities (Naxos disease) is caused by a mutation in a gene encoding a myocyte structural protein (plakoglobin) found in desmosomes and gap junctions. There are at least six other loci for ARVC, and mutated genes have been identified in two:

- *human ryanodine receptor 2* (hRyR2), an ion channel protein involved in calcium homeostasis in the sarcoplasmic reticulum of the myocyte (see p. 727)
- *desmoplakin,* a cytoskeletal protein that interacts with plakoglobin.

Clinical features

Presentation is most commonly with severe symptomatic *ventricular arrhythmias* or *syncope.* Occasionally presentation is with right *heart failure.* Heart failure, however, is more commonly associated with a later stage of disease, in which left ventricular dilatation may also occur, and severity of arrhythmia may paradoxically diminish. The condition is often asymptomatic and the first presentation may be with *sudden death* or alternatively it may be diagnosed as a result of routine medical evaluation or family screening.

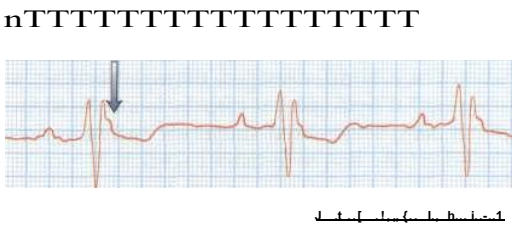

Fig. 13.111 Electrocardiogram from an adult with arrhythmogenic right ventricular cardiomyopathy (ARVC) demonstrating RBBB and precordial T wave insertion with epsilon waves visible at the terminal of the QRS complex (arrow).

Investigations

- **Chest X-ray** is usually unremarkable except in advanced disease.
- **ECG** most commonly demonstrates T wave inversion in precordial leads related to the right ventricle (V_1-V_3). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 13.111). Incomplete or complete RBBB is seen.
- **Signal averaged ECG** may indicate the presence of late potentials, the delayed depolarization of individual muscle cells.
- **Echocardiogram.** In early cases this is often normal and in more advanced cases may demonstrate right ventricular dilatation and aneurysm formation, associated in some cases with concomitant left ventricular dilatation.
- **MRI** demonstrates morphological abnormalities of the RV and is capable of demonstrating fatty infiltration.
- RV angiography demonstrates enlargement and abnormal motion of right ventricular myocardium.
- **RV biopsy** may demonstrate fibrofatty replacement but is often falsely negative.
- **Holter monitoring** often demonstrates frequent extrasystoles of right ventricular origin and runs of non-sustained or sustained ventricular tachycardia.
- **Genetic testing,** although currently in its infancy, may be a vital diagnostic tool, particularly in variably penetrant disease.

Treatment

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone or sotalol may be used for symptomatic arrhythmias, and for refractory or life-threatening arrhythmias an ICD may be required. Occasionally cardiac transplantation is indicated, either for intractable arrhythmia or cardiac failure.

Other cardiomyopathies

Anderson-Fabry disease (AFD) (p. 1147)
The heart is frequently involved in patients with classical disease. Some male patients with residual enzyme activity present in middle age with few if any of the other typical features of the disease. Cardiac abnormalities that occur in AFD include left ventricular hypertrophy, valvular dysfunction, short PR interval, atrioventricular conduction abnormalities and atrial fibrillation. Patients may also develop systolic impairment and regional wall motion abnormalities.

Left ventricular non-compaction
This cardiomyopathy is inherited as an autosomal dominant and has a poor prognosis. It is characterized by chamber dilatation and prominent sacculation of the ventricle, best seen with echocardiography or magnetic resonance imaging. It presents with dyspnoea, cardiac arrhythmia or sudden death. The responsible gene has not yet been identified.

Inflammatory cardiomyopathy
The association of myocarditis or a prominent history of chronic myocarditis, with left ventricular dysfunction (chamber dilatation and hypokinesis) is termed inflammatory cardiomyopathy. The prognosis depends on the rapidity of its development and the status of left ventricular function.

Cancer chemotherapy with anthracyclines can cause cardiomyopathy that may manifest years later, particularly in individuals treated for childhood cancer.

PERICARDIAL DISEASE

The pericardium acts as a protective covering for the heart. It consists of two separate layers, the inner visceral pericardium and the outer parietal pericardium. The visceral pericardium reflects back upon itself at the level of the great vessels to join the parietal pericardium, thus forming a sac. The pericardial sac contains up to 50 mL of pericardial fluid in the normal heart, although this is a potential space for fluid to collect. The pericardium serves to lubricate the surface of the heart, prevents deformation and dislocation of the heart and acts as a barrier to the spread of infection.

Presentations of pericardial disease include:

- acute pericarditis
- pericardial effusion and cardiac tamponade
- constrictive pericarditis.

Acute pericarditis

This refers to inflammation of the pericardium. Classically, fibrinous material is deposited into the pericardial space and pericardial effusion often occurs. Acute pericarditis has numerous aetiologies (Table 13.46). Most commonly in the UK, it is due to viral infection and myocardial infarction, although in many cases the cause is unknown.

Viral pericarditis. The most common viral causes are Coxsackie B virus and echovirus. Viral pericarditis is usually painful but has a short time course and rarely long-term effects. Increasingly, HIV is implicated in the aetiology of pericarditis, both directly and via immuno-suppression, which predisposes the subject to infective

Post-myocardial infarction pericarditis occurs in about 20% of patients in the first few days following MI. It occurs more commonly with anterior Mis and ST elevation Mis with high serum cardiac enzymes, but its incidence is reduced to 5-6% with thrombolysis. It may be difficult to differentiate this pain from recurrent angina when it occurs early (day 1-2 post-infarct) but a good history of the pain and serial ECG monitoring is helpful. Pericarditis may also occur later on in the recovery phase after infarction. This usually occurs as a feature of

Table 13.46 Aetiology of pericarditis

I.	**Infectious pericarditis** Viral (Coxsackievirus, echovirus, mumps, herpes, HIV) Bacterial (staphylococcus, streptococcus, pneumococcus, meningococcus, *Haemophilus influenzae,* mycoplasmosis, borreliosis, *Chlamydia)* Tuberculous Fungal (histoplasmosis, coccidioidomycosis, *Candida)*
II.	**Post-myocardial infarction pericarditis** Acute myocardial infarction (early) Dressler's syndrome (late)
III.	**Malignant pericarditis** Primary tumours of the heart (mesothelioma) Metastatic pericarditis (breast and lung carcinoma, lymphoma, leukaemia, melanoma)
IV.	**Uraemic pericarditis**
V.	**Myxoedematous pericarditis**
VI.	**Chylopericardium**
VII.	**Autoimmune pericarditis** Collagen-vascular (rheumatoid arthritis, rheumatic fever, systemic lupus erythematosus, scleroderma) Drug-induced (procainamide, hydralazine, isoniazid, doxorubicin, cyclophosphamides)
VIII.	**Post-radiation pericarditis**
IX.	**Post-surgical pericarditis** Postpericardiotomy syndrome
X.	**Post-traumatic pericarditis**
XI.	**Familial and idiopathic pericarditis**

Dressler's syndrome, an autoimmune response to cardiac damage occurring 2-10 weeks post-infarct. Autoimmune reaction to myocardial damage is the main aetiology, and antimyocardial antibodies can often be found. Recurrences are common. Differential diagnosis includes a new myocardial infarction or unstable angina.

Uraemic pericarditis is due to irritation of the pericardium by accumulating toxins. It can occur in 6-10% of patients with advanced renal failure if dialysis is delayed. It is an indication for urgent dialysis as it continues to be associated with significant morbidity and mortality.

Bacterial pericarditis may rarely occur with septicaemia or pneumonia or it may stem from an early postoperative infection after thoracic surgery or trauma or may complicate endocarditis.

Staphylococcus aureus is a frequent cause of purulent pericarditis in HIV patients. This form of pericarditis, especially staphylococcal, is fulminant and often fatal.

Other *endemic infectious pericarditis* includes mycoplasmosis and Lyme pericarditis which are often effusive and require pericardial drainage. The diagnosis is based on serological tests of pericardial fluid and identification of organisms in pericardial or myocardial biopsies.

Tuberculous pericarditis usually presents with chronic low-grade fever, particularly in the evening, associated with features of acute pericarditis, dyspnoea, malaise, night sweats and weight loss. Pericardial aspiration is often required to make the diagnosis. Constrictive pericarditis is a frequent outcome.

Fungal pericarditis is a common complication of endemic fungal infections, such as histoplasmosis and coccidioidomycosis but may be also caused by *Candida albicans,* especially in immunocompromised patients, drug addicts or after cardiac surgery.

Malignant pericarditis. Carcinoma of the bronchus, carcinoma of the breast and *Hodgkin's lymphoma* are the most common causes of malignant pericarditis. Leukaemia and malignant melanoma are also associated with pericarditis. A substantial pericardial effusion is very typical and is due to the obstruction of the lymphatic drainage from the heart. The effusion is often haemorrhagic. Radiation and therapy for thoracic tumours may cause radiation injury to the pericardium resulting in serous or haemorrhagic pericardial effusion and pericardial fibrosis. Absence of neoplastic cells in the pericardial fluid in these conditions often helps diagnosis.

Clinical features

Pericardial inflammation produces sharp central *chest pain* exacerbated by movement, respiration and lying down. It is typically relieved by sitting forward. It may be referred to the neck or shoulders. The main differential diagnoses are angina and pleurisy.

The classical clinical sign is a pericardial *friction rub* occurring in three phases corresponding to atrial systole, ventricular systole and ventricular diastole. It may also be heard as a biphasic 'to and fro' rub. The rub is heard best with the diaphragm of the stethoscope at the lower left sternal edge at the end of expiration with the patient leaning forward. There is usually a *fever, leucocytosis* or *lymphocytosis* when pericarditis is due to viral or bacterial infection, rheumatic fever or myocardial infarction. Features of a *pericardial effusion* may also be present (p. 856). Large pericardial effusion can compress adjacent bronchi and lung tissue and may cause *dyspnoea.*

Investigations

ECG is diagnostic. There is concave-upwards (saddle-shaped) ST elevation (Fig. 13.112). These changes evolve over time, with resolution of the ST elevation, T wave flattening/inversion and finally T wave normalization. The early ECG changes must be differentiated from ST elevation found in myocardial infarction.

Sinus tachycardia may result from fever or haemodynamic embarrassment, and rhythm and conduction abnormalities may be present if myocardium is involved. *Cardiac enzymes* should be assayed as they may be elevated if there is associated myocarditis (see p. 848).

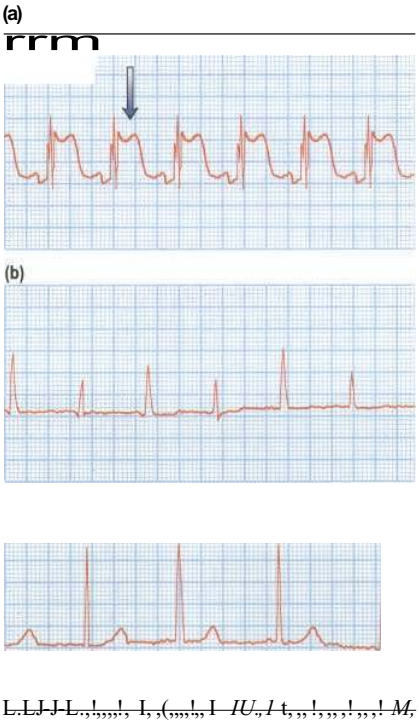

Fig. 13.112 ECGs associated with pericarditis.
(a) Acute pericarditis. Note the raised ST segment, concave upwards (arrow), **(b) Chronic phase of pericarditis** associated with a pericardial effusion. Note the T wave flattening and inversion and the alternation of the QRS amplitude (QRS alternans). (c) The same patient after evacuation of the pericardial fluid. Note that the QRS voltage has increased and the T waves have returned to normal.

Chest X ray, echocardiograms and radionucleotide scans are of little value in uncomplicated acute pericarditis.

Treatment

If a cause is found, this should be treated. Bed rest and oral NSAIDs (high-dose aspirin, indometacin or ibuprofen) are effective in most patients. In the few days following a myocardial infarction, NSAID use is associated with a higher rate of myocardial rupture and these drugs should not be used. Corticosteroids have been used when the disease does not subside rapidly, but they are associated with side-effects. About 20% of cases of acute pericarditis go on to develop idiopathic relapsing pericarditis. The first-line treatment is again oral NSAIDs. In resistant cases, oral corticosteroids are again used to provide symptomatic relief. However, symptoms commonly recur on dose reduction or withdrawal, and prolonged steroid use is associated with its own side-effects. Numerous other treatments have been studied including azathioprine, colchicine, intravenous corticosteroids and pericardiectomy. Current data tend to favour the use of colchicine to prevent recurrent attacks of pericarditis.

If pericarditis persists for 6-12 months following the acute episode, it is considered chronic. If the pericardium thickens and restricts ventricular filling, constrictive pericarditis is said to have developed.

Pericardial effusion and cardiac tamponade

A pericardial effusion is a collection of fluid within the potential space of the serous pericardial sac (Fig. 13.113), commonly accompanying an episode of acute pericarditis. When a large volume collects in this space, ventricular filling is compromised leading to embarrassment of the circulation. This is known as cardiac tamponade.

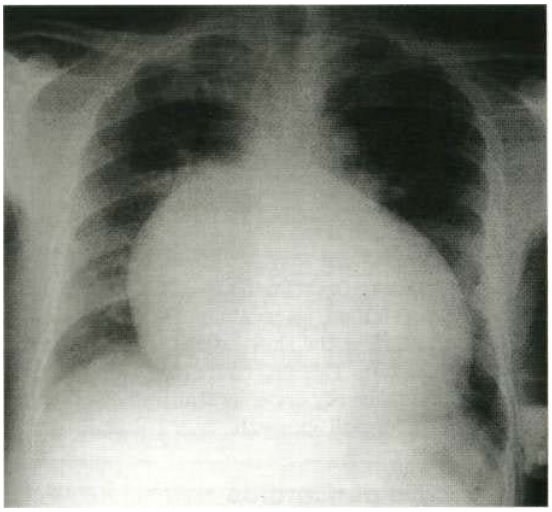

Fig. 13.113 **Chest X-ray showing a pericardial effusion;** the heart appears globular.

Clinical features

Symptoms of a pericardial effusion commonly reflect the underlying pericarditis. On examination:

- Heart sounds are soft and distant.
- Apex beat is commonly obscured.
- A friction rub may be evident due to pericarditis in the early stages, but this becomes quieter as fluid accumulates and pushes the layers of the pericardium apart.
- Rarely, the effusion may compress the base of the left lung, producing an area of dullness to percussion below the angle of the left scapula (Ewart's sign).
- As the effusion worsens, signs of cardiac tamponade may become evident:
  - raised jugular venous pressure with sharp rise and *y* descent (Friedreich's sign)
  - Kussmaul's sign (rise in JVP/increased neck vein distension during inspiration)
  - pulsus paradoxus
  - reduced cardiac output.

Investigations

- *u* **ECG** reveals low-voltage QRS complexes.
- **Chest X-ray** (Fig. 13.113) shows large globular or pear-shaped heart with sharp outlines. Typically, the pulmonary veins are not distended.
- **Echocardiography** (Fig. 13.30, p. 755) is the most useful technique for demonstrating the effusion and looking for evidence of tamponade.
- **MRI** should be considered if haemopericardium (blood in the pericardial space) or loculated pericardial effusions are suspected.
- **Pericardiocentesis** is the removal of pericardial fluid with aseptic technique under echocardiographic guidance. It is indicated when a tuberculous, malignant or purulent effusion is suspected.
- Pericardial biopsy may be needed if tuberculosis is suspected and pericardiocentesis not diagnostic.

Other tests include looking for underlying causes, e.g. blood cultures, autoantibody screen.

Treatment

An underlying cause should be sought and treated if possible. Most pericardial effusions resolve spontaneously. However, when the effusion collects rapidly, tamponade may result. Pericardiocentesis is then indicated to relieve the pressure - a drain may be left in temporarily to allow sufficient release of fluid.

Pericardial effusions may reaccumulate, most commonly due to malignancy (in the UK). This may require pericardial fenestration, i.e. creation of a window in the pericardium to allow the slow release of fluid into the surrounding tissues. This procedure may either be performed transcutaneously under local anaesthetic or using a conventional surgical approach.

Constrictive pericarditis

Certain causes of pericarditis such as tuberculosis, haemopericardium, bacterial infection and rheumatic heart disease result in the pericardium becoming thick, fibrous and calcified. This may also develop late after open-heart surgery. In many cases these pericardial changes do not cause any symptoms. If, however, the pericardium becomes so inelastic as to interfere with diastolic filling of the heart, constrictive pericarditis is said to have developed. As these changes are chronic, allowing the body time to compensate, this condition is not as immediately life-threatening as cardiac tamponade, in which the circulation is more acutely embarrassed.

Constrictive pericarditis should be distinguished from restrictive cardiomyopathy (see p. 851). The two conditions are very similar in their presentation, but the former is fully treatable, whereas most cases of the latter are not. In the later stages of constrictive pericarditis the subepicardial layers of myocardium may undergo fibrosis, atrophy and calcification.

Clinical features

The symptoms and signs of constrictive pericarditis occur due to:

- reduced ventricular filling (similar to cardiac tamponade, i.e. Kussmaul's sign, Friedreich's sign, pulsus paradoxus)
- systemic venous congestion (ascites, dependent oedema, hepatomegaly and raised JVP)
- pulmonary venous congestion (dyspnoea, cough, orthopnoea, PND) less commonly
- reduced cardiac output (fatigue, hypotension, reflex tachycardia)
- rapid ventricular filling ('pericardial knock' heard in early diastole at the lower left sternal border)
- atrial dilatation (30% of cases have atrial fibrillation).

Investigations

- **Chest** X-ray (Fig. 13.114): shows a relatively small heart in view of the symptoms of heart failure. Pericardial calcification is present in up to 50%. A

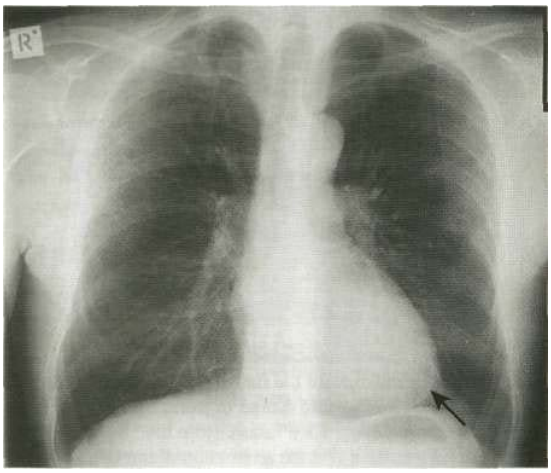

Fig. 13.114 Chest X-ray showing a pericardial calcification (arrow).

lateral chest film may be useful in detecting calcification that is missed on an AP film. However, a calcified pericardium is not necessarily a constricted one.

- ECG reveals low-voltage QRS complexes with generalized T wave flattening or inversion.
- **Echocardiography** shows thickened calcified pericardium, and small ventricular cavities with normal wall thickness. Doppler studies may be useful.
- CT **and MRI** are used to assess pericardial anatomy and thickness (3 mm or greater).
- **Endomyocardial biopsy** may be helpful in distinguishing constrictive pericarditis from restrictive cardiomyopathy in difficult cases.
- **Cardiac catheterization.** End-diastolic pressures in the left and right ventricles measured during this procedure are usually equal, owing to pericardial constriction.

Restrictive cardiomyopathy is a close mimic of constrictive pericarditis and all the above tests may not help to distinguish the two conditions.

Treatment

The treatment for chronic constrictive pericarditis is complete resection of the pericardium. This is a risky procedure with a high complication rate due to the presence of myocardial atrophy in many cases at the time of surgery. Thus early pericardiectomy is suggested in non-tuberculous cases, before severe constriction and myocardial atrophy have developed.

In cases of tuberculous constriction, the presence of pericardial calcification implies chronic disease. Current evidence tends to favour early pericardiectomy with antituberculous drug cover in these cases. If there is no calcification, a course of antituberculous therapy should be attempted first. If the patient's haemodynamic state remains static or deteriorates after 4—6 weeks of therapy, pericardiectomy is recommended.

SYSTEMIC HYPERTENSION

Definitions of hypertension

Elevated arterial blood pressure is a major cause of premature vascular disease leading to cerebrovascular events, ischaemic heart disease and peripheral vascular disease. Blood pressure is a characteristic of each individual, like height and weight, with marked inter-individual variation, and has a continuous (bell-shaped) distribution. The levels of blood pressure observed depend on the characteristics of the population studied - in particular, the age and ethnic background. Blood pressure in industrialized countries rises with age, certainly up to the seventh decade. This rise is more marked for systolic pressure and is more pronounced in men. Hypertension is very common in the developed world. Depending on the diagnostic criteria, hypertension is present in 20-30% of the adult population. Hypertension rates are much higher in black Africans (40-45% of adults).

The definition of an abnormal blood pressure is resolved as indicated in Table 13.47.

The risk of mortality or morbidity rises progressively with increasing systolic and diastolic pressures, with each measure having independent prognostic value; for example, isolated systolic hypertension is associated with a two- to threefold increase in cardiac mortality.

All adults should have blood pressure measured routinely at least every 5 years until the age of 80 years. Seated blood pressure when measured after 5 minutes' resting is usually sufficient, but standing blood pressure

Table 13.47 **Classification of blood pressure levels of the British Hypertension Society**

Category	Systolic blood pressure (mmHg)	Diastolic blood pressure (mmHg)
Blood pressure		
Optimal	< 120	<80
Normal	<130	<85 85-
High normal	130-139	89
Hypertension		
Grade I (mild)	140-149	90-99
Grade 2 (moderate)	160-179	100-109
Grade 3 (severe)	>180	
Isolated systolic hypertension		
Grade 1	140-149	<90
Grade 2	> 160	<90

This classification equates with those of the European Society of Hypertension and the World Health Organization-International Society of Hypertension and is based on clinical blood pressure and not values for ambulatory blood pressure measurement. Threshold blood pressure levels for the diagnosis of hypertension using self/home monitoring are greater than 135/85 mmHg. For ambulatory monitoring, 24-hour values are greater than 125/80 mmHg. If systolic blood pressure and diastolic blood pressure fall into different categories, the higher value should be taken for classification

should be measured in diabetic and elderly subjects to exclude orthostatic hypotension. The cuff should be deflated at 2 mm/s and the blood pressure measured to the nearest 2 mmHg. Two consistent blood pressure measurements are needed to estimate blood pressure, and more are recommended if there is variation in the pressure. When assessing the cardiovascular risk, the average blood pressure at separate visits is more accurate than measurements taken at a single visit.

Causes

The majority (80-90%) of patients with hypertension have primary elevation of blood pressure (i.e. cause not known - essential hypertension), which can be ameliorated only by life-long pharmacological therapy.

Essential hypertension

Essential hypertension has a multifactorial aetiology.

Genetic factors

Blood pressure tends to run in families and children of hypertensive parents tend to have higher blood pressure than age-matched children of people with normal blood pressure. This familial concordance of blood pressure may be explained, at least in part by shared environmental influences. However, there still remains a large, still largely unidentified genetic component.

Fetal factors

Low birthweight is associated with subsequent high blood pressure. This relationship may be due to fetal adaptation to intrauterine undernutrition with long-term changes in blood vessel structure or in the function of crucial hormonal systems.

Environmental factors

Amongst the several environmental factors that have been proposed, the following seem to be the most significant:

Obesity. Fat people have higher blood pressures than thin people. There is a risk, however, of overestimation if the blood pressure is measured with a small cuff. Adjust the bladder size to the arm circumference. Sleep disordered breathing (see p. 906) often seen with obesity may be an additional risk factor.

Alcohol intake. Most studies have shown a close relationship between the consumption of alcohol and blood pressure level. However, subjects who consume small amounts of alcohol seem to have lower blood pressure level than those who consume no alcohol.

Sodium intake. A high sodium intake has been suggested to be a major determinant of blood pressure differences between and within populations around the world. Populations with higher sodium intake have higher average blood pressures than those with lower sodium intake. Migration from a rural to an urban environment is associated with an increase in blood pressure that is in part related to the amount of salt in the diet. Studies of the restriction of salt intake have shown a beneficial effect on blood pressure in hypertensives. There is some evidence that a high-potassium diet can protect against the effects of a high sodium intake.

Stress. Whilst acute pain or stress can raise blood pressure, the relationship between chronic stress and blood pressure is uncertain.

Humoral mechanisms

The autonomic nervous system, as well as the renin-angiotensin, natriuretic peptide and kallikrein-kinin system, plays a role in the physiological regulation of short-term changes in blood pressure and have been implicated in the pathogenesis of essential hypertension. A low renin, salt-sensitive, essential hypertension in which patients have renal sodium and water retention has been described. However, there is no convincing evidence that the above systems are directly involved in the maintenance of hypertension.

Insulin resistance

An association between diabetes and hypertension has long been recognized and a syndrome has been described of hyperinsulinaemia, glucose intolerance, reduced levels of HDL cholesterol, hypertriglyceridaemia and central obesity (all of which are related to insulin resistance) in association with hypertension. This association (also called the 'metabolic syndrome') is a major risk factor for cardiovascular disease.

Secondary hypertension

Secondary hypertension is where blood pressure elevation is the result of a specific and potentially treatable cause. Secondary forms of hypertension include the following:

Renal diseases

These account for over 80% of the cases of secondary hypertension. The common causes are diabetic nephropathy, chronic glomerulonephritis, adult polycystic disease, chronic tubulointerstitial nephritis, and renovascular disease. Hypertension can itself cause or worsen renal disease. The mechanism of this blood pressure elevation is primarily due to sodium and water retention, although there can be inappropriate elevation of plasma renin levels.

Endocrine causes

These include:

- Conn's syndrome
- adrenal hyperplasia
- phaeochromocytoma
- Cushing's syndrome
- acromegaly.

Congenital cardiovascular causes

The major cause is coarctation of the aorta.

Drugs

There are many drugs that have been shown to cause or aggravate hypertension, or interfere with the response to some antihypertensive agents: NSAIDs, oral contraceptive, steroids, carbenoxolone, liquorice, sympathomimetics and vasopressin.

Patients taking monoamine oxidase inhibitors, who consume tyramine-containing foods, may develop paroxysms of severe hypertension.

Pregnancy

Cardiac output rises in pregnancy but, owing to a relatively greater fall in peripheral resistance, blood pressure in pregnant women is usually lower than in those not pregnant. Hypertension is noted in 8-10% of pregnancies; when detected in the first half of pregnancy or persisting after delivery it is usually due to pre-existing essential hypertension. Hypertension presenting in the second half of pregnancy - or 'pregnancy-induced hypertension' - usually resolves after delivery. When the blood pressure increases to > 160/110 mmHg treatment is warranted for the protection of the mother. Pre-eclampsia is a syndrome consisting of pregnancy-induced hypertension with proteinuria. The primary pathology is unknown, but is likely to involve a disturbance of the uteroplacental circulation and result in intrauterine growth restriction. Hypertension in pregnancy, together with pulmonary embolus, are the most common causes of maternal death, with a rate of 10 per million pregnancies. Furthermore, the critical condition of eclampsia, which is associated with severe hypertension, may ultimately lead to convulsions, cerebral and pulmonary oedema, jaundice, clotting abnormalities and fetal death.

Pathophysiology

The pathogenesis of essential hypertension remains unclear. In some young hypertensive patients, there is an early increase in cardiac output, in association with increased pulse rate and circulating catecholamines. This could result in changes in baroreceptor sensitivity, which would then operate at a higher blood pressure level.

In *chronic hypertension,* the cardiac output is normal and it is an increased peripheral resistance that maintains the elevated blood pressure. The resistance vessels (the small arteries and arterioles) show structural changes in hypertension. These are an increase in wall thickness with a reduction in the vessel lumen diameter. There is also some evidence for rarefaction (decreased density) of these vessels. These mechanisms would result in an increased overall peripheral vascular resistance.

Hypertension also causes changes in the large arteries. There is thickening of the media, an increase in collagen and the secondary deposition of calcium. These changes result in a loss of arterial compliance, which in turn leads to a more pronounced arterial pressure wave. Atheroma develops in the large arteries owing to the interaction of these mechanical stresses and low growth factors (see p. 798). Endothelial dysfunction with alternations in agents such as nitric oxide and endothelins appear to be involved.

Left ventricular hypertrophy, which results from increased peripheral vascular resistance, and increased left ventricular load, is a significant prognostic indicator of future cardiovascular events.

Changes in the *renal vasculature* eventually lead to a reduced renal perfusion, reduced glomerular filtration rate and, finally, a reduction in sodium and water excretion. The decreased renal perfusion may lead to activation of the renin-angiotensin system (renin converts angiotensinogen to angiotensin I, which is in turn converted to angiotensin II by angiotensin-converting enzyme) with increased secretion of aldosterone and further sodium and water retention.

Complications

Cerebrovascular disease and coronary artery disease are the most common causes of death, although hypertensive patients are also prone to renal failure and peripheral vascular disease.

Hypertensives have a sixfold increase in stroke (both haemorrhagic and atherothrombotic). There is a threefold increase in cardiac death (due either to coronary events or to cardiac failure). Furthermore, peripheral arterial disease is twice as common.

Malignant hypertension

Malignant or accelerated hypertension occurs when blood pressure rises rapidly and is considered with severe hypertension (diastolic blood pressure > 120 mmHg) (see p. 864). The characteristic histological change is fibrinoid necrosis of the vessel wall and, unless treated, it may lead to death from progressive renal failure, heart failure, aortic dissection or stroke. The changes in the renal circulation result in rapidly progressive renal failure, proteinuria and haematuria. There is also a high risk of cerebral oedema and haemorrhage with resultant encephalopathy, and in the retina there may be flame-shaped haemorrhages, cotton wool spots, hard exudates and papilloedema (Fig. 13.115). Without effective treatment there is a 1-year survival of less than 20%.

Assessment

Management should be considered in three stages: assessment, non-pharmacological treatment, and drug treatment. During the assessment period, secondary causes of hypertension should be excluded, target-organ damage from the blood pressure should be evaluated, and any concomitant conditions (e.g. dyslipidaemia or diabetes) that may add to the cardiovascular burden should be identified.

History

The patient with mild hypertension is usually asymptomatic. Attacks of sweating, headaches and palpitations may point towards the diagnosis of phaeochromocytoma. Higher levels of blood pressure may be associated with headaches, epistaxis or nocturia. Breathlessness may be present owing to left ventricular hypertrophy or cardiac failure, whilst angina or symptoms of peripheral arterial vascular disease suggest the diagnosis of atheromatous

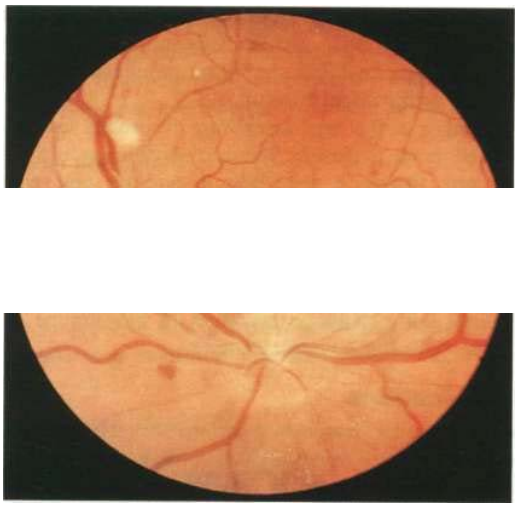

Fig. 13.115 **Fundus showing hypertensive changes:** Grade 4 retinopathy with papilloedema, haemorrhages and exudates.

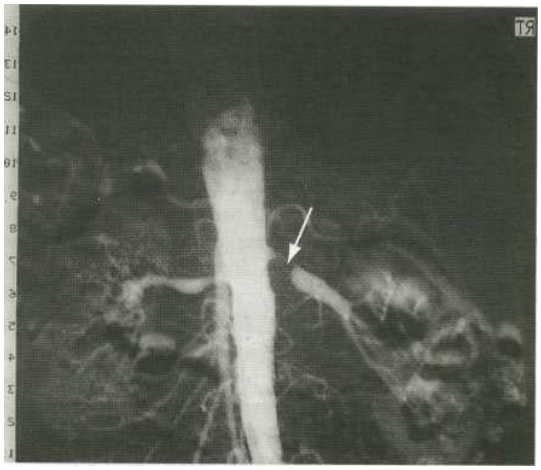

Fig. 13.116 **Digital subtraction angiography, showing typical unilateral atheromatous renal artery stenosis with post-stenotic dilatation.**

renal artery stenosis. This is usually a local manifestation of more generalized atherosclerosis, and patients are often elderly with coexistent vascular disease (Fig. 13.116). Fibromuscular disease of the renal arteries encompasses a group of conditions in which fibrous or muscular proliferation results in morphologically simple or complex stenoses and tends to occur in younger patients. Malignant hypertension may present with severe headaches, visual disturbances, fits, transient loss of consciousness or symptoms of heart failure.

Examination

Elevated blood pressure is usually the only abnormal sign. Signs of an underlying cause should be sought, such as renal artery bruits in renovascular hypertension, or radiofemoral delay in coarctation of the aorta. The cardiac examination may also reveal features of left ventricular hypertrophy and a loud aortic second sound. If cardiac failure develops, there may be a sinus tachycardia and a third heart sound.

Fundoscopy is an essential part of the examination of any hypertensive patient (Fig. 13.115). The abnormalities are graded according to the Keith-Wagener classification:

Grade 1 - tortuosity of the retinal arteries with increased reflectiveness (silver wiring)

Grade 2 - grade 1 plus the appearance of arteriovenous nipping produced when thickened retinal arteries pass over the retinal veins

Grade 3 - grade 2 plus flame-shaped haemorrhages and soft ('cotton wool') exudates actually due to small infarcts

Grade 4 - grade 3 plus papilloedema (blurring of the margins of the optic disc).

Grades 3 and 4 are diagnostic of malignant hypertension.

Ambulatory blood pressure monitoring

Indirect automatic blood pressure measurements can be made over a 24-hour period using a measuring device worn by the patient. The clinical role of such devices remains uncertain, although they are used to confirm the diagnosis in those patients with 'white-coat' hypertension, i.e. in those subjects whose blood pressure is completely normal at all stages except during a clinical consultation (Fig. 13.117a). These patients do not have any evidence of target-organ damage, and unnecessary treatment can be avoided. These devices may also be used to monitor the response of patients to drug treatment and, in particular, can be used to determine the adequacy of 24-hour control with once-daily medication (Fig. 13.117b, c). Ambulatory blood pressure recordings seem to be better predictors of cardiovascular risk than clinic measurements. Analysis of the diurnal variation in blood pressure suggests that those hypertensives with loss of the usual nocturnal fall in blood pressure ('non-dippers') have a worse prognosis than those who retain this pattern.

Investigations

Routine investigation of the hypertensive patient should include:

- ECG
- urine stix test for protein and blood
- fasting blood for lipids (total and high-density lipoprotein cholesterol) and glucose
- serum urea, creatinine and electrolytes.

If the urea or creatinine is elevated, more specific renal investigations are indicated - creatinine clearance, renal ultrasound (in case of polycystic kidney disease, or parenchymal renal artery disease) and a renal isotope scan or renal angiography if renovascular disease (either atheromatous or fibromuscular dysplasia) is suspected. A low serum potassium may indicate an endocrine disorder (either primary hyperaldosteronism or glucocorticoid

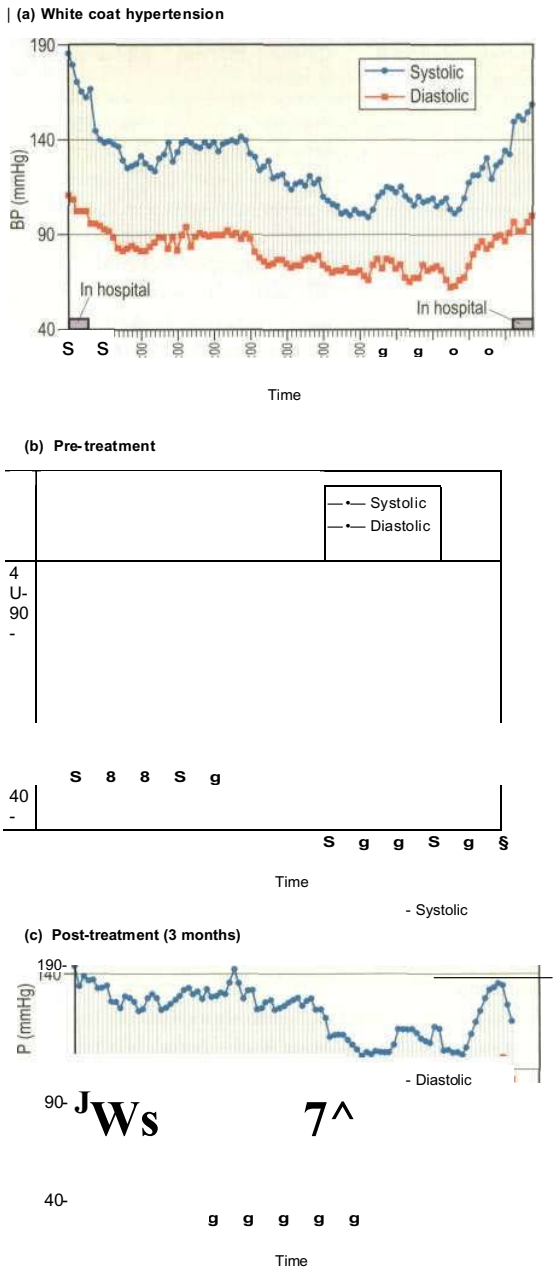

Fig. 13.117 24-hour ambulatory blood pressure monitoring, showing:
(a) white-coat hypertension;
(b) pre-treatment;
(c) after 3 months' treatment.

excess), and aldosterone, cortisol and renin measurements must then be made, preferably prior to initiating pharmacological therapy. Clinical suspicion of phaeochromocytoma should be investigated further with measurement of urinary metanephrines and plasma or urinary catecholamines.

If the ECG shows evidence of coronary artery disease the coronary vascular status should be assessed. If left ventricular hypertrophy is suspected *echocardiography* (or MRI) should be undertaken. A *chest X-ray* is indicated if cardiac involvement or aortic coarctation is likely.

Treatment

Unless the patient has severe or malignant hypertension, there should be a period of assessment with repeated blood pressure measurements, combined with advice and non-pharmacological measures prior to the initiation of drug therapy. The guidelines of the British Hypertension Society (BHS) suggest the following.

Use of non-pharmacological therapy in all hypertensive and borderline hypertensive people:

- weight reduction - BMI should be < 25 kg/m^2
- low-fat and saturated fat diet
- low-sodium diet - < 6 g sodium chloride per day
- limited alcohol consumption - < 21 units/week for men and < 14 units/week for women
- dynamic exercise - at least 30 minutes' brisk walk per day
- increased fruit and vegetable consumption
- reduce cardiovascular risk by stopping smoking and increasing oily fish consumption.

Pharmacological therapy should be based on the following:

- The initiation of antihypertensive therapy in subjects with sustained systolic blood pressure (BP) > 160 mmHg, or sustained diastolic BP > 100 mmHg.
- Decide on treatment in subjects with sustained systolic blood pressure between 140 and 159 mmHg, or sustained diastolic BP between 90 and 99 mmHg, according to the presence or absence of target organ damage or a 10-year cardiovascular disease risk > 20%.
- In patients with diabetes mellitus, the initiation of antihypertensive drug therapy if systolic BP is sustained > 140 mmHg, or diastolic BP is sustained > 90 mmHg.
- In non-diabetic hypertensive subjects, treatment goals: BP < 140/85 mmHg. In some hypertensive subjects these levels may be difficult to achieve.
- The main determinant of outcome following treatment is the level of blood pressure reduction that is achieved rather than the specific drug used to lower blood pressure.
- Most hypertensive patients will require a combination of antihypertensive drugs to achieve the recommended targets.
- In most hypertensive patients therapy with statins and aspirin to reduce the overall cardiovascular risk burden.

Glycaemic control should be optimized in diabetics (HbA_{1c} < 7%).

Drug treatment (Table 13.48)

When to initiate treatment

The decision to commence specific drug therapy should usually be made only after a careful period of assessment, of up to 6 months, with repeated measurements of blood pressure. The aim of drug treatment to reduce the risk of complications of hypertension should be carefully

Table 13.48 Advantages and disadvantages of drugs used in hypertension with respect to associated conditions

	Diuretic	Beta-blocker	ACE inhibitor/angiotensin II receptor antagonist	Calcium-channel blockers	Alpha-blocker
Diabetes	Care*	Care*	Yes	Yes	Yes
Gout	No	Yes	Yes	Yes	Yes
Dyslipidaemia	Care[f]	Caret	Yes	Yes	Yes
Ischaemic heart disease	Yes	Yes	Yes	Yes	Yes
Heart failure	Yes	Yes	Yes	Care*	Yes
Asthma	Yes	No	Yes	Yes	Yes
Peripheral vascular disease	Yes	Care	Care[5]	Yes	Yes
Renal artery stenosis	Yes	Care	**No**	Yes	Yes
Pregnancy	Caution	Not in late pregnancy	**No**	No	Caution

* Diuretics may aggravate diabetes: beta-blockers worsen glucose intolerance and mask symptoms of hypoglycaemia Both diuretics and beta-blockers disturb the lipid profile
Verapamil and diltiazem may exacerbate heart failure, although amlodipine appears to be safe Patients with peripheral vascular disease may also have renal artery stenosis; therefore ACE inhibitors should be used cautiously

explained to the patient and a plan for the patient's treatment (drug dose titration, change of drug, combination of drugs) should be agreed with the patient. All of the drugs used to treat hypertension have side-effects and, since the benefits of drug treatment are not immediate, compliance may be a major problem.

Several classes of drugs are available to treat hypertension. The usual are: (a) ACE inhibitors or angiotensin receptor antagonists; (b) beta-blockers; (c) calcium-channel blockers; or (d) diuretics. It is recommended that drugs are chosen according to the scheme laid out in Figure13.118.

- The rationale for *step 1* is that young Caucasians are more likely to have high renin hypertension, and older patients and blacks usually have low renin hypertension. If a drug within each pair is not tolerated, the alternative drug type can be used (e.g. if an ACE inhibitor is not tolerated, an angiotensin receptor antagonist or beta-blocker may be used). If a drug is not effective, a drug from the other group should be selected. Thus if a calcium-channel blocker is not helpful, an ACE inhibitor, angiotensin receptor antagonist or beta-blocker should be tried. Almost all patients will need more than one drug to effectively lower blood pressure.
- *Step 2* involves combining one drug from each group. It is not advised to combine a diuretic with a beta-blocker since both aggravate diabetes.
- In *step 3* an ACE inhibitor (or angiotensin receptor antagonist) is combined with a calcium-channel blocker and diuretic. If triple therapy is not sufficient to achieve target blood pressure readings, an alpha-blocker, spironolactone or another agent may be used.

Diuretics

Thiazide diuretics such as bendroflumethiazide (2.5-5 mg daily) and cyclopenthiazide (0.25-0.5 mg daily) are well-established agents which have been shown to reduce the

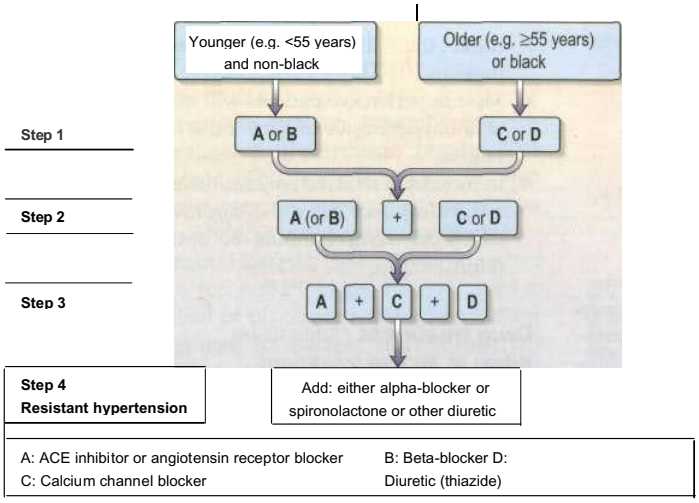

Fig. 13.118 **The British Hypertension Society recommendations for combining blood pressure-lowering drugs.** Adapted from Better blood pressure control: how to combine drugs. *Journal of Human Hypertension* (2003) 17: 81-86.

risk of stroke in patients with hypertension. The lower doses seems to be equally effective as higher doses in the reduction of blood pressure and most have a duration of up to 24 hours. The major concern with these agents is their adverse metabolic effects, particularly increased serum cholesterol, impaired glucose tolerance, hyperuricaemia (which may precipitate gout) and hypokalaemia. These tend to occur with higher doses of thiazide diuretics.

Loop diuretics such as furosemide (40 mg daily) do have a hypotensive effect, but are not routinely used in the treatment of essential hypertension. Potassium-sparing diuretics such as amiloride (5-10 mg daily) or spironolactone (50-200 mg daily) are not effective agents when used alone, with the exception of spironolactone in the treatment of hypertension and hypokalaemia associated with primary hyperaldosteronism.

Beta-adrenoceptor blockers

The beta-blockers have also been shown to improve the prognosis of hypertensives. They have been suggested to exert their effects by attenuating the effects of the sympathetic nervous and the renin-angiotensin systems. They reduce the force of cardiac contraction, as well as resting and exercise-induced increase in heart rate. But, there are differences between these antihypertensive drugs (Table 13.49):

- *Cardioselectivity.* Some have less effect on the β_2 (non-cardiac) receptors and are therefore said to be relatively cardioselective. These include atenolol and bisoprolol.
- *Intrinsic sympathomimetic activity.* Some agents have partial agonist activity and cause less bradycardia. These include oxprenolol and pindolol.
- *Lipid solubility.* The agents that are less lipid-soluble are less likely to cause central nervous system side-effects. These include atenolol.

The major side-effects of this class of agents are bradycardia, bronchospasm, cold extremities, fatigue, bad dreams and hallucinations. These agents are especially useful in the treatment of patients with both hypertension and angina.

Angiotensin-converting enzyme (ACE) inhibitors

These drugs block the conversion of angiotensin I to angiotensin II, which is a potent vasoconstrictor. They also block the degradation of bradykinin, a potent vasodilator. There is evidence that black African patients respond less well to ACE inhibitors unless combined with diuretics. They are particularly useful in diabetics with nephropathy, where they have been shown to slow disease progression, and in those patients with symptomatic or asymptomatic left ventricular dysfunction, where they have been shown to improve survival.

The major potential side-effects are profound hypotension following the first dose, which is usually seen in sodium-depleted patients or in those on treatment with large doses of diuretics, and deterioration of renal function in those with severe bilateral renovascular disease (in whom the production of angiotensin II is playing a major role in maintaining renal perfusion by causing efferent arteriolar constriction at the glomerulus). They also cause mild dry cough in a number of patients, especially if prescribed at high doses, due to their effect on bradykinin.

These are several ACE inhibitors available and there are no significant differences between them in terms of blood pressure effect other than the half-life and therefore the frequency at which they have to be prescribed for 24-hour blood pressure control; those with the longest duration of action may be taken once-daily, which is clearly a benefit in terms of compliance. The drugs include captopril (50-150 mg daily in divided doses), ramipril (2.5-10 mg daily), enalapril or lisinopril (10-20 mg daily), and trandolapril (1^1 mg daily).

Angiotensin II receptor antagonists

This group of agents selectively block the receptors for angiotensin II. They share many of the actions of ACE inhibitors but, since they do not have any effect on bradykinin, do not cause a cough. They are currently used for patients who cannot tolerate ACE inhibitors because of persistent cough. Angioneurotic oedema and renal dysfunction are encountered less with these drugs than with ACE inhibitors. The agents include losartan (50-100 mg daily), candesartan (16 mg daily) valsartan (80-160 mg daily), irbesartan (75-300 mg daily) and telmisartan (20-80 mg/daily).

Calcium-channel blockers

These agents effectively reduce blood pressure by causing arteriolar dilatation, and some also reduce the force of cardiac contraction. Like the beta-blockers, they are especially useful in patients with concomitant ischaemic

Table 13.49 **Main properties of the beta-blockers commonly used for hypertension**

	Cardiac selectivity	Intrinsic sympathomimetic activity	Lipid solubility	Plasma half-life (hours)	Usual dosage
Acebutalol	+	+	0	5	400 mg once or twice daily
Atenolol	+	0	0	6	50 mg once daily
Bisoprolol	++	0	0	10-12	10-20 mg once daily
Celiprolol	0	+	0	5	200 mg once daily
Oxprenolol	0	++	+	1.5	20-80 mg three times daily
Metoprolol	+	0	+	3-10	100-200 mg daily
Propranolol	0	0	+++	5	80-160 mg twice daily
Timolol	0	0	+	5	5-20 mg twice daily

heart disease. The major side-effects are particularly seen with the short-acting agents and include headache, sweating, swelling of the ankles, palpitations and flushing. Many of these side-effects can be lessened by the co-administration of a beta-blocker. The short-acting agents, such as nifedipine (10-20 mg three times daily) are being replaced by once-daily agents that are very well tolerated and include amlodipine (5-10 mg daily) felodipine (5-20 mg daily) and long-acting nifedipine (20-90 mg daily).

Alpha-blockers

These agents cause postsynaptic apreceptor blockade with resulting vasodilatation and blood pressure reduction. Earlier short-acting agents caused serious first-dose hypotension, but the newer longer-acting agents are far better tolerated. These include doxazosin (1-4 mg daily). Labetalol is an agent that has combined alpha- and beta-blocking properties, but is not commonly used, except in pregnancy-induced hypertension.

Other vasodilators

These include hydralazine (up to 100 mg daily) and minoxidil (up to 50 mg daily). Both are extremely potent vasodilators that are reserved for patients resistant to other forms of treatment. Hydralazine can be associated with tachycardia, fluid retention and a systemic lupus erythematosus-like syndrome. Minoxidil can cause severe oedema and excessive hair growth and coarse facial features. If these agents are used, it is usually in combination with a beta-blocker.

Centrally acting drugs

Reserpine is used in a low dose of 0.05 mg per day, which provides almost all its antihypertensive action with fewer side-effects than higher doses. It has a slow onset of action (measured in weeks). Methyldopa is still widely used despite central and potentially serious hepatic and blood side-effects. It acts on central a_2-receptors, usually without slowing the heart. Clonidine and moxonidine provide all the benefits of methyldopa with none of the rare (but serious) autoimmune reactions.

Management of severe or malignant hypertension

Patients with severe hypertension (diastolic pressure > 140 mmHg), malignant hypertension (grades 3 or 4 retinopathy), hypertensive encephalopathy or with severe hypertensive complications, such as cardiac failure, should be admitted to hospital for immediate initiation of treatment. However, it is unwise to reduce the blood pressure too rapidly since this may lead to cerebral, renal, retinal or myocardial infarction, and the blood pressure response to therapy must be carefully monitored, preferably in a high-dependency unit. In most cases, the aim is to reduce the diastolic blood pressure to 100-110 mmHg over 24-^8 hours. This is usually achieved with oral medication, e.g. atenolol or amlodipine. The blood pressure can then be normalized over the next 2-3 days.

When rapid control of blood pressure is required (e.g. in an aortic dissection), the agent of choice is intravenous sodium nitroprusside. Alternatively, an infusion of labetalol can be used. The infusion dosage must be titrated against the blood pressure response. Fenoldopam, a selective peripheral dopamine receptor agonist, is as effective as nitroprusside.

Management of hypertension in pregnancy

Many antihypertensive agents are contraindicated in pregnancy. Mild hypertension can be treated with methyldopa, which has been established as being safe in pregnancy, or labetalol. Pre-eclamptic hypertension can be treated with the same agents, or nifedipine, although the only method for reversal of overt pre-eclampsia is delivery. More severe hypertension or eclampsia requires treatment with intravenous hydralazine and may even require termination of the pregnancy.

Prognosis

The prognosis from hypertension depends on a number of features:

- level of blood pressure
- presence of target-organ changes (retinal, renal, cardiac or vascular)
- coexisting risk factors for cardiovascular disease, such as hyperlipidaemia, diabetes, smoking, obesity, male sex
- age at presentation.

Several studies have confirmed that the treatment of hypertension, even mild hypertension, will reduce the risk not only of stroke but of coronary artery disease as well.

HEART DISEASE IN THE ELDERLY

As the average age of the population increases, and as patients with cardiac disease survive for longer periods of time, the number of elderly patients with heart disease has increased markedly and is likely to continue to escalate in years to come. The elderly are vulnerable to

hypertension, coronary artery disease, heart failure, arrhythmias and degenerative pathologies.

Normal findings

Diagnosis of mild forms of heart disease may be difficult in the elderly. The wear and tear of age results in some features that would be regarded as abnormal in the young. For example, a fourth heart sound and a systolic aortic ejection murmur are common findings on examining normal elderly adults. Basal crackles in the elderly are common and may not necessarily imply left-sided heart failure. The ECG often shows slight PR interval prolongation (up to 0.22 s), left axis deviation and T wave flattening. On the chest X-ray there is frequently a degree of tissue calcification. This is seen in the valvular annuli, the aortic arch, and the coronary and pulmonary vasculature, but the cardiac silhouette is usually normal, although changes in the shape of the chest wall may distort normal anatomy. The echocardiogram may show mild myocardial hypertrophy and buckling of the ventricular septum mimicking hypertrophic cardiomyopathy.

It is sometimes difficult to diagnose and define hyper tension in the elderly. Cuff blood pressure usually over estimates intravascular pressure since the arterial wall is stiff (pseudohypertension). Normally, blood pressure steadily increases with age, at least up to the age of 70 years; furthermore blood pressure is particularly labile in the elderly. . . .

Disease presentation

Cardiac disease often presents in unexpected ways in an old person. It is not unusual for significant bradycardia to present as a fractured hip owing to a fall resulting from transient asystole. Left heart failure may present as an acute confusional state due to poor cerebral perfusion, rather than with the classical symptom of breathlessness, and frequently accompanies pneumonia. Myocardial infarction may not cause any chest pain ('silent' myocardial infarction) in up to 20% of patients but presents as weakness, abdominal pain, confusion, or a more general deterioration in well-being. Infective endocarditis can cause much diagnostic confusion, particularly in the elderly who may not display fever, and present with symptoms from almost any organ system. Elderly patients may present with heart failure despite a normal-sized heart on X-ray and normal systolic myocardial function on echocardiogram (diastolic heart failure).

Treatment

Age is no bar to effective treatment of heart disease and the principles of treatment of heart disease in the elderly are usually no different from those governing treatment in the young. Drug pharmacokinetics are changed in the elderly: absorption is reduced, renal and hepatic clearance are delayed, body fat increases and lean body mass decreases. Elderly patients frequently have coexistent disease and are taking other medication which interacts with both their cardiac medication and their heart disease. For example, non-steroidal anti-inflammatory drugs for arthritis may cause fluid retention and worsen heart failure. Old people may forget to take their medication or be confused about the correct dose and timing.

In general, therapy in elderly patients (who have a limited life span) is more likely to be focused on effective relief of symptoms rather than substantial prolongation of life. However, systolic hypertension results in a marked increase in cardiac and cerebrovascular complications, and this risk can be effectively reduced with adequate blood pressure control. Coronary angioplasty, mitral and, less commonly, aortic valvuloplasty can be undertaken in patients too frail for cardiac surgery, which carries a much greater (approximately two to five times) risk in the elderly. As with younger patients, the absolute risk of cardiac surgery is dependent upon the state of the myocardium, the extent of cardiac disease and the condition of other organ systems.

Specific heart problems in the elderly

There are a few cardiac conditions that are largely confined to the elderly.

Aortic sclerosis

Aortic sclerosis results from fibrosis and calcification on the aortic side of an otherwise normal tri-leaflet aortic valve. The resultant obstruction to left ventricular outflow is often trivial; however, true aortic stenosis requiring aortic valve replacement may be necessary if the obstruction is severe.

Mitral annulus calcification

Mitral annulus calcification occurs predominantly in elderly women. It is diagnosed from the chest X-ray and it is not usually responsible for any symptoms.

Endocarditis

A non-bacterial thrombotic form of endocarditis (marantic endocarditis) may occur in the elderly. It is sometimes associated with malignancy and presents with cachexia, thrombosis and embolization. Anticoagulation may be needed.

Lev's disease

Disruption of His-Purkinje conduction by fibrosis and calcification is most common in the old, when it is known as Lev's disease. It presents with Stokes-Adams attacks and must be treated by pacemaker insertion. Age is not a contraindication to pacing, even when the most sophisticated physiological devices are used. Pacemakers should be prescribed on similar criteria in the young and the old.

Carotid sinus hypersensitivity

This is a common cause of syncope in the elderly and is responsible for many admissions for falls, fractures, and dizzy spells. The syndrome is frequently not diagnosed. It is thought to be due to abnormal sensitivity of the carotid baroreceptors resulting in a fall in heart rate, a drop in

blood pressure, or both. Diagnosis is made by carotid sinus massage (after excluding carotid stenosis by auscultation). Treatment with a pacemaker may significantly help some patients with the syndrome (see p. 762).

Atrial fibrillation

Atrial fibrillation is much more common in the elderly and is a common cause of stroke in this group of patients. It is often well tolerated and may not need any active treatment for control of heart rate. Anticoagulation is usually advised (see p. 774), except in the very elderly, those prone to falls and those who cannot be relied upon to take their medication regularly.

Martin A, Camm AJ (1994) *Heart Disease in the Elderly.* Chichester: John Wiley.

PERIPHERAL VASCULAR DISEASE

PERIPHERAL ARTERIAL DISEASE

Peripheral vascular disease (PVD) is commonly caused by atherosclerosis and usually affects the aorto-iliac or infra-inguinal arteries. It is present in 7% of middle-aged men and 4.5% of middle-aged women but these patients are more likely to die of myocardial infarction or stroke than lose their leg.

Limb ischaemia may be classified as chronic or acute.

Chronic lower limb ischaemia

Symptoms

On exercise, patients complain of a *severe cramp,* usually in the calf, which resolves when they stop walking. They may be unable to continue walking with the *pain* and often the symptoms are worse walking uphill but never occur at rest. This is called intermittent claudication. Patients may experience similar pain in buttocks and thighs associated with male impotence, the 'Leriche syndrome'. *Claudication* can occur in both legs but is often worse in one leg.

Rest pain is defined as a severe unremitting pain in the foot, which stops a patient from sleeping. It is partially relieved by dangling the foot over the edge of the bed or standing on a cold floor. Patients with severe PVD or critical lower limb ischaemia may have *ulceration* or *necrosis* of the tissue (gangrene).

Signs

The lower limbs are cold with dry skin and lack of hair. Pulses may be diminished or absent. Ulceration may occur in association with dark discoloration of the toes or gangrene.

Risk factors

Common risk factors are:

- smoking
- diabetes
- hypercholesterolaemia
- hypertension.

Premature atherosclerosis in patients aged < 45 years may be associated with thrombophilia and hyperhomocysteinaemia.

Differential diagnosis

Symptoms may be confused with those of:

- spinal canal claudication (but all pulses are present)
- osteoarthritis hip/knee (knee pain often at rest)
- peripheral neuropathy (associated with numbness and tingling)
- popliteal artery entrapment (young patients who may have normal pulses)
- venous claudication (bursting pain on walking with a previous history of a DVT)
- fibromuscular dysplasia
- 'Buerger's' disease (young males, heavy smokers).

Investigations

An estimation of the anatomical level of disease may be possible with the examination of pulses. The severity of disease is indicated by *ankle/brachial pressure index* (ABPI). This is a measurement of the cuff pressure at which blood flow is detectable by Doppler in the posterior tibial or anterior tibial arteries compared to the brachial artery (ankle/brachial pressure). Intermittent claudication is associated with an ABPI of 0.4-0.9. Values of < 0.4 are associated with critical limb ischaemia. The sensitivity of the test may be improved by a fall in ABPI after exercise. If the arteries are heavily calcified and incompressible, i.e. in renal or diabetic disease, the ABPI will be falsely elevated. In these patients toe pressure values are more sensitive.

Diagnostic angiograms are now performed less commonly as *Doppler* and *duplex imaging* give an accurate anatomical assessment of the level and degree of disease. Angiograms are performed via a percutaneous arterial catheter and allow therapeutic interventions to be performed (Fig. 13.119).

Magnetic resonance and *CT angiography* are not routinely performed.

Management

Medical

All patients with peripheral vascular disease need aggressive *risk factor management.* Patients are encouraged to stop smoking and need smoking cessation advice. Patients with diabetes mellitus need regular chiropody care and diabetic management. Hypercholesterolaemia should be treated as this reduces disease progression. It has now been shown by the Heart Protection Study that even the reduction of a normal cholesterol level reduces mortality from cardiovascular disease. Low-dose aspirin reduces the risk of myocardial infarction and stroke in patients with peripheral vascular disease. There are as yet no proven oral medications that are of benefit in patients

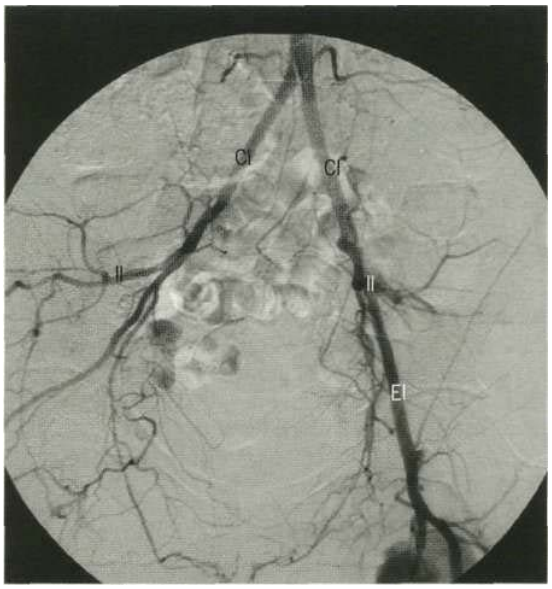

Fig. 13.119 **Angiogram showing occlusion of the right external iliac artery.** Cl, common iliac; II, internal iliac; EI, external iliac.

with claudication. Supervised exercise programmes significantly improve walking distance and quality of life.

Surgical/radiological

These are only considered in patients who have had their risk factors addressed and who feel that their lifestyle is disabled by their symptoms. For instance a person who can only walk 50 yards before claudicating but who also has severe breathing problems may never need lower limb intervention.

Percutaneous transluminal angioplasty is the first option and is carried out via a catheter inserted into the femoral artery. The long-term patency rates decrease as the angioplasty becomes more distal. The long-term results of angioplasty appear to be similar to those of a continued exercise program. Arterial stents may be deployed in recurrent iliac disease, and drug-eluting stents allowing long-term patency are being investigated.

Bypass procedures may be performed using Dacron, polytetrafluroethylene (PTFE) or autologous veins. Bypasses to distal vessels have poorer long-term patencies. Prosthetic grafts have equal patencies in above-knee bypasses but are inferior to veins below the knee.

In severe ischaemia with unreconstructable arterial disease an *amputation* may be necessary. An amputation may lead to loss of independence, with only 70% of below-knee and 30% of above-knee amputees achieving full mobility.

Acute lower limb ischaemia

Symptoms

Patients complain of the *five P's*. They complain of pain, that the leg looks white (pallor), paraesthesia, paralysis and that it feels perishingly cold. The pain is unbearable and normally requires opioids for relief.

Signs

The limb is cold with mottling or marbling of the skin. Pulses are diminished or absent. The sensation and movement of the leg are reduced in severe ischaemia. Patients may develop a compartment syndrome with pain in the calf on compression.

Causes

Acute limb ischaemia (ALI) may occur because of *embolic* or *thrombotic* disease. Embolic disease is commonly due to cardiac thrombus and cardiac arrhythmias. Rheumatic fever is now an uncommon cause and the frequency of cardiac embolic ALI is also on the decline. Emboli may also occur secondary to aneurysm thrombus or thrombus on atherosclerotic plaques. Emboli from atrial myxomas are rare.

Acute limb ischaemia is now often due to thrombotic disease. Acute thrombus may form on a chronic atherosclerotic stenosis in a patient who has previously reported symptoms of claudication. Thrombus may also form in normal vessels in patients, who are hypercoagulable because of malignancy or thrombophilia defects. Prosthetic or venous grafts may also thrombose either de novo or secondary to a developing stenosis either in the graft or in the native vessels. Popliteal aneurysms may thrombose or embolize distally. Acute upper limb ischaemia may be caused by similar processes or occur secondary to external compression with a cervical rib/band.

Investigation and management

Investigations are similar to those described for chronic lower limb disease.

Medical

Management is dependent on the degree of ischaemia. Patients showing improvement may be treatable with heparin and appropriate treatment of the underlying cause. Patients with emboli following myocardial infarction or atrial fibrillation need long-term warfarin.

Surgical/radiological

Patients with mild to moderate ischaemic symptoms who have occluded a graft may need graft thrombolysis. Intra-arterial thrombolysis may reveal an underlying stenosis within a graft or native vessel that could be treated with angioplasty. Patients with an embolus may benefit from its surgical removal (embolectomy). A bypass graft may be required after occlusion of a popliteal aneurysm or acute-on-chronic lower limb arterial disease. When an ischaemic limb is revascularized, the sudden improvement in blood flow can cause reperfusion injury with release of toxic metabolites into the circulation. In muscle compartments the consequent oedema may lead to a 'compartment syndrome', which requires fasciotomies (release of the fascia to prevent muscle damage). An amputation may be warranted in unreconstructable or

severe ischaemia. In patients dying from other causes, acute limb ischaemia may occur and intervention may then be inappropriate.

Aneurysmal disease

Aneurysms are classified as true and false. An aneurysm is defined if there is a permanent dilatation of the artery to twice the normal diameter. In true aneurysms the arterial wall forms the wall of the aneurysm. The arteries most frequently involved are the abdominal aorta, iliac, popliteal, femoral artery and thoracic aorta (in decreasing frequency).

In false aneurysms (pseudoaneurysms) the surrounding tissues form the wall of the aneurysm. False aneurysms can occur following femoral artery puncture. A haematoma is formed because of inadequate compression of the entry site and continued bleeding into the surrounding compressed soft tissue forms the wall of this aneurysm.

Abdominal aortic aneurysm

Abdominal aortic aneurysms (AAA) occur most commonly below the renal arteries (infrarenal). The incidence increases with age, being present in 5% of the population > 60 years. They occur five times more frequently in men and in one in four male children of an affected individual. Aneurysms may occur secondary to atherosclerosis, infection (syphilis, *Escherichia coli, Salmonella)* and trauma, or may be genetic (Marfan's syndrome, Ehlers-Danlos syndrome).

Symptoms

Most aneurysms are asymptomatic and are found on routine abdominal examination, plain X-ray or during urological investigations. Rapid expansion or rupture of an AAA may cause *severe pain* (epigastric pain radiating to the back). A ruptured AAA causes *hypotension, tachycardia, profound anaemia* and *sudden death.* The symptoms of rupture may mimic renal colic, diverticulitis and severe lower abdominal or testicular pain. Gradual erosion of the vertebral bodies may cause non-specific back pain. The aneurysm may embolize distally. Inflammatory aneurysms can obstruct adjacent structures, e.g. ureter, duodenum and vena cava. Rarely patients with aneurysms can present with severe haematemesis secondary to an aortoduodenal fistula.

Signs

The aorta is retroperitoneal and in overweight patients there may be no overt signs. An aneurysm is suspected if **a** pulsatile, expansile abdominal mass is felt. The presence of an AAA should alert a clinician to the possibility of popliteal aneurysms. Patients may present with 'trash feet', dusky discoloration of the digits secondary to emboli from the aortic thrombus.

Investigations

An AAA is first assessed by *ultrasound.*

CT scan is more accurate and relates the anatomical relationship to the renal and visceral vessels.

Management

Like any operation the management of an asymptomatic aneurysm depends on the balance of operative risk and conservative management. The UK Small Aneurysm Trial showed that patients with infrarenal AAA did best with an operation if the aneurysm was:

- > 5.5 cm diameter
- expanding > 1 cm/year
- symptomatic.

Medical

Patients with aneurysmal disease need careful control of hypertension, to stop smoking and to have lipid-lowering medication. Patients with AAA < 5.5 cm are followed up by regular ultrasound surveillance.

Surgical/radiological

Open AAA repair is justified by long-term outcome data but endovascular aneurysm repair (EVAR) is still undergoing assessment within trials. When an aneurysm ruptures, emergency surgery is necessary but the mortality rate is ~ 50%. Elective AAA repair is much less risky (mortality rate ~ 5%) but these patients often have cardiorespiratory and renal disease and need careful preoperative assessment of risk.

Prognosis

After repair, patients with an AAA should return to normal activity within a few months.

Thoraco-abdominal aneurysm (TAA)

The ascending, arch or descending thoracic aorta may become aneurysmal. Ascending TAAs occur most commonly in patients with Marfan's syndrome or hypertension. Descending or arch TAAs occur secondary to atherosclerosis and are now rarely due to syphilis.

Symptoms

Most aneurysms are asymptomatic and are found on routine chest X-ray or cardiological investigation (Fig. 13.120). Rapid expansion may cause severe pain (chest pain radiating to the upper back) and rupture is associated with hypotension, tachycardia and death. Chest symptoms from expansion may include stridor (compressed bronchial tree), haemoptysis (aortobronchial fistula) and hoarseness (compression of the recurrent laryngeal nerve). Aorto-oesophageal fistula uncommonly causes haematemesis.

Investigations

- CT **scan** is used for assessment of a TAA.
- **Aortography** may be used to assess the position of the key branches in relation to the aneurysm
- **Transoesophageal echocardiography** can be helpful by identifying an aortic dissection.

Management

If the aneurysm is > 6 cm then operative repair or stenting may be appropriate but these can be technically difficult

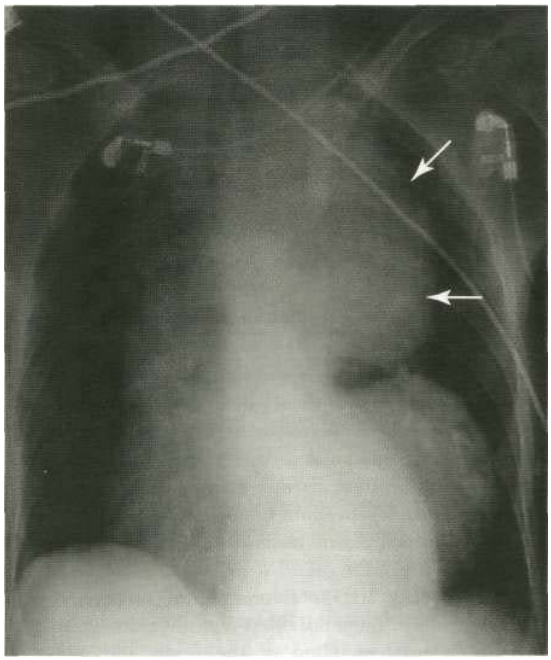

Fig. 13.120 Plain PA chest X-ray demonstrating a markedly enlarged mediastinum due to an aneurysm of the arch of the aorta (arrows).

and carry a high risk of mortality and paraplegia. EVAR is at present the procedure of choice for isolated descending thoracic aneurysms but no long-term results are available at present.

Aortic dissection

Aortic dissection usually begins with a tear in the intima. Blood penetrates the diseased medial layer and then cleaves the intimal laminal plain leading to dissection. Thoracic aortic dissection may be classified into:

- *Type A:* involving the aortic arch and aortic valve proximal to the left subclavian artery origin
- *Type B:* involving the descending thoracic aorta distal to the left subclavian artery origin.

Symptoms

Severe and central *chest pain* often radiates to the back and down the arms mimicking myocardial infarction.

Signs

Patients may be shocked and may have neurological symptoms secondary to loss of blood supply to the spinal cord. They may develop renal failure, acute lower limb ischaemia or visceral ischaemia. Peripheral pulses may be absent.

Investigations

The mediastinum may be widened on *chest X-ray,* and *CT scan* or *transoesophageal echocardiogmphy* will confirm the diagnosis (Fig. 13.98b).

Management

At least 50% of patients are hypertensive and they may require urgent antihypertensive medication. Type A dissections should undergo surgery (arch replacement) if fit enough, as medical management carries a high mortality. Type B dissections should be managed medically unless they develop complications.

Raynaud's phenomenon or Raynaud's disease

Raynaud's phenomenon consists of spasm of the digital arteries usually precipitated by cold and relieved by heat. If there is no underlying cause, it is known as Raynaud's disease. This affects 5% of the population, mostly women. The disorder is usually bilateral with fingers affected more commonly than toes.

Symptoms

Vasoconstriction causes *skin pallor* followed by *cyanosis* due to sluggish blood flow, then redness secondary to hyperaemia. The duration of the attacks is variable but they can sometimes last for hours. Numbness, a burning sensation and *severe pain* occur as the fingers warm up. In chronic, severe disease tissue *infarction* and *digital loss* can

Diagnosis

Primary Raynaud's disease needs to be differentiated from secondary treatable causes leading to Raynaud's phenomenon. These are the connective tissue disorders such as systemic sclerosis (see p. 577). It can be associated with atherosclerosis or occupations that involve the use of vibrating tools. Ergot-containing drugs and beta-blockers and smoking can aggravate symptoms.

Management

Patients should avoid cold provocation by wearing gloves and warm clothes and stop smoking. Vasodilators can be prescribed but are often unacceptable as cerebral vasodilatation causes severe headaches. Sympathectomy or prostacyclin infusion can be helpful in severe disease.

Takayasu's disease

This is rare, except in Japan. It is known as the pulseless disease or aortic arch syndrome. It is of unknown aetiology and occurs in females. There is a vasculitis involving the aortic arch as well as other major arteries. There is also a systemic illness, with pain and tenderness over the affected arteries. Absent peripheral pulses and hypertension are common. Corticosteroids help the constitutional symptoms. Eventually heart failure and strokes may occur but most patients survive for at least 5 years. Treatment may require a surgical bypass to improve perfusion of the affected areas .....

Thromboangiitis obliterans (Buerger's disease)

This disease, involving the small vessels of the lower limbs, occurs in young men who smoke. It is thought by some workers to be indistinguishable from atheromatous disease. However, pathologically there is inflammation of the arteries and sometimes veins that may indicate a separate disease entity. Clinically it presents with severe claudication and rest pain leading to gangrene. A thrombophlebitis is sometimes present. Treatment is as for all peripheral vascular disease, but patients must stop smoking.

Cardiovascular syphilis

This gives rise to:

- uncomplicated aortitis
- aortic aneurysms, usually in the ascending part
- aortic valvulitis with regurgitation
- stenosis of the coronary ostia.

The diagnosis is confirmed by serology. Treatment is with penicillin. Aneurysms and valvular disease are treated as necessary by the usual methods.

PERIPHERAL VENOUS DISEASE

Varicose veins

Varicose veins are a common problem, sometimes giving rise to pain. They are treated by injection or surgery.

Venous thrombosis

Thrombosis can occur in any vein, but the veins of the leg and the pelvis are the most common sites.

Superficial thrombophlebitis

This commonly involves the saphenous veins and is often associated with varicosities. Occasionally the axillary vein is involved, usually as a result of trauma. There is local superficial inflammation of the vein wall, with secondary thrombosis.

The clinical picture is of a painful, tender, cord-like structure with associated redness and swelling.

The condition usually responds to symptomatic treat ment with rest, elevation of the limb and analgesics (e.g. non-steroidal anti-inflammatory drugs). Anticoagulants are not necessary, as embolism does not occur from superficial thrombophlebitis. , - -

Deep-vein thrombosis

A thrombus forms in the vein, and any inflammation of the vein wall is secondary to this.

Thrombosis commonly occurs after periods of immobilization, but it can occur in normal individuals for no obvious reasons. The precipitating factors are discussed on page 477.

A deep-vein thrombosis in the legs occurs in 50% of patients after prostatectomy (without prophylactic heparin) or following a cerebral vascular event. In addition, 10% of patients with a myocardial infarct have a clinically detected deep-vein thrombosis.

Thrombosis can occur in any vein of the leg, but is particularly found in veins of the calf. It is often undetected; autopsy figures give an incidence of over 60% in hospitalized patients. Axillary vein thrombosis occasionally occurs, sometimes related to trauma, but usually for no obvious reason.

Clinical features

The individual may be asymptomatic, presenting with clinical features of pulmonary embolism (see p. 844).

A major presenting feature is *pain* in the calf, often with swelling, redness and *engorged superficial veins.* The affected calf is often warmer and there may be ankle oedema. *Homan's sign* (pain in the calf on dorsiflexion of the foot) is often present, but is not diagnostic and occurs with all lesions of the calf.

Thrombosis in the iliofemoral region can present with severe pain, but there are often few physical signs apart from occasional swelling of the thigh and/ or ankle *oedema.*

Complete occlusion, particularly of a large vein, can lead to a *cyanotic discoloration* of the limb and severe oedema, which can very rarely lead to venous gangrene.

Pulmonary embolism can occur with any deep-vein thrombosis but is more frequent from an iliofemoral thrombosis and is rare with thrombosis confined to veins below the knee. In 20-30% of patients, spread of thrombosis can occur proximally without clinical evidence, so careful monitoring of the leg, usually by ultrasound, is required.

Investigations

Clinical diagnosis is unreliable but combined with D-dimer level it has a sensitivity of 80%. Confirmation of an iliofemoral thrombosis can usually be made with *B mode venous compression, ultrasonogmphy* or *Doppler ultrasound* with a sensitivity and specificity over 90%.

Below-knee thromboses can be detected reliably only by *venography* with non-invasive techniques, ultrasound, fibrinogen scanning and impedance plethysmography, having a sensitivity of only 70 %. A venogram is performed by injecting a vein in the foot with contrast, which will detect virtually all thrombi that are present.

Treatment

The main aim of therapy is to prevent pulmonary embolism, and all patients with thrombi above the knee must be anticoagulated. Anticoagulation of below-knee thrombi is now recommended for 6 weeks as 30% of patients will have an extension of the clot proximally. Bed rest is advised until the patient is fully anticoagulated. The patient should then be mobilized, with an elastic stocking giving graduated pressure over the leg.

Low-molecular-weight heparins (LMWH) (see p. 480) have replaced unfractionated heparin as they are more

effective, they do not require monitoring and there is less risk of bleeding. DVTs are being treated at home with low-molecular-weight heparin. Warfarin is started immediately and the heparin stopped when the INR is in the target range. The duration of *warfarin* treatment is debatable - 3 months is the period usually recommended, **but** 4 weeks is long enough if a definite risk factor (e.g. bed rest) has been present. Recurrent DVTs need permanent anticoagulants. The target INR should be 2.5. Anticoagulants do not lyse the thrombus **that** is already present. Unfractionated heparin should only be used if LMWH is unavailable.

Thrombolytic therapy (see p. 813) is occasionally used for patients with a large iliofemoral thrombosis.

Prognosis

Destruction of the deep-vein valves produces a clinically painful, swollen limb that is made worse by standing and is accompanied by oedema and sometimes venous eczema. It occurs in approximately half of the patients with clinically symptomatic deep-vein thrombosis, and it means that elastic support stockings are then required for life.

Prevention

Subcutaneous low-molecular-weight heparin (see p. 480) should be given to patients with cardiac failure, a myocardial infarct or surgery to the leg or pelvis.

Early ambulation is indicated, as most thromboses occur within the first 72 hours following surgery. Leg exercises should be encouraged and patients should not sit in a chair with their legs immobilized on a stool. An elastic support stocking should be given to patients at high risk (e.g. those with a history of thrombosis or with obesity).

Respiratory disease

The main role of the respiratory system is to extract oxygen from the external environment and dispose of waste gases, principally carbon dioxide. This requires the lungs to function as an efficient bellows, expelling used air, bringing fresh air in and mixing it efficiently with the air remaining in the lungs. The lungs have to provide a large surface area for gas exchange and the alveoli walls have to present minimal resistance to gas diffusion. For maximum efficiency, ventilation must be matched accurately to blood flow through the pulmonary capillary bed. Altogether, this means the lungs have to present a large area to the environment and this can be damaged by dusts, gases and infective agents. Host defence is therefore a key priority for the lung and is achieved by a combination of structural and immunological defences.

STRUCTURE OF THE RESPIRATORYSYSTE

The nose, pharynx and larynx

See Chapter 20 (pp. 1156 and 1159).

The trachea, bronchi and bronchioles

The trachea is 10-12 cm in length. It lies slightly to the right of the midline and divides at the carina into right and left main bronchi. The carina lies under the junction of the manubrium sternum and the second right costal cartilage. The right main bronchus is more vertical than the left and, hence, inhaled material is more likely to end up in the right lung.

The right main bronchus divides into the upper lobe bronchus and the intermediate bronchus, which further subdivides into the middle and lower lobe bronchi. On the left the main bronchus divides into upper and lower lobe bronchi only. Each lobar bronchus further divides into segmental and subsegmental bronchi. There are about 25 divisions in all between the trachea and the alveoli.

The first seven divisions are bronchi that have:

- walls consisting of cartilage and smooth muscle
- epithelial lining with cilia and goblet cells
- submucosal mucus-secreting glands
- endocrine cells - Kulchitsky or APUD (amine pre cursor and uptake decarboxylation) containing 5-hydroxytryptamine.

The next 16-18 divisions are bronchioles that have:

- no cartilage and a muscular layer that progressively becomes thinner
- a single layer of ciliated cells but very few goblet cells
- granulated Clara cells that produce a surfactant-like substance.

The ciliated epithelium is a key defence mechanism. Each cell bears approximately 200 cilia beating at 1000 beats

per minute in organized waves of contraction. Each cilium consists of nine peripheral parts and two inner longitudinal fibrils in a cytoplasmic matrix (Fig. 14.1). Nexin links join the peripheral pairs. Dynein arms consisting of ATPase protein project towards the adjacent pairs. Bending of the cilia results from a sliding movement between adjacent fibrils powered by an ATP-dependent shearing force developed by the dynein arms. Absence of dynein arms leads to immotile cilia. Mucus, which contains macrophages, cell debris, inhaled particles and bacteria, is moved by the cilia towards the larynx at about 1.5 cm/min (the 'mucociliary escalator', see below). The bronchioles finally divide within the acinus into smaller respiratory bronchioles that have alveoli arising from the surface (Fig. 14.2). Each respiratory bronchiole supplies approximately 200 alveoli via alveolar ducts. The term 'small airways' refers to bronchioles of less than 2 mm; there are 30 000 of these in the average lung.

The alveoli

There are approximately 300 million alveoli in each lung. Their total surface area is 40-80 m^2. The epithelial lining

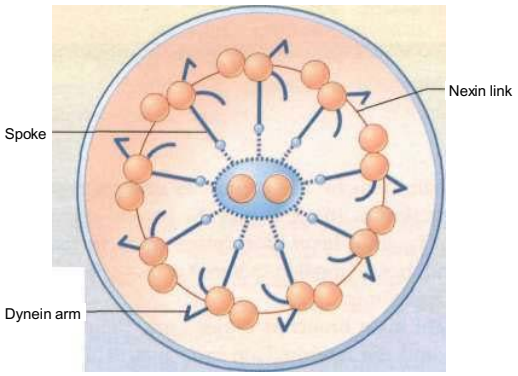

Fig. 14.1 **Cross-section of a cilium.** Nine outer microtubular doublets and two central single microtubules are linked by spokes, nexin links and dynein arms.

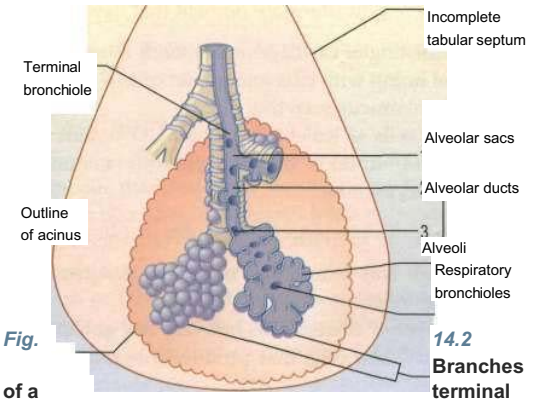

Fig. 14.2 **Branches of a terminal bronchiole ending in the alveolar sacs.**

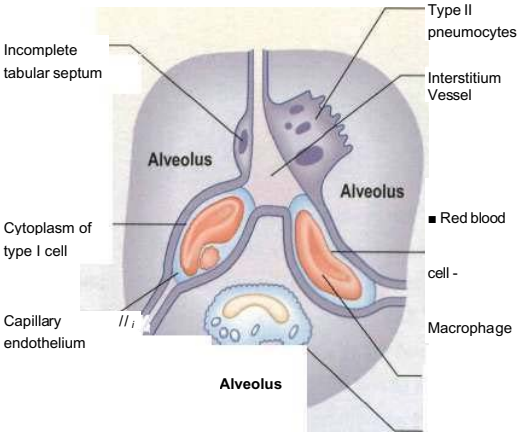

Fig. 14.3 **The structure of alveoli, showing the pneumocytes and capillaries.**

consists largely of *type I pneumocytes* (Fig. 14.3). These cells have an extremely attenuated cytoplasm, and thus provide only a thin barrier to gas exchange. They are derived from type II pneumocytes. *Type I cells* are connected to each other by tight junctions that limit the fluid movements in and out of the alveoli. *Type II pneumocytes* are slightly more numerous than type I cells but cover less of the epithelial lining. They are found generally in the borders of the alveolus and contain distinctive lamellar vacuoles, which are the source of surfactant. Macrophages are also present in the alveoli and are involved in the defence mechanisms of the lung.

The pores of Kohn are holes in the alveolar wall allowing communication between alveoli of adjoining lobules.

The lungs

The lungs are separated into lobes by invaginations of the pleura, which are often incomplete. The right lung has three lobes, whereas the left lung has two. The positions of the oblique fissures and the right horizontal fissure are shown in Figure 14.4. The upper lobe lies mainly in front of the lower lobe and therefore physical signs on the right side in the front of the chest are due to lesions of the upper lobe or the middle lobe. Because of the contrast in density between healthy and diseased lung, plain radiography enables accurate localization of disease processes, especially if postero-anterior (PA) and lateral views are taken (Fig. 14.5).

Each lobe is further subdivided into bronchopulmonary segments by fibrous septa that extend inwards from the pleural surface. Each segment receives its own segmental bronchus.

The bronchopulmonary segment is further divided into individual lobules approximately 1 cm in diameter and generally pyramidal in shape, the apex lying towards the bronchioles supplying them. Within each lobule a terminal bronchus supplies an acinus, and within this

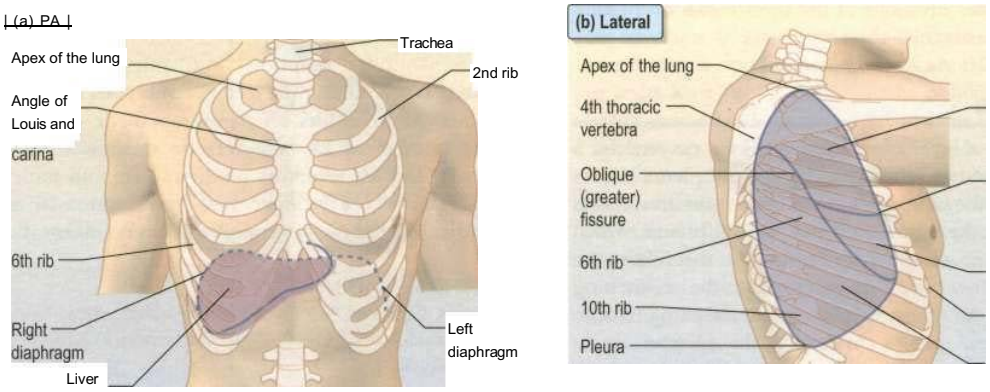

Fig. 14.4 **Surface anatomy of the chest, (a)** PA. **(b)** Lateral.

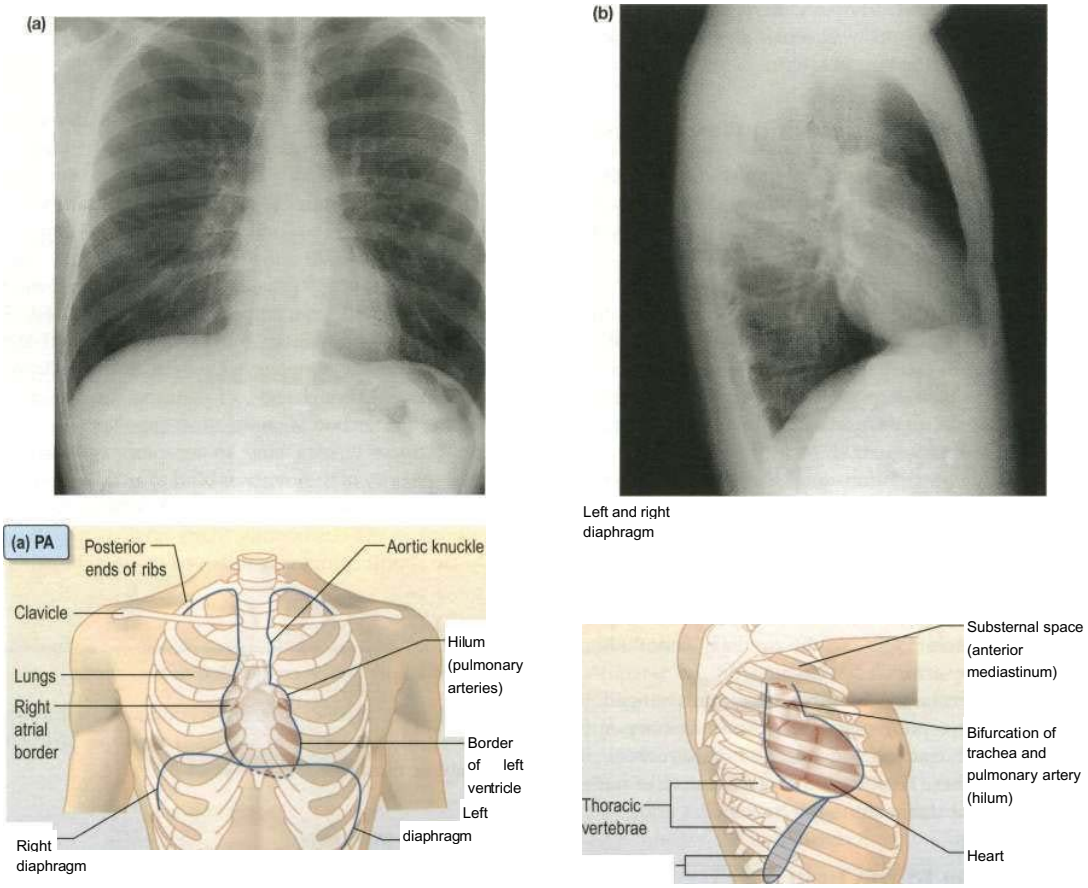

Fig. 14.5 **Chest X-rays, (a)** PA. **(b)** Lateral.

structure further divisions of the bronchioles eventually give rise to the alveoli.

The pleura

The pleura is a layer of connective tissue covered by a simple squamous epithelium. The visceral pleura covers the surface of the lung, lines the interlobar fissures, and is continuous at the hilum with the parietal pleura, which lines the inside of the hemithorax. At the hilum the visceral pleura continues alongside the branching bronchial tree for some distance before reflecting back to join the parietal pleura. In health, the pleurae are in apposition apart from a small quantity of lubricating fluid.

The diaphragm

The diaphragm is covered by parietal pleura above and peritoneum below. Its muscle fibres arise from the lower ribs and insert into the central tendon. Motor and sensory nerve fibres go separately to each half of the diaphragm via the phrenic nerves. Fifty per cent of the muscle fibres are of the slow-twitch type with a low glycolytic capacity; they are relatively resistant to fatigue.

Pulmonary vasculature and lymphatics

The lung is unusual in having a dual blood supply. It receives deoxygenated blood from the right ventricle via the pulmonary artery and also has a systemic supply via the bronchial circulation.

The pulmonary artery divides to accompany the bronchi. The arterioles accompanying the respiratory bronchioles are thin-walled and contain little smooth muscle. The pulmonary venules drain laterally to the periphery of the lobules, pass centrally in the interlobular and intersegmental septa, and eventually join to form the four main pulmonary veins.

The bronchial circulation arises from the descending aorta. These bronchial arteries supply tissues down to the level of the respiratory bronchiole. The bronchial veins drain into the pulmonary vein, forming part of the physiological shunt observed in normal individuals.

Lymphatic channels lie in the interstitial space between the alveolar cells and the capillary endothelium of the pulmonary arterioles.

The tracheobronchial lymph nodes are arranged in five main groups: pulmonary, bronchopulmonary, subcarinal, superior tracheobronchial and paratracheal. In practical terms these form a continuous network of nodes from the lung substance up to the trachea.

Nerve supply to the lung

The innervation of the lung remains incompletely understood. Parasympathetic (from the vagus) and sympathetic (from the adjacent sympathetic chain) nerve supplies entwine in a plexus at the nerve root and branches accompany the pulmonary arteries and the airways. Airway smooth muscle is innervated by vagal afferents, postganglionic muscarinic vagal efferents and vagally derived non-adrenergic non-cholinergic (NANC) fibres. Neurotransmitters (peptides and purines) may be involved. Three muscarinic receptor subtypes have been identified: M-, receptors on parasympathetic ganglia, a smaller number of M_2 receptors on muscarinic nerve terminals, and M_3 receptors on airway smooth muscle. The parietal pleura is innervated from intercostal and phrenic nerves but the visceral pleura has no innervation.

PHYSIOLOGY OF THE RESPIRATORY SYSTEM

The nose

The major functions of nasal breathing are:

- to heat and moisten the air
- to remove particulate matter.

About 10 000 L of air are inhaled daily. The relatively low flow rates and turbulence of inspired air are ideal for particle deposition, and few particles greater than 10 microns pass through the nose. Deposited particles are removed from the nasal mucosa within 15 minutes, compared with 60-120 days from the alveolus. Nasal secretion contains many protective proteins in the form of IgA antibodies, lysozyme and interferon. In addition, the cilia of the nasal epithelium move the mucous gel layer rapidly back to the oropharynx where it is swallowed. Bacteria have little chance of settling in the nose. Mucociliary protection against viral infections is more difficult because viruses bind to receptors on epithelial cells. The majority of rhinoviruses bind to an adhesion molecule, intercellular adhesion molecule 1 (1CAM-1), shared by neutrophils and eosinophils. Many noxious gases, such as SO2, are almost completely removed by nasal breathing.

Breathing

Lung ventilation can be considered in two parts:

- the mechanical process of inspiration and expiration
- the control of respiration to a level appropriate for the metabolic needs.

Mechanical process

Inspiration is an active process and results from the descent of the diaphragm and movement of the ribs upwards and outwards under the influence of the intercostal muscles. In healthy individuals at rest, inspiration is almost entirely due to contraction of the diaphragm. Respiratory muscles are similar to other skeletal muscles but are less prone to fatigue. However, muscle fatigue contributes to respiratory failure in patients with severe

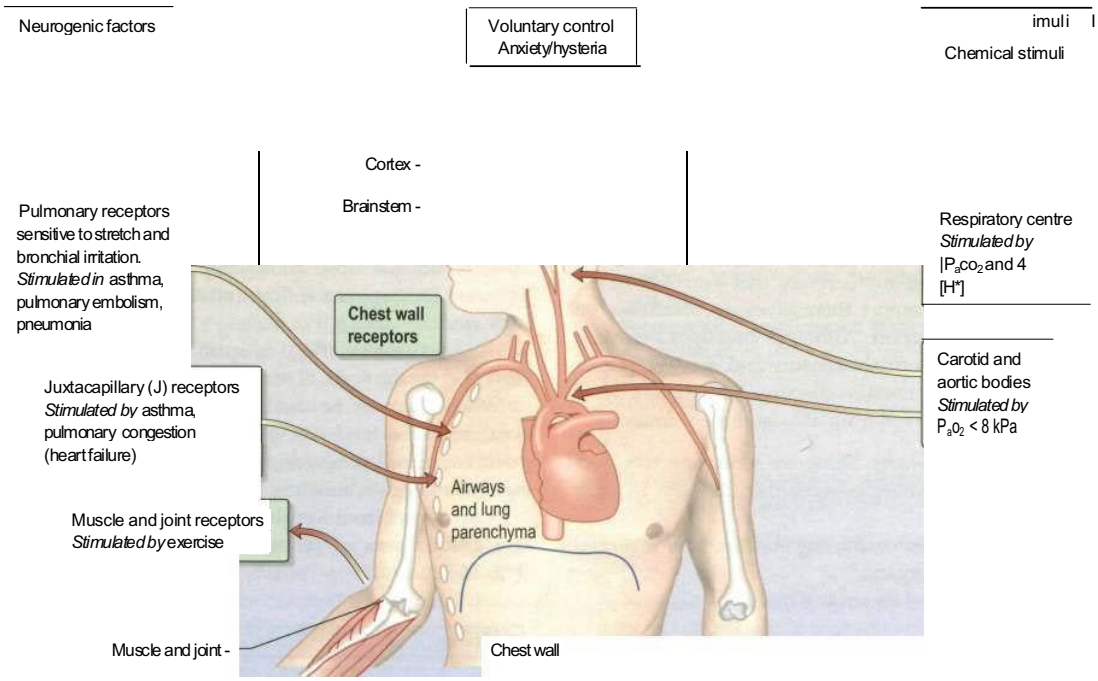

***Fig. 14.6* Chemical and neurogenic factors in the control of ventilation.** The strongest stimulant to ventilation is a rise in P_aCO_2 which increases $[H^+]$ in CSF. Sensitivity to this may be lost in COPD. In these patients hypoxaemia is the chief stimulus to respiratory drive; oxygen treatment may therefore reduce respiratory drive and lead to a further rise in P_aCO_2. An increase in $[H^+]$ due to metabolic acidosis as in diabetic ketoacidosis will increase ventilation with a fall in P_aCO_2 causing deep sighing (Kussmaul) respiration. The respiratory centre is depressed by severe hypoxaemia and sedatives (e.g. opiates) and stimulated by doxapram, large doses of aspirin and pyrexia. COPD, chronic obstructive pulmonary disease. Derived from Manning HL, Schwartzstein RM (1995) *New England Journal of Medicine* **333:** 1547-1553.

chronic airflow limitation. Muscle weakness can also result from primary neurological and muscle disorders.

Expiration follows passively as a result of gradual relaxation of the intercostal muscles, allowing the lungs to collapse under the influence of their own elastic forces.

Inspiration against increased resistance may require the use of the accessory muscles of ventilation, such as the sternomastoid and scalene muscles. Forced expiration is also accomplished with the aid of accessory muscles, chiefly those of the abdominal wall, which help to push up the diaphragm.

The lungs have an inherent elastic property that causes them to tend to collapse away from the thoracic wall, generating a negative pressure within the pleural space. The strength of this retractive force relates to the volume of the lung; thus, at higher lung volumes the lung is stretched more, and a greater negative intrapleural pressure is generated.

Lung compliance is a measure of the relationship between this retractive force and lung volume. It is defined as the change in lung volume brought about by unit change in transpulmonary (intrapleural) pressure and is measured in litres per kilopascal (L/kPa). At the end of a quiet expiration, the retractive force exerted by the lungs is balanced by the tendency of the thoracic wall to spring outwards. At this point, respiratory muscles are resting and the volume of air in the lung is known as the *functional residual capacity* (FRC).

Diseases that affect the movement of the thoracic cage and diaphragm can have a profound effect on ventilation. These include diseases of the thoracic spine such as ankylosing spondylitis and kyphoscoliosis, neuropathies (e.g. the Guillain-Barre syndrome), injury to the phrenic nerves, and myasthenia gravis.

The control of respiration

Coordinated respiratory movements result from rhythmical discharges arising in an anatomically ill-defined group of interconnected neurones in the reticular substance of the brainstem, known as the respiratory centre. Motor discharges from the respiratory centre travel via the phrenic and intercostal nerves to the respiratory musculature.

The pressures of oxygen and carbon dioxide in arterial blood are closely controlled. In a typical normal adult at rest:

- The pulmonary blood flow of 5 L/min carries 11 mmol/min (250 mL/min) of oxygen from the lungs to the tissues.
- Ventilation at about 6 L/min carries 9 mmol/min (200 mL/min) of carbon dioxide out of the body.

The normal pressure of oxygen in arterial blood (P_ao_2) is between 11 and 13 kPa (83 and 98 mmHg).

- The normal pressure of carbon dioxide in arterial blood (P_aco_2) is 4.8-6.0 kPa (36-45 mmHg).

Ventilation is controlled by a combination of neurogenic and chemical factors (Fig. 14.6).

Breathlessness on physical exertion is normal and not considered a symptom unless the level of exertion is very light, such as when walking slowly. Recent surveys of healthy western populations reveal that over 20% of the general population report themselves as breathless on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:

- *Changes in lung volume.* These are sensed by receptors in thoracic wall muscles signalling changes in their length.
- *Tension developed by contracting muscles.* This is sensed by Golgi tendon organs.
- *Central perception of the sense of effort.*

The airways of the lungs

From the trachea to the periphery, **the** airways become smaller in size (although greater in number). The cross-sectional area available for airflow increases as the total number of airways increases. The flow of air is greatest in the trachea and slows progressively towards the periphery (as the velocity of airflow depends on the ratio of flow to cross-sectional area). In the terminal airways, gas flow occurs solely by diffusion. The resistance to airflow is very low (0.1-0.2 kPa/L in a normal tracheobronchial tree), steadily increasing from the small to the large airways.

Airways expand as lung volume is increased, and at full inspiration *(total lung capacity,* TLC) they are 30-40% larger in calibre than at full expiration *(residual volume,* RV). In chronic obstructive pulmonary disease (COPD) the small airways are narrowed and this can be partially compensated by breathing at a larger lung volume.

Control of airway tone

Bronchomotor tone is maintained by vagal efferent nerves and, even in a normal subject, is reduced by atropine or P-adrenoceptor agonists. Adrenoceptors on the surface of bronchial muscles respond to circulating catecholamines; there is no direct sympathetic innervation. Airway tone shows a *circadian rhythm,* which is greatest at 04.00 and lowest in the mid-afternoon. Tone can be increased transiently by inhaled stimuli acting on epithelial nerve endings, which trigger reflex bronchoconstriction via the vagus. These stimuli include cigarette smoke, solvents, inert dust and cold air; airway responsiveness to these increases following respiratory tract infections even in healthy subjects. In asthma, the airways are very irritable and as the circadian rhythm remains the same, asthmatic symptoms are usually worse in the early morning.

Airflow

Movement of air through the airways results from a difference between the pressure in the alveoli and the atmospheric pressure; alveolar pressure is positive in expiration and negative in inspiration. During quiet breathing the pleural pressure is sub-atmospheric throughout the breathing cycle. With vigorous expiratory efforts (e.g. cough), the central airways are compressed by positive pleural pressures exceeding 10 kPa, but the airways do not close completely because the driving pressure for expiratory flow (alveolar pressure) is also increased.

Alveolar pressure (P_{ALV}) is equal to the pleural pressure (Ppi) plus the elastic recoil pressure (P_{Ei}) of the lung.

When there is no airflow (i.e. during a pause in breathing) the tendency of the lungs to collapse (the positive recoil pressure) is exactly balanced by an equivalent negative pleural pressure.

As air flows from the alveoli towards the mouth there is a gradual loss of pressure owing to flow resistance (Fig. 14.7a).

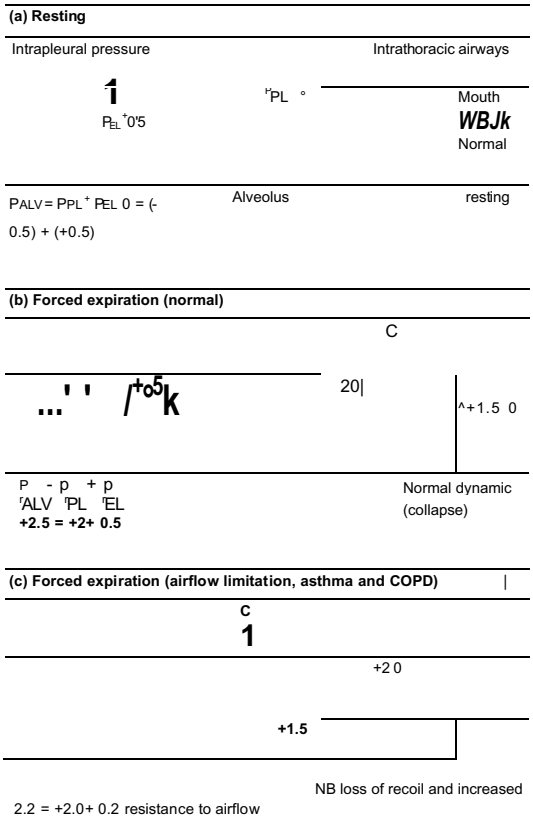

Fig. 14.7 **Diagrams showing ventilatory forces.** **(a)** During resting at functional residual capacity, (b) During forced expiration in normal subjects, (c) During forced expiration in a patient with COPD. The respiratory system is represented as a piston with a single alveolus and the collapsible part of the airways within the piston (see text). C, collapse point; P_{ALV}, alveolar pressure; P_{EL}, elastic recoil pressure; P_{PL}, pleural pressure.

In forced expiration, as mentioned above, the driving pressure raises both the alveolar pressure and the intrapleural pressure. Between the alveolus and the mouth, there is a point (C in Fig. 14.7b) where the airway pressure equals the intrapleural pressure, and the airway collapses. However, this collapse is temporary, as the transient occlusion of the airway results in an increase in pressure behind it (i.e. upstream) and this raises the intra-airway pressure so that the airways open and flow is restored. The airways thus tend to vibrate at this point of 'dynamic collapse'.

The elastic recoil pressure of the lungs decreases with decreasing lung volume and the 'collapse point' moves upstream (i.e. towards the smaller airways - see Fig. 14.7c). Where there is pathological loss of recoil pressure (as in chronic obstructive pulmonary disease, COPD), the 'collapse point' starts even further upstream and causes expiratory flow limitation. The measurement of the forced expiratory volume in 1 second (FEV_1) is a useful clinical index of this phenomenon. To compensate, these patients often 'purse their lips' in order to increase airway pressure so that their peripheral airways do not collapse. On inspiration, the intrapleural pressure is always less than the intraluminal pressure within the intrathoracic airways, so there is no limitation to airflow with increasing effort. Inspiratory flow is limited only by the power of the inspiratory muscles.

Flow-volume loops

The relationship between maximal flow rates on expiration and inspiration is demonstrated by the maximal flow-volume (MFV) loops. Figure 14.8a shows this in a normal subject.

In subjects with healthy lungs, effects of flow limitation will not be apparent, since maximal flow rates are rarely achieved even during vigorous exercise. However, in patients with severe COPD, limitation of expiratory flow occurs even during tidal breathing at rest (see Fig. 14.8b). To increase ventilation these patients have to breathe at higher lung volumes and allow more time for expiration which both reduce the tendency for airway collapse. To compensate they increase flow rates during inspiration, where there is relatively less flow limitation.

The measure of the volume that can be forced in from the residual volume in 1 second (FIV_1) will always be greater than that which can be forced out from TLC in 1 second (FEV_1). Thus, the ratio of FEV_1 to FIV_1 is below 1. The only exception to this occurs when there is significant obstruction to the airways outside the thorax, such as with a tumour mass in the upper part of the trachea. Under these circumstances expiratory airway narrowing is prevented by the tracheal resistance (a situation similar to pursing the lips) and expiratory airflow becomes more effort-dependent. During forced inspiration this same resistance causes such negative intraluminal pressure that the trachea is compressed by the surrounding atmospheric pressure. Inspiratory flow thus becomes less effort-dependent, and the ratio of FEV_1 to FIV_1 becomes greater than 1. This phenomenon, and the characteristic flow-volume loop, is used to diagnose extrathoracic airways obstruction (Fig. 14.8c).

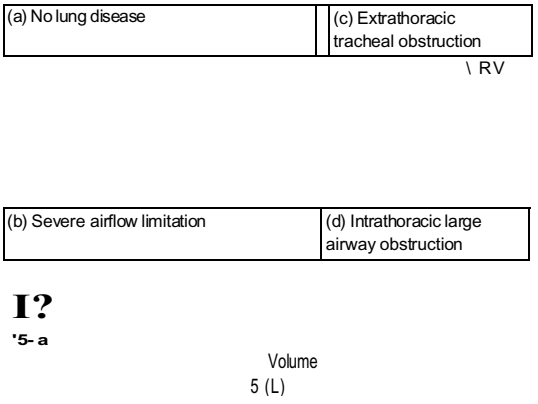

Fig. 14.8 **(a and b) Maximal flow-volume loops, showing the relationship between maximal flow rates on expiration and inspiration, (a)** In a normal subject, (b) In a patient with severe airflow limitation. Flow-volume loops during tidal breathing at rest (starting from the functional residual capacity (FRC)) and during exercise are also shown. The highest flow rates are achieved when forced expiration begins at total lung capacity (TLC) and represent the peak expiratory flow rate (PEFR). As air is blown out of the lung, so the flow rate decreases until no more air can be forced out, a point known as the residual volume (RV). Because inspiratory airflow is only dependent on effort, the shape of the maximal inspiratory flow-volume loop is quite different, and inspiratory flow remains at a high rate throughout the manoeuvre. **(c and d) Flow-volume loops of patients with large airway (tracheal) obstruction, showing plateauing of maximal expiratory flow, (c)** Extrathoracic tracheal obstruction with a proportionally greater reduction of maximal inspiratory (as opposed to expiratory) flow rate, (d) Intrathoracic large airway obstruction; the expiratory plateau is more pronounced and inspiratory flow rate is less reduced than in (c). In severe airflow limitation the ventilatory demands of exercise cannot be met (cf. a and b), greatly reducing effort tolerance.

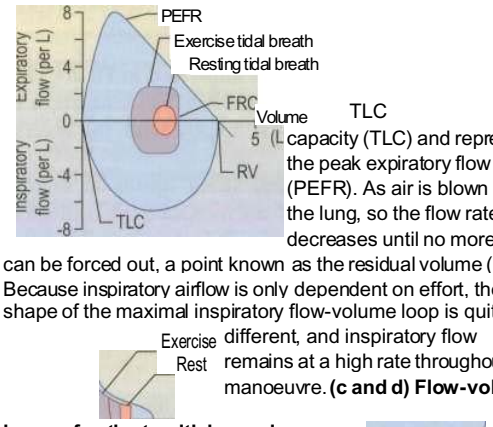

When obstruction occurs in large airways within the thorax (lower end of trachea and main bronchi), expiratory flow is impaired more than inspiratory flow but a characteristic plateau to expiratory flow is seen (Fig. 14.8d). ■

Ventilation and perfusion relationships

For efficient gas exchange there must be a match between ventilation of the alveoli (V_A) and their perfusion (Q). There is a wide variation in the V_A/Q ratio throughout both normal and diseased lung. In the normal lung the extreme relationships between alveolar ventilation and perfusion are:

ventilation with reduced perfusion (physiological deadspace)
- perfusion with reduced ventilation (physiological shunting).

These and the 'ideal' match are illustrated in Figure 14.9. In normal lungs there is a tendency for ventilation to exceed perfusion towards the apices, with the reverse occurring at the bases.

An increased physiological shunt results in arterial hypoxaemia. The effects of an increased physiological deadspace can usually be overcome by a compensatory increase in the ventilation of normally perfused alveoli. In advanced disease this compensation cannot occur, leading to increased alveolar and arterial $Pco_{2/}$ together with hypoxaemia which cannot be compensated by increasing ventilation.

Hypoxaemia occurs more readily than hypercapnia because of the different ways in which oxygen and carbon dioxide are carried in the blood. Carbon dioxide can be considered to be in simple solution in the plasma, the volume carried being proportional to the partial pressure. Oxygen is carried in chemical combination with haemoglobin in the red blood cells, and the relationship between the volume carried and the partial pressure is not linear (see Fig. 15.5, p. 960). Alveolar hyperventilation reduces the alveolar Pco_2 and diffusion leads to a proportional fall in the carbon dioxide content of the blood. However, as the haemoglobin is already saturated with oxygen, there is no significant increase in the blood oxygen content as a result of increasing the alveolar Po_2 through hyperventilation. The hypoxaemia of even a small amount of physiological shunting cannot therefore be compensated for by hyperventilation.

In individuals who have mild disease of the lung causing slight V_A/Q mismatch, the P_aO_2 and P_aCO_2 may still be normal. Increasing the requirements for gas exchange by exercise will widen the V_A/Q mismatch and the P_aO_2 will fall. V_A/Q mismatch is by far the most common cause of arterial hypoxaemia.

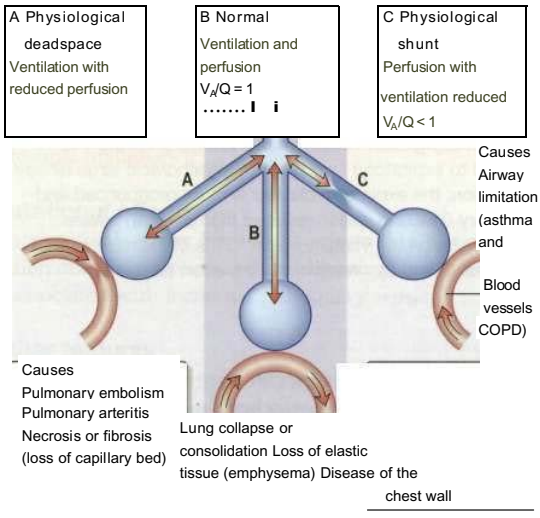

***Fig. 14.9* Relationships between ventilation and perfusion: a schematic diagram showing the alveolar-capillary interface.** The centre (B) shows normal ventilation and perfusion. On the left (A) there is a block in perfusion (physiological deadspace), while on the right (C) there is reduced ventilation (physiological shunting).

Alveolar stability

The alveoli of the lung are essentially hollow spheres. Surface tension acting at the curved internal surface tends to cause the sphere to decrease in size. The surface tension within the alveoli would make the lungs extremely difficult to distend were it not for the presence of surfactant. The type II cells within the alveolus secrete an insoluble lipoprotein largely consisting of dipalmitoyl lecithin, which forms a thin monomolecular layer at the air-fluid interface. Surfactant reduces surface tension so that alveoli remain stable.

Fluid surfaces covered with surfactant exhibit a phenomenon known as hysteresis; that is, the surface-tension-lowering effect of the surfactant can be improved by a transient increase in the size of the surface area of the alveoli. During quiet breathing, small areas of the lung undergo collapse, but it is possible to re-expand these rapidly by a deep breath; hence the importance of sighs or deep breaths as a feature of normal breathing. Failure of such a mechanism — which can occur, for example, in patients with fractured ribs - gives rise to patchy basal lung collapse. Surfactant levels may be reduced in a number of diseases that cause damage to the lung (e.g. pneumonia). Lack of surfactant plays a central role in the respiratory distress syndrome of the newborn. Severe reduction in perfusion of the lung causes impairment of surfactant activity and may well account for the characteristic areas of collapse associated with pulmonary embolism.

DEFENCE MECHANISMS OF THE RESPIRATORY TRACT

Pulmonary disease often results from a failure of the many defence mechanisms that usually protect the lung in a healthy individual (Fig. 14.10). These can be divided into physical and physiological mechanisms and humoral and cellular mechanisms.

Physical and physiological mechanisms

Humidification

This prevents dehydration of the epithelium.

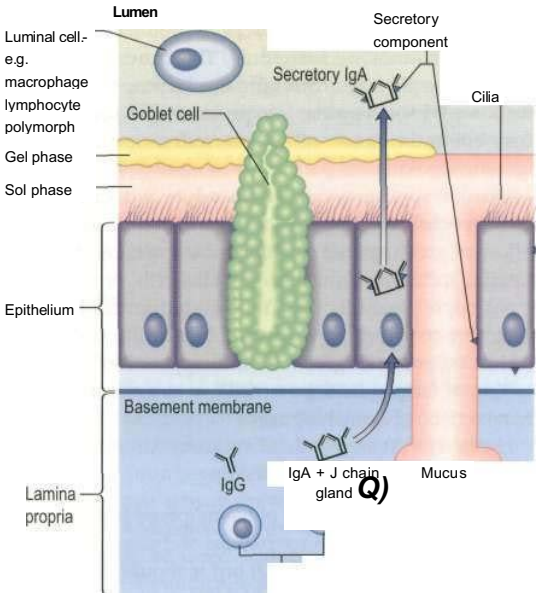

Fig. 14.10 **Defence mechanisms present at the epithelial**

Particle removal

Over 90% of particles greater than 10 |im diameter are removed in the nostril or nasopharynx. This includes most pollen grains which are typically > 20 microns in diameter. Particles between 5-10 microns become impacted in the carina. Particles smaller than 1 micron tend to remain airborne, thus the particles capable of reaching the deep lung are confined to the 1-5 micron range.

Particle expulsion

This is effected by coughing, sneezing or gagging.

Respiratory tract secretions

The mucus of the respiratory tract is a gelatinous substance consisting chiefly of acid and neutral poly-saccharides. The mucus consists of a thick gel that is relatively impermeable to water. This floats on a liquid or sol layer that is present around the cilia of the epithelial cells. The gel layer is secreted from goblet cells and mucous glands as distinct globules that coalesce increasingly in the central airways to form a more or less continuous mucus blanket. Under normal conditions the tips of the cilia are in contact with the under surface of the gel phase and coordinate their movement to push the mucus blanket upwards. Whilst it may only take 30-60 minutes for mucus to be cleared from the large bronchi, there may be a delay of several days before clearance is achieved from respiratory bronchioles. One of the major long-term effects of cigarette smoking is a reduction in mucociliary transport. This contributes to recurrent infection and in the larger airways it prolongs contact with carcinogens. Air pollutants, local and general anaesthetics and bacterial and viral infections also reduce mucociliary clearance.

Congenital defects in mucociliary transport occur. In the *'immotile cilia'* syndrome there is an absence of the dynein arms in the cilia themselves, and in *cystic fibrosis* an abnormal mucus is associated with ciliary dyskinesia. Both diseases are characterized by recurrent infections and eventually with the development of bronchiectasis.

Humoral and cellular mechanisms

Non-specific soluble factors

- *a,Antitrypsin* ($a_r$antiprotease, see p. 902) is present in lung secretions derived from plasma. It inhibits chymotrypsin and trypsin and neutralizes proteases and elastase.
- *Antioxidant defences* include enzymes such as superoxide dismutase and low-molecular-weight antioxidant molecules (ascorbate, urate) in the epithelial lining fluid. In addition, lung cells are protected by an extensive range of intracellular defences, especially members of the glutathione S-transferase (GST) superfamily.
- *Lysozyme* is an enzyme found in granulocytes that has bactericidal properties.
- *Lactoferrin* is synthesized from epithelial cells and neutrophil granulocytes and has bactericidal properties.
- *Interfewn* (see p. 202) is produced by most cells in response to viral infection. It is a potent modulator of lymphocyte function. It renders other cells resistant to infection by any other virus.
- *Complement* is present in secretions and is derived by diffusion from plasma. In association with antibodies, it plays a major cytotoxic role.

a *Surfactant protein* A (SP_A) is one of four species of surfactant proteins which opsonizes bacteria/particles, enhancing phagocytosis by macrophages.

- *Defensins* are bactericidal peptides present in the azurophil granules of neutrophils.

Pulmonary alveolar macrophages

These are derived from precursors in the bone marrow and migrate to the lungs via the bloodstream. They phagocytose particles, including bacteria, and are removed by the mucociliary escalator, lymphatics and bloodstream. They are the dominant cell in the airways at the level of the alveoli and comprise 90% of all cells obtained by bronchoalveolar lavage.

Alveolar macrophages work principally as scavengers and are not particularly good at presenting antigens to the immune system. The key antigen-presenting cells in the airways are dendritic cells which form a network throughout the airways.

Lymphoid tissue (see also p. 205) The lung contains large numbers of lymphocytes which are scattered throughout the airways. In animals, aggregates of bronchus-associated lymphoid tissue (BALT) can be identified but these are not normally found in humans. Sensitized lymphocytes contribute to local immunity through differentiation into IgA-secreting plasma cells. IgG and IgE are found in low concentrations in airway secretions from a combination of local and systemic production.

In addition to these resident cells, the lung has the usual range of acute inflammatory responses and can mobilize neutrophils promptly in response to injury or infection and play a major part in inflammatory conditions such as asthma (p. 916).

SYMPTOMS

Runny, blocked nose and sneezing

Nasal symptoms are extremely common. It can be difficult to distinguish between the common cold or allergic rhinitis as a cause of 'runny nose' (rhinorrhoea), nasal blockage and attacks of sneezing. In allergic rhinitis, symptoms may be seasonal, following contact with grass pollen, or perennial, when the house-dust mite is the allergen. Colds are frequent during the winter but if the symptoms persist for weeks the patient is probably suffering from perennial rhinitis rather than from persistent infection due to a virus.

Nasal secretions are usually thin and runny in rhinitis but thicker and yellowish green in the common cold. Nose bleeds and blood-stained nasal discharge are common occurrences and are not as serious as haemoptysis. However, a blood-stained nasal discharge associated with nasal obstruction and pain may be the presenting feature of a nasal tumour (p. 1158). Total nasal blockage with loss of smell is often a feature of nasal polyps.

Cough (see also p. 911)

Cough is the most common symptom of lower respiratory tract disease. It is caused by the mechanical or chemical stimulation of the cough receptors in the epithelium of the pharynx, larynx, trachea and bronchi. Afferent receptors go to the cough centre in the medulla where efferent signals are generated to the expiratory musculature. Smokers often have a morning cough with little sputum. A productive cough is the cardinal feature of chronic bronchitis, while dry coughing, particularly at night, can be a symptom of asthma. Cough also occurs in asthmatics after mild exertion or following a forced expiration. A cough can also occur for psychological reasons.

A worsening cough is the most common presenting symptom of a bronchial carcinoma. The explosive character of a normal cough is lost when a vocal chord is paralysed - a bovine cough - usually as a result of a carcinoma of the bronchus infiltrating the left recurrent laryngeal nerve. Cough can be accompanied by stridor in whooping cough and in the presence of laryngeal or tracheal obstruction.

Sputum

Approximately 100 mL of mucus is produced daily in a healthy, non-smoking individual. This flows at a regular pace up the airways, through the larynx, and is then swallowed. Excess mucus is expectorated as sputum. The most common cause of excess mucus production is cigarette smoking.

Mucoid sputum is clear and white but can contain black specks resulting from the inhalation of carbon. Yellow or green sputum is due to the presence of cellular material, including bronchial epithelial cells, or neutrophil or eosinophil granulocytes. Yellow sputum is not necessarily due to infection, as eosinophils in the sputum, as seen in asthma, can give the same appearance. The production of large quantities of yellow or green sputum is characteristic of bronchiectasis.

Haemoptysis (blood-stained sputum) varies from small streaks of blood to massive bleeding.

- The most common cause of haemoptysis is acute infection, particularly in exacerbations of chronic obstructive pulmonary disease (COPD) but it should not be attributed to this without investigation.
- Other common causes are pulmonary infarction, bronchial carcinoma and tuberculosis.
- In lobar pneumonia, the sputum is rusty in appearance when blood is present.
- Pink, frothy sputum is seen in pulmonary oedema.
- In bronchiectasis, the blood is often mixed with purulent sputum.
- Massive haemoptyses (> 200 mL of blood in 24 hours) are usually due to bronchiectasis or tuberculosis.
- Uncommon causes of haemoptyses are idiopathic pulmonary haemosiderosis, Goodpasture's syndrome, microscopic polyangiitis, trauma, blood disorders and benign tumours.

Haemoptysis should always be investigated. Often, the diagnosis can be made from a chest X-ray, but a normal chest X-ray does not exclude disease.

Firm plugs of sputum may be coughed up by patients suffering from an exacerbation of allergic bronchopulmonary aspergillosis. Sometimes such sputum may appear as firm threads representing casts from inflamed bronchi.

Breathlessness

Breathlessness should be assessed in relation to the patient's lifestyle. For example, a moderate degree of breathlessness may be totally disabling if the patient has to climb many flights of stairs to reach home.

Dyspnoea is a sense of awareness of increased respiratory effort that is unpleasant and that is recognized by the patient as being inappropriate. It is highly unlikely that this term will be used by the patient. Patients may complain of tightness in the chest; this must be differentiated from angina.

Orthopnoea (see p. 733) is breathlessness on lying down and is partly due to the weight of the abdominal contents pushing the diaphragm up into the thorax. Such patients may also become breathless on bending over.

Tachypnoea and hyperpnoea refer, respectively, to an increased rate of breathing and an increased level of ventilation, which may be appropriate to the situation (e.g. during exercise).

Hyperventilation is inappropriate overbreathing. This may occur at rest or on exertion and results in a lowering of the alveolar and arterial Pco_2 (see p. 1298).

Paroxysmal nocturnal dyspnoea is described on page 733.

Wheezing

Wheezing is a common complaint and is the result of airflow limitation due to any cause. The symptom of wheezing is not diagnostic of asthma; it may be absent in the early stages of this disease, and may also occur in patients with bronchiolitis or chronic obstructive pulmonary disease.

Chest pain

The most common type of chest pain encountered in respiratory disease is a localized sharp pain, often referred to as pleuritic. It is made worse by deep breathing or coughing and can be precisely localized by the patient. Localized anterior chest pain may be accompanied by tenderness of a costochondral junction as a symptom of costochondritis. Pain in the shoulder tip suggests irritation of the diaphragmatic pleura, whereas central chest pain radiating to the neck and arms is typically of cardiac origin. Retrosternal soreness may occur in patients with tracheitis, and a constant, severe, dull pain may be the result of invasion of the thoracic wall by carcinoma.

EXAMINATION OF THE RESPIRATORY SYSTEM

The nose (p. 1157)

Table 14.1 **Physical signs of respiratory disease**

Pathological process	Chest wall movement (reduced)	Mediastmal displacement	Percussion note	Breath sounds	Vocal resonance	Added sounds
Consolidation (i.e. lobar pneumonia)	Affected side	None	Dull	Bronchial	Increased	Fine crackles
Collapse Major bronchus	Affected side	Towards lesion	Dull	Diminished or absent	Reduced or absent	None Fine
Peripheral bronchus	Affected side	Towards lesion	Dull	Bronchial	Increased	crackles
Fibrosis Localized	Affected side	Towards lesion	Dull	Bronchial	Increased	Coarse crackles
Generalized (e.g. cryptogenic fibrosing alveolitis)	Both sides	None	Normal	Vesicular	Increased	Fine crackles
Pleural effusion (>500mL)	Affected side	Away from lesion (in massive effusion)	Stony dull	Vesicular reduced or absent	Reduced or absent	None
Large pneumothorax	Affected side	Away from lesion	Normal or hyperresonant	Reduced or absent	Reduced or absent	None
Asthma	Both sides	None	Normal	Vesicular Prolonged expiration	Normal	Expiratory polyphonic wheeze
Chronic obstructive pulmonary disease	Both sides	None	Normal	Vesicular Prolonged expiration	Normal	Expiratory polyphonic wheeze and coarse crackles

The Chest (Table 14.1)

Examination of the chest

Inspection

Look for mental alertness, cyanosis, breathlessness at rest, use of accessory muscles, any deformity or scars on the chest and movement on both sides. A coarse tremor or flap of the outstretched hands indicates CO_2 intoxication. Prominent veins on the chest may imply obstruction of the superior vena cava.

Cyanosis (see p. 735) is a dusky colour of the skin and mucous membranes, due to the presence of more than 5 g/dL of desaturated haemoglobin. When due to central causes, cyanosis is visible on the tongue (especially the underside) and lips, and indicates a P_aO_2 below 6 kPa. Patients with central cyanosis will also be cyanosed peripherally. Peripheral cyanosis without central cyanosis is caused by a reduced peripheral circulation and is noted on the fingernails and skin of the extremities with associated coolness of the skin.

Finger clubbing is present when the normal angle between the base of the nail and the nail fold is lost. The base of the nail is fluctuant owing to increased vascularity, and there is an increased curvature of the nail in all directions, with expansion of the end of the digit. Some causes of clubbing are given in Table 14.2. Clubbing is not a feature of uncomplicated COPD.

Palpation and percussion

Check the position of the trachea and apex beat. Examine the supraclavicular fossa for enlarged lymph nodes. The distance between the sternal notch and the cricoid cartilage (three to four finger breadths in full expiration) is reduced in patients with severe airflow limitation. Check chest expansion. A tape measure may be used if precise measurements are needed, e.g. in ankylosing spondylitis. Local discomfort over the sternochondral joints may suggest costochondritis. Compression of the chest laterally and anteroposteriorly may produce localized pain suggestive of a rib fracture. On *percussion* liver dullness is usually detected anteriorly at the level of the sixth rib. Liver and cardiac dullness are lost with over-inflated lungs. Other changes are shown in Table14.1.

Table 14.2 **Some causes of finger clubbing**

Respiratory
Bronchial carcinoma, especially epidermoid (squamous cell) type (major cause) Chronic suppurative lung disease: Bronchiectasis
Lung abscess Empyema
Pulmonary fibrosis (e.g. cryptogenic fibrosing alveolitis) Pleural and mediastinal tumours (e.g. mesothelioma)
Cryptogenic organizing pneumonia

Cardiovascular
Cyanotic heart disease
Subacute infective endocarditis
Atrial myxoma

Miscellaneous
Congenital - no disease
Cirrhosis
Inflammatory bowel disease

Auscultation

The patient is asked to take deep breaths through the mouth. Inspiration sounds more prolonged than expiration. Healthy lungs filter off most of the high-frequency component, which is mainly due to turbulent flow in the larynx. Normal breath sounds are harsher anteriorly over the upper lobes (particularly on the right) and described as vesicular.

Bronchial breathing is heard best over consolidated or collapsed lung and sometimes over areas of localized fibrosis or bronchiectasis. Such areas conduct the high-frequency hissing component of breath sounds well. Characteristically, the noise heard during inspiration and expiration is equally long but separated by a short silent phase. Whispering pectoriloquy (whispered, higher-pitched, sounds heard distinctly through a stethoscope) invariably accompanies bronchial breathing.

Added sounds

Wheeze. Wheeze is usually heard during expiration and results from vibrations in the collapsible part of the airways when apposition occurs as a result of the flow-limiting mechanisms. Wheezes are heard in asthma and in chronic obstructive pulmonary disease, but are not invariably present. In the most severe cases of asthma a wheeze may not be heard, as airflow may be insufficient to generate the sound. Wheezes may be monophonic (single large airway obstruction) or polyphonic (narrowing of many small airways). An end-inspiratory (as opposed to expiratory) 'squeak' may be heard in obliterative bronchiolitis.

Crackles. These brief crackling sounds are probably produced by opening of previously closed bronchioles, and their timing during breathing is of significance - early inspiratory crackles are associated with diffuse airflow limitation, whereas late inspiratory crackles are characteristically heard in pulmonary oedema, fibrosis of the lung and bronchiectasis.

Pleural rub. This is a creaking or groaning sound that is usually well localized. It is indicative of inflammation and roughening of the pleural surfaces, which normally glide silently over one another.

Vocal resonance. Healthy lung attenuates high-frequency notes, leaving the booming low-pitched components of speech. Consolidated lung has the reverse effect, transmitting the high frequencies; the spoken word then takes on a bleating quality. Whispered (and therefore high-pitched) speech can barely be heard over healthy lung, whereas consolidation allows its clear transmission. Sonorous sounds such as 'ninety-nine' are well transmitted across healthy lung to produce vibration that can be felt over the chest wall. Consolidated lung transmits these low-frequency noises less well, and pleural fluid

severely dampens or obliterates the vibrations altogether. Tactile vocal fremitus is the palpation of this vibration, usually by placing the edge of the hand on the chest wall. For all practical purposes this duplicates the assessment of vocal resonance and is no longer considered a routine part of the chest examination.

Cardiovascular system examination (p. 735) gives additional information about the lungs.

Additional tests

Since so many patients with respiratory disease have airflow limitation, airflow should be routinely measured using a peak flow meter or spirometer. This will provide a much more accurate assessment of airflow limitation than any physical sign.

INVESTIGATION OF RESPIRATORY DISEASE

Haematological and biochemical tests

It is useful to measure:

- haemoglobin, to detect the presence of anaemia or polycythaemia
- packed cell volume (secondary polycythaemia occurs with chronic hypoxia)
- routine biochemistry (often disturbed in carcinoma and infection).
- B-type natriuretic peptide may be a useful test to distinguish cardiac from non-cardiac breathlessness. A rapid bedside test is available but is not yet in routine clinical use.
- D-dimer can be measured to detect intravascular coagulation. A negative test makes pulmonary embolism very unlikely.

Other blood investigations sometimes required include Oi-antitrypsin levels, *Aspergillus* antibodies, viral and mycoplasma serology, autoantibody profiles and specific IgE measurements.

Sputum

Sputum should be inspected for colour:

- yellowish green indicates inflammation (infection or allergy)
- the presence of blood suggests neoplasm or pulmonary infarct (see haemoptysis, p. 882).

Microbiological studies (Gram stain and culture) are not helpful in upper respiratory tract infections or in acute or chronic bronchitis. They are of value in:

- pneumonia
- the diagnosis of tuberculosis (Ziehl-Neelsen or auramine-phenol stains)
- unusual clinical problems
- *Aspergillus* lung disease.

Sputum cytology

This is extremely useful in the diagnosis of bronchial carcinoma. Advantages are:

- a quick result
- cheapness
- it is non-invasive.

However, its value depends on the production of sputum and the presence of a reliable cytologist. Sputum can be induced following the inhalation of nebulized hypertonic saline (5%). This is unpleasant and it is better to proceed to bronchoscopy and bronchial washings (see p. 891), or occasionally, transtracheal aspiration.

Transtracheal aspiration

This technique involves pushing a needle through the cricothyroid membrane, through which a catheter is threaded to a position just above the carina. This procedure induces coughing, and specimens are collected by aspiration or by the introduction and subsequent aspiration of sterile saline. Although not often required, it is an excellent technique for assessing infection in the lower respiratory tract because it avoids contamination of the specimen with bacteria from the pharynx and mouth.

Imaging

Radiology is an essential adjunct to examination of the chest. Diseases such as tuberculosis or lung cancer may not be detectable on clinical examination but are obvious on the chest X-ray. Conversely, the abnormal physical signs in asthma or chronic bronchitis may be associated with a normal chest X-ray. Always try to get previous films for comparison.

Chest X-ray

The following must be taken into account when viewing films:

- *Centring of the film.* The distance between each clavicular head and the spinal processes should be equal.
- *Penetration* (check film is not too dark).
- *The view.* Routine films are taken PA, i.e. the film is placed in front of the patient with the X-ray source behind. Anteroposterior (AP) films are taken only in very ill patients who are unable to stand up or be taken to the radiology department; the cardiac outline appears bigger and the scapulae cannot be moved out of the way. A lateral chest X-ray helps in localization of pathology.

Look at:

- the shape and bony structure of the chest wall
- whether the trachea is central
- whether the diaphragm is elevated or flat
- the shape, size and position of the heart
- the shape and size of the hilar shadows
- the size and shape of any lung abnormalities and vascular shadowing.

X-ray abnormalities

Collapse and consolidation

A chest X-ray showing collapse of a whole lung is shown in Figure 14.11 and causes are shown in Table 14.3. Loss of volume in the relevant hemithorax should raise the possibility of lobar collapse. The lung lobes collapse in characteristic directions. The lower lobes collapse downward and towards the mediastinum, the left upper lobe collapses forwards against the anterior chest wall, while the right upper lobe collapses upwards and outwards, forming the appearance of an arch over the remaining lung. The right middle lobe collapses anteriorly and inward, obscuring the right heart border. If a whole lung collapses, the mediastinum will shift towards the side of the collapse. Consolidated lobes remain the same size; uncomplicated consolidation does not cause mediastinal shift or loss of lung volume.

Pleural effusion (see Fig. 14.45)

Pleural effusions need to be more than 500 mL to cause much more than blunting of the costophrenic angle. On an erect film they produce a characteristic shadow with a curved upper edge rising into the axilla. If very large, the whole of one side of the thorax may be opaque, with shift of the mediastinum to the opposite side.

Table 14.3 **Causes of collapse of the lung**

- Enlarged tracheobronchial lymph nodes due to malignant disease, tuberculosis
- Inhaled foreign bodies (e.g. peanuts) in children, usually in the right main bronchus
- Bronchial casts or plugs (e.g. allergic bronchopulmonary aspergillosis)
- Retained secretions - postoperatively and in debilitated patients

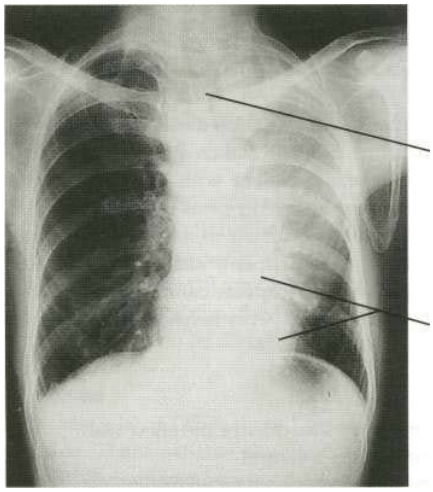

Table 14.4 **Causes of round shadows (> 3 cm) in the lung**

- Carcinoma
- Metastatic tumours (usually multiple shadows)
- Lung abscess (usually with fluid level)
- Encysted interlobar effusion (usually in horizontal fissure)
- Hydatid cysts (rare and often with a fluid level)
- Arteriovenous malformations (usually adjacent to a vascular shadow)
- Aspergilloma
- Rheumatoid nodules
- Tuberculoma (may be calcification within the lesion)

Rare causes:
Bronchial carcinoid
Cylindroma
Chondroma Lipoma

Other shadows related to mediastinum:

Seen on lateral chest X-ray
Pericardium
Oesophagus

Fibrosis

Localized fibrosis causes streaky shadowing, and the accompanying loss of lung volume causes mediastinal structures to move to the same side. More generalized fibrosis in the lung can lead to a honeycomb appearance (see p. 943), seen as diffuse shadows containing multiple circular translucencies a few millimetres in diameter.

Spinal cord

to the left

Heart and apex beat deviated to the left

Trachea deviated

Fig. 14.11 **Collapse of the left lung.** Chest X-ray showing hazy shadowing in the left upper zone with a raised left diaphragm. There is compensatory emphysema of the right lung.

Round shadows

Lung cancer is the commonest cause of large round shadows but many other causes are recognized (Table14.4).

Miliary mottling

This term describes numerous minute opacities, 1-3 mm in size, which are caused by many pathological processes. The most common causes are miliary tuberculosis, pneumoconiosis, sarcoidosis, fibrosing alveolitis (idiopathic pulmonary fibrosis) and pulmonary oedema (see Fig. 13.18), though the latter is usually perihilar and accompanied by larger, fluffy shadows. A rare but striking cause of miliary mottling is pulmonary microlithiasis.

Computed tomography

Modern CT scanners provide excellent images of the lungs and mediastinal structures. Different settings are required to show the parenchymal tissue and the central structures (Fig. 14.12). Mediastinal structures may be shown more clearly by injecting intravenous contrast medium to enhance the vascular structures.

The advent of rapid *volumetric* or *'spiral' scanning* means that scans can be obtained rapidly (within seconds) during contrast injection. This is a useful technique for directly demonstrating pulmonary emboli within pulmonary vessels. *Conventional CT* is valuable in bronchial carcinoma staging to demonstrate mediastinal, pleural or chest wall invasion and to determine operability. CT-guided needle biopsy is the preferred means of obtaining samples from peripheral masses.

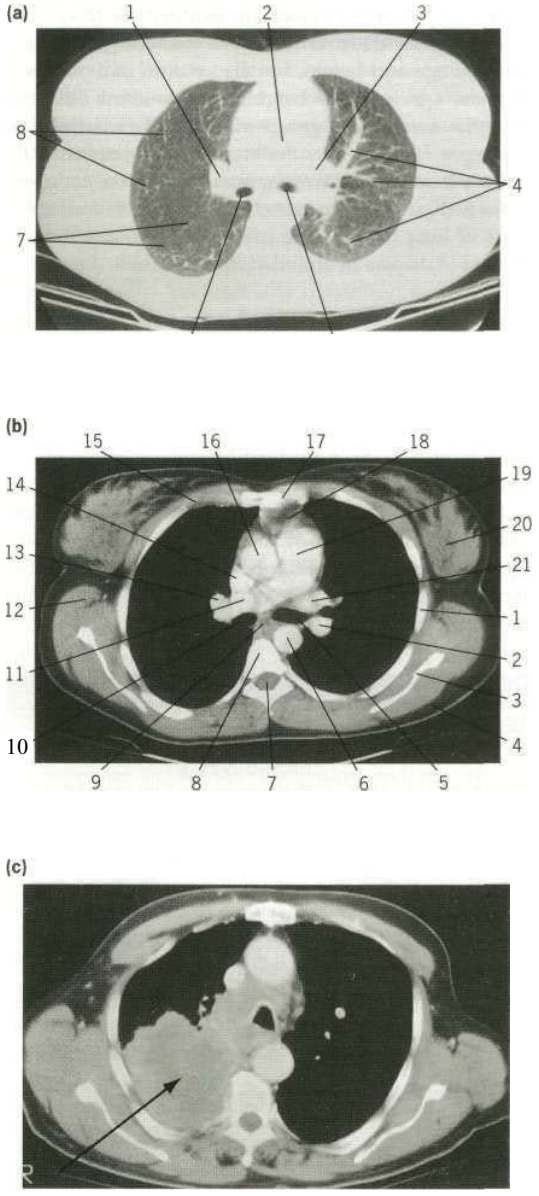

Fig. 14.12 **CT scan of the lung.**
(a) Lung setting - showing normal lung markings. 1, right hilum; 2, mediastinum; 3, left hilum; 4, lung vessels; 5, L. main bronchus; 6, R. main bronchus; 7, position of oblique fissure; 8, peripheral lung vessels.
(b) Mediastinal (soft tissue) setting - showing normal mediastinal structures following intravenous contrast enhancement. 1, rib; 2, descending L. pulmonary artery; 3, scapula; 4, subcutaneous fat; 5, L. main bronchus; 6, descending aorta; 7, spinal canal; 8, vertebral body; 9, oesophagus; 10, R. main bronchus; 11, R. pulmonary artery; 12, muscle; 13, R. superior pulmonary vein; 14, superior vena cava; 15, costal cartilage; 16, ascending aorta; 17, sternum; 18, thymic remnant; 19, pulmonary trunk; 20, breast tissue; 21, L. superior pulmonary vein.
(c) Post-contrast scan showing large right upper zone carcinoma *(arrow)* with enlarged lymph nodes in the mediastinum surrounding the trachea.

Enlarged mediastinal nodes (> 1 cm) may be either malignant or reactive and may require biopsy. Scanning should include assessment of liver, adrenals and brain, which are likely sites for metastatic disease.

High-resolution CT scanning (sampling lung parenchyma with 1-2 mm thickness scans at 10-20 mm intervals) allows assessment of diffuse lung parenchymal processes, particularly interstitial disease. It is valuable in the following situations:

- Detection of diffuse interstitial pulmonary involvement in any type of interstitial lung disease, including sarcoidosis, cryptogenic and extrinsic allergic alveolitis, occupational lung disease, and any other form of interstitial pulmonary fibrosis.
- Diagnosis of bronchiectasis. High-resolution CT has a sensitivity and specificity of greater than 90%. Inspiratory and expiratory scans may allow demonstration of air trapping in small airway disease. This technique has replaced bronchography.
- Distinguishing emphysema from interstitial lung disease or pulmonary vascular disease as a cause of a low gas transfer factor with otherwise normal lung function
- Diagnosis of lymphangitis carcinomatosa.

Magnetic resonance imaging

Problems with motion artefact, both respiratory and cardiac, make magnetic resonance imaging (MRI) less valuable than CT in assessment of lung parenchyma. In the mediastinum, MRI with ECG-gating allows accurate images of the heart and aortic aneurysms to be obtained, and MRI retains a place in staging lung cancer, for assessing tumour invasion in the mediastinum, chest wall and at the lung apex, because it produces good images in the sagittal and coronal planes. Vascular structures can be clearly differentiated as flowing blood produces a signal void on MRI.

Positron emission tomography (PET)

Tumours take up a tracer, e.g. fluorodeoxyglucose (FDG), which emits positrons that can be imaged and this helps differentiate benign from malignant tumours. PET scanning is now the investigation of choice for assessing lymph nodes and metastatic disease in bronchial carcinoma.

Scintigraphic imaging

This technique is used widely for the detection of pulmonary emboli although it is now performed less often owing to widespread use of D-dimer measurements to screen for thromboembolism.

Perfusion scan

Macro-aggregated human albumin labelled with technetium-99m is injected intravenously. The particles are of such a size that they impact in pulmonary

capillaries, where they remain for a few hours. A gamma camera is then used to detect the position of the macroaggregated human albumin. The resultant pattern indicates the distribution of pulmonary blood flow; cold areas occur where there is defective blood flow (e.g. in pulmonary emboli).

Ventilation-perfusion scan (see p. 845) *Xenon-133 gas* is inhaled into the lung and its distribution is detected at the same time as the perfusion scan. Using the two scans, a pulmonary embolus can be seen to cause a striking diminution of perfusion relative to ventilation. Other lung diseases (e.g. asthma or pneumonia) impair both ventilation and perfusion. Unfortunately, however, a pulmonary embolus often produces substantial changes in the lung substance (e.g. atelectasis) so that such a clear distinction is not always obvious. Nevertheless, this is a better technique than perfusion scan alone.

Respiratory function tests (Table 14.5)

In clinical practice, airflow limitation can be assessed by relatively simple tests that have good intra-subject repeatability. Normal values are required for their interpretation since these tests vary considerably, not only with sex, age and height, but also within individuals of the same age, sex and height. The standard deviation about the mean for a group of individuals is therefore very high; for example, the standard deviation for the peak expiratory flow rate is approximately 50 L/min, and for the FEVj it is approximately 0.4 L. Repeated measurements of lung function are useful for assessing the progression of disease in an individual patient.

Tests of ventilatory function

These tests are used mainly to assess the degree of airflow limitation present during expiration.

Peak expiratory flow rate (PEFR)

This is an extremely simple and cheap test. Subjects are asked to take a full inspiration to total lung capacity and then blow out forcefully into the peak flow meter (Fig. 14.13), which is held horizontally. The lips must be placed tightly around the mouthpiece. The best of three tests is recorded.

Table 14.5 **Respiratory function tests and exercise tests**

Test	Use	Advantages	Disadvantages
PEFR	Monitoring changes in airflow limitation in asthma	Portable Can be used at the bedside	Effort-dependent Poor measure of chronic airflow limitation
FEV, FVC, FEV,/FVC	Differentiation between Assessment of airflow limitation The best single test		Bulky equipment but smaller portable machines available
Flow-volume curves	Assessment of flow at lower lung volumes Detection of large airway obstruction both intra- and extrathoracic (e.g. tracheal stenosis, tumour)		Sophisticated equipment needed for full test but expiratory loop now possible with compact spirometry
Airways resistance	Assessment of airflow limitation	Sensitive	Technique difficult to perform
Lung volumes	restrictive and obstructive lung disease		Sophisticated equipment needed
Gas transfer	Assessment and monitoring of extent of interstitial lung disease and emphysema	Reproducible Relatively effort-independent Recognition of patterns of flow-volume curves for different diseases	Sophisticated equipment needed
Blood gases	Assessment of respiratory failure	Effort-independent, complements FEV,	Invasive
Pulse oximetry	Postoperative, sleep studies and respiratory failure	Non-invasive (compared with lung biopsy or radiation from repeated chest X-rays and CT)	Measures saturation only
Exercise tests (6-min walk)	Practical assessment for disability and effects of therapy	Can detect early lung disease when measured during exercise	Time-consuming Learning effect At least two walks required
Cardiorespiratory assessment	Early detection of lung/ heart disease Fitness assessment	Continuous monitoring Non-invasive No equipment required Differentiates breathlessness due to lung or heart disease	Expensive and complicated equipment required

888

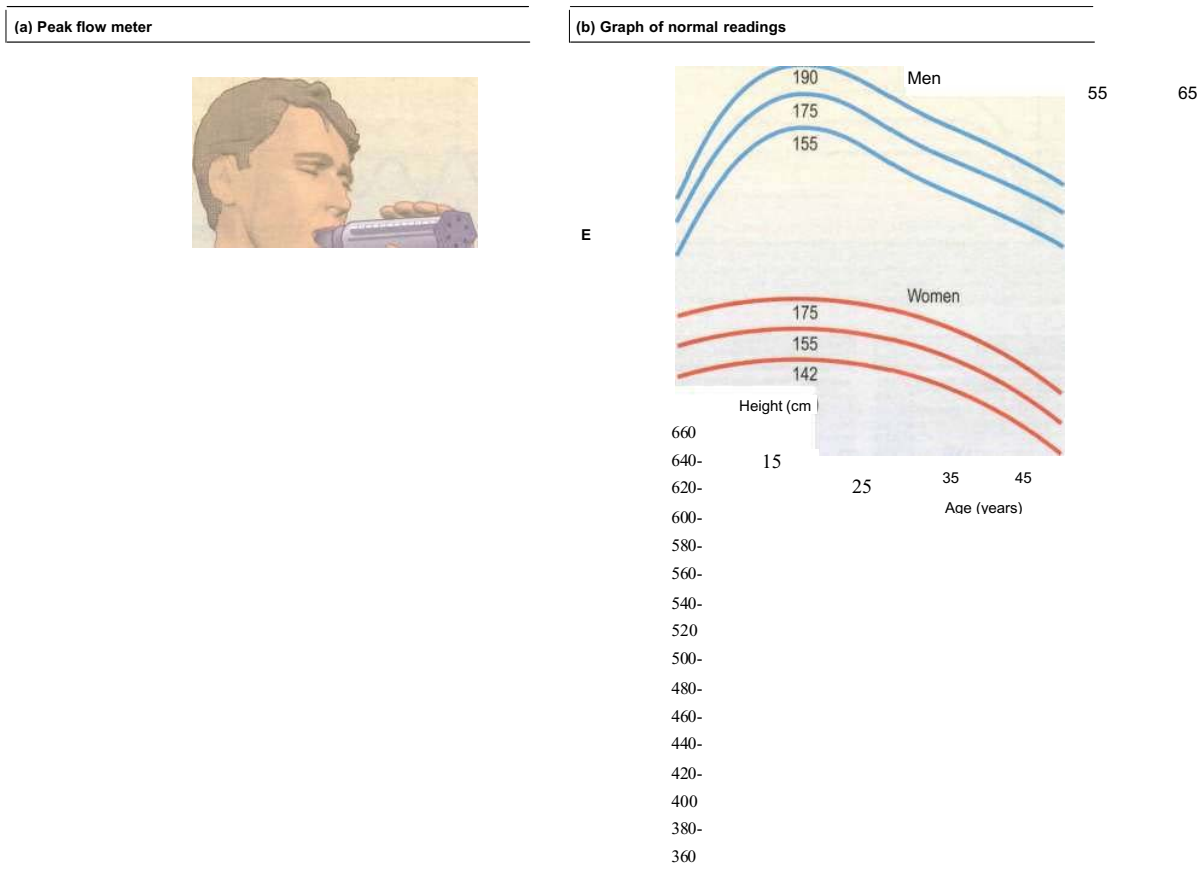

Fig. 14.13 **Peak flow measurements, (a)** Peak flow meter: the lips should be tight around the mouthpiece, (b) Graph of normal readings for men and women.

Although reproducible, PEFR is not a good measure of airflow limitation since it measures the expiratory flow rate only in the first 2 ms of expiration and overestimates lung function in patients with moderate airflow limitation. PEFR is best used to monitor progression of disease and its treatment. Regular measurements of peak flow rates on waking, during the afternoon, and before bed demonstrate the wide diurnal variations in airflow limitation that characterize asthma and allow an objective assessment of treatment to be made (Fig. 14.14).

Spirometry

The spirometer measures the FEV¡ and the forced vital capacity (FVC). Both the FEV¡ and FVC are related to height, age and sex. The technique involves a maximum inspiration followed by a forced expiration (for as long as possible) into the spirometer. The act of expiration triggers the moving record chart, which measures volume against time. The record chart moves for a total of 5 s, but expiration should continue until all the air has been expelled from the lungs, as patients with severe airflow limitation may have a very prolonged forced expiratory time. This is demonstrated on the record chart in Figure 14.15.

The FEV¡ expressed as a percentage of the FVC is an excellent measure of airflow limitation. In normal subjects it is around 75%. With *increasing airflow limitation* the FEVi falls proportionately more than the FVC, so that the FEVj/FVC ratio is reduced. With *restrictive lung disease* the FEV] and the FVC are reduced in the same proportion and the FEVj/FVC ratio remains normal or may even increase because of the enhanced elastic recoil.

In chronic airflow limitation (particularly in emphysema and asthma) the total lung capacity (TLC) is usually increased, yet there is nearly always some reduction in the FVC. This is the result of disease in the small airways causing obstruction to airflow before the normal RV is reached. This trapping of air within the lung (giving an increased RV) is a characteristic feature of these diseases.

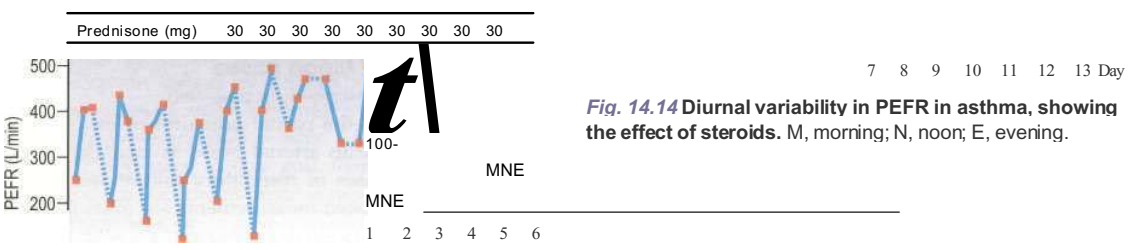

Fig. 14.14 **Diurnal variability in PEFR in asthma, showing the effect of steroids.** M, morning; N, noon; E, evening.

Other tests

Measurement of airways resistance in a body plethysmograph is more sensitive but the equipment is expensive and the necessary manoeuvres are too exhausting for many patients with chronic airflow limitation.

Flow-volume loops

The ability to measure flow rates against volume (flow-volume loops, see Fig. 14.8) enables a more sophisticated analysis to be made of the site of airflow limitation within the lung. At the start of expiration from TLC, the site of maximum resistance is the large airways, and this

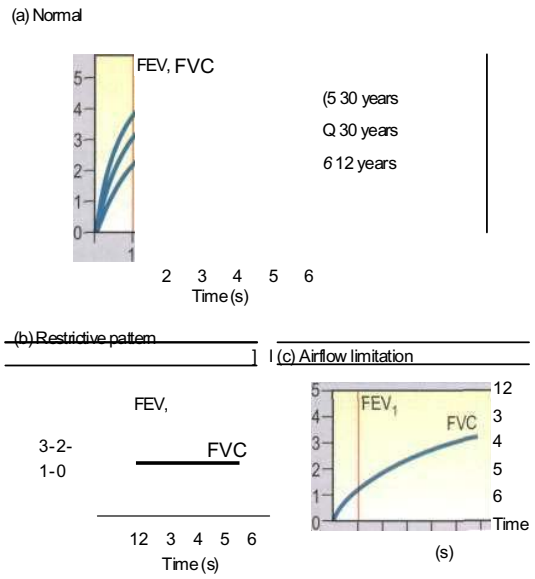

Fig. 14.15 **Spirometry.** Volume-time curves showing (a) normal patterns for age and sex, (b) restrictive pattern (FEV, and FVC reduced), (c) airflow limitation (FEV-, only reduced).

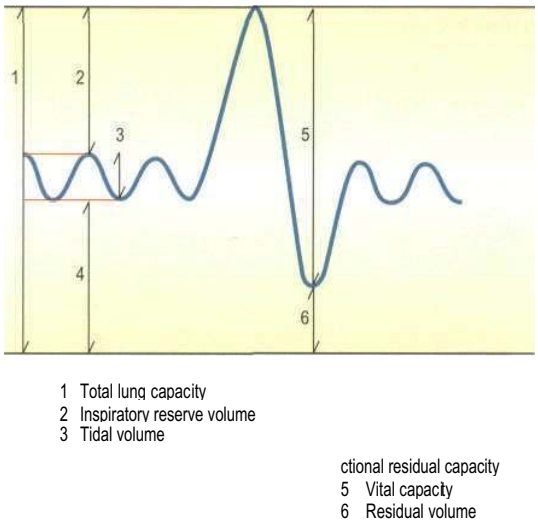

Fig. 14.16 The subdivisions of the lung volume.

accounts for the flow reduction in the first 25% of the curve. As the lung volume reduces further, so the elastic pressures within the lung holding open the smaller airways reduce, and disease of the lung parenchyma or the small airways themselves becomes apparent. For example, in diseases such as chronic obstructive pulmonary disease (COPD), where the brunt of the disease falls upon the smaller airways, expiratory flow rates at 50% or 25% of the vital capacity may be disproportionately reduced when compared with flow rates at larger lung volumes.

Lung volume

The subdivisions of the lung volume are shown in Figure 14.16. Tidal volume and vital capacity can be measured using a simple spirometer, but the TLC and RV need to be measured by an alternative technique. TLC is measured by connecting the lungs to a reservoir containing a known amount of non-absorbable gas (helium) that can readily be measured. If the concentration of the gas in the reservoir is known at the start of the test and is measured after equilibration of the gas has occurred (when the patient has breathed in and out of the reservoir), the dilution of the gas will reflect the TLC. This technique is known as *helium dilution.* RV can be calculated by subtracting the vital capacity from the TLC.

The TLC measured using this technique is inaccurate if large cystic spaces are present in the lung, because the helium cannot diffuse into them. Under these circumstances the thoracic gas volume can be measured more accurately using a body plethysmograph. The difference between the two measurements can be used to define the extent of non-communicating air space within the lungs.

Transfer factor

This measures the transfer of gas across the alveolar-capillary membrane and reflects the uptake of oxygen from the alveoli into the red cells. A low concentration of carbon monoxide is inhaled and is avidly taken up in a linear fashion by circulating haemoglobin, the amount of which must be known when the test is performed. In normal lungs the transfer factor is a true measure of the diffusing capacity of the lungs for oxygen and depends on the thickness of the alveolar-capillary membrane. In lung disease the diffusing capacity (D_{co}) also depends on the V_A/Q relationship as well as on the area and thickness of the alveolar membrane. To control for differences in lung volume, the uptake of carbon monoxide is related to the lung volume; this is known as the transfer coefficient (Kco).

Gas transfer is usually reduced in patients with severe degrees of emphysema and fibrosis. Overall gas transfer can be thought of as a relatively non-specific test of lung function but one that can be particularly used in the early detection and assessment of progress of diseases affecting the lung parenchyma (e.g. cryptogenic pulmonary fibrosis, sarcoidosis, asbestosis).

Measurement of blood gases

This technique is described on page 980.

Measurement of the partial pressures of oxygen and carbon dioxide within arterial blood is essential in the management of cases of respiratory failure and severe asthma, when repeated measurements are often the best guide to therapy.

Arterial oxygen saturation (S_aO_2) can be continuously measured using an oximeter with either ear or finger probes. The oximeter measures the differential absorption of light by oxy- and deoxyhaemoglobin and measures saturation to within 5% of that obtained by blood gas analysis.

Exercise tests

The predominant symptom in respiratory medicine is that of breathlessness. The degree of disability produced by breathlessness can be assessed before and after treatment by asking the patient to walk for 6 minutes along a measured track. This has been shown to be a reproducible and useful test once the patient has undergone an initial training walk to overcome the learning effect.

Exercise tests incorporating assessment of both lung and heart function are of particular value in the investigation of breathlessness. Such tests involve the use of sophisticated equipment enabling measurement of uptake of oxygen (Vo_2), work performed, heart rate and blood pressure together with serial ECGs. Correlation of these variables allows:

- the early detection of lung disease
- the detection of myocardial ischaemia
- the distinction between lung and heart disease
- assessment of fitness.

Pleural aspiration

Diagnostic aspiration is necessary for all but very small effusions. A needle attached to a 20 mL syringe is inserted through an intercostal space over an area of dullness. Fluid is withdrawn and the presence of any blood is noted. Samples are sent for protein estimation, cytology and bacteriological examination, including culture and Ziehl-Neelsen stain for tuberculosis. Large amounts of fluid can be aspirated through a large needle to help relieve extreme breathlessness. Because of the risk of introducing infection into the pleural space, with the subsequent development of an empyema, this technique must be performed using full aseptic precautions.

Pleural aspiration and drainage are now often performed using ultrasound to localize the fluid.

Pleural biopsy

Blind pleural biopsy (Fig. 14.17) is a useful technique if performed by an experienced operator, and will yield positive results in up to 80% of cases of tuberculosis and in 60% of cases of malignancy provided multiple biopsies are taken (Practical box 14.1). Better yields can be obtained by biopsy under direct vision using thoracoscopy.

Intercostal drainage

This is carried out when large effusions are present producing severe breathlessness or for drainage of an empyema (see Practical box 14.2). Pleurodesis is performed for recurrent/malignant effusion.

Mediastinoscopy and scalene node biopsy

This technique can be used in the management of carcinoma of the bronchus. It involves inspection of the mediastinal structures using a mediastinoscope inserted by blunt dissection downwards from behind the proximal end of the clavicle. Subsequent biopsy of tissue will reveal the presence or absence of malignant cells in enlarged lymph nodes previously detected by CT, allowing accurate staging of the disease.

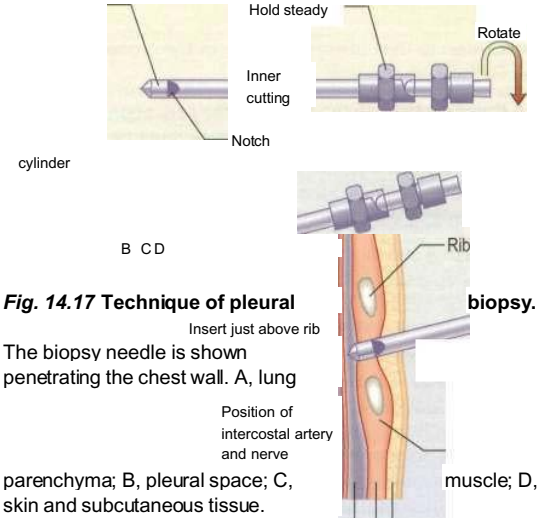

Fig. 14.17 **Technique of pleural biopsy.** The biopsy needle is shown penetrating the chest wall. A, lung parenchyma; B, pleural space; C, muscle; D, skin and subcutaneous tissue.

Practical Box 14.1
Pleural biopsy

- Explain to the patient the nature of the procedure.
- Get written consent.

1. Pleural biopsy is best performed after the aspiration of diagnostic fluid samples but before draining large volumes of fluid.
2. A small skin incision is made, as the end of the Abrams' pleural biopsy needle is blunt.
3. Once in place through the pleura, the back part of the needle is rotated to open the notch; this is kept pointing forward.
4. With lateral pressure the needle is withdrawn so that the notch will snag against the pleura.
5. The needle is held firmly and the hexagonal grip is twisted clockwise to cut the biopsy. To avoid damage to the intercostal vessel or nerve, the notch should never be directed upwards when the biopsy is taken.
6. Several biopsies should be taken at different angles by repeated insertion of the needle.
7. Specimens should be put in sterile saline for culture for tuberculosis and into 10% formol saline for histological examination.

FibreoptiC bronchOSCOpy (Practical box 14.3)

Central bronchial lesions can be biopsied readily.

Washings can be taken from lobes containing more peripheral lesions for cytological examination for malig-

Practical Box 14.2
Intercostal drainage

Explain to the patient the nature of the procedure. Get written consent.

Carefully sterilize the skin over the aspiration site. Sterile gloves, cap, gown and mask must be worn.

2. Anaesthetize the skin, muscle and pleura with 2% lidocaine.
3. Make a small incision, then push a 28 French gauge Argyle catheter into the pleural space.
4. Attach to a three-way tap and 50 mL syringe.
5. Aspirate up to 1000 mL. Stop aspiration if patient becomes uncomfortable - shock may ensue if too much fluid is withdrawn too quickly.
6. A Silastic pigtail catheter can be inserted under X-ray/ultrasound control and attached to tubing and bag for slower aspiration. For drainage and effusions, an 8-12 French gauge pigtail is inserted using the Seldinger technique in which the needle used to enter the pleural space is withdrawn over a control wire along which the catheter is then passed. A 14-16 French gauge pigtail catheter is used for drainage of empyema.

For pleurodesis

Sterile talc (2-5 g), tetracycline 500 mg or bleomycin 15 units in 30-50 mL sodium chloride 0.9% solution is instilled into the pleural cavity to achieve pleurodesis in recurrent/malignant effusion.

nant cells, and appropriate staining and culture for, for example, *Pneumocystis carinii, Mycobacterium.*

Diffuse parenchymal lung disease can be investigated using transbronchial biopsy. The biopsy forceps are pushed as far as possible to the periphery of the lung, the patient is asked to breathe in and the forceps are opened. The patient then breathes out and the jaws of the forceps are closed, removing a small piece of peripheral airway and surrounding lung parenchyma.

Video-assisted thoracoscopic lung biopsy

This technique reduces the need for open thoracotomy when a lung biopsy is required (p. 942).

Bronchoalveolar lavage

This technique can be used both in patients who have disease confined to one lobe and in those with more diffuse lung disease. The tip of the fibreoptic bronchoscope is lodged in the segmental orifice and 20 mL of 0.9% sterile saline is squirted down the suction port of the bronchoscope and immediately aspirated. This is repeated five times; about 40-60% of the total volume is recovered. Fluid is strained through two layers of surgical gauze and the volume is noted. The cells are then spun down and resuspended at a concentration of 1×10^7 cells/mL for differential counting. Since there is a considerable

Practical Box 14.3
Fibreoptic bronchoscopy

This enables the direct visualization of the bronchial tree as far as the subsegmental bronchi under a local anaesthetic. Informed consent should be obtained after explaining the nature of the procedure.

Indications

Lesions requiring biopsy seen on chest X-ray.
Haemoptysis. Stridor.
Positive sputum cytology for malignant cells with no chest X-ray abnormality.
Collection of bronchial secretions for bacteriology, especially tuberculosis.
Recurrent laryngeal nerve paralysis of unknown aetiology.
Infiltrative lung disease (to obtain a transbronchial biopsy).

- Investigation of collapsed lobes or segments and aspiration of mucus plugs.

Procedure

The patient is starved overnight. Atropine 0.6 mg i.m. is given 30 min before the procedure.
Topical anaesthesia (lidocaine 2% gel) is applied to the nose, nasopharynx and pharynx. . Intravenous sedation (e.g. diazepam 10 mg or midazolam 2.5-10 mg) is given.
The bronchoscope is passed through the nose, nasopharynx and pharynx under direct vision to minimize trauma.
Lidocaine (2 mL of 4%) is dropped through the instrument on to the vocal cords.
The bronchoscope is passed through the cords into the trachea.
All segmental and subsegmental orifices should be identified.
Biopsies and brushings should be taken of macroscopic abnormalities or occasionally from peripheral lesions under radiographic control.

Disadvantages

All patients require sedation to tolerate the procedure.
Minor and transient cardiac dysrhythmias occur in up to 40% of patients on passage of the bronchoscope through the larynx.
Oxygen supplementation is required in patients with P_{aO_2} below 8 kPa.
Fibreoptic bronchoscopy should be performed with care in the very sick, and transbronchial biopsies avoided in ventilated patients owing to the increased risk of pneumothorax.
Massive bleeding may occur on accidental biopsy of vascular lesions or carcinoid tumours. Rigid bronchoscopy may be required to allow adequate access to the bleeding point for haemostasis.

overlap in the distribution of cells seen in bronchoalveolar wash specimens in different diseases, this technique has no value in diagnosis. However, it can be used to monitor progression of disease, since improvement is characterized by a reduction in the number of cells and a return towards the normal proportions of different cell types.

Skin-prick tests

Allergen solutions are placed on the skin (usually the volar surface of the forearm) and the epidermis is broken using a 1 mm tipped lancet. A separate lancet should be used for each allergen. If the patient is sensitive to the allergen a weal develops and the diameter of the induration should be measured after 10 minutes. A weal of at least 3 mm diameter is regarded as positive provided that the negative control test is truly negative. The results should be interpreted in the light of the history. Skin tests are not affected by bronchodilators or corticosteroids but antihistamines should be discontinued at least 48 hours before testing.

SMOKING AND AIR POLLUTION

SMOKING

Prevalence

General household surveys in the UK showed a decline in the prevalence of cigarette smoking in the early nineties. More recent data show that this decline has halted and smoking in the UK is on the increase. At present, 28% of men and women aged 16 years and over smoke. Cigarette smoking is most common between the ages of 16 and 34 years (40% in both sexes) and it is in this age group that the increase has occurred. At the age of 15 more girls (33%) than boys (13%) smoke cigarettes. A greater proportion of manual workers than professional workers smoke. In the USA only 26% of men smoke and 22% of women. However, cigarette consumption is rising in Central and Eastern Europe and many developing countries including China.

Toxic effects

Cigarette smoke contains polycyclic aromatic hydrocarbons and nitrosamines, which are potent carcinogens and mutagens in animals. It causes release of enzymes from neutrophil granulocytes and macrophages that are capable of destroying elastin and leading to lung damage. Pulmonary epithelial permeability increases even in symptomless cigarette smokers, and correlates with the concentration of carboxyhaemoglobin in blood. This altered permeability possibly allows easier access to carcinogens.

The dangers

Cigarette smoking is addictive. People usually start smoking in adolescence for psychosocial reasons and, once it is a regular habit, the pharmacological properties of nicotine play a major part in persistence, conferring some advantage to the smoker's mood. Very few cigarette smokers (less than 2%) can limit themselves to occasional or intermittent smoking. The dangers are listed in Table 14.6. There is a significant dose-response relationship between the smoking of 0^10 cigarettes daily and lung cancer mortality (Table 14.7). Sputum production and

Table 14.6 **The dangers of cigarette smoking**

General

Lung cancer COPD Carcinoma of the oesophagus Ischaemic heart disease Peripheral vascular disease Bladder cancer An increase in abnormal spermatozoa Memory problems

Maternal smoking

A decrease in birthweight of the infant An increase in fetal and neonatal mortality An increase in asthma

Passive smoking

Risk of asthma, pneumonia and bronchitis in infants of smoking parents
An increase in cough and breathlessness in smokers and non-smokers with COPD and asthma
Increased cancer risk

Table 14.7 **Effects of smoking on the lung**

Large airways

Increase in submucosal gland volume Increase in number of goblet cells Chronic inflammation Metaplasia and dysplasia of the surface epithelium

Small airways

Increase in number and distribution of goblet cells
Airway inflammation and fibrosis
Epithelial metaplasia/dysplasia
Carcinoma

Parenchyma

Proximal acinar scarring
Increase in alveolar macrophage numbers
Emphysema (centri-acinar, pan-acinar)

airflow limitation increase with daily cigarette consumption, and effort tolerance decreases, partly owing to high levels of carboxyhaemoglobin in bronchitis patients. Smoking and asbestos exposure are synergistic in producing bronchial carcinoma, increasing the risk in asbestos workers by up to five to eight times that of non-smokers exposed to asbestos.

Cigarette smokers who change to other forms of tobacco can reduce the risk, even if they continue to inhale, and are better off changing to cigars or pipes. However, all pipe and cigar smokers also have a greater risk of lung cancer than lifelong non-smokers or former smokers.

Environmental tobacco smoke ('passive smoking') has been shown to cause more frequent and more severe attacks of asthma in children and possibly increases the number of cases of asthma. It is also associated with a small but definite increase in lung cancer.

Stopping smoking

If the entire population could be persuaded to stop smoking, the effect on healthcare use would be enormous. National campaigns, bans on advertising and a substantial increase in the cost of cigarettes are the best ways of achieving this at the population level. Meanwhile, active encouragement to stop smoking remains a useful approach for individuals. Smokers who want to stop should have access to smoking cessation clinics to provide behavioural support. Nicotine replacement therapy (NRT) and buproprion are effective aids to smoking cessation in those smoking more than 10 cigarettes per day. Both should only be used in smokers who commit to a target stop date, and the initial prescription should be for 2 weeks beyond the target stop date. NRT is the preferred choice; there is no evidence that combined therapy offers any advantage. Therapy should be changed after 3 months if abstinence is not achieved.

AIR POLLUTION

Atmospheric air pollution, due to the burning of coal for energy and heat, has been a characteristic of urban living in developed countries for at least two centuries. It consists of black smoke and sulphur dioxide (SO_2). Air pollution of this type peaked in the 1950s in the UK, until legislation led to restrictions on coal burning. Such pollution continues to increase in newly industrialized countries (India, China) and continues in Eastern Europe and Russia. The combustion of petroleum and diesel oil in motor vehicles has led to new air pollution, consisting of primary pollutants such as the oxides of nitrogen (NO and NO_2), diesel particulates, polyaromatic hydrocarbons and the secondary pollutant ozone (O_3) generated by photochemical reactions in the atmosphere. Levels of NO_2 can be higher in poorly ventilated kitchens and living rooms where gas is used for cooking and in fires. In Europe 70% of the particulates present in urban air result from the combustion of diesel fuel. Very small particles (<2.5 |a,m, particulate matter PM_{25}) remain airborne for long periods and are carried into rural areas. In the UK, ozone concentrations are highest in sunny rural areas.

Epidemiology

Classical studies in the 1950s showed that winter-time episodes of severe air pollution (smog) were associated with substantial numbers of deaths from respiratory disease, particularly when temperature inversion trapped black smoke and SO_2 over urban areas. Air pollution of this type continues to cause excess deaths from respiratory and cardiovascular disease in older populations, and symptoms of bronchitis in children. Pollution resulting primarily from motor vehicles has been shown to cause:

- Increased deaths from respiratory and cardiovascular causes in the elderly - particulates less than 10 |im in diameter(PM_{10}).
- Increased respiratory symptoms, hospital admissions and reduced lung function in children and younger adults - SO_2, NO^ O_3, PM_{10}. Frequently there is a lag of 1-2 days between peaks in air pollution and disease effects.
- Increase in lung cancer - polyaromatic hydrocarbons.

It has been proposed at various times that air pollution is one of the causes of the dramatic increase in asthma and other allergic diseases (Table 14.8). There is no current evidence that this is true, but both NO_2 and ozone have been shown to enhance the nasal and lung airway responses to inhaled allergen, in those with established allergic disease. Air pollution has, however, been shown to have an adverse effect on lung development in teenage children.

Management

Asthmatics are advised to avoid exercising outdoors when air quality is poor and to increase their anti-inflammatory medication (i.e. inhaled corticosteroids).

Short- and long-term measures are required to reduce air pollution, particularly diesel particulates (which are predicted to increase as more diesel engines are used). Such measures include increased motor engine efficiency, catalytic converters, diesel particulate traps, and decreased reliance on cars and trucks.

DISEASES OF THE UPPER RESPIRATORY TRACT .

The common cold (acute coryza)

This highly infectious illness causes a mild systemic upset and prominent nasal symptoms. It is due to infection by rhinoviruses, the majority of which belong to the picornavirus group and exist in at least 100 different antigenic strains. Infectivity from close personal contact (nasal mucus on hands) or droplets is high in the early stages of the infection, and spread is facilitated by overcrowding and poor ventilation. On average, individuals suffer two to three colds per year; but the incidence lessens with age, presumably as a result of accumulating immunity to the causative virus strains. The incubation is from 12 hours to an upper limit of 5 days.

The clinical features are tiredness, slight pyrexia, malaise and a sore nose and pharynx. Profuse, watery nasal discharge, eventually becoming thick and mucopurulent, persists for up to a week. Sneezing is present in the early stage. Secondary bacterial infection occurs only in a minority.

Rhinitis

Rhinitis is present if sneezing attacks, nasal discharge or blockage occur for more than an hour on most days for:

- a limited period of the year (seasonal rhinitis)
- throughout the whole year (perennial rhinitis).

Seasonal rhinitis

This is often called 'hayfever' and is the most common of all allergic diseases. It is better described as seasonal allergic rhinitis. World-wide prevalence rates vary from 2% to 20%. Prevalence is maximum in the second decade, and up to 30% of young British people suffer symptoms in June and July.

Nasal irritation, sneezing and watery rhinorrhoea are the most troublesome symptoms, but many also suffer from itching of the eyes and soft palate and occasionally even itching of the ears because of the common innervation of the pharyngeal mucosa and the ear. In addition, approximately 20% suffer from seasonal attacks of asthma. The common seasonal allergens are shown in Figure 14.18. Since pollination of plants that give rise to high pollen counts varies from country to country, seasonal

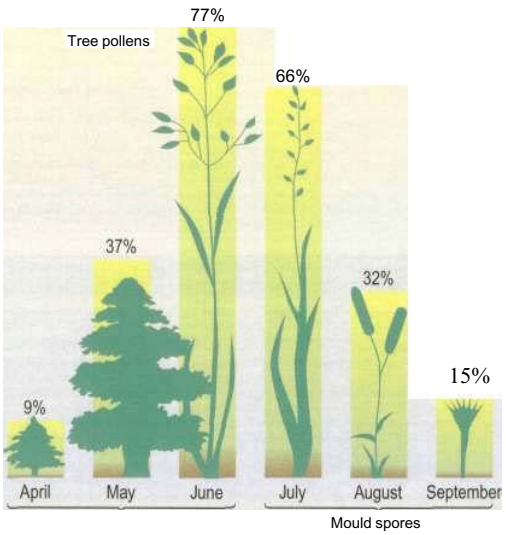

***Fig. 14.18* Seasonal allergic rhinitis.** Bar graph showing the proportion of patients whose symptoms are worst in the month or months indicated. The causative agents are also shown.

rhinitis and accompanying conjunctivitis and asthma may occur at different times of the year.

Perennial rhinitis

Patients with perennial rhinitis rarely have symptoms that affect the eyes or throat. Half have symptoms predominantly of sneezing and watery rhinorrhoea, whilst the other half complain mostly of nasal blockage. The patient may lose the sense of smell and taste. A swollen mucosa can obstruct drainage from the sinuses, causing sinusitis in half of the patients. Perennial rhinitis is most frequent in the second and third decades, decreasing with age, and can be divided into four main types.

Perennial allergic rhinitis

The major cause of this is allergy to the faecal particles of the house-dust mite *Dermatophagoides pteronyssinus* or D. *farinae;* these particles are approximately 20 urn in diameter (Fig. 14.19), not dissimilar in size to pollen grains. The house-dust mite itself is under 0.5 mm in size, invisible to the naked eye (Fig. 14.19), and is found in dust throughout the house, particularly in older, damp dwellings. It depends for nourishment on desquamated human skin scales and is found in abundance (4000 mites per gram of surface dust) in human bedding.

The next most common allergens come from domestic pets (especially cats) and are proteins derived from urine or saliva spread over the surface of the animal as well as skin protein. Allergy to urinary protein from small mammals is a major cause of morbidity amongst laboratory workers.

Industrial dust, vapours and fumes cause occupationally related perennial rhinitis more often than asthma.

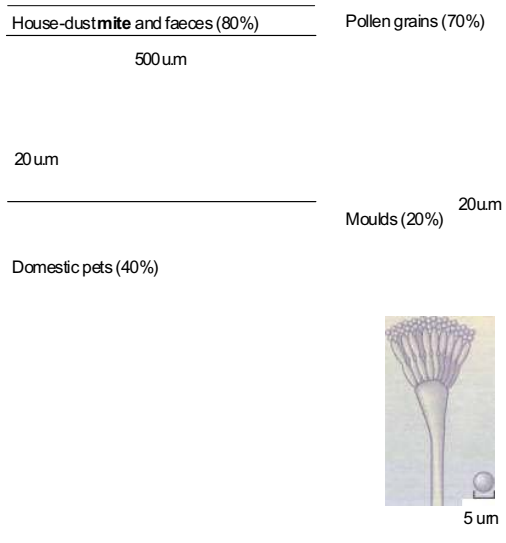

Fig. 14.19 **Common allergens causing allergic rhinitis and asthma.** The house-dust mite, faeces of house-dust mites, pollen grains, domestic pets and moulds. Percentages are those of positive skin-prick tests to these allergens in patients with allergic rhinitis.

The presence of perennial rhinitis makes the nose more reactive to non-specific stimuli such as cigarette smoke, washing powders, household detergents, strong perfumes and traffic fumes. Although patients often think they are allergic to these stimuli, these are irritant responses and do not involve allergic immune reactions.

Perennial non-allergic rhinitis with eosinophilia

No extrinsic allergic cause can be identified in these patients, either from the history or on skin testing; but, as in patients with perennial allergic rhinitis, eosinophilic granulocytes are present in nasal secretions. Aspirin and NSAID intolerance is found in this group.

Vasomotor rhinitis

These patients with perennial rhinitis have no demonstrable allergy or eosinophilia in nasal secretions. Watery secretions and nasal congestion are triggered by, for example, cold air, smoke, perfume, possibly because of an imbalance of the autonomic nervous system innervating the erectile tissue (sinusoids) in the nasal mucosa.

Nasal polyps

These are round, smooth, soft, semi-translucent, pale or yellow, glistening structures attached to the sinus mucosa by a relatively narrow stalk or pedicle, occurring in patients with both allergic and vasomotor rhinitis. They contain mast cells, eosinophils and mononuclear cells in large numbers and cause nasal obstruction, loss of smell and taste, and mouth breathing, but rarely sneezing, since the mucosa of the polyp is largely denervated. The mechanism(s) of their formation is not known.

Pathogenesis

Sneezing, increased secretion and changes in mucosal blood flow are mediated both by efferent nerve fibres and by released mediators (see p. 916). Mucus production results largely from parasympathetic stimulation, whilst blood vessels are under both sympathetic and parasympathetic control. Sympathetic fibres maintain tonic contraction of blood vessels, keeping the sinusoids of the nose partially constricted with good nasal patency. Stimulation of the parasympathetic system dilates these blood vessels. This stimulation varies spontaneously in a cyclical fashion so that air intake alternates slowly over several hours from one nostril to the other. The erectile cavernous nasal sinusoids can be influenced by emotion, which, in turn, can affect nasal patency.

Allergic rhinitis develops as a result of interaction between the inhaled allergen and adjacent molecules of IgE antibody present on the surface of mast cells found in increased numbers in nasal secretions and within the nasal epithelium. Release of preformed mediators, in particular histamine, causes an increase in permeability of the epithelium, allowing allergen to reach IgE-primed mast cells in the lamina propria. Sneezing, largely caused by histamine, results from stimulation of afferent nerve endings and begins within minutes of the allergen entering the nose. This is followed by nasal exudation and secretion and eventually nasal blockage at a maxi-

mum of 15-20 minutes after contact with the allergen. The cysteinyl leukotrienes and vasodilator prostaglandins (PGD_2, PGE_2 and PGI_2) released from mast cells, eosinophils and macrophages are especially potent in causing nasal blockage.

Although the mast cell contains or can generate many other potent vasomotor and chemotactic factors (see Fig. 14.34), the exact role for each of these is unclear. It is likely that histamine plays a more significant role in the development of allergic rhinitis than of asthma, since the antihistamines are effective treatment for allergic rhinitis but are of little value in the everyday management of asthma. The increase in nasal response observed as the pollen season progresses is in part explained by a progressive increase in mast cells colonizing the mucosa. The mechanisms for recruitment of mast cells under these circumstances probably involve the release of stem cell factor (c-kit) and interleukin-3 from epithelial cells and interleukins -3, -4 and -9 from T cells.

Investigations and diagnosis

The allergic factors causing rhinitis are usually obtained from the history.

Skin-prick testing indicates that the mechanisms leading to allergic rhinitis (or asthma) are present in human skin. A positive test does not necessarily mean that the particular allergen producing the weal causes the respiratory disease. However, if there is a positive clinical history for that allergen, a causative role is likely. Specific serum IgE antibody against the particular allergen (RAST test) provides the same information as the skin-prick test. Blood tests are much more expensive and should be reserved for use in patients who cannot be skin tested for some reason (e.g. dermatographism, active eczema or using antihistamines and unable to stop for 3 days before skin tests).

Treatment Allergen avoidance

Removal of a household pet or total enclosure of industrial processes releasing sensitizing agents can lead to cure of rhinitis and, indeed, asthma.

Pollen avoidance is impossible. Contact may be diminished by wearing sunglasses, driving with the car windows shut, avoiding walks in the countryside (particularly in the late afternoon when the number of pollen grains is highest at ground level), and keeping the bedroom window shut at night. These measures are rarely sufficient in themselves to control symptoms. Exposure to pollen is generally lower at the seaside, where sea breezes keep pollen grains inland.

The house-dust mite infests most areas of the house, but particularly the bedroom. Mite counts are extremely low in hospitals where carpets are absent, floors are cleaned frequently and mattresses and pillows are covered in plastic sheeting that can be wiped down. Mite allergen exposure can be reduced by enclosing bedding in fabric specifically designed to prevent the passage of mite allergen, while allowing water vapour through. This is both comfortable and reduces symptoms. Acaricides are less effective and cannot be recommended. Increased room ventilation and reduced soft furnishings including carpets, curtains and soft toys are all helpful in reducing the mite load.

Antihistamines

Antihistamines remain the most common therapy for rhinitis, and many can be purchased directly over the counter in the UK. They are particularly effective against sneezing, but are less effective against rhinorrhoea and have little influence on nasal blockage. The first-generation antihistamines cause sedation. Second-generation drugs such as cetirizine (10 mg once daily), loratadine (10 mg once daily), desloratadine (5 mg daily) and fexofenadine (120 mg daily) are highly specific for H_1 receptors; they do not cross the blood-brain barrier and are therefore not associated with sedation. Fatal cardiac arrhythmias (torsades de pointes) have been described with terfenadine and astemizole and these drugs should be replaced with those that do not influence the ECG QT interval. Antihistamines also control itching in the eyes and palate.

Decongestants

Drugs with sympathomimetic activity (a-adrenergic agents) are widely used for the treatment of nasal obstruction. They may be taken orally or more commonly as nasal drops or sprays (e.g. ephedrine nasal drops). Xylometazoline and oxymetazoline are widely used because they have a prolonged action and tachyphylaxis does not develop. Secondary nasal hyperaemia can occur some hours later as a rebound effect and rhinitis medicamentosa can develop if patients go on taking increasing quantities of the local decongestant to overcome this phenomenon. Although local decongestants are an effective treatment for vasomotor rhinitis, patients must be warned about rebound nasal obstruction and must use the drug carefully. Usually, such preparations should be prescribed for only a limited period to open the nasal airways for administration of other therapy, particularly topical corticosteroids.

Anti-inflammatory drugs

Sodium cromoglicate and nedocromil sodium influence a number of aspects of inflammation, including mast cell and eosinophil activation and nerve function. They act by blocking an intracellular chloride channel and preventing cell activation. Sodium cromoglicate applied topically in spray or powder form is of limited value in the treatment of allergic rhinitis, though along with nedocromil sodium, it is very effective in the management of allergic conjunctivitis.

Corticosteroids

The most effective treatment for rhinitis is to use small doses of topically administered corticosteroid preparations (e.g. beclometasone spray twice daily or fluticasone propionate spray once daily). The amount used is insufficient to cause systemic effects and the effect is primarily anti-inflammatory. Preparations should be started prior to the beginning of seasonal symptoms. The

combination of a topical corticosteroid with a non-sedative antihistamine taken regularly is particularly effective. Special attention needs to be given to teaching patients how to use the aqueous dispensers or metered-dose inhalers to produce optimal drug deposition. It may be necessary to use an a-adrenergic agonist to decongest the nose prior to taking the topical corticosteroid.

If other therapy has failed, seasonal and perennial rhinitis respond readily to a short course (2 weeks) of treatment with oral prednisolone 5-10 mg daily. Nasal polyps respond well to such oral doses of corticosteroids and their recurrence may be prevented by continuous application of topical corticosteroids.

Pharyngitis

The most common viruses causing pharyngitis belong to the adenovirus group, which consists of about 32 serotypes. Endemic adenovirus infection causes the common sore throat, in which the oropharynx and soft palate are reddened and the tonsils are inflamed and swollen. Within 1-2 days the tonsillar lymph nodes enlarge. Occasionally, localized epidemics occur, particularly in schools in the summer-time, with episodes of fever, conjunctivitis, pharyngitis and lymphadenitis of the neck glands; these are due to adenovirus serotype 8. These diseases are self-limiting, and symptomatic treatment is all that is required.

In the past about one-third of sore throats were due to bacterial infections, e.g. haemolytic streptococcus, but this proportion appears to be falling. Persistent and severe tonsillitis requires antibiotic therapy. Phenoxymethylpenicillin (500 mg four times a day) or cefaclor (250 mg three times daily) can be used. Avoid amoxicillin and ampicillin if there is a possibility of infectious mononucleosis (p. 47).

Acute laryngotracheobronchitis

Acute laryngitis is an occasional but striking complication of upper respiratory tract infections, particularly those caused by viruses of the parainfluenza group and the measles virus. Inflammatory oedema extends to the vocal cords and the epiglottis, causing considerable narrowing of the airway; in addition, there may be associated tracheitis or tracheobronchitis. Children under the age of 3 years are most severely affected. The voice becomes hoarse, the cough assumes a barking quality (croup) and there is audible laryngeal stridor. Progressive airways obstruction may occur, with recession of the soft tissue of the neck and abdomen during inspiration, and in severe cases central cyanosis may occur. Inhalation of steam may be helpful; in severe cases endotracheal intubation may be necessary. Oxygen and adequate fluids should be given. Rarely, a tracheostomy may be required.

Acute epiglottitis

H. influenzae type b (Hib) can cause life-threatening infection of the epiglottis, a condition that is rare over the age of 5 years. The young child becomes extremely ill with a high fever, and severe airflow obstruction may rapidly occur. This is a life-threatening emergency and requires urgent endotracheal intubation and intravenous ceftazidime (25-150 mg/kg in children). Chloramphenicol (50-100 mg/kg in children) can also be used. The epiglottis, which is red and swollen, should not be inspected until facilities to maintain the airways are available.

Other manifestations of Hib infection are meningitis, septic arthritis and osteomyelitis. Immunization is achieved with a purified polyribosylribitol phosphate from the capsule of Hib linked to a non-toxic diphtheria toxin PRP-T to increase immunogenicity. It is highly effective when given to infants at 2, 3 and 4 months with primary immunization against diphtheria, tetanus and pertussis (DTP), reducing death rates from Hib infections virtually to zero.

After the advent of the Hib immunization there was an 88% reduction in notification in England and Wales but more recently the rate of infection has increased, for reasons that remain unclear.

Influenza (see also p. 55)

The influenza virus belongs to the orthomyxovirus group and exists in two main forms, A and B. Influenza B is associated with localized outbreaks of milder nature, whereas influenza A is the cause of world-wide pandemics. Influenza A has a capacity to develop new antigenic variants at irregular intervals. Human immunity develops against the haemagglutinin (H) antigen and the neuraminidase (N) antigen on the viral surface. Major shifts in the antigenic make-up of influenza A viruses provide the necessary conditions for major pandemics, whereas minor antigenic drifts give rise to less severe epidemics because immunity in the population is less blunted.

The most serious pandemic of influenza occurred in 1918, and was associated with more than 20 million deaths world-wide. In 1957, a major shift in the antigenic make-up of the virus led to the appearance of influenza A2 type H2N2, which caused a world-wide pandemic. A further pandemic occurred in 1968 owing to the emergence of Hong Kong influenza type H3N2, and minor antigenic drifts have caused outbreaks around the world ever since. In 1997, avian H5N1 strain of influenza A was found in humans and represented a major change in viral surface antigens. In South East Asia it has recently been transmited from poultry to man (avian influenza).

Clinical features

The incubation period of influenza is usually 1-3 days. The illness starts abruptly with a fever, shivering and generalized aching in the limbs. This is associated with severe headache, soreness of the throat and a persistent dry cough that can last for several weeks. Influenza viruses can cause a prolonged period of debility and depression that may take weeks or months to clear; this is known as the postviral syndrome.

Complications

Secondary bacterial infection, particularly with *Strep, pneumoniae* and *H. influenzae,* is common following influenza virus infection. Rarer, but more serious, is the development of pneumonia caused by *Staph. aureus,* which has a mortality of up to 20%. Postinfectious encephalomyelitis rarely occurs after infection with influenza virus.

Diagnosis and treatment

Laboratory diagnosis is not usually necessary, but a definitive diagnosis can be established by demonstrating a fourfold increase in the complement-fixing antibody or the haemagglutinin antibody when measured before and after an interval of 1-2 weeks or demonstration of the virus in throat or nasal secretion.

Treatment is by bed rest and paracetamol, together with antibiotics for individuals who have chronic bronchitis, heart or renal disease.

The recent introduction of neuraminidase inhibitors may prove helpful in shortening the duration of symptoms **in** patients with influenza. The cost-benefit of zanamivir and oseltamivir remains unproven but these are currently recommended in the UK for patients with suspected influenza over the age of 65 and 'at-risk' adults, as part of a strategy to reduce admissions to hospital when influenza is circulating in the community.

Prophylaxis

Protection by influenza vaccines is only effective in up to 70% of people and is of short duration, usually lasting for only a year. Influenza vaccine should not be given to individuals who are allergic to egg protein as some are manufactured in chick embryos. New vaccines have to be prepared to cover each change in viral antigenicity and are therefore in limited supply at the start of an epidemic. Nevertheless, routine vaccination is recommended for all individuals over 65 years of age and also for younger people with chronic heart disease, chronic lung disease (including asthma), chronic renal failure, diabetes mellitus and those who are immunosuppressed. During pandemics key hospital and health service personnel should also be vaccinated.

Inhalation of foreign bodies
