Children inhale foreign bodies, e.g. peanuts, more commonly than do adults. In the adult, inhalation often occurs after an excess of alcohol or under general anaesthesia (loose teeth or dentures).

When the foreign body is large it may impact in the trachea. The person chokes and then becomes silent; death occurs unless the material is quickly removed (see Emergency box 14.1).

Impaction usually occurs in the right main bronchus and produces:

- choking
- persistent monophonic wheeze
- later, persistent suppurative pneumonia
- lung abscess (common).

Emergency Box 14.1
Treatment of inhaled foreign bodies (Heimlich manoeuvre)

Emergency
The Heimlich manoeuvre is used to expel the obstructing object:

1. Stand behind the patient.
2. Encircle your arms around the upper part of the abdomen just below the patient's rib cage.
3. Give a sharp, forceful squeeze, forcing the diaphragm sharply into the thorax. This should expel sufficient air from the lungs to force the foreign body out of the trachea.

Non-emergency
Rigid bronchoscopy should be performed.

DISEASES OF THE LOWER RESPIRATORY TRACT

Lower respiratory tract infection accounts for approximately 10% of the world-wide burden of morbidity and mortality. Seventy-five per cent of all antibiotic usage is for these diseases, despite the fact that they are mainly due to viruses.

Acute bronchitis

Acute bronchitis in previously healthy subjects is often viral. Bacterial infection with organisms such as *Strep, pneumoniae* and *H. influenzae* is a common sequel to viral infections, and is more likely to occur in individuals who are cigarette smokers and in those with chronic obstructive pulmonary disease (COPD).

The illness begins with an irritating, unproductive cough, together with discomfort behind the sternum. This may be associated with tightness in the chest, wheezing and shortness of breath. The cough becomes productive, the sputum being yellow or green. There is a mild fever and a neutrophil leucocytosis; wheeze with occasional crackles can be heard on auscultation. In otherwise healthy adults the disease improves spontaneously in 4-8 days without the patient becoming seriously ill.

Treatment with antibiotics is usually given (e.g. amoxidllin 250 mg three times daily), though it is not known whether this hastens recovery in otherwise healthy individuals.

Chronic obstructive pulmonary disease (COPD)

The global Initiative in Obstructive Lung Disease **(GOLD)** predicts that COPD will become the third most common cause of death and fifth most common cause of disability world-wide by 2020.

The term 'chronic obstructive pulmonary disease' (COPD) was introduced to bring together a variety of clinical syndromes associated with destruction of the lung and airflow obstruction. The terms 'chronic obstructive airways disease' (COAD) and 'chronic obstructive lung disease' (COLD) are used as synonyms in different parts of the world. Prior to 1979, patients with these conditions were often classified by symptoms (chronic bronchitis, chronic asthma), by pathological changes (emphysema) or by physiological correlates (pink puffers, blue bloaters). It was the recognition that these entities overlapped and often coexisted which led to the need for the new term COPD.

Definition **of** COPD

'COPD is a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases' (GOLD).

Epidemiology and aetiology

COPD is caused by long-term exposure to toxic particles and gases. In developed countries, cigarette smoking accounts for over 90% of cases. In developing countries cigarette smoking, as well as the inhalation of smoke from biomass fuels used in heating and cooking in poorly ventilated areas, are causal factors. However, only 10-20% of heavy smokers develop COPD, indicating individual susceptibility. The development of COPD is also related to the number of cigarettes smoked per day; the risk of death from COPD in patients smoking 30 cigarettes daily is 20 times that of a non-smoker. The bronchitis mortality amongst male doctors in relation to the number of cigarettes smoked is shown in Figure 14.20. Autopsy studies have also shown that substantial numbers of centri-acinar emphysematous spaces are found in the lungs of 50% of British smokers over the age of 60 years and are unrelated to the diagnosis of significant respiratory disease before death.

Climate and air pollution are of less importance, but there is a great increase in mortality from COPD during periods of heavy atmospheric pollution (p. 894). The effect of urbanization, social class and occupation may also play a part in aetiology, but these effects are difficult to separate from that of smoking. Some animal studies suggest that diet could be a risk factor for COPD; but this has not been proven in humans.

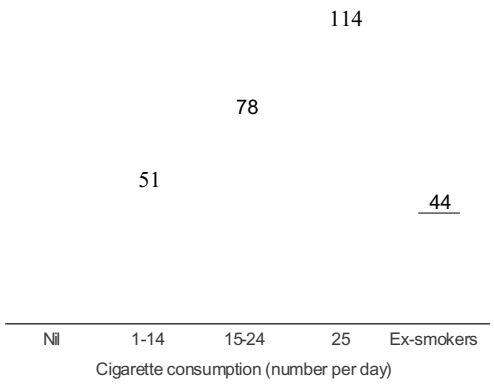

Fig. 14.20 **Bronchitis death rates per 100 000 British male doctors according to their smoking habits.** From Doll R, Peto R (1976) *British Medical Journal* 2: 1525.

The socio-economic burden of COPD is considerable. In the UK, COPD causes approximately 18 million lost working days for men and 2.1 million lost working days for women per year, accounting for some 7% of all days of absence from work due to sickness. Nevertheless, the number of patients discharged from hospitals in the UK with this diagnosis has been falling steadily; the death rate has also fallen in the last 25 years from 200 to 70 per 100 000.

Pathophysiology

The most consistent pathological finding is hypertrophy and increase in number of the mucus-secreting goblet cells of the bronchial tree, evenly distributed throughout the lung but mainly seen in the larger bronchi (Fig. 14.21). In more advanced cases, the bronchi themselves are obviously inflamed and pus is seen in the lumen. Microscopically there is infiltration of the walls of the bronchi

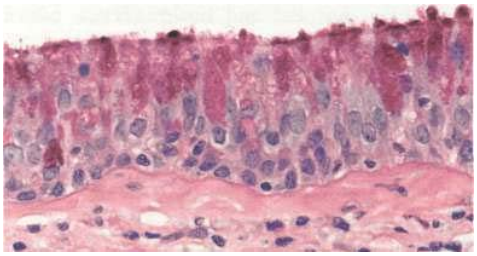

Fig. 14.21 **COPD.** Section of bronchial mucosa stained for mucus glands by PAS showing increase in mucus-secreting goblet cells (courtesy of Dr J Wilson and Dr S Wilson, University of Southampton).

and bronchioles with acute and chronic inflammatory cells and lymphoid follicles in severe disease. In contrast to asthma, the lymphocytic infiltrate is predominantly $CD8^+$. The epithelial layer may become ulcerated and, when the ulcers heal, squamous epithelium may replace the columnar cells. The inflammation is followed by scarring and a remodelling process that thickens the walls and leads to widespread narrowing in the small airways (Fig. 14.22).

The small airways are particularly affected early in the disease, initially without the development of any significant breathlessness. This initial inflammation of the small airways is reversible and accounts for the improvement in airway function if smoking is stopped early. In later stages the inflammation continues, even if smoking is stopped.

Further progression of the disease leads to progressive squamous cell metaplasia, and fibrosis of the bronchial walls. The physiological consequence of these changes is the development of airflow limitation. If the airway narrowing is combined with emphysema (causing loss of the elastic recoil of the lung with collapse of small airways during aspiration) the resulting airflow limitation is even more severe.

Emphysema is defined pathologically as dilatation and destruction of the lung tissue distal to the terminal bronchiole. It is classified according to the site of damage:

- *Centri-acinar emphysema*. Distension and damage of lung tissue is concentrated around the respiratory bronchioles, whilst the more distal alveolar ducts and alveoli tend to be well preserved. This form of emphysema is extremely common; when of modest extent, it is not necessarily associated with disability. Severe centri-acinar emphysema is associated with substantial airflow limitation.
- *Pan-acinar emphysema*. This is less common. Distension and destruction appear to involve the whole of the acinus, and in the extreme form the lung becomes a mass of bullae. Severe airflow limitation and V_A/Q mismatch occur. This type of emphysema occurs in Opantitrypsin deficiency (see p. 902).
- *Irregular emphysema*. There is scarring and damage affecting the lung parenchyma patchily without particular regard for acinar structure.

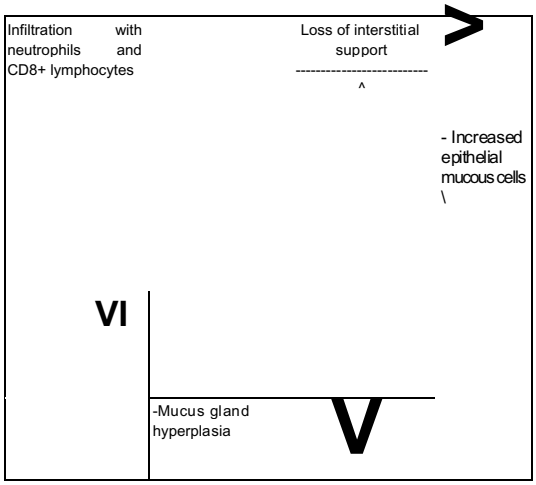

Fig. 14.22 Pathological changes in the airways in chronic bronchitis and emphysema.

Emphysema leads to expiratory airflow limitation and air trapping. The loss of lung elastic recoil results in an increase in TLC while the loss of alveoli with emphysema results in decreased gas transfer.

V_A/Q mismatch occurs partly because of damage and mucus plugging of smaller airways from chronic inflammation, and partly because of the rapid expiratory closure of the smaller airways owing to loss of elastic recoil from emphysema. This leads to a fall in P_aO_2 and an increase in the work of respiration.

CO_2 excretion is not impaired to the same extent and indeed many patients will show low normal P_aCO_2 values. These patients are the 'pink puffers' who seek to maintain normal blood gases by increasing their respiratory effort. Other patients fail to maintain their respiratory effort and as a consequence their carbon dioxide levels increase. In the short term, the rise in CO_2 leads to stimulation of respiration but in the long term, these patients often become insensitive to CO_2 and come to depend on hypoxaemia to drive their ventilation. These patients appear less breathless and because they run low P_aO_2 values, they start to retain fluid and stimulate the production of erythrocytes (polycythaemia). In consequence they become bloated, plethoric and cyanosed, the typical appearance of the 'blue bloater'. Attempts to abolish hypoxaemia by administering oxygen can make the situation much worse by decreasing respiratory drive in these patients who rely on hypoxia to drive their ventilation.

Carbon dioxide is normally the major stimulant of the respiratory centre. In the face of a prolonged high P_aCO_2 this sensitivity is diminished and hypoxaemia becomes the chief drive to respiration. In this situation an attempt to abolish hypoxaemia by administration of oxygen can result in an increase in P_aCO_2 by decreasing the respiratory drive, worsening respiratory failure.

The classic Fletcher and Peto studies (Fig. 14.23) show that there is a loss of 50 mL per year in FEVj in COPD compared to 20 mL per year in healthy people.

In summary, three mechanisms have been suggested for this limitation of airflow in small airways (< 2 mm in diameter).

- Loss of elasticity and alveolar attachments of airways due to emphysema. This reduces the elastic recoil and the airways collapse during expiration.
- Inflammation and scarring cause the small airways to narrow.
- Mucus secretion which blocks the airways.

These all cause narrowing of the small airways and trapping of air leading to hyperinflation of the lungs and breathlessness.

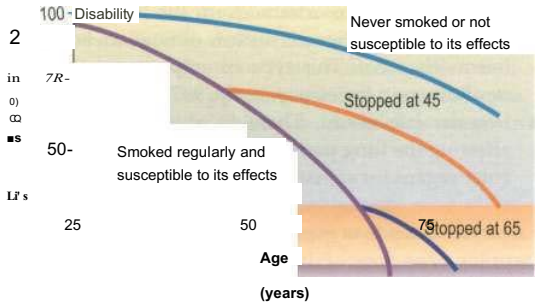

Fig. 14.23 Influence of smoking on airflow limitation. From Fletcher CM, Peto R (1977) *British Medical Journal* 1: 1645.

Pathogenesis

Cigarette smoking

Bronchoalveolar washes have shown that smokers have neutrophil granulocytes present within the lumen of the bronchial tree that are absent in non-smokers. Additionally, the small airways of smokers are infiltrated by granulocytes. These granulocytes are capable of releasing elastases and proteases, which possibly help to produce emphysema. It is suggested that an imbalance between protease and antiprotease activity may produce the damage. ttpAntitrypsin is a major serum antiprotease which can be inactivated by cigarette smoke (see below). The hypertrophy of mucous glands in the larger airways is thought to be a direct response to persistent irritation resulting from the inhalation of cigarette smoke. The smoke has an adverse effect on surfactant, favouring overdistension of the lungs.

Infections

Patients with COPD cope badly with respiratory infections, which are often the precipitating cause of acute exacerbations of the disease. However, the role of infection in the development of the progressive airflow limitation that characterizes disabling COPD is far less clear. Prompt use of antibiotics and routine influenza vaccinations are appropriate.

o^-Antitrypsin deficiency (see also p. 388) Oi-Antitrypsin inhibitor is an antiproteinase inhibitor produced in the liver, secreted into the blood and which diffuses into the lung. Here it functions as an antiprotease that inhibits neutrophil elastase, a proteolytic enzyme capable of destroying alveolar wall connective tissue.

More than 75 alleles of the Oj-antitrypsin inhibitor gene have been described. The three main phenotypes are MM (normal), MZ (heterozygous deficiency) and ZZ (homozygous deficiency). About 1 child in 5000 in Britain is born with the homozygous deficiency, but not all develop chest disease. Those who do develop breathlessness under the age of 40 years have radiographic evidence of basal emphysema and are usually, but not always, cigarette smokers. Hereditary deficiency of rx,-antitrypsin inhibitor accounts for about 2% of emphysema cases. A small minority develop liver disease (see p. 388).

Clinical features

Symptoms

The characteristic symptoms of COPD are cough with the production of sputum, wheeze and breathlessness following many years of a smoker's cough. Colds seem to 'go down to the chest' and frequent infective exacerbations occur, giving purulent sputum. Symptoms can be worsened by factors such as cold, foggy weather and atmospheric pollution. With advanced disease, breathlessness becomes severe even after mild exercise such as dressing.

Signs

In mild disease there are no signs apart from 'wheeze' throughout the chest. In severe disease, the patient is tachypnoeic, with prolonged expiration. The accessory muscles of respiration are used and there may be intercostal indrawing on inspiration and pursing of the lips on expiration (see p. 878). Chest expansion is poor, the lungs are hyperinflated, and there is loss of the normal cardiac and liver dullness.

Patients who remain responsive to CO_2 are usually breathless and rarely cyanosed. Heart failure and oedema are rare features except as terminal events. Patients who become insensitive to CO_2 are often oedematous and cyanosed but not particularly breathless. Those with hypercapnia may have peripheral vasodilatation, a bounding pulse, and when the P_aco_2 is above about 10 kPa, a coarse flapping tremor of the outstretched hands. Severe hypercapnia will lead to confusion and progressive drowsiness. At this stage papilloedema may be present but is neither specific nor sensitive as a diagnostic feature.

Complications

Respiratory failure

The later stages of COPD are characterized by the development of respiratory failure. For practical purposes this is said to occur when there is either a P_ao_2 of less than 8 kPa (60 mmHg) or a P_aco_2 of more than 7 kPa (55 mmHg) (see Ch. 15).

The persistence of chronic alveolar hypoxia and hypercapnia leads to constriction of the pulmonary arterioles and subsequent pulmonary arterial hypertension. Cardiac output is normal or increased but salt and fluid retention occurs as a result of renal hypoxia.

Cor pulmonale

Patients with advanced COPD may develop cor pulmonale (see p. 843), which is defined as heart disease secondary to disease of the lung. It is characterized by pulmonary hypertension, right ventricular hypertrophy, and eventually right heart failure. On examination, the patient is centrally cyanosed (owing to the lung disease) and, when heart failure develops, the patient becomes more breathless and ankle oedema occurs. Initially a prominent parasternal heave may be felt that is due to

Table 14.9 **COPD - Global Initiative in Obstructive Lung Disease (GOLD) criteria**

Stage of COPD	FEV, (%)	Symptoms
0 At risk	>80	None
I Mild	>80	± Variable
II Moderate	50-79	+ Mild to moderate
III Severe	30-49	++ Limit exertion
IV Very severe	<30	+++ Limit daily activities

After Fabbri LM, Hurd SS (2003 update) Global strategy for the diagnosis, management and prevention of COPD. *European Respiratory Journal* 22 !: 1-2

right ventricular hypertrophy and a loud pulmonary second sound may be heard. In very severe pulmonary hypertension there is incompetence of the pulmonary valve. With right heart failure, tricuspid incompetence may develop with a greatly elevated jugular venous pressure (JVP), ascites and upper abdominal discomfort owing to swelling of the liver.

Diagnosis

This is usually clinical (GOLD criteria, Table 14.9). There is **a** history of breathlessness and sputum production in a lifetime smoker. In the absence of a history of cigarette smoking a working diagnosis of asthma is usual unless there is a family history of lung disease suggestive of a deficiency of (Xj-antitrypsm inhibitor.

The patient may have signs of hyperinflation and typical pursed lip respiration. No individual clinical feature is diagnostic. Emphysema is often incorrectly diagnosed on signs of overinflation of the lungs (e.g. loss of liver dullness on percussion), but this may occur with other diseases such as asthma. Furthermore, centri-acinar emphysema may be present without signs of over-inflation. Some elderly men (without emphysema) develop a barrel-shaped chest as a result of osteoporosis of the spine, and a consequent decrease in height.

Investigations

- **Lung function tests** show evidence of airflow limitation (see Figs 14.8 and 14.15). The ratio of the FEVj to the FVC is reduced and the PEFR is low. In many patients the airflow limitation is reversible to some extent (usually a change in $F\sim EV_1$ of < 15%), and the distinction between asthma and COPD can be difficult. Lung volumes may be normal or increased, and the gas transfer coefficient of carbon monoxide is low when significant emphysema is present.
- **Chest X-ray** is often normal, even when the disease is advanced. The classic features are the presence of bullae, severe overinflation of the lungs with low, flattened diaphragms, and a large retrosternal air space on the lateral film. There may also be a deficiency of blood vessels in the periphery of the lung fields compared with relatively easily visible proximal vessels.
- **Haemoglobin level and PCV** can be elevated as a result of persistent hypoxaemia (secondary polycythaemia, see p. 454).
- **Blood gases** are often normal. In the advanced case there is evidence of hypoxaemia and hypercapnia.
- **Sputum examination** is unnecessary in the ordinary case as *Strep, pneumoniae* or *H. influenzae* are the only common organisms to produce acute exacerbations. Occasionally *Moraxella catarrhalis* may cause infective exacerbations.
- **Electrocardiogram.** In advanced cor pulmonale the P wave is taller (P pulmonale) and there may be right bundle branch block (RSR' complex) and the changes of right ventricular hypertrophy (see p. 845).
- **Echocardiogram** - performed to assess cardiac function.
- **04-Antitrypsin levels.** The normal range is 2-4 g/L.

Management (Fig. 14.24)

Smoking cessation

Persuading the patient to stop smoking is vital. Even at a late stage of the disease this may slow down the rate of deterioration and prolong the time before disability and death occur (see Fig. 14.23).

Drug therapy

This is used both for the short-term management of exacerbations and for the long-term relief of symptoms. In many cases the drugs used are similar to those used in asthma (see p. 919).

Bronchodilators

Many patients feel less breathless following the inhalation of a (3-adrenergic agonist such as salbutamol (200 ug every 4—6 hours). More prolonged and greater bronchodilatation is achieved with antimuscarinic agents: tiotropium (18 ug daily), ipratropium (40 ug four times daily) or oxitropium (200 ug twice daily). Patients find inhalers difficult to use and spacer devices improve delivery. Objective evidence of improvement in the peak flow or FEV! may be small and decisions to continue or stop therapy should be based on the patient's reported symptoms. Long-acting preparations of theophylline are of little benefit.

Corticosteroids

In symptomatic patients with COPD, a trial of corticosteroids is always indicated, since a proportion of patients have a large, unsuspected, reversible element to their disease and airway function may improve considerably. Prednisolone 30 mg daily should be given for 2 weeks, with measurements of lung function before and after the treatment period. If there is objective evidence of a substantial degree of improvement in airflow limitation (FEV! increase > 15%), prednisolone should be discontinued and replaced by inhaled corticosteroids (beclometasone 400 ug twice daily in the first instance, adjusted according to response). The long-term value of regular inhaled corticosteroids in all patients with COPD has not been proven.

Antibiotics

Prompt antibiotic treatment shortens exacerbations and should always be given in acute episodes as it may

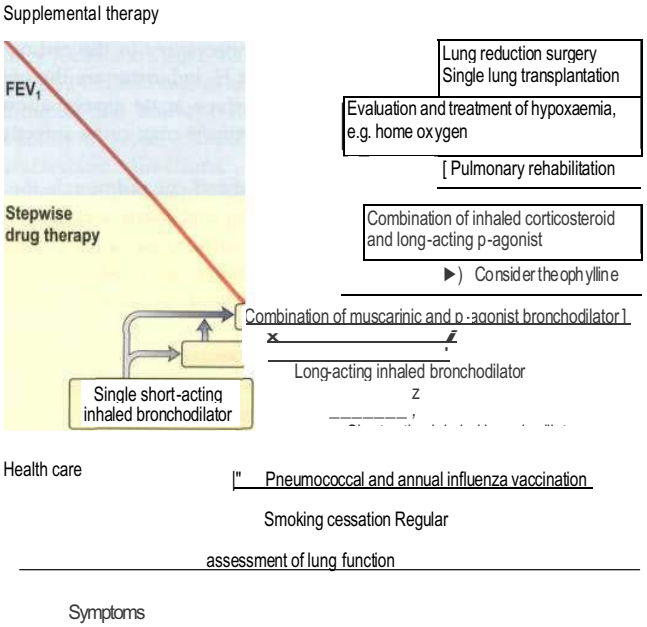

Fig. 14.24 **Algorithm for the treatment of COPD.** The various components of management are shown as the *FE\Z,* decreases and the symptoms become more severe. After Sutherland ER, Cherniack RM (2004) Management of chronic obstructive pulmonary disease. *New England Journal of Medicine* **350:** 2689-2697. Copyright © 2004 Massachusetts Medical Society. All rights reserved.

prevent hospital admission and further lung damage. Patients can be given a supply of antibiotics to keep at home to start as soon as their sputum turns yellow or green. Although amoxicillin-resistant *H. influenzae* is increasing (occurring in 10-20% of isolates from sputum) it is not a serious clinical problem. Resistance to cefaclor 500 mg 8-hourly or cefixime 400 mg once daily is significantly less frequent; co-amoxiclav is a useful alternative.

Long-term treatment with antibiotics remains controversial. They were once thought to be of no value, but eradication of infection and keeping the lower respiratory tract free of bacteria may help to prevent deterioration in lung function.

Diuretic therapy (see p. 697)

This is necessary for all oedematous patients. Daily weights should be recorded during acute inpatient episodes.

a,Antitrypsin replacement

Weekly or monthly infusions of ocj-antitrypsin have been recommended for patients with serum levels of this compound below 310 mg/L and abnormal lung function. Whether this modifies the long-term progression of the disease has still to be determined.

Vaccines

Patients with COPD should receive yearly influenza vaccine. These patients should also receive one dose of the polyvalent pneumococcal polysaccharide vaccine (a single dose usually provides lifelong immunity).

Other measures

- *Heart failure* should be treated (p. 790).
- *Secondary polycythaemia* - venesection is recommended if the PCV is >55%.
- *Air travel*. Commercial cabin pressures are equivalent to an altitude of 2750 m. At this level the P_aO_2 will fall from 13.5 to 10 kPa with a fall of 3% in oxygen saturation. This has no effect on healthy travellers but in patients with moderate COPD, a fall in P_aO_2 to below 6.5 kPa can occur and oxygen is necessary. Intended travellers with moderate or severe COPD (Table 14.9) should get medical advice and contact the airline.

Treatment of respiratory failure

There are many causes of respiratory failure (Fig. 14.25) but COPD is by far the most common. The primary aim of the management of respiratory failure is to improve the Pa°2 by continuous oxygen therapy. In type I respiratory failure (low P_aO_2, normal P_aco_2) it is safe to administer as much oxygen as is required to return the P_aO_2 to normal. In type II respiratory failure the P_aco_2 is elevated and giving additional oxygen will nearly always lead to a rise in the P_aco_2 (see p. 981). Small increases in P_aCO_2 can be tolerated but not if the pH falls dramatically. The pH should not be allowed to fall below 7.25; under such circumstances, increased ventilation must be achieved either by the use of a respiratory stimulant or by artificial ventilation.

Figure 14.26 shows a fixed-performance mask (Venturi mask) for the administration of oxygen. This style of mask is used to deliver low concentrations of oxygen. It should be compared with the variable-performance face mask (see Fig. 15.22).

Initially, 24% oxygen is given, which is only slightly greater than the concentration of oxygen in air. However, because of the shape of the oxygen-haemoglobin dis-

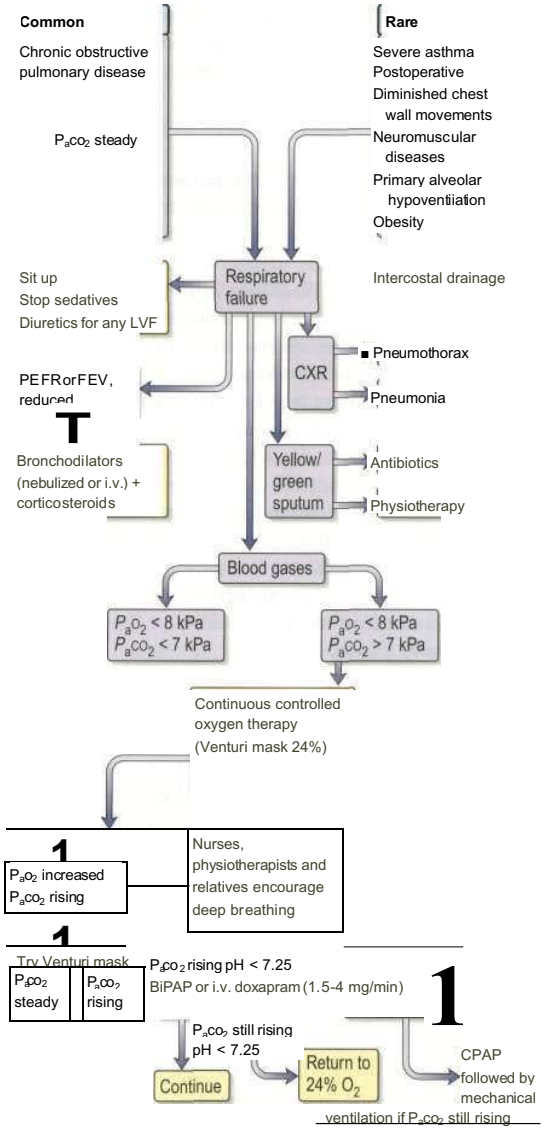

Fig. 14.25 **Algorithm for the treatment of respiratory failure.** LVF, left ventricular failure; CPAP, continuous positive airway pressure; BiPAR bilevel positive airway pressure.

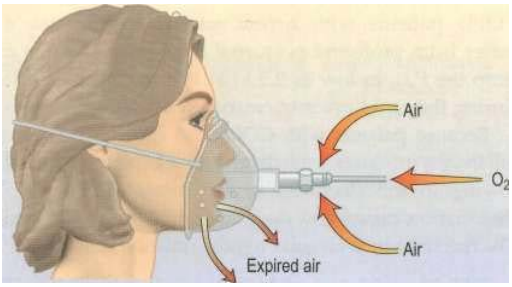

Fig. 14.26 **'Fixed-performance' device for administration of oxygen to spontaneously breathing patients (Venturi mask).** Oxygen is delivered through the injector of the Venturi mask at a given flow rate. A fixed amount of air is entrapped and the inspired oxygen can be predicted accurately. Masks are available to deliver 24%, 28% and 35% oxygen.

sociation curve (see Fig. 15.5), this small increase in oxygen is valuable. The concentration of inspired oxygen can be gradually increased if the P_aCO_2 does not rise unacceptably.

Additional measures

- *Removal of retained secretions.* The patient should be encouraged to cough to remove secretions. Physiotherapy is helpful. If this fails, bronchoscopy and/or aspiration via an endotracheal rube may be necessary. A tracheostomy is only rarely required.
- *Respiratory support* (see p. 981). Non-invasive ventilatory techniques can be very helpful in avoiding the need for endotracheal intubation. The best current technique uses tight-fitting facial masks to deliver bilevel positive airway pressure ventilatory support (BiPAP). Assisted ventilation with an endotracheal tube is occasionally used for patients with COPD with severe respiratory failure when there is a definite precipitating factor and the overall prognosis is reasonable. Assessing the relative reversibility in an acute setting can present a difficult ethical problem.
- *Respiratory stimulants.* The use of respiratory stimulants has declined in recent years, largely because of the increasing availability of respiratory support services. Doxapram, 1.5-4.0 mg/min by slow i.v. infusion, may help in the short term to arouse the patient and to stimulate coughing, with clearance of some secretions.
- *Corticosteroids, antibiotics and bronchodilators* should be administered in the acute phase and then reassessed once the patient has recovered (see above).

Further management at home

Oxygen

Two controlled trials (chiefly in males) have indicated that life can be prolonged by the continuous administration of oxygen at 2 L/min via nasal prongs to achieve an oxygen saturation of greater than 90% for large proportions of the day and night. Survival curves from these two studies are shown in Figure 14.27.

Only 30% of those not receiving long-term oxygen therapy survived for more than 5 years. A fall in pulmonary artery pressure was achieved if oxygen was given for 15 hours daily, but substantial improvement in mortality was only achieved by the administration of oxygen for 19 hours daily. These results suggest that long-term continuous domiciliary oxygen therapy will benefit patients who have:

- A P_aO_2 of < 7.3 kPa (55 mmHg) when breathing air. Measurements should be taken on two occasions at least 3 weeks apart after appropriate bronchodilator therapy (Box 14.1).
- A P_aO_2 7.3-8 kPa with secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension.
- Carboxyhaemoglobin of less than 3% (i.e. patients who have stopped smoking).

The provision of 19 hours of oxygen daily at a flow rate of 1-3 L/min using a 28% oxygen mask is best achieved using an oxygen concentrator. To achieve this with

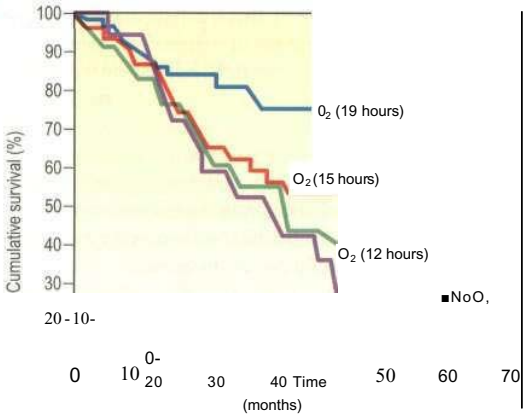

Fig. 14.27 **Cumulative survival curves for patients receiving oxygen.** Oxygen closes are in hours per day.

Sox *14.1* Guidelines for domiciliary oxygen (Royal College of Physicians, 1999)

Chronic obstructive pulmonary disease with P_aO_2 < 7.3 kPa when breathing air during a period of clinical stability.

Chronic obstructive pulmonary disease with P_aO_2 7.3-8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension.

Diffuse lung disease with P_aO_2 < 8 kPa and in patients with P_aO_2 > 8 kPa with disabling dyspnoea.

Cystic fibrosis when P_aO_2 < 7.3 kPa or if P_aO_2 7.3-8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, pulmonary hypertension or peripheral oedema.

Pulmonary hypertension without parenchymal lung involvement when P_aO_2 < 8 kPa.

Neuromuscular or skeletal disorders, after specialist assessment.

Obstructive sleep apnoea despite continuous positive airways pressure therapy, after specialist assessment.

Pulmonary malignancy or other terminal disease with disabling dyspnoea.

Heart failure with daytime P_aO_2 < 7.3 kPa (on air) or with nocturnal hypoxaemia.

oxygen cylinders would require 20 standard cylinders per week, which is unacceptably expensive. Oxygen concentrators are available through the UK National Health Service for patients who fulfil the above criteria.

Drugs

Pulmonary hypertension can be partially relieved by the use of oral (3-adrenergic stimulants such as salbutamol (4 mg three times daily), but whether this is useful in the long term is unknown.

The sensation of breathlessness can be reduced by the use of either promethazine 125 mg daily or dihydrocodeine 1 mg/kg by mouth. Reduced breathlessness and increased exercise tolerance also result from the combined administration of dihydrocodeine and oxygen delivered from a portable cylinder. Although opiates are the most effective treatment for intractable breathlessness they depress ventilation and carry risk of increasing respiratory failure.

Surgery

Some patients with large emphysematous bullae (which reduce lung capacity) can benefit from bullectomy, enabling adjacent areas of collapsed lung to re-expand and function again. In addition, carefully selected patients with severe COPD (FEV_1 < 1 L), have been offered *lung volume reduction surgery.* This surgery increases elastic recoil, which reduces the expiratory collapse of the airway and decreases expiratory airflow limitation. It also enables the diaphragm to work at a better advantage. Initial studies suggested that ventilation was improved and patients felt less breathless, but mortality was unchanged. A recent controlled trial in severe emphysema, however, showed an increased mortality and no improvement in patients' condition.

Single lung transplantation (see p. 911) is used for end-stage emphysema, with 3-year survival rates of 75%. The principal benefit is to improve quality of life but it does not statistically improve survival.

Pulmonary rehabilitation

A modest increase in exercise capacity with diminution in the sense of breathlessness and improved general well-being can result from exercise training. Regular training periods can be instituted at home; climbing stairs or walking fixed distances can be combined with regular clinic visits for encouragement. Breathing exercises are probably of less value. Quality of life can be improved by a multidisciplinary approach involving physiotherapy, exercise and education, although this does not alter life expectancy or the rate of decline in lung function.

Prognosis

In general, 50% of patients with severe breathlessness die within 5 years (Fig. 14.27), but even in the severe group, stopping smoking will improve the prognosis.

Nocturnal hypoxia

COPD patients with severe arterial hypoxaemia also suffer from profound nocturnal hypoxaemia which may drop the P_aO_2 as low as 2.5 kPa (19 mmHg), particularly during the rapid eye movement (REM) phase of sleep.

Because patients with COPD are already hypoxic, the fall in P_aO_2 produces a much larger fall in oxygen saturation (owing to the steepness of the oxygen - haemoglobin dissociation curve) and desaturation of up to 50% occurs. The mechanism is alveolar hypoventilation due to:

- inhibition of intercostal and accessory muscles in REM sleep
- shallow breathing in REM sleep, which reduces ventilation, particularly in severe COPD
- an increase in upper airway resistance because of a reduction in muscle tone.

These nocturnal hypoxaemic episodes are associated with a further rise in pulmonary arterial pressure owing to vasoconstriction, and the majority of deaths in patients with COPD occur during the night, possibly from cardiac arrhythmias. These patients additionally show severe secondary polycythaemia, partly as a result of the severe nocturnal hypoxaemia.

Each episode of desaturation is usually terminated by arousal from sleep, so that normal sleep is reduced and the patient suffers from daytime sleepiness.

Treatment

Patients with arterial hypoxaemia should not be given sleeping tablets, which will further depress respiratory drive. Treatment is with nocturnal administration of oxygen and ventilatory support.

Positive-pressure ventilation can be administered non-invasively through a tightly fitting nasal mask with bilevel positive airway pressure - inspiratory to provide inspiratory assistance and expiratory to prevent alveolar closure, each adjusted independently. Although these devices to maintain adequate ventilation during sleep and to allow respiratory muscles to rest at night are effective in chronic chest wall disease (e.g. kyphoscoliosis) or neuromuscular disease (e.g. previous poliomyelitis), they do not improve respiratory function, respiratory muscle strength, exercise tolerance or breathlessness in patients with COPD.

Obstructive sleep apnoea

This condition occurs most often in overweight middle-aged men and affects 1-2% of the population. It can occur in children, particularly those with enlarged tonsils. The major symptoms and their frequency are listed in Table 14.10. During sleep, activity of the respiratory muscles is reduced, especially during REM sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the airway at the back of the throat is sucked closed when breathing in during sleep. When awake this tendency is overcome by the action of opening muscles of the upper airway, the genioglossus and palatal muscles, which become hypotonic during sleep (Fig. 14.28). Partial narrowing results in snoring, occlusion in apnoea and critical narrowing in hypopnoeas. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts until the patient overcomes the resistance. The combination of the effort and the central hypoxic stimulation wakes the patient from sleep. These awakenings are so brief that the patient remains unaware of them but may be woken hundreds of times per night leading to sleep deprivation, especially a reduction in REM sleep,

Table 14.10 **Symptoms of obstructive sleep apnoea**

Loud snoring (95%)	Nocturnal choking (30%) Reduced libido (20%) Morning drunkenness (5%) Ankle swelling (5%)
Daytime sleepiness (90%)	
Unrefreshed sleep (40%)	
Restless sleep (40%)	
Morning headache (30%)	

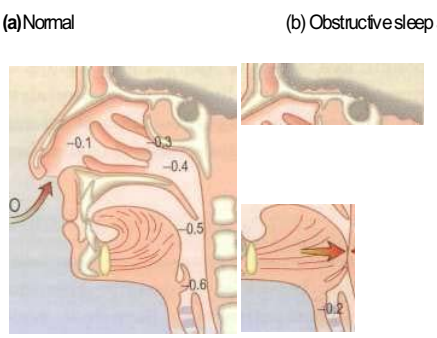

Fig. 14.28 **Section through head, showing pressure changes (in kPa) in (a) the normal situation and (b) obstructive sleep apnoea.** There is a pressure drop during inspiration as air is sucked through the turbinates. In patients with obstructive sleep apnoea this is sufficient to collapse the pharynx, obstructing inspiration.

with consequent daytime sleepiness and impaired intellectual performance. Contributory factors are obesity, a small pharyngeal opening and coexistent COPD.

Correctable factors occur in about one-third of cases and include:

- encroachment on pharynx - obesity, acromegaly, enlarged tonsils
- nasal obstruction - nasal deformities, rhinitis, polyps, adenoids
- respiratory depressant drugs - alcohol, sedatives, strong analgesics.

Diagnosis

In many cases this can be made on the combination of a good history of the snore-silence-snore cycle reported by the patient's relatives. The Epworth Sleepiness Scale (Table 20.5) helps discriminate apnoea from simple snoring. This can be supported by non-invasive ear or finger oximetry performed at home. Characteristically, arterial oxygen saturation will fall significantly in a cyclical manner. If the oximetry is negative or equivocal, inpatient assessment is indicated, preferably in a room specifically adapted for sleep studies rather than a normal ward side-room. Oximetry is supplemented by video recording. Full polysomnographic studies are rarely necessary for clinical diagnosis but are useful in research labs. These involve oximetry, direct measurements of thoracic and abdominal movement to assess breathing, and electroencephalography to record patterns of sleep and arousal. Some centres also measure oronasal airflow. The diagnosis of sleep apnoea/hypopnoea is confirmed if there are more than 15 apnoeas or hypopnoeas in any 1 hour of sleep. There is, however, overlap with central sleep apnoea (see p. 1227).

Management

Management consists of correction of treatable factors (see above) with, if necessary, nasal continuous positive

airway pressure (CPAP) delivered by a nasal mask during sleep. Such systems raise the pressure in the pharynx by about 1 kPa, keeping the walls apart. CPAP results in improvement of symptoms, quality of life, daytime alertness and survival. Up to 50%, however, cannot tolerate CPAP. Modafinil (a CNS stimulant) is useful in the short term.

Bronchiectasis

The term 'bronchiectasis' is used to describe abnormal and permanently dilated airways. Bronchial walls become inflamed, thickened and irreversibly damaged. The mucociliary transport mechanism is impaired and frequent bacterial infections ensue. Clinically, the disease is characterized by cough production of large amounts of sputum and dilated and thickened bronchi, detected on CT scanning of the thorax.

Aetiology

The causes are shown in Table 14.11. Cystic fibrosis is the most common cause in developed countries.

Clinical features

Patients with mild bronchiectasis only produce yellow or green sputum after an infection. Localized areas of the lung may be particularly affected, when sputum production will depend on position. As the condition worsens, the patient suffers from persistent halitosis, recurrent febrile episodes with malaise, and episodes of pneumonia. Clubbing occurs, and coarse crackles can be heard over the infected areas, usually the bases of the lungs. When the condition is severe there is continuous production of foul-smelling, thick, khaki-coloured sputum. Haemoptysis can occur either as blood-stained sputum or as a massive haemorrhage. Breathlessness may result from airflow limitation.

Table 14.11 **Causes of bronchiectasis**

	Young's syndrome - azoospermia, sinusitis

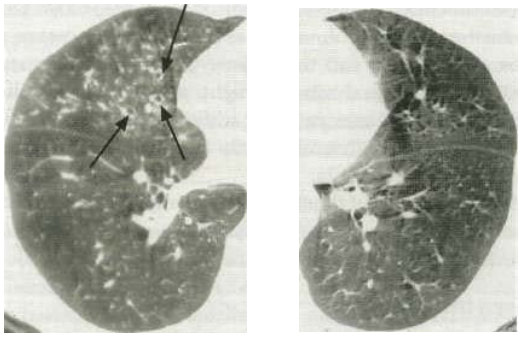

Fig. 14.29 **CT scan showing bronchiectasis in the right middle lobe.** Note dilated bronchi with thickened wall and adjacent artery giving a signet ring appearance.

Investigations

- **Chest X-ray** may be normal or may show dilated bronchi with thickened bronchial walls and sometimes multiple cysts containing fluid.
- **High-resolution CT scanning** (see p. 887) shows bronchial dilatation and wall thickening (Fig. 14.29) with a sensitivity of 97%.
- **Sputum** examination with culture and sensitivity of the organisms is essential for adequate treatment. The major pathogens are *Staph. aureus, Pseudomonas aeruginosa, H. influenzae* and anaerobes. Other pathogens include *Strep, pneumoniae* and *Klebsiella pneumoniae. Aspergillus fumigatus* can be isolated from 10% of sputum specimens in cystic fibrosis, but the role of this organism is uncertain.
- **Sinus X-rays.** Thirty per cent have concomitant purulent rhinosinusitis.
- **Serum immunoglobulins.** Ten per cent of adults have immune deficiency.
- **Sweat electrolytes** - if appropriate (see p. 910).
- **Mucociliary clearance** (nasal clearance of saccharin). A 1 mm cube of saccharin is placed on the inferior turbinate and the time to taste measured (normally less than 30 minutes).

Treatment

Postural drainage

Postural drainage is essential and patients must be trained by physiotherapists to tip themselves into a position in which the lobe to be drained is uppermost at least three times daily for 10-20 minutes. Most patients find that lying over the side of the bed with head and thorax down is the most effective position.

Antibiotics

Experience from the treatment of cystic fibrosis suggests that bronchopulmonary infections need to be eradicated

if progression of the disease is to be halted. In mild cases, intermittent chemotherapy with cefaclor 500 mg three times daily or ciprofloxacin 500 mg twice daily may be the only therapy needed. Flucloxacillin 500 mg 6-hourly is the best treatment if *Staph. aureus* is isolated.

If the sputum remains yellow or green despite regular physiotherapy and intermittent chemotherapy, or if lung function deteriorates despite treatment with bronchodilators, it is likely that there is infection with *P. aeruginosa*. Treatment requires parenteral or aerosol chemotherapy at regular 3-month intervals. Ceftazidime 2 g intravenously 8-hourly or by inhalation (1 g twice daily) has been shown to be effective. Ciprofloxacin 750 mg twice daily orally may be equally effective in the short term, but rapid development of resistance is a problem. High sputum levels of some antibiotics, e.g. tobramycin, can be achieved by inhalation.

Bronchodilators

Bronchodilators are useful in patients with demonstrable airflow limitation.

Anti-inflammatory agents

Inhaled or oral steroids can decrease the rate of progression.

Surgery

Unfortunately, it is rare for bronchiectasis to be sufficiently localized for a resection to be performed. Lung or heart-lung transplantation is sometimes required.

Complications

The incidence of complications has fallen with antibiotic therapy. Pneumonia, pneumothorax, empyema and metastatic cerebral abscess can occur. Severe, life-threatening haemoptysis can also occur, particularly in patients with cystic fibrosis.

Massive haemoptysis originates from the high-pressure systemic bronchial arteries and has a mortality of 25%. Other causes of massive haemoptysis are pulmonary tuberculosis (most common), aspergilloma, lung abscess and primary and secondary malignant tumours.

Treatment of the haemoptysis consists of bed rest and antibiotics, when most stop bleeding. Blood transfusion is given if required. Urgent fibreoptic bronchoscopy is occasionally necessary to detect the source of bleeding. If the haemoptysis does not settle rapidly the treatment of choice is bronchial artery embolization. Surgical resection may be required if embolization fails.

Prognosis

The advent of effective antibiotic therapy has greatly improved the prognosis. Ultimately, most patients with severe bronchiectasis will develop respiratory failure because of chronic deterioration of the lung tissue. Cor pulmonale is also a well-recognized complication.

Cystic fibrosis

In cystic fibrosis (CF) there is an alteration in the viscosity and tenacity of mucus produced at epithelial surfaces. The classical form of the syndrome includes bronchopulmonary infection and pancreatic insufficiency, with a high sweat sodium and chloride concentration. It is an autosomal recessive inherited disorder with a carrier frequency in Caucasians of 1 in 22 (see p. 190). There is a gene mutation on the long arm of chromosome 7 (7q21.3 —> 7q22.1). The commonest abnormality is a specific deletion at position 508 in the amino acid sequence [AF_{508}] - which results in a defect in a transmembrane regulator protein (see p. 192). This is the cystic fibrosis transmembrane conductance regulator (CFTR), which is a critical chloride channel (Fig. 14.30). The mutation alters the secondary and tertiary structure of the protein,

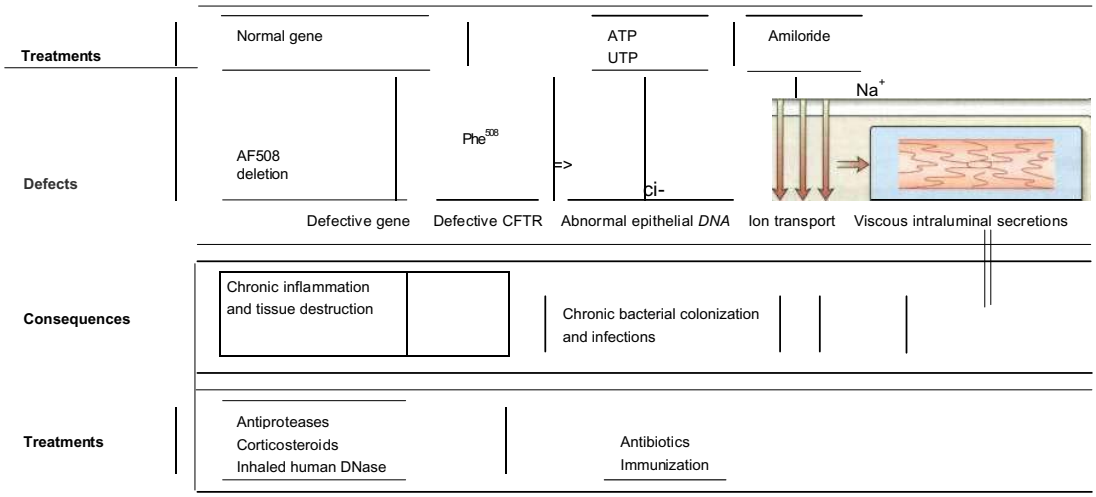

Fig. 14.30 Cystic fibrosis. Abnormalities and therapeutic advances (see text). CFTR, cystic fibrosis transmembrane conductance regulator.

leading to a failure of opening of the chloride channel in response to elevated cyclic AMP in epithelial cells. This results in decreased excretion of chloride into the airway lumen and an increased reabsorption of sodium into the epithelial cells. With less excretion of salt there is less excretion of water and increased viscosity and tenacity of airway secretions. A possible reason for the high salt content of sweat is that there is a CFTR-independent mechanism of chloride secretion in the sweat gland with an impaired reabsorption of sodium chloride in the distal end of the duct. Many genetic variants are known. The frequency of ΔF_{508} mutation in CF is 70% in the USA and UK, under 50% in southern Europe and 30% in Ashkenazi families.

Clinical features

Respiratory effects

Although the lungs of babies born with CF are structurally normal at birth, frequent respiratory infections soon develop and are often the presenting feature. CF is now the commonest cause of recurrent bronchopulmonary infection in childhood, and is a major cause in early adult life. Sinusitis is almost universal and nasal polyps are common. Breathlessness and haemoptysis occur in the later stages as airflow limitation and bronchiectasis develop. Spontaneous pneumothorax may occur. Respiratory failure and cor pulmonale eventually develop.

Gastrointestinal effects

About 85% of patients have symptomatic steatorrhoea owing to pancreatic dysfunction (see p. 413). Children may be born with meconium ileus owing to the viscid consistency of meconium in CF, and later in life develop the meconium ileus equivalent syndrome, a form of small intestinal obstruction unique to CF. Cholesterol gallstones appear to occur with increased frequency. Cirrhosis develops in about 5% of older patients and there are increased incidences of peptic ulceration and gastrointestinal malignancy.

Nutritional effects

Many patients suffer from malnutrition due to a combination of malabsorption and maldigestion. Poor nutrition is associated with increased pulmonary sepsis.

Other features

Puberty and skeletal maturity are delayed in most CF patients. Males are almost always infertile owing to failure of development of the vas deferens and epididymis. Females are able to conceive, but often develop secondary amenorrhoea as the disease progresses. Arthropathy and diabetes mellitus (in 11 % of adults with CF) also occur.

Diagnosis

The diagnosis of CF in older children and adults is based on the clinical history and:

- a family history of the disease
- a high sweat sodium concentration over 60 mmol/L (meticulous technique by laboratories performing regular sweat analysis is essential, but the test is still difficult to interpret in adults)
- blood DNA analysis of gene defect
- radiology showing features seen in bronchiectasis (see p. 908)
- absent vas deferens and epididymis
- blood immunoreactive trypsin levels - these are not useful diagnostically but may be useful in screening.

Treatment

Oxygen should be given as necessary (Box 14.1). Antibiotic treatment for respiratory infections is as described under bronchiectasis on page 909; treatment of pancreatic insufficiency and malnutrition is described on page 413. Seventy per cent of adults with CF have pseudomonas infection in their sputum. A meta-analysis has demonstrated that nebulized anti-pseudomonal antibiotic therapy improves lung function and decreases the risk of infective exacerbations and hospitalization in these patients. The effects on long-term benefits are still awaited. Better understanding of the basic abnormality in CF has led to dramatic changes in treatment. Potential treatments to improve hydration of secretions include blocking of sodium reabsorption with amiloride or stimulating chloride secretion with adenosine or uridine triphosphates (ATP or UTP) which stimulate nucleotide receptors by a pathway independent of cAMP. DNA from dead inflammatory cells is a major contributor to the viscosity of sputum. Inhalation of recombinant human DNase (using a jet nebulizer) has been shown to improve FEV! by 20% in some patients. Inhaled antibiotics and corticosteroids can also reduce inflammation and improve lung function. Human experimental studies have been conducted on the delivery to the epithelium of the normal CFTR gene using, as a vector, a replication-deficient adenovirus containing normal human CFTR complementary DNA which is trophic for epithelial cells. Gentamicin can suppress premature termination codons, and nasal administration has been shown to correct the physiological abnormality. These studies are in their early stages. The recent difficulties have been in establishing an effective vector. Lung or heart—lung transplantation may be necessary in the later stages of the disease (p. 911).

Prognosis and screening

Almost all CF patients develop progressive respiratory failure but the prognosis has consistently improved. Ninety per cent of children now survive into their teens and the median survival for those born after 1990 is estimated at 40 years. A major problem is sputum infection with *Burkholderia cepacia* (formerly classified as *Pseudomonas),* a plant pathogen, previously considered a harmless commensal. Its acquisition can be associated with accelerated disease and rapid death. Multiple antibiotic resistance is common and spread occurs from person to person. Strategies to limit transmission include rigid segregation of both inpatients and outpatients and advice to CF sufferers not to socialize together. Sadly, groups formed for mutual support and education have been disrupted, leading to considerable distress.

Genetic screening is available for the four most common mutations and this identifies 85-95% of carriers. Screening for the carrier state should be offered to persons or couples with a family history of CF, together with counselling (see p. 191).

Chronic cough (see p. 882)

Pathological coughing results from two mechanisms:

- stimulation of sensory nerves in the epithelium by secretions, foreign bodies, cigarette smoke and tumours
- sensitization of the cough reflex in which there is an abnormal increase in the sensitivity of the cough receptors demonstrable by inhalation of capsaicin or hypotonic chloride solutions.

Sensitization of the cough reflex presents clinically as a persistent tickling sensation in the throat with paroxysms of coughing induced by changes in air temperature, aerosol sprays, perfumes and cigarette smoke. It is found in association with viral infections, oesophageal reflux, postnasal drip, cough-variant asthma, idiopathic cough, and in 15% of patients taking angiotensin-converting enzyme (ACE) inhibitors. The association with ACE inhibitors implicates neuropeptides, prostaglandins E_2 and F_{2a} and bradykinin as a cause of the cough. In the absence of chest X-ray abnormalities, possible investigations include:

- ENT examination (p. 1157) and sinus CT for postnasal drip
- lung function tests and histamine bronchial provocation testing (p. 918) for cough-variant asthma
- ambulatory oesophageal pH monitoring for oesophageal reflux
- CT scan of thorax for interstitial lung disease
- *V/Q* scans for recurrent pulmonary embolism
- fibreoptic bronchoscopy for inhaled foreign body or tumour
- ECG, echocardiography and exercise testing for cardiac causes
- hyperventilation testing and psychiatric appraisal.

The absence of any pathology makes the management of unexplained cough difficult. Morphine will depress the sensitized cough reflex but its unwanted effects limit its use in the long term. Dihydrocodeine linctus may be of value in some patients. Demulcent preparations and cough sweets provide temporary relief only. Patients taking ACE inhibitors should be changed to an angiotensin-II receptor antagonist, e.g. losartan (see p. 793), which does not block bradykinin.

Lung and heart-lung transplantation

Indications and donor selection

The main diseases treated by transplantation are:

- pulmonary fibrosis
- primary pulmonary hypertension
- cystic fibrosis
- bronchiectasis
- emphysema - particularly Oi-antitrypsin inhibitor deficiency
- Eisenmenger's syndrome.

Indications for this treatment are patients under 60 years with a life expectancy of less than 18 months, no underlying cancer and no serious systemic disease.

Donor selection includes age under 40 years, good cardiac and lung function, and chest measurements slightly smaller than those of the recipient. Matching for ABO blood group is essential, but rhesus blood group compatibility is not essential. Since donor material is limited, single lung transplantation is preferred to double lung or heart-lung transplantation and can be successfully undertaken in pulmonary fibrosis, pulmonary hypertension and emphysema. Bilateral lung transplantation is required in infective conditions to prevent spillover of bacteria from the diseased lung to a single lung transplant. Eisenmenger's syndrome requires heart-lung transplant.

Complications and their treatment

- *Early* - post-transplant pulmonary oedema requires diuretics and respiratory support by ventilation.
- *Infections,* particularly within first 3 months:
  Bacterial pneumonia - antibiotics
  Cytomegalovirus - ganciclovir
  Herpes simplex - aciclovir
- P. *carinii* - prophylactic co-trimoxazole.
- *Immunosuppression* is with ciclosporin or tacrolimus, azathioprine or mycophenolate mofetil and prednisolone.
- *Rejection:*
  Early (first few weeks) - high-dose i.v. corticosteroids
  Late (after 3 months) - in obliterative bronchiolitis, high-dose i.v. corticosteroids are sometimes effective.
  Post-transplant lymphoproliferative disease may respond to rituximab, a monoclonal antibody which causes lysis of B lymphocytes.

Prognosis. There is a 2-year survival of 75% and 5-year survival of almost 50%.

ASTHMA

Asthma is a common chronic inflammatory condition of the lung airways whose cause is incompletely understood. Symptoms are cough, wheeze, chest tightness and shortness of breath, often worse at night. It has three characteristics:

- *airflow limitation* which is usually reversible spontaneously or with treatment
- *airway hyperresponsiveness* to a wide range of stimuli (see below)
- *inflammation of the bronchi* with eosinophils, T lymphocytes and mast cells with associated plasma exudation, oedema, marked smooth muscle hypertrophy, mucus plugging and epithelial damage.

In chronic asthma, inflammation may be accompanied by irreversible airflow limitation.

The underlying pathology in pre-school children may be different, in that they may not exhibit appreciable bronchial hyperreactivity. There is no evidence that chronic inflammation is the basis for the episodic wheezing associated with viral infections.

Prevalence

In many countries the prevalence of asthma is increasing, particularly in the second decade of life where this disease affects 10-15% of the population. There is also a geographical variation, with asthma being common in more developed countries, some of the highest rates being in New Zealand, Australia and the UK, but being much rarer in Far Eastern countries such as China and Malaysia, and in Africa and Central and Eastern Europe. Long-term follow-up in developing countries suggests that the disease may become more frequent as individuals become more 'westernized'. Studies of occupational asthma suggest that a high percentage of the workforce, perhaps up to 20%, may become asthmatic if exposed to potent sensitizers.

Classification

Asthma can be divided into:

- *extrinsic* - implying a definite external cause
- *intrinsic* or *cryptogenic* - when no causative agent can be identified.

Extrinsic asthma occurs most frequently in atopic individuals who show positive skin-prick reactions to common inhalant allergens. Positive skin-prick tests to inhalant allergens are shown in 90% of children and 50% of adults with persistent asthma. Childhood asthma is often accompanied by eczema (see p. 1327). An overlooked cause of late-onset asthma in adults is sensitization to chemicals or biological products in the workplace.

Intrinsic asthma often starts in middle age ('late onset'). Nevertheless, many patients with adult-onset asthma show positive skin tests and on close questioning give a history of respiratory symptoms compatible with childhood asthma.

Non-atopic individuals may develop asthma in middle age from extrinsic causes such as sensitization to occupational agents or aspirin intolerance, or because they were given (3-adrenoceptor-blocking agents for concurrent hypertension or angina. Extrinsic causes must be considered in all cases of asthma and, where possible, avoided.

Aetiology and pathogenesis

There are two major factors involved in the development of asthma and many other stimuli that can precipitate attacks (Fig. 14.31).

Atopy and allergy

The term 'atopy' was used by clinicians at the beginning of the century to describe a group of disorders, including asthma and hayfever, that appeared:

- to run in families
- to have characteristic wealing skin reactions to common allergens in the environment

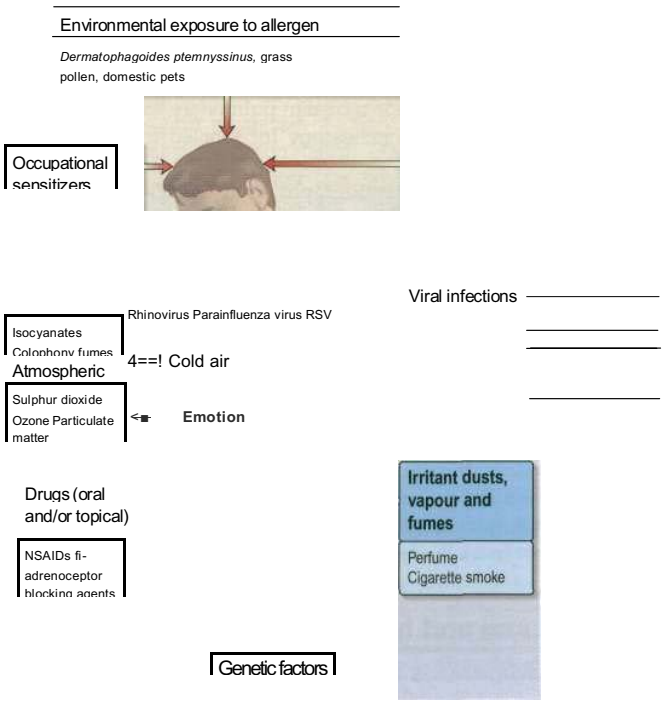

Fig. 14.31 Causes and triggers of asthma. RSV, respiratory syncytial virus; NSAIDs, non-steroidal anti-inflammatory drugs.

- to have circulating antibody in their serum that could be transferred to the skin of non-sensitized individuals.

The term is best used to describe those individuals who readily develop antibodies of IgE class against common materials present in the environment. Such antibodies are present in 30-40% of the UK population, and there is a link between serum IgE levels and both the prevalence of asthma and airway hyperresponsiveness. Genetic and environmental factors affect serum IgE levels. The use of DNA microsatellite markers to scan the entire genome has uncovered 22 chromosomal regions of interest containing candidate genes. Some of these, in combination with environmental factors, may turn out to play a key role in the development of asthma. The genes controlling the production of the cytokines IL-3, IL-4, IL-5, IL-9, IL-13 and GM-CSF - which in turn affect mast and eosinophil cell development and longevity as well as IgE production - are present in a cluster on chromosome 5q31-33 (the IL-4 gene cluster). A gene on chromosome 2, *PHF11,* which controls IgE synthesis is strongly associated with atopy whereas *ADAM33* on chromosome 20 is more strongly associated with airway hyperresponsiveness and the tissue changes of remodelling.

Early childhood exposure to allergens and maternal smoking have a major influence on IgE production. Much current interest focuses on the role of intestinal bacteria and childhood infections in shaping the immune system in early life. It has been suggested that growing up in a relatively 'clean' environment may predispose towards an IgE response to allergens (the hygiene hypothesis). Conversely, growing up in a 'dirtier' environment may allow the immune system to avoid developing allergic responses. Components of bacteria (e.g. lipopolysaccharide endotoxin; immunostimulatory CpG DNA sequences), viruses (e.g. DS RNA) and fungi (e.g. chiton, a cell wall component) are able to stimulate toll receptors expressed on immune cells to direct the immune and inflammatory response away from the allergic pathways. Thus early life exposure to inhaled and ingested products of microorganisms may be critical in helping shape the subsequent risk of a child becoming allergic and/or developing asthma.

The allergens involved in asthma are similar to those in rhinitis. Allergens from the faecal particles of the house-dust mite are the most significant extrinsic cause of asthma world-wide. Cockroach allergy has been implicated in asthma in US inner-city children, while allergens from furry pets are also becoming increasingly common causes of asthma, rhinitis and urticaria. The fungal spores from *Aspergillus fumigatus* give rise to a complex series of lung disorders, including asthma (see p. 939). Many allergens including those from *Aspergillus* have intrinsic biological properties, e.g. proteolytic enzymes that facilitate their passage through the airway epithelium to increase their sensitizing capacity.

Increased responsiveness of the airways of the lung (airway hyperresponsiveness)

Bronchial hyperresponsiveness can be demonstrated by asking the patient to inhale gradually increasing concentrations of either histamine or methacholine *(bronchial provocation tests).* This induces transient airflow limitation in susceptible individuals (approximately 20% of the population); the dose of the agonist (provocation dose) necessary to produce a 20% fall in FEVj is known as the PD_{20} FEVj (or PC_{20} FEV,). Patients with clinical symptoms of asthma respond to very low doses of methacholine; i.e. they have a low PD_{20} *TEV1* (< 11 |i,mol). In general, the greater the degree of hyperreactivity, the more persistent the symptoms and the greater the need for treatment.

Some patients also react to methacholine but at *higher doses* and include those with:

- attacks of asthma only on extreme exertion
- wheezing or prolonged periods of coughing following a viral infection
- cough variant asthma
- seasonal wheeze in pollen season
- allergic rhinitis, but not complaining of any lower respiratory symptoms until specifically questioned
- some subjects with no respiratory symptoms.

Although the degree of hyperresponsiveness can itself be influenced by allergic mechanisms (see p. 914 and Fig. 14.34), its pathogenesis and mode of inheritance involve a combination of airway inflammation and tissue remodelling.

Precipitating factors

Occupational sensitizers

Over 200 materials encountered at the workplace give rise to occupational asthma. The causes are recognized occupational diseases in the UK, and patients in insurable employment are therefore eligible for statutory compensation provided they apply within 10 years of leaving the occupation in which the asthma developed (Table 14.12).

Table 14.12 **Occupational asthma in the UK**

Cause	Source
Non-IgE related	
Isocyanates	Polyurethane varnishes Industrial coatings
	Spray painting
	Soldering/welders Electronics industry
Colophony fumes	
IgE related	
Allergens from animals, insects and antibiotics	Laboratories
Allergens from flour and grain	Farmers
	Millers/bakers
	Grain handlers
Latex	Health workers
Proteolytic enzymes	Manufacture (but not use) of 'biological' washing powders
Complex salts of platinum	Metal refining
Acid anhydrides and polyamine hardening agents	Industrial coatings

Asthma due to flour, organic dusts and other large protein molecules involves specific IgE antibodies. In contrast, reactive chemicals such as isocyanates and acid anhydrides bond chemically to epithelial cells to activate them as well as provide haptens recognized by T cells. The risk of developing some forms of occupational asthma increases in smokers.

The proportion of employees developing occupational asthma depends primarily upon the level of exposure. Proper enclosure of industrial processes or appropriate ventilation greatly reduces the risk. Atopic individuals develop occupational asthma more rapidly when exposed to agents causing the development of specific IgE antibody. Non-atopic individuals can also develop asthma when exposed to such agents, but after a longer period of exposure.

Non-specific factors

The characteristic feature of bronchial hyperresponsiveness in asthma means that, as well as reacting to specific antigens, the airways will also respond to a wide variety of non-specific direct and indirect stimuli.

Cold air and exercise

Most asthmatics wheeze after prolonged exercise. Typically, the attack does not occur while exercising but afterwards. The inhalation of cold, dry air will also precipitate an attack. Exercise-induced wheeze is driven by histamine and leukotrienes which are released from mast cells when the epithelial lining fluid of the bronchi becomes hyperosmolar owing to drying and cooling during exercise. The phenomenon can be shown by exercise, cold air and hypertonic (e.g. saline or mannitol) provocation tests.

Atmospheric pollution and irritant dusts, vapours and fumes

Many patients with asthma experience worsening of symptoms on contact with cigarette smoke, car exhaust fumes, strong perfumes or high concentrations of dust in the atmosphere. Major epidemics have been recorded when large amounts of allergens are released into the air, e.g. soy bean epidemic in Barcelona. Asthma exacerbations increase in both summer and winter air pollution episodes associated with climatic temperature inversions. Epidemics of the disease have occurred in the presence of high concentrations of ozone, particulates and NO_2 in the summer and particulates, NO_2 and SO_2 in the winter.

Diet

Increased intakes of fresh fruit and vegetables have been shown to be protective, possibly owing to the increased intake of antioxidants. Genetic variation in antioxidant enzymes is associated with more severe asthma.

Emotion

It is well known that emotional factors may influence asthma, but there is no evidence that patients with the disease are any more psychologically disturbed than their non-asthmatic peers.

Drugs

Non-steroid anti-inflammatory drugs (NSAIDs). NSAIDs, particularly aspirin and propionic acid derivatives, e.g. indometacin, have a major role in the development and precipitation of attacks in approximately 5% of patients with asthma. This effect is especially prevalent in those individuals who have both nasal polyps and asthma. It is thought that treatment with these drugs leads to an imbalance in the metabolism of arachidonic acid. NSAIDs inhibit arachidonic acid metabolism via the cyclo-oxygenase (COX) pathway, preventing the synthesis of prostaglandins. It is suggested that under these circumstances there is a reduced production of prostaglandin E_2 which, in a sub-proportion of genetically susceptible subjects, induces the overproduction of cysteinyl leukotrienes by eosinophils, mast cells and macrophages. In such patients there is evidence for polymorphisms involving the promoter region of the LTC_4 synthase gene that controls the level of activity of this terminal enzyme of the leukotriene-generating pathway (Fig. 14.32). Interestingly, asthma in intolerant patients is not precipitated by COX-2 inhibitors, indicating that it is blockade of COX-1 that is linked to impaired PGE_2 production.

Beta-blockers. The airways have a direct parasympathetic innervation that tends to produce bronchoconstriction. There is no direct sympathetic innervation of the smooth muscle of the bronchi, and antagonism of parasympathetically induced bronchoconstriction is critically dependent upon circulating epinephrine (adrenaline) acting through (3_2-receptors on the surface of smooth muscle cells. Inhibition of this effect by P-adrenoceptor-blocking drugs such as propranolol leads to bronchoconstriction and airflow limitation, but only in asthmatic subjects. The so-called selective $p_1$adrenergic-blocking drugs such as atenolol may still induce attacks of asthma; their use to treat hypertension or angina in asthmatic patients is best avoided.

Allergen-induced asthma

The experimental inhalation of allergen by atopic asthmatic individuals leads to the development of different types of reaction, as illustrated in Figure 14.33.

Immediate asthma (early reaction)

Airflow limitation begins within minutes of contact with the allergen, reaches its maximum in 15-20 minutes and subsides by 1 hour.

Dual and late-phase reactions

Following an immediate reaction many asthmatics develop a more prolonged and sustained attack of airflow limitation that responds less well to inhalation of bronchodilator drugs such as salbutamol. Isolated late-phase reactions with no preceding immediate response can occur after the inhalation of some occupational sensitizers such as isocyanates.

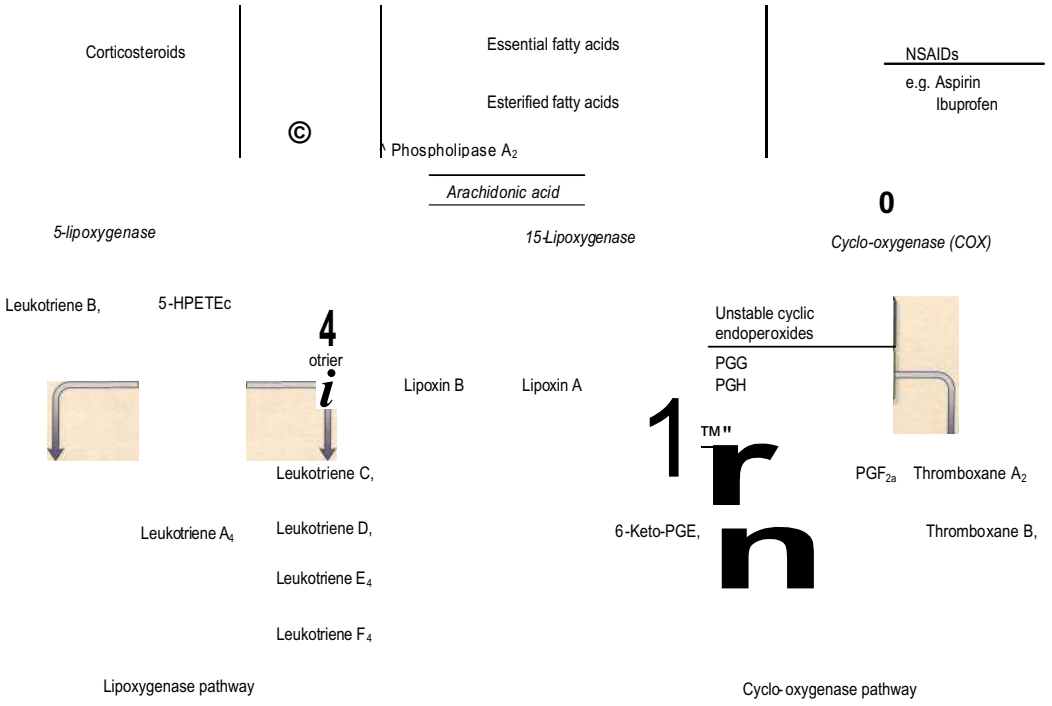

Fig. 14.32 **Arachidonic acid metabolism and the effect of drugs.** The enzyme cyclo-oxygenase occurs in three isoforms, COX-1 (constitutive), COX-2 (inducible) and COX-3 (in brain). PG, prostaglandin.

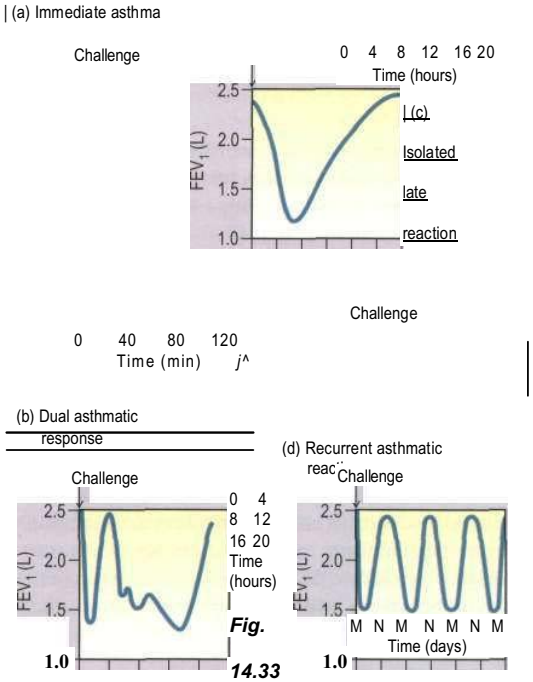

Fig. 14.33

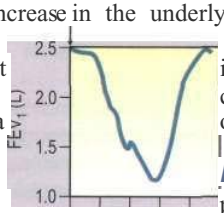
Different types of asthmatic reactions following challenge with allergen, (a) Immediate asthma. (b) Dual asthmatic response, (c) Isolated late reaction. (d) Recurrent asthmatic reactions. M, midnight; N, noon.

Recurrent asthmatic reactions

The development of the late-phase reaction is associated with an increase in the underlying level of airway hyperresponsiveness such that individuals may show continuing episodes of asthma on subsequent days.



Pathogenesis

The pathogenesis of asthma is complex and not fully understood. It involves a number of cells, mediators, nerves and vascular leakage that can be activated by several different mechanisms, of which exposure to allergens is among the most significant (Fig. 14.34). The varying clinical severity and chronicity of asthma is dependent on an interplay between airway inflammation and airway wall remodelling. The inflammatory component is driven by Th2-type T lymphocytes which facilitate IgE synthesis through production of IL-4 and eosinophilic inflammation through IL-5 (Fig. 14.34).

Inflammation

Several key cells are involved in the inflammatory response that characterizes all types of asthma.

Mast cells (see also p. 200). These are increased in both the epithelium and surface secretions of asthmatics and can generate and release powerful mediators acting on smooth muscle and small blood vessels, such as histamine, tryptase, prostaglandin D_2 (PGD_2) and leukotriene C_4 (LTC_4), which cause the immediate asthmatic reaction. Since potent (3_2-adrenoceptor agonists such as salbutamol

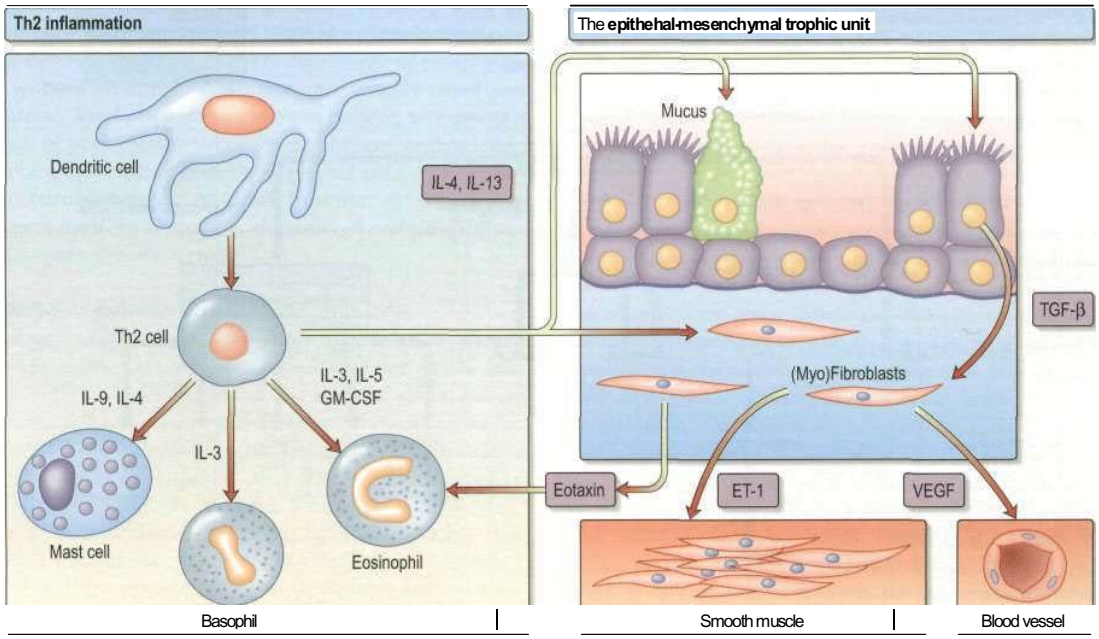


Fig. 14.34 **Pathogenesis of asthma.** Antigen-presenting cells (dendritic cells) activate Th2 T cells causing them to release cytokines which attract mast cells and eosinophils. IL-9 and IL-4 activate mast cells to release LTC_4, PGD_2 and histamine which act on smooth muscle and blood vessels. IL-3, IL-5 and GM-CSF attract eosinophils; these are also attracted by chemokines which act on type 3 C-C chemokine receptors (CCR-3, e.g. eotaxin, RANTES, MCP-1, -3 and -4). Activated eosinophils release LTC_4, MBP, ECP and peroxidase (EPX) which are toxic to epithelial cells.
IL-4 and IL-13 produced by activated T cells maintain the allergic reaction and cause mucus secretion and smooth muscle contraction. IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; RANTES, regulated upon activation, normal T cell expressed and secreted; MBP, major basic protein; ECP, eosinophilic cationic protein; LTC_4, leukotriene C_4; MCP, monocytic chemoattractant protein; PDGF, platelet-derived growth factor; PGD_2, prostaglandin D_2; TGF-J3, transforming growth factor-p; VEGF; vascular endothelial growth factor; ET-1, endothelin-1.

have little effect on airway inflammation or hyperresponsiveness but inhibit mast cell mediator release, many other factors are involved in the pathogenesis of late and recurrent asthmatic reactions leading to more severe disease.

Eosinophils. These cells are found in large numbers in the bronchial wall and secretions of asthmatics. They are attracted to the airways by the eosinophilopoietic cytokines IL-3, IL-5 and GM-CSF as well as by chemokines which act on type 3 C-C chemokine receptors (CCR-3) (i.e. eotaxin, RANTES, MCP-1, MCP-3 and MCP-4). These mediators also prime eosinophils for enhanced mediator secretion. When activated, they release LTC_4, and basic proteins such as major basic protein (MBP), eosinophil cationic protein (ECP) and peroxidase (EPX) that are toxic to epithelial cells. Both the number and activation of eosinophils is rapidly decreased by corticosteroids.

Macrophages (dendritic cells) and lymphocytes. These cells are abundant in the mucous membranes of the airways and the alveoli. Dendritic cells have a role in the initial uptake and presentation of allergens to lymphocytes. They can release prostaglandins, thromboxane, LTC_4 and LTB_4 and platelet-activating factor (PAF). T helper lymphocytes (CD4) show evidence of activation (Fig. 14.34) and the release of their cytokines play a key part in the migration and activation of mast cells (IL-3, IL-4, IL-9) and eosinophils (IL-3, IL-5, GM-CSF). In addition, production of IL-4 leads to the maintenance of the allergic (Th2) T cell phenotype, favouring switching of antibody production by B lymphocytes to IgE. In asthma there occurs a selective upregulation of Th2 T cells with reduced evidence of the Thl phenotype (producing gamma-interferon and IL-2). This polarization is mediated by dendritic cells and involves a combination of antigen presentation, costimulation and exposure to polarizing cytokines. The activity of both macrophages and lymphocytes is influenced by corticosteroids but not p_2-adrenoceptor agonists. »

Remodelling

A characteristic feature of chronic asthma is an alteration of structure and functions of the *formed elements oi* the airways. Together, these structural changes interact with inflammatory cells and mediators to cause the characteristic features of the disease. Deposition of matrix proteins, swelling and cellular infiltration cause an expansion of the submucosa beneath the epithelium so

that for a given degree of smooth muscle shortening there is excess airway narrowing. Swelling outside the smooth muscle layer spreads the retractile forces exerted by the surrounding alveoli over a greater surface area so that the airways close more easily. Several factors contribute to these changes.

The epithelium. In asthma the epithelium of the conducting airways is stressed and damaged with loss of ciliated columnar cells onto the lumen. Metaplasia occurs with a resultant increase in the number and activity of mucus-secreting goblet cells. The epithelium is a major source of mediators, cytokines and growth factors that serve to enhance inflammation and promote tissue remodelling. Damage and activation of the epithelium make it more vulnerable to infection by common respiratory viruses, e.g. rhinovirus, coronavirus, and to the effects of air pollutants.

Epithelial basement membrane. A pathognomonic feature of asthma is the deposition of repair collagens (types I, III and V) in the *lamina reticularis* beneath the basement membrane. This, along with the deposition of other matrix proteins such as laminin, tenascin and fibronectin, causes the appearance of a thickened basement membrane observed by light microscopy in asthma. This collagen deposition reflects activation of an underlying sheath of fibroblasts that transform into contractile myofibroblasts which also have an increased capacity to secrete matrix. Aberrant signalling between the epithelium and underlying myofibroblasts is thought to be the principal cause of airway wall remodelling, since the cells are prolific producers of a range of tissue growth factors such as epidermal growth factors (EGF), transforming growth factor-(3 (TGF-(3), connective tissue-derived growth factor, platelet-derived growth factor (PDGF), endothelin (ET), insulin-like growth factors (IGF), nerve growth factors and vascular endothelial growth factors (Fig. 14.34). The same interaction between epithelium and mesenchymal tissues is central to branching morphogenesis in the developing fetal lung. It has been suggested that these mechanisms are reactivated in asthma, but instead of causing airway growth and branching, they lead to thickening of the airway wall (remodelling). Increased deposition of collagens, proteoglycans and matrix proteins creates a microenvironment conducive to ongoing inflammation since these complex molecules also possess cell-signalling functions which prolong inflammatory cell survival and prime them for mediator secretion.

Smooth muscle. A prominent feature of asthma is hyperplasia of the helical bands of airways smooth muscle. In addition to increasing in amount, the smooth muscle alters in function to contract more easily and stay contracted because of a change in actin-myosin cross-link cycling. These changes allow the asthmatic airways to contract too much and too easily at the least provocation. Asthmatic smooth muscle also secretes a wide range of cytokines and growth factors that help sustain the chronic inflammatory response. *ADAM33,* the newly described asthma gene, may be involved in driving increased airway smooth muscle and other features of remodelling through increased generation of growth factors.

Nerves. Neural reflexes, both central and peripheral, contribute to the irritability of asthmatic airways. Central reflexes involve stimulation of nerve endings in the epithelium and submucosa with transmission of impulses via the spinal cord and brain back down to the airways where release of acetylcholine from nerve endings stimulates M_2 receptors on smooth muscle causing contraction. Local neural reflexes involve antidromic neurotransmission and the release of a variety of neuropeptides. Some of these are smooth muscle contractants (substance P, neurokinin A), some are vasoconstrictors (e.g. calcitonin gene-related peptide, CGRP) and some vasodilators (e.g. neuropeptide Y, vasoactive intestinal polypeptide). Bradykinin generated by tissue and serum proteolytic enzymes (including mast cell tryptase) is also a potent stimulus of local neural reflexes involving (non-myelinated) nerve fibres.

Clinical features

The principal symptoms of asthma are wheezing attacks and episodic shortness of breath. Symptoms are usually worst during the night. Cough is a frequent symptom that sometimes predominates and is often misdiagnosed as bronchitis. Nocturnal cough can be a presenting feature.

There is a tremendous variation in the frequency and duration of the attacks. Some patients have only one or two attacks a year that last for a few hours, whilst others have attacks lasting for weeks. Some patients have chronic symptoms. Attacks may be precipitated by a wide range of triggers (Fig. 14.31). Asthma is a major cause of impaired quality of life with impact on work, recreational, as well as physical activities and emotions.

Investigations

There is no single satisfactory diagnostic test for all asthmatic patients.

Respiratory function tests

Measurements of peak expiratory flow (PEF) on waking, prior to taking a bronchodilator and before bed after a bronchodilator, are particularly useful in demonstrating the variable airflow limitation that characterizes the disease. An example is shown in Figure 14.14 (p. 889). The diurnal variation in PEF is a good measure of asthma activity and is of help in the longer-term assessment of the patient's disease and its response to treatment. To assess possible occupational asthma, peak flows need to be measured for at least 2 weeks at work and 2 weeks off work.

Spirometry is useful, especially in assessing reversibility. Asthma can be diagnosed by demonstrating a greater than 15% improvement in FEVj or PEF following the inhalation of a bronchodilator. However, this degree of response may not be present if the asthma is in remission

or in severe chronic asthma when little reversibility can be demonstrated or if the patient is already being treated with long-acting bronchodilators.

The carbon monoxide transfer test is normal in asthma.

Exercise tests

These have been widely used in the diagnosis of asthma in children. Ideally, the child should run for 6 minutes on a treadmill at a workload sufficient to increase the heart rate above 160 beats per minute. Alternative methods use cold air challenge, isocapnoeic hyperventilation (forced overbreathing with artificially maintained P_aco_2) or aerosol challenge with hypertonic solutions. A negative test does not automatically rule out asthma.

Histamine or methacholine bronchial provocation test (see p. 913)

This test indicates the presence of airway hyperresponsiveness, a feature found in most asthmatics, and can be particularly useful in investigating those patients whose main symptom is cough. The test should not be performed on individuals who have poor lung function (FEV, < 1.5 L) or a history of 'brittle' asthma.

Trial of corticosteroids

All patients who present with severe airflow limitation should undergo a formal trial of corticosteroids. Prednisolone 30 mg orally should be given daily for 2 weeks with lung function measured before and immediately after the course. A substantial improvement in FEVj (> 15%) confirms the presence of a reversible element and indicates that the administration of inhaled steroids will prove beneficial to the patient. If the trial is for 2 weeks or less, the oral steroids can be withdrawn without tailing off the dose, and should be replaced by inhaled corticosteroids in those who have responded and are thought will benefit.

Blood and sputum tests

Patients with asthma may have an increase in the number of eosinophils in peripheral blood (> 0.4 x 10^9/L). The presence of large numbers of eosinophils in the sputum is a more useful diagnostic tool.

Chest X-ray

There are no diagnostic features of asthma on the chest X-ray, although overinflation is characteristic during an acute episode or in chronic severe disease. A chest X-ray may be helpful in excluding a pneumothorax, which can occur as a complication, or in detecting the pulmonary shadows associated with allergic bronchopulmonary aspergillosis. ... , ... … …… ..... , ...

Skin tests

Skin-prick tests should be performed in all cases of asthma to help identify allergic causes.

Allergen provocation tests

Allergen challenge is not required in the clinical investigation of patients, except in cases of suspected occupational asthma. Another controversial exception is the investigation of food allergy causing asthma. This diagnosis is difficult, although many patients are concerned about the possibility. If the patient has asthma without any other systemic features, then food allergy is most unlikely to be the cause. Open food challenges are unreliable and if the diagnosis is seriously entertained, blind oral challenges with the food disguised in opaque gelatine capsules are necessary to confirm or refute a causative link (see p. 261).

Management

Asthma is extremely common and causes considerable morbidity. The aims of treatment are to:

- abolish symptoms
- restore normal or best possible lung function
- reduce the risk of severe attacks
- enable normal growth to occur in children
- minimize absence from school or employment.

This involves:

- patient and family education about asthma
- patient and family participation in treatment
- avoidance of identified causes where possible
- use of the lowest effective doses of convenient medications to minimize short-term and long-term side-effects.

Many asthmatics belong to self-help groups whose aim is to further their understanding of the disease and to foster self-confidence and fitness.

Control of extrinsic factors

Measures must be taken to avoid causative allergens such as the house-dust mite, pets, moulds and certain foodstuffs (see allergic rhinitis), particularly in childhood.

Avoidance of the house-dust mite is possible with effective and comfortable covers for bedding and changes to living accommodation. Active and passive smoking should be avoided, as should beta-blockers in either tablet or eyedrop form.

Individuals intolerant to aspirin may benefit by avoiding dietary salicylates and should avoid NSAIDs. Other agents (e.g. preservatives and colouring materials such as tartrazine) should be avoided if shown to be a causative factor. Fifty per cent of individuals sensitized to occupational agents may be cured if they are kept permanently away from exposure. The remaining 50% continue to have symptoms that may be as severe as when exposed to materials at work, especially if they were symptomatic for a long time before the diagnosis was made.

This emphasises:

- the importance of the rapid identification of extrinsic causes of asthma and their removal wherever possible (e.g. occupational agents, family pets)
- once extrinsic asthma is initiated, it may become self-perpetuating possibly by non-immune mechanisms.

Drug treatment

The mainstay of asthma therapy is the use of therapeutic agents delivered as aerosols or powders directly into the lungs (Practical box 14.4). The advantages of this method of administration are that drugs are delivered direct to the lung and the first-pass metabolism in the liver is avoided; thus lower doses are necessary and systemic unwanted effects are minimized.

Both national and international guidelines have been published on the stepwise treatment of asthma (Box 14.2) based on three principles:

- Asthma self-management with regular asthma monitoring using peak flow meters and individual treatment plans discussed with each patient and written down.
- The appreciation that asthma is an inflammatory disease and that anti-inflammatory (controller) therapy should be started even in mild cases.
- Use of short-acting inhaled bronchodilators (e.g. salbutamol and terbutaline) only to relieve break through symptoms. Increased use of bronchodilator treatment to relieve increasing symptoms is an indi cation of deteriorating disease.

A list of drugs used in asthma is shown in Box 14.3.

Practical Box 14.4
Inhaled therapy

Use of a metered-dose inhaler

1. The canister is shaken.
2. The patient exhales to functional residual capacity (not residual volume), i.e. normal expiration.
3. The aerosol nozzle is placed to the open mouth.
4. The patient simultaneously inhales rapidly and activates the aerosol.
5. Inhalation is completed.
6. The breath is held for 10 seconds if possible.

Even with good technique only 15% of the contents is inhaled and 85% is deposited on the wall of the pharynx and ultimately swallowed. NB: Chlorofluorocarbon (CFC) propellants are being replaced by hydrofluoralkane (HFA) propellants. The new aerosols may feel and taste differently and patients will need reassurance of their efficacy.

Spacers

These are plastic conical spheres inserted between the patient's mouth and the inhaler. They are designed to reduce particle velocity so that less drug is deposited in the mouth. Spacers also diminish the need for coordination between aerosol activation and inhalation. They are useful in children and in the elderly and they reduce the risk of candidiasis.

$2-adrenergic agonists

The most widely used bronchodilator preparations contain (3_2-adrenergic agonists that are selective for the respiratory tract and do not stimulate the pVadrenoceptors of the myocardium. These drugs are potent bronchodilators because they cause relaxation of bronchial smooth muscle. Such treatment is very effective in relieving symptoms but does little for the underlying inflammatory nature of the disease. Only the mildest asthmatics with intermittent attacks should rely on bronchodilator treatment alone. Inhalants such as salbutamol (100 |ig) or terbutaline (250 |ag) should be prescribed as 'two puffs as required'. Some patients use nebulizers at home for self-administration of salbutamol or terbutaline. Such treatment is effective, but patients must not rely on repeated home administration of nebulized (3_2-adrenoceptor agonists for worsening asthma, and must be encouraged to seek medical advice urgently if their condition does not improve. The excessive use of f3_2 agonists has been linked to the two epidemics of asthma mortality in the 1960s and 1980s.

Salmeterol and formoterol are highly selective and potent long-acting (3_2-adrenoceptor agonists effective by inhalation for up to 12 hours, thereby reducing the need for administration to once or twice daily. Long-acting (3_2-adrenoceptor agonists improve symptoms, lung function and reduce exacerbations in patients who are poorly controlled on standard doses of inhaled steroids. They should never be used alone but always in combination with an inhaled corticosteroid.

Box 14.2 **The stepwise management of asthma**

Step	PEFR	Treatment
1 Occasional symptoms, less frequent than daily	100% predicted	As-required bronchodilators If used more than once daily, move to step 2
2 Daily symptoms	< 80% predicted	Anti-inflammatory drugs Sodium cromoglicate or low-dose inhaled corticosteroids up to 800 ug If not controlled, move to step 3 High-dose
3 Severe symptoms	50-80% predicted	inhaled corticosteroids up to 2000 ug daily Add regular long-acting
4 Severe symptoms uncontrolled with high-dose inhaled corticosteroids	50-80% predicted	p_2 agonists (e.g. salmeterol) Add
5 Severe symptoms deteriorating	< 50% predicted	prednisolone 40 mg daily Hospital
6 Severe symptoms deteriorating in spite of prednisolone	< 30% predicted	admission

Short-acting bronchodilator treatment taken at any step on as-required basis

Box 14.3 **Drugs used in asthma Inhaled**

oral steroids Short-acting relievers

(salbutamol, terbutaline)

Long-acting relief/disease controllers

Long-acting p_2 agonists - salmeterol, formoterol
Sodium cromoglicate
Leukotriene modifiers - montelukast, zafirlukast, pranlukast, zileuton

Other agents with bronchodilator activity

Antimuscarinic agents (ipratropium, oxitropium)
Theophylline preparations

Steroid-sparing agents

Methotrexate
Ciclosporin
Gold
Intravenous immunoglobulin
Anti-IgE monoclonal antibody - omalizumab

(5_2-adrenoceptor agonists are less effective when given by mouth than when the drug is inhaled, and to help those who cannot coordinate activation of the aerosol and inhalation, several breath-activated or dry powder devices have been developed.

Antimuscarinic bronchodilators

Muscarinic receptors are found in the respiratory tract; large airways contain mainly M_3 receptors whereas the peripheral lung tissue contains M_3 and Mj receptors (see p. 876). Non-selective muscarinic antagonists - ipratropium bromide (2CW0 u.g three or four times daily) or oxitropium bromide (200 u,g twice daily) - by aerosol inhalation may be additive to (3_2-adrenoceptor stimulants, especially during asthma exacerbations.

Anti-inflammatory drugs

Sodium cromoglicate and nedocromil sodium prevent activation of many inflammatory cells, particularly mast cells, eosinophils and epithelial cells, but not lymphocytes, by blocking a specific chloride channel which in turn prevents calcium influx. These drugs are effective in patients with milder asthma. Sodium cromoglicate is taken regularly either in the form of a Spincap containing 20 mg or in aerosol form from a metered-dose inhaler delivering 5 mg per puff. The dose should be two puffs four times daily from an inhaler, or one Spincap three or four times daily. Nedocromil sodium is taken as an aerosol at a dose of 4 mg (two puffs) two to four times daily. Recent asthma guidelines advise that inhaled corticosteroids are more efficacious than the cromones, but the latter are free of side-effects and, therefore, may offer some advantages in children.

Inhaled corticosteroids

All patients who have regular persisting symptoms need regular treatment with inhaled corticosteroids delivered in a stepwise fashion or as a high dose followed by a reduction to maintenance levels. Beclometasone dipropionate is the most widely used inhaled steroid and is available in doses of 50, 100, 200 and 250 ng per puff. Other inhaled steroids include budesonide, fluticasone, mometasone and triamcinolone.

Much of the inhaled dose does not reach the lung but is either swallowed or exhaled. Deposition in the lung varies between 10% and 25% depending on inhaler technique and the technical characteristics of the aerosol device. Drug which is deposited in the airways reaches the systemic circulation directly, through the bronchial circulation, while any drug that is swallowed has to pass through the liver before it can reach the systemic circulation. Gram for gram, fluticasone and mometasone are more potent than beclometasone with considerably less systemic bioavailability, owing to their greater sensitivity to hepatic metabolism. The newer hydrofluoroalkane (HFA) aerosols of beclometasone deliver a higher proportion of useable drug than the old CFC-based aerosols, and the effective dosage of HFA-beclometasone is equivalent to the same dose of HFA-fluticasone, whereas previously the effective dose ratio was 2:1. Absorption of beclometasone and budesonide does not seem to present a risk at doses up to 800 fig/day, but when using high-dose inhaled steroids in patients who have not responded to standard doses, fluticasone or mometasone may be preferred because of their lower bioavailability. The dose-response curve for inhaled corticosteroids is flat beyond 800 |ig beclometasone or equivalent, and in patients with moderate asthma who are taking this daily, addition of salmeterol or formoterol is more effective than doubling the dose of inhaled corticosteroid.

The unwanted effects of inhaled corticosteroids are oral candidiasis (5% of patients), and hoarseness due to the effect of corticosteroids on the laryngeal muscles. Subcapsular cataract formation is rare but can occur in the elderly. Abnormalities of bone metabolism can be detected when inhaled corticosteroids are taken in high doses (beclometasone or budesonide > 800 |ig daily). In children, inhaled corticosteroids at doses greater than 400 |ig daily have been shown to retard short-term growth. Inhaled corticosteroid use should be stepped down once asthma comes under control. Candidiasis and GI absorption can be reduced by using spacers, mouthwashing and teeth cleaning after use.

Oral corticosteroids

Oral corticosteroids may be necessary for those individuals not controlled on inhaled corticosteroids. The dose should be kept as low as possible to minimize side-effects. The effect of short-term treatment with prednisolone 30 mg daily is shown in Figure 14.14 (p. 889). Some patients require continuing treatment with oral corticosteroids. Several studies suggest that treatment with low doses of methotrexate (15 mg weekly) can significantly reduce the dose of prednisolone needed to control the disease in some patients, and ciclosporin also improves lung function in some steroid-dependent asthmatics. Several other steroid-sparing strategies

including methotrexate and immunoglobulin have also been tried but with varying success.

Cysteinyl leukotriene receptor antagonists (LTRAs)

This class of anti-asthma therapy targets one of the principal asthma mediators by inhibiting the cysteinyl LTj receptor. A second receptor (cyst LT_2) has recently been identified on inflammatory cells. Montelukast, pranlukast (only available in SE Asia) and zafirlukast are given orally and are effective in a subpopulation of patients. However, it is not possible to predict which individuals will benefit: a 4-week trial of LTRA therapy is recommended before a decision is made to continue or stop. LTRAs should be considered in any patient who is not controlled on low to medium doses of inhaled steroids. Their action is additive to that of long-acting (3_2 agonists. LTRAs are particularly useful in patients with aspirin-intolerant asthma and in those patients requiring high-dose inhaled or oral corticosteroids.

Monoclonal antibodies

Newer agents that modulate IgE-associated inflammation are being developed. The most promising of these is a recombinant humanized monoclonal antibody that complexes with free IgE - omalizumab - blocking its interaction with mast cells and basophils. Clinical trials in children and adults with severe asthma despite corticosteroids show good efficacy when omalizumab is given subcutaneously two to four times weekly.

Antibiotics

Although wheezing frequently occurs in infective exacerbations of COPD, there is no evidence that antibiotics are helpful in the management of patients with asthma. Yellow or green sputum containing eosinophils and bronchial epithelial cells may be coughed up in | acute exacerbations of asthma. This is normally due to viral, not bacterial, infection and antibiotics are not required. Occasionally, mycoplasma and chlamydia infections can cause chronic relapsing asthma. The use of appropriate antimicrobials is worthwhile only if a bacterial diagnosis has been established by culture or serology.

Management of asthma exacerbations

(Emergency box 14.2)

The term 'status asthmaticus' was defined as asthma that had failed to resolve with therapy in 24 hours. Although this term is still used occasionally, it has now been discarded and replaced by 'acute severe asthma', i.e. severe asthma that has not been controlled by the patient's use of medication.

Asthma attack

If the PEF is greater than 150 L/min, patients may improve dramatically on nebulized therapy and may not require hospital admission. Their regular treatment should be increased, to include treatment for 2 weeks with 30 mg of prednisolone followed by a gradual reduction in the oral dose and substitution by an inhaled corticosteroid preparation.

Emergency Box 14.2 Treatment of severe asthma

At home

1. The patient is assessed. Tachycardia, a high respiratory rate and inability to speak in sentences indicate a severe attack.
2. If the PEFR is less than 150 L/min (in adults), an ambulance should be called. (All doctors should carry peak flow meters.)
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is administered.
4. Hydrocortisone sodium succinate 200 mg i.v. is given.
5. Oxygen 40-60% is given if available.
6. Prednisolone 60 mg is given orally.

At hospital

1. The patient is reassessed.
2. Oxygen 40-60% is given.
3. The PEFR is measured using a low-reading peak flow meter, as an ordinary meter measures only from 60 L/min upwards.
   Measure O_2 saturation with a pulse oximeter.
4. Nebulized salbutamol 5 mg or terbutaline 10 mg is repeated and administered 4-hourly.
5. Add nebulized ipratropium bromide 0.5 mg to nebulized salbutamol/terbutaline.
6. Hydrocortisone 200 mg i.v. is given 4-hourly for 24 hours.
7. Prednisolone is continued at 60 mg orally daily for 2 weeks.
8. Arterial blood gases are measured; if the P_aco_2 is greater than 7 kPa, ventilation should be considered.
9. A chest X-ray is performed to exclude pneumothorax.
10. One of the following intravenous infusions is given if no improvement is seen: salbutamol 3-20 ug/min, or terbutaline 1.5-5.0 ug/min, or magnesium sulphate 1.2-2 g over 20 min.

Patients with *acute severe asthma* typically have:

- inability to complete a sentence in one breath
- respiratory rate > 25 breaths per minute
- tachycardia > 110 beats/min (pulsus paradoxus, p. 736, is not useful as it is only present in 45% of cases)
- PEF < 50% of predicted normal or best.

Features of life-threatening attacks are:

- a silent chest, cyanosis or feeble respiratory effort
- exhaustion, confusion or coma
- bradycardia or hypotension
- PEF < 30% of predicted normal or best (approximately 150 L/min in adults).

Arterial blood gases should always be measured in asthmatic patients requiring admission to hospital. Pulse oximetry is useful in monitoring oxygen saturation during the admission and reduces the need for repeated arterial puncture. Features suggesting very severe life-threatening attacks are: ■. .

a high P_aco_2 > 6 kPa
- severe hypoxaemia P_ao_2 < 8 kPa despite treatment with oxygen
- a low and falling arterial pH.

Treatment is commenced with 5 mg of nebulized salbutamol or 10 mg terbutaline with oxygen as the driving gas. Nebulized antimuscarinics (e.g. ipratropium bromide) are also helpful. A chest X-ray is taken to exclude a pneumothorax. If no improvement occurs with nebulized therapy, intravenous infusions of f5-agonist (salbutamol or terbutaline 250 ng over 10 min) and/ or magnesium sulphate (1.2-2 g over 20 min) should be used. Intravenous aminophylline is not now given as trials show no benefit. Hydrocortisone 200 mg i.v. should be administered 4-hourly for 24 hours, and 60 mg of prednisolone should be given orally daily. In patients who do not respond to this regimen, ventilation is often required.

Ideally, patients should be kept in hospital for at least 5 days, since the majority of sudden deaths occur 2-5 days after admission. During this time oxygen saturation should be monitored by oximetry. Oral prednisolone can be reduced from 60 mg to 30 mg once improvement occurs. Further reduction should be gradual on an outpatient basis until an appropriate maintenance dose or substitution by inhaled corticosteroid aerosols can be achieved.

Management of catastrophic sudden severe (brittle) asthma

This is an unusual variant of asthma in which patients are at risk from sudden death in spite of the fact that their asthma may be well controlled between attacks. Severe life-threatening attacks may occur within hours or even minutes. Such patients require a carefully worked out management plan agreed by respiratory physician, primary care physician and patient, and require:

- emergency supplies of medications at home, in the car and at work
- oxygen and resuscitation equipment at home and at work
- nebulized (3_2 agonists at home and at work
- self-injectable epinephrine (adrenaline): two Epipens of 0.3 mg epinephrine at home, at work and to be carried by the patient at all times
- prednisolone 60 mg
- Medic Alert bracelet.

On developing wheeze, the patient should attend the nearest hospital immediately. Direct admission to intensive care may be required.

Prognosis of asthma

Although asthma often improves in children as they reach their teens, it is now realized that the disease frequently returns in the second, third and fourth decades. In the past the data indicating a natural decrease in asthma through teenage years have led to childhood asthma being treated as an episodic disorder. However, airway inflammation is present continuously from an early age and usually persists even if the symptoms resolve. Moreover, airways remodelling accelerates the process of decline in lung function over time. This has led to a reappraisal of the treatment strategy for asthma, mandating the early use of controller drugs and environmental measures from the time asthma is first diagnosed.

PNEUMONIA

Pneumonia may be defined as an inflammation of the substance of the lungs. It is usually caused by bacteria. Clinically it presents as an acute illness characterized in the majority of cases by the presence of cough, purulent sputum and fever together with physical signs or radiological changes compatible with consolidation of the lung. The advent of antibiotics has decreased dramatically the mortality from pneumonia among young people but it remains a dangerous condition. Pneumonia is a major cause of death in individuals over the age of 70 years. Bacterial pneumonia is more frequent in HIV-infected individuals than in the general population, particularly in HIV-infected intravenous drug users. The causative agents are the same as found in non-HIV community-acquired pneumonia.

Classification

Pneumonia can be classified both anatomically and on the basis of the aetiology.

Classification by site

Pneumonias are either localized, with the whole of one or more lobes affected, or diffuse, when they primarily affect the lobules of the lung, often in association with the bronchi and bronchioles - a condition referred to as 'bronchopneumonia'. , ,..-.,,.-. -..,..,..;..

Table 14.13 **The aetiology of pneumonia in the UK**

Infecting agent	Frequency as a cause of pneumonia (%)	Clinical circumstances
	50	Community pneumonia patients usually previously fit
Streptococcus pneumoniae		As above As above
Mycoplasma pneumoniae		
Influenza A virus (usually with a bacterial component)		Pre-existing lung disease: COPD Community-acquired pneumonia Contact with birds (though not inevitable) Children, intravenous drug abusers, associated with influenza virus infections Institutional outbreaks (hospitals and hotels), sporadic, endemic Abattoir and animal-hide workers Cystic fibrosis
Haemophilus influenzae	5	
Chlamydia pneumoniae	5	
Chlamydia psittaci	3	
Staphylococcus aureus	2	
Legionella pneumophila	2	
Coxiella burnetii	1	AIDS, lymphomas, leukaemias, use of cytotoxic drugs and corticosteroids
Pseudomonas aeruginosa	<1	
Pneumocystis carinii		
Actinomyces israelii		
Nocardia asteroides	<1	Inhalation pneumonia, alcohol abuse, postoperative
Cytomegalovirus		
Aspergillus fumigatus		
Anaerobic organisms	<1	
None isolated	20	

Classification by aetiology

An aetiological factor can be discovered in approximately 75% of patients. The term 'atypical pneumonia' has been used to describe pneumonia caused by agents such as *Mycoplasma, Legionella, Chlamydia* and *Coxiella burnetii.* While these pneumonias can differ from pneumococcal disease, there is a considerable overlap in clinical presentation and as these agents account for almost one-fifth of the cases of pneumonia (Table 14.13), the term 'atypical' has been dropped. Pneumonias may also result from:

- chemical causes, such as in the aspiration of vomit (see p. 927)
- radiotherapy (see p. 944)
- allergic mechanisms (see p. 939).

Mycobacterium tuberculosis is a cause of pneumonia; it is considered separately (p. 930), since both its mode of presentation and its treatment are very different from the other infective agents.

Precipitating factors

m Strep, pneumoniae - often follows viral infection with influenza or parainfluenza.

- Hospitalized 'ill' patients - often infected with Gram-negative organisms.
- Cigarette smoking (the strongest independent risk factor for invasive pneumococcal disease).
- Alcohol excess.
- Bronchiectasis (e.g. in cystic fibrosis).
- Bronchial obstruction (e.g. carcinoma) - occasionally associated with infection with 'non-pathogenic' organisms.
- Immunosuppression (e.g. AIDS or treatment with cytotoxic agents) - organisms include *Pneumocystis carinii, Mycobacterium avium-intracellulare,* cytomegalovirus.
- Intravenous drug abuse - frequently associated with *Staph. aureus* infection.
- Inhalation from oesophageal obstruction - often associated with infection with anaerobes.

Clinical features

The clinical presentation varies according to the immune state of the patient and the infecting agent. In the most common type of pneumonia - caused by *Strep, pneumoniae* - there is often a preceding history of a viral infection.

With *Strep, pneumoniae* infection the patient rapidly becomes more ill with a high temperature (up to 39.5°C), pleuritic pain and a dry cough. A day or two later, rusty-coloured sputum is produced and at about the same time the patient may develop labial herpes simplex. The patient breathes rapidly and shallowly, the affected side of the chest moves less, and signs of consolidation may be present together with a pleural rub. See Box 14.4 for severe community-acquired pneumonia.

Investigations

Chest X-ray confirms the area of consolidation (Fig. 14.35), but radiological changes lag behind the clinical course so that X-ray changes may be minimal at the start of the illness. Conversely, consolidation may remain on the chest X-ray for several weeks after the patient is clinically cured. The chest X-ray usually returns to normal by 6 weeks, except in patients with severe airflow limitation. Persistent changes on the chest X-ray after this time suggest a bronchial abnormality, usually a carcinoma, with persisting secondary pneumonia. Chest X-rays should rarely be repeated more frequently than at

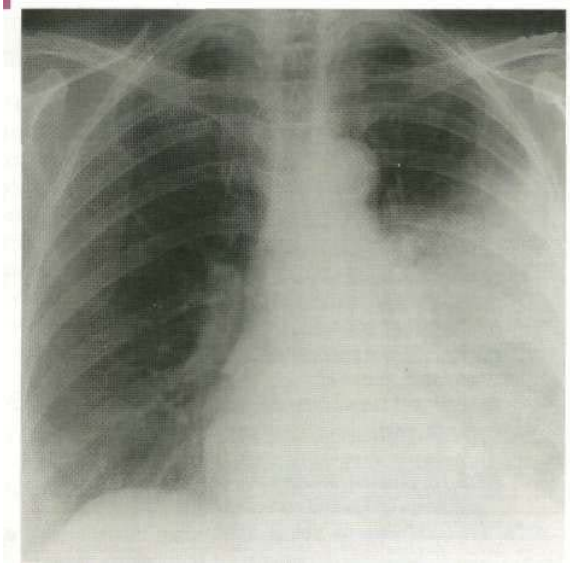

Fig. 14.35 Chest X-ray showing lobar pneumonia.

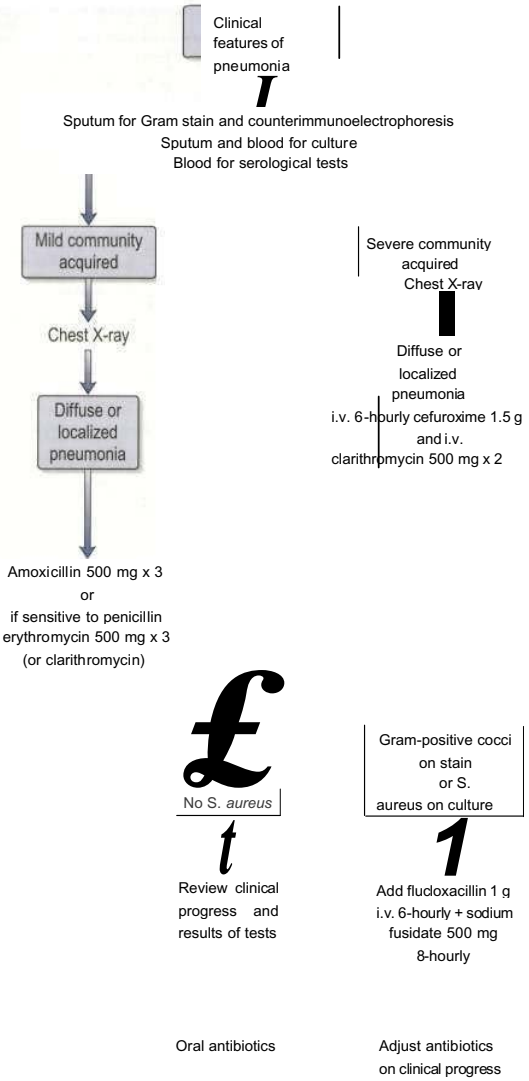

Fig. 14.36 **Algorithm for the** management of pneumonia (see also p. 928).

weekly intervals during the acute illness and then at 6 weeks after discharge from hospital.

In *Strep, pneumoniae* pneumonia, there is often a white blood cell count that is greater than 15 x 10^9/L (90% polymorphonuclear leucocytosis) and an erythrocyte sedimentation rate (ESR) greater than 100 mm/h.

TYPES OF PNEUMONIA

The individual features of various pneumonias are given below. The overall investigation and management is shown in Figure 14.36 and discussed on page 928.

Mycoplasma pneumonia

Mycoplasma pneumonia is relatively common and occurs in cycles of 3-4 years. It often occurs in patients in their teens and twenties, frequently amongst those living in boarding institutions. Generalized features such as headaches and malaise often precede the chest symptoms by 1-5 days. Cough may not be obvious initially and physical signs in the chest may be scanty.

On chest X-ray, usually only one lobe is involved but sometimes there may be dramatic shadowing in both lungs. There is frequently no correlation between the X-ray appearances and the clinical state of the patient.

The white blood cell count is not raised. Cold agglutinins occur in half of the cases. The diagnosis is confirmed by a rising antibody titre. Treatment is with macrolides, e.g. erythromycin 500 mg four times daily for 7-10 days. Tetracycline is also effective.

Although most patients recover in 10-14 days, the disease can be protracted, with cough and X-ray changes lasting for weeks and relapses occurring. Lung abscesses and pleural effusions are rare.

Extrapulmonary complications can occur at any time during the illness and occasionally dominate the clinical picture. Most are rare but they include:

myocarditis and pericarditis ■ ,
rashes and erythema multiforme : /
haemolytic anaemia and thrombocytopenia
myalgia and arthralgia
meningoencephalitis and other neurological abnormalities ■ gastrointestinal symptoms (e.g. vomiting, diarrhoea).

Viral pneumonia

Primary viral pneumonia is uncommon in adults, influenza A virus or adenovirus infection being the

commonest causes. More often, viral infection predisposes patients to bacterial pneumonia by damaging the respiratory epithelium and facilitating bacterial infection.

Influenza A (HSNI) normally does not affect humans but recently has been transmitted from fowls (Avian flu), crossing the species barrier. Patients present with fever, breathlessness, cough (similar to the Hong Kong outbreak in 1997 - H5NI) and diarrhoea. Lymphopenia and thrombocytopenia are present and pulmonary infiltrates are seen on chest X-ray. There is a high mortality. Live poultry markets in Asian countries are the breeding ground, and mass culling of chicken and other poultry was performed in 1997,1999 and 2004.

Severe acute respiratory syndrome (SARS) is due to a novel coronavirus (see p. 38). The incubation period is approximately 5 days with spread between humans mainly by droplet infection. The outbreak in 2003 affected many healthcare workers. Fever, malaise, headache and rigors were followed in the second week by cough, breathlessness and diarrhoea. Lymphopenia, thrombocytopenia and pulmonary infiltrates (mainly in the lower zones) occur. At the end of the second week 20% of patients deteriorate, developing ARDS, and the mortality is high.

Other pneumonias

Haemophilus influenzae

H. influenzae is a frequent cause of exacerbation of chronic bronchitis and can cause pneumonia in COPD patients. The pneumonia can be diffuse or confined to one lobe. There are no special features to separate it from other bacterial pneumonias. It responds well to treatment with oral amoxicillin 500 mg x 4 daily.

Chlamydia psittaci (see also p. 67) Typically the individual has been exposed to infected birds, especially parrots, but cases may occur without a history of contact. The incubation period is 1-2 weeks and the disease may pursue a very low-grade course over several months. Symptoms include malaise, high fever, cough and muscular pains. The liver and spleen are occasionally enlarged, and scanty 'rose spots' may be seen on the abdomen. The chest X-ray shows segmental or a diffuse pneumonia. Occasionally the illness presents with a high, swinging fever and dramatic prostration with photophobia and neck stiffness that can be confused with meningitis. The diagnosis is confirmed by the demonstration of a rising titre of complement-fixing antibody. Macrolides or tetracycline are the antibiotics of choice.

Chlamydia pneumoniae

Outbreaks of *C. pneumoniae* have been reported in institutions and within families, suggesting person-to-person spread without any avian or animal reservoir. Serological tests on patients admitted to hospital with community-acquired pneumonia suggest that 5-10% may be the result of *C. pneumoniae* infection. In general, disease is mild with 50% of *C. pneumoniae* infections presenting as pneumonia, 28% as acute bronchitis, 10% with a flu-like illness and 12% with upper respiratory illnesses. Type-specific microimmunofluorescence tests are required to distinguish *C. pneumoniae* from *C. psittaci* and *C. trachomatis*. Treatment is with macrolides or tetracycline.

Staphylococcus aureus

Staph. aureus rarely cause pneumonia except after a preceding influenzal viral illness. The infection starts in the bronchi, leading to patchy areas of consolidation in one or more lobes, which break down to form abscesses. These may appear as cysts on the chest X-ray.

Pneumothorax, effusion and empyemas are frequent. Septicaemia develops with metastatic abscesses in other organs. All patients with staphylococcal pneumonia are very ill; intravenous antibiotics must be administered promptly, but are not always effective. Fulminating staphylococcal pneumonia can lead to death in hours.

Areas of pneumonia (septic infarcts) are also seen in staphylococcal septicaemia. This is frequently seen in intravenous drug abusers, and in patients with central catheters being used for parenteral nutrition. The infected puncture site is the source of the staphylococcus. Pulmonary symptoms are often few but breathlessness and cough occur and the chest X-ray reveals areas of consolidation. Abscess formation is frequent.

Diagnosis and treatment are shown in Figure 14.36.

***Coxiella burnetii* (Q-fever)** (see also p. 78) The patient develops systemic symptoms of fever, malaise and headache, often associated with multiple lesions on the chest X-ray. The illness may run a chronic course and is occasionally associated with endocarditis. Diagnosis is made by an increase in the titre of complement-fixing antibody. Treatment is usually with macrolides or tetracycline. Severe cases may require rifampicin.

Legionella pneumophila

Three epidemiological patterns of this disease are recognized:

- outbreaks among previously fit individuals staying in hotels, institutions or hospitals where the shower facilities or cooling systems have been contaminated with the organism
- sporadic cases where the source of the infection is unknown; most cases involve middle-aged and elderly men who are smokers, but it is also seen in children
- outbreaks occurring in immunocompromised patients, e.g. on corticosteroid therapy.

Legionella grows well in water up to 40°C in temperature, and the infection is almost certainly spread by the aerosol route. Adequate chlorination and temperature control of the water supply are necessary to prevent the disease.

The incubation period is 2-10 days. Males are affected twice as commonly as females. The infection may be

mild, but the characteristic picture is of malaise, myalgia, headache and a fever with rigors and a pyrexia of up to 40°C. Half of the patients have gastrointestinal symptoms, with nausea, vomiting, diarrhoea and abdominal pain. Patients may be acutely ill, with mental confusion and other neurological signs. Haematuria occurs and occasionally renal failure.

The patient is tachypnoeic with an initially dry cough that later may become productive and purulent. The chest X-ray usually shows lobar and then multilobar shadowing, sometimes with a small pleural effusion. Cavitation is rare.

A strong presumptive diagnosis of *L. pneumophila* infection is possible in the majority of patients if they have three of the four following features:

- a prodromal virus-like illness
- a dry cough, confusion or diarrhoea
- lymphopenia without marked leucocytosis
- hyponatraemia.

Hypoalbuminaemia and high serum levels of liver aminotransferases are also common in this disease.

Diagnosis is confirmed by the direct immunofluorescent staining of the organism in the pleural fluid, sputum or bronchial washings. The organism is not seen on Gram staining. Culture on special media is possible but takes up to 3 weeks. A urinary antigen test is commercially available and is highly specific. Retrospective confirmation can be made by demonstrating a four-fold increase in antibody titre in the blood.

Treatment is usually with one of the macrolides, clarithromycin now being the drug of choice. Ciprofloxacin is also effective and rifampicin can be used in addition in ill patients. Mortality can be up to 30% in elderly patients but most patients recover fully.

Gram-negative bacteria

These are the cause of many hospital-acquired pneumonias but they are occasionally responsible for cases in the community.

Klebsiella pneumoniae

Pneumonia due to *Klebsiella* usually occurs in elderly people with a history of heart or lung disease, diabetes, alcohol excess or malignancy. The onset is often sudden, with severe systemic upset. The sputum is purulent, gelatinous or blood-stained. The upper lobes are more commonly affected and the consolidation is often extensive. There is often swelling of the infected lobe so that on the lateral chest X-ray there is bulging of the fissures. The organism can be found in the sputum or in the blood.

Treatment is dependent on the sensitivity of the organism, but a cephalosporin is usually required. The mortality is high, partly owing to the presence of the predisposing condition.

Pseudomonas aeruginosa

Pneumonia due to *Pseudomonas* is of considerable significance in patients with cystic fibrosis, since it correlates with a worsening clinical condition and mortality. It is also seen in patients with neutropenia following cytotoxic chemotherapy. The isolation of *P. aeruginosa* from sputum must be interpreted with care because the organism grows well on bacterial culture medium and may simply represent contamination from the upper airways.

Treatment. Pseudomonas and other Gram-negative infections respond well to treatment with the 4-quinolone antibiotic ciprofloxacin (200^100 mg i.v. over 30-60 minutes twice daily) or ceftazidime (2 g bolus i.v. 8-hourly). Ticarcillin (15-20 g daily i.v. infusion) and piperacillin are active against these bacilli. These penicillins are usually given in combination with an aminoglycoside, e.g. gentamicin or netilmicin, for maximum benefit.

Treatment regimens may have to be modified in the light of sensitivity testing. Aminoglycosides are nephrotoxic and ototoxic, so blood levels should be monitored (p. 995).

Moraxella catarrhalis

This organism has been found to be associated with exacerbations of COPD and occasionally with fatal pneumonia. Some strains produce a pHactamase capable of destroying amoxicillin. The exact role of this organism in bronchopulmonary infection remains to be determined.

Anaerobic bacteria

Infections with these organisms usually occur in patients with an underlying condition, such as diabetes, and are often associated with aspiration. Bacteroides is the most common organism and is sensitive to metronidazole. The prognosis depends largely on the precipitating cause.

Pneumonias due to opportunistic infections

Immunocompromised patients develop pneumonia with all the usual organisms and with a number of organisms which do not normally cause illness in healthy hosts. However, with HAART (p. 143) the incidence of these infections has fallen dramatically in AIDS patients.

Pneumocystis carinii

This is by far the most common opportunistic infection, accounting for 50% of the cases of pneumonia in patients with acquired immunodeficiency syndrome (AIDS) (see p. 136) particularly when the CD4 lymphocyte count is $< 200/mm^3$. It is also seen in patients receiving immunosuppressive therapy. In the developing world, however, *Pneumocystis carinii* pneumonia (PCP) is not infrequently found in malnourished children. P. *carinii* is found in the air, and pneumonia arises from reinfection rather than reactivation of persisting organisms acquired in childhood. Clinically the pneumonia is associated with a high fever, breathlessness and dry cough. In patients with

AIDS, the clinical features are described on page 132. The typical radiographic appearance of PCP is of a diffuse bilateral alveolar and interstitial shadowing beginning in the perihilar regions and spreading out in a butterfly pattern. Other chest X-ray appearances include localized infiltration, nodules, cavitation or a pneumothorax. In patients receiving aerosolized pentamidine for prophylaxis, in countries where HAART is not available, infiltrates may be localized to the upper zones. Empirical treatment of PCP is justified in very sick high-risk cases, but wherever possible a firm diagnosis should be obtained by stimulation of sputum with hypertonic saline or fibreoptic bronchoscopy with bronchoalveolar lavage; the diagnosis can be made in 90% of cases by staining sputum using indirect immunofluorescence with monoclonal antibodies.

Other causes of shadowing on the chest X-ray in AIDS patients include:

cytomegalovirus
M. avium-intracellulare
M. *tuberculosis*
L. pneumophila
Cryptococcus
pyogenic bacteria
Kaposi's sarcoma
lymphoid interstitial pneumonia
non-specific interstitial pneumonitis.

Treatment of PCP is with high-dose co-trimoxazole (see p. 136).

Actinomyces israelii (see also p. 90) The clinical picture is that of severe pneumonia, lung abscess or empyema. Treatment is surgical drainage when appropriate, with high-dose intravenous penicillin for 4–6 weeks.

Nocardia asteroides

This produces a similar picture to *Actinomyces,* though of greater severity. The chest X-ray often shows irregular opacities in one or both lungs, particularly in the mid-zones. Treatment is with sulfadiazine in doses up to 9 g daily.

Cytomegalovirus (see also p. 46)

Bronchitis and pneumonia may occur but these are usually a more minor part of the generalized systemic illness.

Aspergillus fumigatus (see also p. 939)

This fungus gives rise to a widespread invasion of lung tissue in patients who are immunocompromised. It is a serious pneumonia that is usually rapidly fatal. Treatment is with amphotericin and flucytosine.

Mycobacterium avium-intracellulare (MAI)

This bacterium causes lung disease in patients with AIDS primarily as part of disseminated disease when CD4 lymphocyte counts are < 100/mm^3, with the pulmonary complications being of less significance than the extrapulmonary involvement. Therapeutic regimens include combinations of rifabutin or rifampicin, with ethambutol, clofazimine and clarithromycin. Azithromycin and ciprofloxacin with rifabutin and ethambutol is also used.

Cryptococcus

Infection with this fungus is usually disseminated but pulmonary involvement includes intrathoracic lymph node enlargement and effusions.

Kaposi's sarcoma (see also pp. 142 and 1353) This malignancy affecting HIV-infected homosexual men is seen rarely since the introduction of HAART (see p. 143). Intrathoracic involvement usually follows cutaneous manifestations and includes nodules or infiltrates in the lungs with lymph node enlargement and endobronchial lesions. Symptoms are those of progressive dyspnoea and cough. Chest X-ray appearances are non-specific. Bronchoscopy reveals multiple red or purple flat lesions which are not biopsied because of difficulty with histological diagnosis in crushed fragments and risk of haemorrhage. Treatment is with chemotherapy, vincristine 2 mg and bleomycin 10 mg/m^2 every 3 weeks.

Lymphoid interstitial pneumonia

This condition is more common in children than in adults and is characterized by infiltration with lymphocytes, plasma cells and immunoblasts. It is thought to be a viral pneumonia and causes diffuse reticulonodular infiltrates on the chest X-ray. Corticosteroid therapy appears to be of benefit, as is zidovudine.

Rare causes of pneumonia

Pneumonia may be seen as a minor feature in the course of infection by *Bordetella pertussis,* typhoid and paratyphoid bacillus, brucellosis, leptospirosis and a number of viral infections including measles, chickenpox and glandular fever. Details of these infections are described in Chapter 2.

Aspiration pneumonia

The acute aspiration of gastric contents into the lungs can produce an extremely severe and sometimes fatal illness owing to the intense destructiveness of gastric acid. This has been termed Mendelson's syndrome and can complicate anaesthesia, particularly during pregnancy.

In the absence of a tracheo-oesophageal fistula, aspiration occurs only during periods of impaired consciousness (e.g. during sleep), in reflux oesophagitis with an oesophageal stricture, or in bulbar palsy. Because of the bronchial anatomy, the most usual sites for spillage are the apical and posterior segments of the right lower lobe. The persistent pneumonia is often due to anaerobes and it may progress to lung abscess or even bronchiectasis. It is vital to identify any underlying problem, since appropriate corrective measures can lead to resolution of the pulmonary problems.

Treatment is discussed on page 929.

Cryptogenic organizing pneumonia (COP)

This condition, also called bronchiolitis obliterans organizing pneumonia (BOOP), is an organizing pneumonia of unknown aetiology. No infective agent has been described. Typically, patients present with single or recurrent episodes of malaise associated with cough, breathlessness and fever. Pleuritic chest pain is sometimes present but finger clubbing is very rare. Chest X-rays show confluent bilateral parenchymal shadowing. Lung function tests may show a restrictive defect. The white blood count is normal, but the ESR may be raised. Open lung biopsy will reveal characteristic buds of connective tissue in respiratory bronchioles and in alveolar ducts. These are diagnostic, but the diagnosis is usually made on history and X-ray appearances. The disease responds rapidly to corticosteroid treatment but may recur episodically especially in older women.

Diffuse pneumonia (bronchopneumonia)

Diffuse pneumonia is very common. It is differentiated from severe bronchitis by signs of bronchial breathing or patchy shadows on the chest X-ray. Widespread diffuse pneumonia is a common terminal event, resulting from an inability of patients dying from other conditions (e.g. cancer) to cough up retained secretions, allowing infection to develop throughout the lungs. Decisions on therapy will vary according to the particular clinical circumstances but aggressive antibacterial treatment is rarely appropriate.

GENERAL MANAGEMENT OF PNEUMONIA

Refer to the algorithm given in Figure 14.36. Sputum and blood should always be sent for culture but antibiotic treatment should not be delayed. Severe cases need to be admitted to hospital and a chest X-ray performed. Other investigations, e.g. blood gases, are useful to detect respiratory failure and provide a baseline for comparison if the patient deteriorates.

Further investigations may be necessary for the diagnosis of certain types of pneumonia:

- *Pneumococcal antigen* - counter-immunoelectrophoresis (CIE) of sputum, urine and serum (three to four times more sensitive than sputum or blood cultures)
- *Mycoplasma antibodies* (IgM and IgG) - in acute and convalescent samples - cold agglutinins present in 50%
- *Legionella and Chlamydia antibodies* - immunofluorescent tests
- *Legionella antigen* - in urine.

The choice of antibiotics is inevitably empirical, especially in those patients treated in the community. Empirical therapy is largely directed at *Strep, pneumoniae* infections. Apart from mycoplasma, the other pathogens are responsible for a small minority of infections. Acquired antibiotic resistance of common respiratory bacterial pathogens is recognized as a concern, but is still rare in the UK and rarely causes clinical failure. There is no convincing evidence that newer antibiotics provide any significant therapeutic advantage over established therapies. For treatment of mild community-acquired pneumonia, oral amoxicillin remains the preferred agent, but should be given at a dose of at least 500 mg 8-hourly. Oral erythromycin (or clarithromycin, which is better tolerated) is an alternative choice for those sensitive to penicillin. For more severe cases treated in hospital, combined therapy with amoxicillin and a macrolide (erythromycin or clarithromycin) is recommended. When oral therapy is contraindicated, parenteral ampicillin or benzylpenicillin should be combined with clarithromycin. If *Staph. aureus* infection is suspected or is proven on culture, intravenous flucloxacillin ± sodium fusidate should be added. Fluoroquinolones are recommended for those intolerant of penicillins or macrolides. For severe cases, parenteral antibiotics should be given with the combination of a broad-spectrum lactamase-stable beta-lactam antibiotic (co-amoxiclav or cefuroxime) and clarithromycin. Parenteral antibiotics should be switched to oral once the temperature has settled for a period of 24 hours and provided there is no contraindication to oral therapy. The choice of antibiotics may be narrowed once microbiological results are available but it should be remembered that up to 10% of pneumonias may have mixed infections.

The overall mortality for patients admitted to hospital with community-acquired pneumonia is currently 5%, except for pneumonia due to *Staph. aureus* where it exceeds 25%. Patients who die from pneumonia usually have not received the appropriate antibiotics in sufficient doses before or during the early stages of hospital admission.

Box 14.4 shows features of *severe community-acquired pneumonia* which indicate a poorer prognosis. In spite of treatment in the intensive care unit, approximately 50% of such patients will die.

General measures

These include care of the mouth and skin. Fluids should be given to avoid dehydration. The patient is normally nursed sitting up or in the most comfortable position.

Box 14.4 **Criteria for the diagnosis of *severe* community-acquired pneumonia**

Clinical features

- Respiratory rate > 30/min
- Diastolic blood pressure < 60 mmHg
- Confusion
- High mortality particularly in those > 65 years old
- Co-morbidity

Investigations

- Chest X-ray - more than one lobe involved
- P_aO_2 < 8 kPa
- Low albumin (< 35 g/L)
- White cell count (low < 10^9/L or high > 20 x 10^9/L)
- Raised serum urea (> 7 mmol/L)
- Blood culture - positive

Cough should normally be encouraged, but if it is unproductive and distressing, suppressants such as codeine linctus can be given. Physiotherapy is needed to help and encourage the patient to cough. Pleuritic pain may require analgesia, but powerful analgesia (e.g. opiates) should be used with care because they cause respiratory depression. In severe hypoxia, oxygen therapy should be given. However, since the hypoxia is often due to a physiological shunt, it makes little difference to the hypoxaemia.

Hospital-acquired (nosocomial) pneumonias

Patients with mild forms of hospital-acquired pneumonias need to be reviewed carefully to make sure that there is nothing else responsible for their deterioration (e.g. heart failure, pulmonary embolism). Although very mild forms of hospital-acquired pneumonia may be treated with co-amoxiclav 500 mg three times daily, most cases will have co-morbidities which will dictate more aggressive antibiotic therapy. These should be managed in the same way as severe community-acquired pneumonias once appropriate samples for culture and sensitivities have been taken. Gram-negative bacteria are common and treatment should normally include a third-generation cephalosporin (e.g. cefuroxime) and aminoglycosides (e.g. gentamicin). Patients with chronic chest infection and others in whom *Pseudomonas* infection is suspected should receive i.v. ciprofloxacin or ceftazidime. Immunosuppressed patients may require very high-dose broad-spectrum antibiotics as well as antifungal and antiviral agents. Aspiration pneumonia (p. 927) is relatively common in hospital and usually involves infection with multiple bacteria, including anaerobes. The oral route is usually inappropriate in these patients. A combination of metronidazole (intravenous or rectal) and either co-amoxiclav or cefuroxime i.v. is recommended.

COMPLICATIONS OF PNEUMONIA

Lung abscess

This term is used to describe severe localized suppuration in the lung associated with cavity formation on the chest X-ray, often with the presence of a fluid level, and not due to tuberculosis.

There are many causes of lung abscesses, but the most common is aspiration, particularly amongst alcohol abusers following aspiration pneumonia. Lung abscesses also frequently follow the inhalation of a foreign body into a bronchus and occasionally occur when the bronchus is obstructed by a bronchial carcinoma. Chronic or subacute lung abscesses follow an inadequately treated pneumonia.

Abscesses may develop during the course of specific pneumonias, particularly when the infecting agent is *Staph. aureus* or *Klebsiella pneumoniae*. Septic emboli, usually staphylococci, result in multiple lung abscesses. Infarcted areas of lung occasionally cavitate and rarely become infected. Amoebic abscesses may occasionally develop in the right lower lobe following transdiaphragmatic spread from an amoebic liver abscess.

The clinical features are those of persisting and worsening pneumonia associated with the production of large quantities of sputum, which is often foul-smelling owing to the growth of anaerobic organisms. There is usually a swinging fever; malaise and weight loss occur. The chest signs may be few but clubbing often develops if the condition is not rapidly cured. The patient is often anaemic with a high ESR. ....

Empyema

Empyema means the presence of pus within the pleural cavity. This usually arises from bacterial spread from a severe pneumonia or after the rupture of a lung abscess into the pleural space. Typically an empyema cavity becomes infected with anaerobic organisms and the patient is severely ill with a high fever and a neutrophil granulocytosis.

Investigations

Bacteriological investigation of lung abscess and empyema is best conducted on specimens obtained by transtracheal aspiration, bronchoscopy or percutaneous transthoracic aspiration with ultrasound or CT guidance. Bronchoscopy is helpful to exclude carcinomas and foreign bodies.

Treatment

Although anaerobic organisms are found in up to 70% of lung abscesses and empyemas, there is usually a mixed flora, often with aerobes, particularly *Strep, milleri*. Anaerobic cocci, black-pigmented bacteroids and fusobacteria are the anaerobes found most commonly.

Empyemas should be treated by prompt tube drainage or by rib resection and drainage of the empyema cavity under ultrasound control. Appropriate antibiotic treatment is given for up to 6 weeks. Antibiotics should be given to cover both aerobic and anaerobic organisms. An appropriate initial choice is cefuroxime 1 g i.v. 6-hourly and metronidazole 500 mg i.v. 8-hourly for 5 days, followed by oral cefaclor and metronidazole for a prolonged period depending on bacterial sensitivities. Abscesses occasionally require surgery.

TUBERCULOSIS

Following many decades of decline, tuberculosis is on the increase in developed countries, because of AIDS, the use of immunosuppressive drugs which depress the host defence mechanisms, decreased socio-economic conditions, as well as increased immigration of persons from areas of high endemicity. In developing countries it is 20-50 times more common. There were 9 million new cases in 2000 world-wide. The major reason for this increase was because of the rapid rise in cases from sub-Saharan Africa (due to AIDS) and Russia.

Epidemiology

Tuberculosis is the world's leading cause of death from a single infectious disease, with two million deaths (without HIV infection) in 2000. This is the result of:

- inadequate programmes for disease control with poorly supervised treatment
- multiple drug resistance (MDR)
- co-infection with HIV
- a rapid rise in the world's population of young adults - the age group with the highest mortality from tuberculosis
- overcrowding and poor nutrition.

Tuberculosis is a notifiable disease in the UK; the number of cases is stable, with 6669 notifications in 2001. The incidence of tuberculosis in immigrants from the Asian subcontinent and from the West Indies is respectively forty and four times as common as in the native white population. This has led to great variation in the frequency of the disease in different areas of the UK.

Pathology

The first infection with M. *tuberculosis* is known as primary tuberculosis. It is usually subpleural, often in the mid to upper zones (Ghon focus). Within an hour of reaching the lung, tubercle bacilli reach the draining lymph nodes at the hilum of the lung and a few escape into the bloodstream.

The initial reaction comprises an exudative response and infiltration with neutrophil granulocytes. These are rapidly replaced by macrophages that ingest the bacilli. These interact with T lymphocytes, with the development of cellular immunity that can be demonstrated 3-8 weeks after the initial infection by a positive reaction in the skin to an intradermal injection of protein from tubercle bacilli (tuberculin/PPD). A delayed hypersensitivity-type reaction occurs, resulting in tissue necrosis, and at this stage the classical pathology of tuberculosis can be seen. Granulomatous lesions consist of a central area of necrotic material of a cheesy nature, called caseation, surrounded by epithelioid cells and Langhans' giant cells with multiple nuclei, both cells being derived from the macrophage. Lymphocytes are present and there is a varying degree of fibrosis. Subsequently the caseated areas heal completely and many become calcified. It is known that at least 20% of these calcified primary lesions contain tubercle bacilli, initially lying dormant but capable of being activated by depression of the host defence system. Reactivation leads to typical post-primary pulmonary tuberculosis with cavitation, usually in the apex or upper zone of the lung. 'Post-primary tuberculosis' refers to all forms of tuberculosis that occur after the first few weeks of the primary infection when immunity to the mycobacterium has developed.

Clinical features and investigations

Primary tuberculosis is symptomless in the great majority of individuals. Occasionally there may be a vague illness, sometimes associated with cough and wheeze. A small transient pleural effusion or erythema nodosum may occur, both representing hypersensitivity manifestations of the infective process.

Enlargement of lymph nodes compressing the bronchi can give rise to collapse of segments or lobes of the lung. Apart from cough and a monophonic wheeze, the individual remains remarkably well and the collapse disappears as the primary complex heals. Occasionally, persistent collapse can give rise to subsequent bronchiectasis, often in the middle lobe (Brock's syndrome).

The manifestations of primary and post-primary tuberculosis are shown in Figure 14.37, together with the times when they usually occur. Extrapulmonary manifestations are summarized on page 86. Miliary tuberculosis can occur within a year of the primary infection, or can occasionally occur much later as a manifestation of reactivation or, rarely, reinfection with tubercle bacillus.

Reactivation in the lung, or indeed in any extrapulmonary location, can occur as immunity wanes, usually with age or chronic ill-health. All manifestations are shown in Figure 14.37.

Miliary tuberculosis

This disease is the result of acute diffuse dissemination of tubercle bacilli via the bloodstream. It can be a difficult diagnosis to make, especially in older people, where it is particularly covert. This form of disseminated tuberculosis is universally fatal without treatment.

It may present in an entirely non-specific manner with the gradual onset of vague ill-health, loss of weight and then fever. Occasionally the disease presents as tuberculous meningitis. Usually there are no abnormal physical signs in the early stages, although eventually the spleen and liver become enlarged. Choroidal tubercles are seen in the eyes. These lesions are about one-quarter of the diameter of the optic disc and are yellowish and slightly shiny and raised in nature, later becoming white in the centre. There may be one or many in each eye.

The chest X-ray may be entirely normal in miliary tuberculosis as the tubercles are not visible until uniform miliary shadows 1-2 mm in diameter are seen throughout the lung; they have a hard outline. The lesions can increase in size up to 5-10 mm. Sarcoidosis and staphylococcal or *Mycoplasma* pneumonia can mimic the chest X-ray appearance of miliary tuberculosis. CT scanning may reveal lung parenchymal abnormalities at an earlier stage.

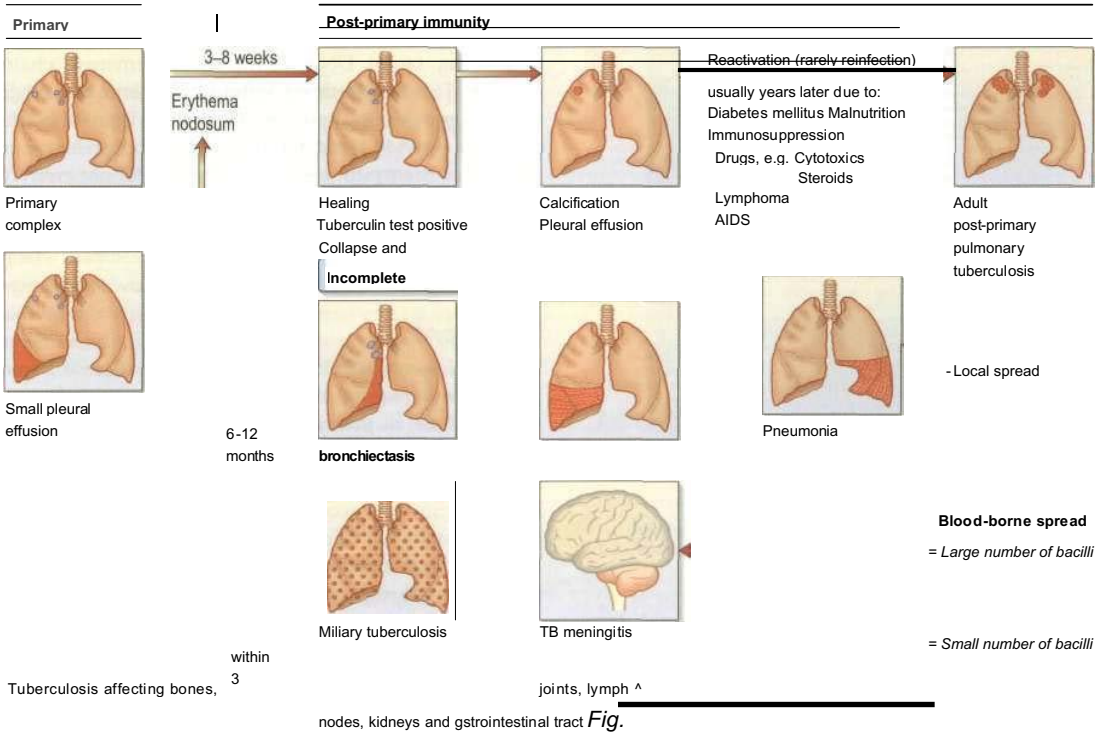

Fig. 14.37 Manifestations of primary and post-primary tuberculosis.

The Mantoux test is usually positive but may be negative in 30-50% of people with very severe disease. Trans-bronchial biopsies are frequently positive before any abnormality is visible on the chest X-ray.

Biopsy and culture of liver and bone marrow may be necessary in patients presenting with a pyrexia of unknown origin (PUO). A trial of antituberculous therapy can be used in individuals with a PUO. The fever should settle within 2 weeks of starting chemotherapy if it is due to tuberculosis. This approach is used in susceptible individuals when a diagnosis cannot be confimed by other means.

Adult post-primary pulmonary tuberculosis

Typically there is gradual onset of symptoms over weeks or months. Tiredness, malaise, anorexia and loss of weight together with a fever and cough remain the outstanding features of pulmonary tuberculosis. Drenching night sweats are rather uncommon and are more usually due to anxiety. Sputum in tuberculosis may be mucoid, purulent or blood-stained. Many patients suffer a dull ache in the chest and it is not uncommon for patients to complain of recurrent colds. A pleural effusion or pneumonia can be the presenting feature of tuberculosis.

Physical examination reveals little. Finger clubbing is only present if the disease is advanced and associated with considerable production of purulent sputum. There are often no physical signs in the chest even in the presence of extensive radiological changes, though occasionally persistent crackles may be heard. Physical signs of an associated effusion, pneumonia or fibrosis may be present.

Chest X-ray

An abnormal chest X-ray is often found with no symptoms, but the reverse is extremely rare - pulmonary tuberculosis is unlikely in the absence of any radiographic abnormality.

The chest X-ray (Fig. 14.38) typically shows patchy or nodular shadows in the upper zones, loss of volume, and fibrosis with or without cavitation. Calcification may be present. The X-ray appearances alone can strongly suggest tuberculosis, but every effort must be made to obtain microbiological evidence. A single X-ray does not give an indication of the activity of the disease. Very similar chest X-ray appearances occur in histoplasmosis and other fungal infections of the lung, including cryptococcosis, coccidioidomycosis, blastomycosis and aspergillosis, as well as in bronchial carcinoma or cavitating pulmonary infarcts.

Lymph node presentation of tuberculosis

The patient presents with a tender lump or fluctuant mass, usually supraclavicular or in the anterior triangle of the neck.

This form of tuberculosis is discussed on page 87.

Tuberculosis in HIV-infected persons

(see also p. 140)

Tuberculosis in an HIV-infected person is an AIDS-

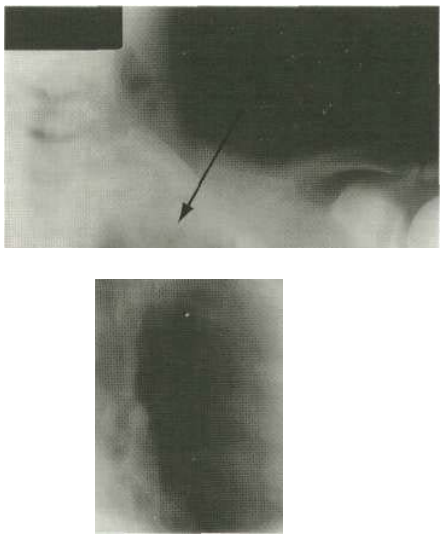

Fig. 14.38 Chest X-ray showing tuberculosis of left upper lobe with cavitation.

defining illness. Disease may arise from rapid progression of primary infection, by reactivation and by reinfection. The clinical pattern of disease is described on page 141. Treatment is with conventional therapy, but with four rather than three drugs, and it should be supervised (directly observed therapy short course, DOTS). Adverse drug reactions are common and the prognosis may be poor, especially if treatment is not supervised. Multiple drug resistance (MDR) occurs in about 6% of cases of tuberculosis in HIV-positive individuals.

Diagnosis

The diagnosis of tuberculosis is made on the basis of the following investigations:

- **Imaging.** Chest X-ray (see above), and CT scan if necessary.
- **Staining.** The sputum is stained with Ziehl-Neelsen (ZN) stain for acid and alcohol-fast bacilli (AAFB) or an auramine-phenol fluorescent test performed.
- **Culture.** The sputum is cultured on Ogana or Lowenstein-Jensen medium for 4-8 weeks. Liquid culture (Bactec (Becton-Dickinson)) is used in many laboratories and has the advantage of shorter culture times. Cultures to determine the sensitivity of the bacillus to antibiotics take a further *3-i* weeks.
- **Fibreoptic bronchoscopy** with washings from the affected lobes is useful if no sputum is available. This has replaced former techniques such as gastric washings. Transbronchial biopsies can also be obtained for histology and microbiological assessment.
- **Biopsies** of the pleura, lymph nodes and solid lesions within the lung (tuberculomas) may be required to confirm the diagnosis.

The slow growth of *M. tuberculosis* in culture has hindered the ability to make a rapid definitive diagnosis. Radiolabelled DNA and RNA probes specific for various mycobacterial species can identify organisms in culture. The sensitivity of these methods has been enhanced by amplifying target DNA using the polymerase chain reaction. This allows direct testing of sputum and other fluids to provide a laboratory diagnosis within 48 hours and may provide rapid information on the presence or absence of rifampicin resistance. This is still not entirely reliable and should not be accepted as a final diagnosis, particularly in the difficult case when it is most likely to be used. ELISA techniques have been developed which have high specificities, but unfortunately low sensitivity.

Treatment

Bed rest does not affect the outcome of the disease. Some patients will require hospitalization for a brief period; these include ill patients, smear-positive, highly infectious patients (particularly multidrug-resistant TB), those in whom the diagnosis is uncertain and those individuals from whom it is essential to gain cooperation. The most key factor in the successful treatment of tuberculosis is the continuous self-administration of drugs for 6 months; lack of patient compliance is a major reason why 5% of patients do not respond to treatment. In vitro resistance to one or more of the antituberculous drugs used to occur in fewer than 1% of patients in the UK, but the rate of resistance is gradually increasing (isoniazid resistance 4-6%, multidrug resistance 1%).

Directly observed therapy short course (DOTS)

In order to improve compliance, special clinics are used to supervise treatment regimens directly. Incentives to attend (e.g. free meals, cash payments) may be helpful. The effectiveness of DOTS is, however, variable in different countries and compliance is still a problem. Long-stay hospital treatment is required only for persistently uncooperative patients, many of whom are homeless and abuse alcohol.

Six-month regimen

Six-months' treatment with once-daily rifampicin 600 mg and isoniazid 300 mg is standard practice for patients with pulmonary and lymph node disease. (For those whose bodyweight is below 55 kg, rifampicin is reduced to 450 mg daily.) These are given as combination tablets and are taken 30 minutes before breakfast, since the absorption of rifampicin is influenced by food. This is supplemented for the first 2 months by pyrazinamide at a dose of 1.5 g (bodyweight < 50 kg) or 2.0 g daily. Pyrazinamide is of particular value in treating mycobacteria present within macrophages, and for this reason it may have a very valuable effect on preventing subsequent relapse. Pyridoxine 10 mg daily is given to reduce the risk of isoniazid-induced neuropathy. Current recommendations advise the addition of ethambutol (using 1 kg per day) if the risk of drug resistance is increased.

Longer regimens

Treatment of bone tuberculosis should be continued for a total of 9 months, and of tuberculous meningitis for

1 year. The drugs used are the same as for pulmonary tuberculosis, with pyrazinamide prescribed for the first 2 months only and for drug-resistant disease.

Drug-resistant organisms

The development of resistance after initial drug sensitivity *{secondary drug resistance)* occurs in patients who do not comply with the treatment regimens. *Primary drug resistance* is seen in immigrants to the UK and those exposed to others infected with resistant organisms. Multidrug resistance (MDR) is a major therapeutic problem with a high mortality and occurs mainly in HIV-infected patients. Nosocomial transmission of multidrug-resistant tuberculosis to healthcare workers and to other patients is recognized and poses a major public health problem. The drug treatment of suspected drug resistance in HIV-positive and HIV-negative patients is as follows:

- with multiple drug resistance use at least three drugs to which the organism is sensitive
- with resistance to one of the four main drugs, use the other three.

Therapy should be continued for up to 2 years and in HIV-positive patients for at least 12 months after negative cultures. Second-line drugs available for treatment of resistant *M. tuberculosis* are capreomycin, cycloserine, clarithromycin, azithromycin, ciprofloxacin, ofloxacin, ethionamide, kanamycin, amikacin, moxifloxacin and rifabutin.

Unwanted effects of drug treatment

Rifampicin induces liver enzymes, which may be transiently elevated in the serum of many patients. The drug should be stopped only if the serum bilirubin becomes elevated or if transferases are >3x elevated, which is uncommon. Thrombocytopenia has been reported. Rifampicin stains body secretions pink and the patients should be warned of the change in colour of their urine, tears (contact lens) and sweat. Induction of liver enzymes means that concomitant drug treatment may be made less effective (see Ch. 16). Oral contraception will not be effective, so alternative birth-control methods should be used. Rifabutin, a new rifamycin, is similar and is used for prophylaxis against *M. avium-intracellulare* complex infection in HIV patients with CD4 counts $<200\ mm^3$. .-.. \ ; >.

Isoniazid has very few unwanted effects. At high doses it may produce a polyneuropathy but this is extremely rare when the normal dose of 200-300 mg is given daily. Nevertheless, it is customary to prescribe pyridoxine 10 mg daily to prevent this effect. Occasionally, isoniazid gives rise to allergic reactions in the form of a skin rash and fever, with hepatitis occurring in fewer than 1% of cases. The latter, however, may be fatal if the drug is continued.

Pyrazinamide may cause hepatic toxicity, though this is much rarer with present dosage schedules. Pyrazinamide reduces the renal excretion of urate and may precipitate hyperuricaemic gout.

Ethambutol can cause a dose-related optic retrobulbar neuritis that presents with colour blindness for green, reduction in visual acuity and a central scotoma (commoner at doses of 25 mg/kg). This usually reverses provided the drug is stopped when symptoms develop; patients should therefore be warned of its effects. All patients prescribed the drug should be seen by an ophthalmologist prior to treatment and doses of 15 mg/kg should be used.

Streptomycin can cause irreversible damage to the vestibular nerve. It is more likely to occur in the elderly and in those with renal impairment. Allergic reactions to streptomycin are more common than to rifampicin, isoniazid and pyrazinamide. This drug is used only if patients are very ill, have multidrug-resistant TB or are not responding adequately to therapy.

Follow-up

Patients should be seen regularly for the duration of chemotherapy and once more after 3 months, since relapse, though very unlikely, usually occurs within this period of time. Patients with multidrug-resistant TB should be followed up for at least 1 year after treatment is completed.

Chemoprophylaxis

Patients who have any chest X-ray changes compatible with previous tuberculosis and who are about to undergo long-term treatment that has an immunosuppressive effect, such as renal dialysis or treatment with corticosteroids, should receive chemoprophylaxis with isoniazid 300-450 mg daily.

Prevention BCG vaccination

Vaccination with BCG (bacille Calmette-Guerin) has been given to schoolchildren in the UK since 1954. BCG is live attenuated vaccine derived from *M. bovis* (a bovine strain of M. *tuberculosis)* that lost its virulence after growth in the laboratory for many passages. Early trials showed that it decreases the risk of developing tuberculosis by about 70%. With the continuing decrease in the incidence of tuberculosis in most parts of the UK it is becoming less cost-effective to administer this vaccine, and the procedure is being stopped in many areas of the UK. However, in other areas of the UK with a high immigrant population, the vaccine is being administered at birth rather than at the traditional age of 13 years. This is to prevent the disease from developing in young children, where it can progress extremely rapidly and in whom any delay in diagnosis can be fatal. BCG has been shown to be particularly effective in preventing miliary tuberculosis and tuberculous meningitis. In meta-analysis the protective efficacy is around 50%. However, the efficacy of BCG vaccination varies throughout the world from zero to 94% protection and appears to depend on latitude, being most beneficial in Norway, Sweden and Denmark (80-94%) and least so in the southern states of the USA and in India (0-20%). This lack of efficacy is thought to be related to a number of local factors including the

frequency of infection with environmental mycobacteria (e.g. *M.fortuitum, M. kansasii),* which may induce a degree of protection similar to but not enhanced by BCG.

BCG is given only to individuals who are tuberculin-negative; those with positive tests are further screened by a chest X-ray. BCG should be given at a dose of 0.1 mL intradermally to children and adults, but at a dose of 0.05 mL to infants percutaneously.

Contact tracing

Tuberculosis is spread from person to person, and effective tracing of close contacts has helped to limit spread of the disease as well as to identify diseased individuals at an early stage. Screening procedures involve screening all close family members or other individuals who share the same kitchen and bathroom facilities. Close contacts at work or school may also be screened. Contacts who are ill should be thoroughly investigated for tuberculosis. If they are well, a chest X-ray is taken and a tuberculin test is performed (Practical box 14.5).

In adults, even if the tuberculin test is positive, provided the chest X-ray is negative nothing more need be done. Chemoprophylaxis should be considered in patients whose recent tuberculin conversion has been documented and for young adults (16-34 years) who are Heaf Grade *3-4* positive without BCG history and found at new immigrant screening. In patients with HIV infection, who have not had BCG, chemoprophylaxis with isoniazid is given, reducing the relative risk of developing active TB by 40% in highly endemic areas.

In children, a positive tuberculin test is usually taken as evidence of infection, and treatment is instituted. If the tuberculin test is negative in children and young adults (< 35 years), it is repeated at 6 weeks, and if it remains negative then BCG is administered. Children under the age of 1 year who have a family member with tuberculosis are given chemoprophylaxis with a daily dose of isoniazid 5-10 mg/kg for 6 months together with immunization with a strain of BCG that is resistant to isoniazid.

In general, in the UK much greater emphasis is placed on contact tracing and investigation of those under the age of 35 years and in some immigrant groups (African, Asian and Eastern European) in whom the disease is more prevalent.

Practical Box 14.5
Tuberculin testing

Mainly used for:
a Contact tracing
35 BCG vaccination programmes.

It is rarely of any value in the diagnosis of tuberculosis.

Patients are tested with:
- Purified protein derivative (PPD) of *Mycobacterium tuberculosis.*

The test is based on cell-mediated immunity with the development of induration and inflammation at the site of infection due to infiltration with mainly T lymphocytes. In patients with AIDS the test may be falsely negative owing to impairment of delayed hypersensitivity.

The Mantoux test
This is used for individual patients.

1. 0.1 mL of a 1 : 1000 strength PPD (equivalent to 10 tuberculin units) is injected intradermally.
2. The induration (not the erythema) is measured after 72 hours. The test is positive if the induration is 10 mm or more in diameter.

The Heaf test
This is a simple test used for large-scale screening.

1. A small amount of PPD (100 000 IU/mL) is placed on the flexor surface of the left forearm.
2. The 6-point disposable apparatus is actuated through the solution.
3. The Heaf reaction is graded 0-4 depending on the degree of induration: 0 and 1 (where there is only discrete induration at the puncture site) is a negative result after 3-10 days.

Other mycobacteria

M. kansasii occurs in water and milk, though not in soil. Disease caused by this mycobacterium has mainly been described in Europe and the USA. It rarely causes a relatively benign type of human pulmonary disease, more common in HIV+ individuals, usually in middle-aged males. Men working in dusty jobs (e.g. miners) appear to be especially at risk, as are those who have underlying COPD. *M. avium-intracellulare* is a cause of pulmonary infection in AIDS patients (see p. 141).

DIFFUSE DISEASES OF THE LUNG PARENCHYMA

Diffuse parenchymal lung disorders (DPLD, also referred to as interstitial lung disease) are a heterogeneous group of disorders accounting for about 15% of respiratory clinical practice. Pathological features typically include inflammation of alveolar walls with fluid in alveolar air spaces leading to progressive bilateral destruction of the lung parenchyma.

GRANULOMATOUS LUNG DISEASI

A granuloma is a mass or nodule composed of chronically inflamed tissue formed by the response of the mono-

nuclear phagocyte system (macrophage/histiocyte) to a slowly soluble antigen or irritant. If the foreign substance is inert (e.g. an inhaled dust), the phagocytes turn over slowly; if the substance is toxic or reproducing, the cells turn over faster, producing a granuloma. A granuloma is characterized by epithelioid multinucleate giant cells, as seen in tuberculosis. Granulomas are also seen in other infections, including fungal and helminthic, in sarcoidosis, and in extrinsic allergic alveolitis, and can also be due to foreign bodies (e.g. talc). Granulomatosis with pulmonary vasculitis is discussed on page 938.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder, commonly affecting young adults and usually presenting with bilateral hilar lymphadenopathy, pulmonary infiltration and skin or eye lesions. Beryllium poisoning can produce a clinical and histological picture identical to sarcoidosis, though contact with this element is now strictly controlled.

Epidemiology and aetiology

Sarcoidosis is a common disease of unknown aetiology that is often detected by routine chest X-ray. There is great geographical variation. The prevalence in the UK is approximately 19 in 100 000 of the population. It is common in the USA but is uncommon in Japan. The course of the disease is much more severe in American blacks than in whites. There is no relation with any histocompatibility antigen, but cases of sarcoidosis are seen within families, possibly suggesting an environmental factor. Other aetiological factors suggested are an atypical mycobacterium or fungus, the Epstein-Barr virus, and occupational, genetic, social or other environmental factors (a higher incidence occurs in rural than in urban populations). None of these has been substantiated.

Immunopathology

m Typical sarcoid granulomas consist of focal accumulations of epithelioid cells, macrophages and lymphocytes, mainly T cells.

- There is depressed cell-mediated reactivity to tuberculin and other antigens such as *Candida albicans*.

m There is overall lymphopenia: circulating T lymphocytes are low but B cells are slightly increased.

- Bronchoalveolar lavage shows a great increase in the number of cells; lymphocytes are greatly increased (particularly CD4 helper cells).
- The number of alveolar macrophages is increased but they represent a reduced percentage of the total number of bronchoalveolar lavage cells.
- Transbronchial biopsies show infiltration of the alveolar walls and interstitial spaces with leucocytes, mainly T cells, prior to granuloma formation.

It seems likely that the decrease in circulating T lymphocytes and changes in delayed hypersensitivity responses are the result of sequestration of lymphocytes within the lung. There is no evidence to suggest that patients with sarcoidosis suffer from an overall defect in cellular immunity, since the frequency of fungal, viral and bacterial infections is not increased and there is no substantiated evidence of a greater risk of developing malignant neoplasms.

Clinical features

The peak incidence is in the third and fourth decades, with a female preponderance. Sarcoidosis can affect many different organs of the body. The most common presentation is with respiratory symptoms or abnormalities found on chest X-ray (50%). Fatigue or weight loss occurs in 5%, peripheral lymphadenopathy in 5% and a fever in 4%. A chest X-ray may be negative in up to 20% of non-respiratory cases, though lesions may be detected later.

Bilateral hilar lymphadenopathy

This is a characteristic feature of sarcoidosis. It is often symptomless and simply detected on a routine chest X-ray. Occasionally, the bilateral hilar lymphadenopathy is associated with a dull ache in the chest, malaise and a mild fever.

Although the chest X-ray may not show any evidence of infiltration in the lung fields, evidence from CT scanning (Fig. 14.39), transbronchial biopsies and bronchoalveolar lavage indicates that the lung parenchyma is nearly always involved.

The differential diagnosis of bilateral hilar lymphadenopathy includes:

- lymphoma - though it is rare for this to affect only the hilar lymph nodes
- pulmonary tuberculosis - though it is rare for the hilar lymph nodes to be symmetrically enlarged
- carcinoma of the bronchus with malignant spread to the contralateral hilar lymph nodes - again it is rare for this to give rise to a typical symmetrical picture.

In the early stages it may be difficult to distinguish enlarged lymph nodes on the chest X-ray from the pulmonary arteries, and lymph node enlargement is not always symmetrical. It is for these reasons that, in the

Fig. 14.39 CT scan in sarcoidosis. Note enlarged glands at the hilum (black arrow) and nodular shadowing, particularly in right middle lobe (white arrow).

absence of erythema nodosum (see below), further confirmation of the disease process is advisable.

Pulmonary infiltration

This type of sarcoidosis may be progressive and may lead to increasing effort dyspnoea and eventually cor pulmonale and death. The chest X-ray shows a mottling in the mid-zones proceeding to generalized fine nodular shadows. Eventually, widespread pulmonary line shadows develop, reflecting the underlying fibrosis. A honeycomb appearance can occasionally occur. Pulmonary function tests show a typical restrictive lung defect (see below).

The combination of pulmonary infiltration and normal lung function tests is highly suggestive of sarcoidosis. The principal differential diagnoses are tuberculosis, pneumoconiosis, cryptogenic fibrosing alveolitis and alveolar cell carcinoma. However, these other conditions do have their own X-ray appearances and usually cause both symptoms and abnormal lung function tests.

Extrapulmonary manifestations

Skin and ocular sarcoidosis are the most common extrapulmonary presentations.

Skin lesions occur in 10% of cases. Sarcoidosis is the most common cause of erythema nodosum (see p. 1341). The association of bilateral symmetrical hilar lymphadenopathy with erythema nodosum occurs only in sarcoidosis. A chilblain-like lesion known as lupus pernio is also seen, as are skin nodules (see p. 1345).

***Ocular** and **associated** effects.* Anterior uveitis is common and may present with misting of vision, pain and a red eye, but posterior uveitis may present simply as progressive loss of vision. Although ocular sarcoidosis accounts for about 5% of uveitis presenting to ophthalmologists, evidence of asymptomatic uveitis may be found in up to 25% of patients with sarcoidosis. Conjunctivitis may occur and retinal lesions have also been reported. *Uveoparotid fever* is a syndrome of bilateral uveitis and parotid gland enlargement together with occasional development of facial nerve palsy and is sometimes seen with sarcoidosis.

***Keratoconjunctivitis** sicca* and lacrimal gland enlargement may also occur.

Metabolic manifestations. It is rare for sarcoidosis to present with problems of calcium metabolism, though hypercalcaemia is found in 10% of established cases. Hypercalcaemia and hypercalciuria can lead to the development of renal calculi and nephrocalcinosis. The cause of the hypercalcaemia is due to an increase in circulating 1,25-dihydroxyvitamin D_3, with lo> hydroxylation occurring in sarcoid macrophages in the lung in addition to that taking place in the kidney.

The central nervous system. Involvement of the central nervous system (CNS) is rare (2%) but can lead to severe neurological disease (see p. 1242).

*Bone **and** joint **involvement.*** Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts are found, particularly in the digits, with associated swelling. In the absence of swelling, routine X-rays of the hands are unnecessary.

Hepatosplenomegaly Sarcoidosis is a cause of hepatosplenomegaly, though it is rarely of any clinical consequence. A liver biopsy is occasionally performed when the diagnosis is in doubt and shows granulomas.

Cardiac involvement. Cardiac involvement is rare (3%). Ventricular dysrhythmias, conduction defects and cardiomyopathy with congestive cardiac failure are seen.

Investigations

- **Imaging.** Chest X-ray (see above). CT is useful for assessment of diffuse lung involvement.
- **Full blood count.** There is mild normochromic, normocytic anaemia with raised ESR.
- **Serum biochemistry.** Serum calcium is often raised and there is hypergammaglobulinaemia.
- **Transbronchial biopsy** is the most useful investigation. Positive results are seen in 90% of cases of pulmonary sarcoidosis with or without X-ray evidence of lung involvement. Pulmonary non-caseating granulomas are found in approximately one-half of patients with clinically extrapulmonary sarcoidosis in whom the chest X-ray is normal.
- **Serum level of angiotensin-converting enzyme (ACE)** is two standard deviations above the normal mean value in over 75% of patients with untreated sarcoidosis. Raised (but lower) levels are also seen in patients with lymphoma, pulmonary tuberculosis, asbestosis and silicosis, limiting the diagnostic value of the test. However, the test is useful in assessing the activity of the disease and therefore as a guide to treatment with corticosteroids. Reduction of serum ACE during treatment with corticosteroids does not, however, reflect resolution of the disease.
- **Lung function tests** show a restrictive lung defect in patients with pulmonary infiltration. There is a decrease in TLC, a decrease in both FEV_1 and FVC, and a decrease in gas transfer.
- **The tuberculin skin test** is negative in 80% of patients with sarcoidosis; this is of interest but has no diagnostic value.

Treatment

Both the need to treat and the value of corticosteroid therapy are contested in many aspects of this disease. Hilar lymphadenopathy on its own with no evidence on chest X-ray of involvement of the lungs or decrease in lung function tests does not require treatment. Persisting infiltration on the chest X-ray or abnormal lung function tests are unlikely to improve without corticosteroid treatment. If the disease is not improving spontaneously 6 months after diagnosis, treatment should be started with prednisolone 30 mg for 6 weeks, reducing to alternate-day treatment with prednisolone 15 mg for

6-12 months. Although there have been no co ntrolled trials that have proved the efficacy of such treatment, it is difficult to withhold corticosteroids when there is continuing deterioration of lung function. Systemic prednisolone should be given to patients with involvement of the eyes or persistent hypercalcaemia.

If the erythema nodosum of sarcoidosis is severe or persistent it will respond rapidly to a 2-week course of prednisolone 5-15 mg daily, as will patients with uveoparotid fever. Myocardial sarcoidosis and neurological manifestations are also treated with prednisolone.

Prognosis

Sarcoidosis is a much more severe disease in certain racial groups, particularly American blacks, where death rates of up to 10% have been recorded. It is probable that the disease is fatal in fewer than 5% of cases in the UK, most often as a result of respiratory failure and cor pulmonale but, rarely, from myocardial sarcoidosis and renal damage. The chest X-ray provides a guide to prognosis. The disease remits within 2 years in over two-thirds of patients with hilar lymphadenopathy alone, in approximately one-half with hilar lymphadenopathy plus chest X-ray evidence of pulmonary infiltration, but in only one-third of patients with X-ray evidence of infiltration without any demonstrable lymphadenopathy. Lung function tests are the most useful way to monitor progression.

Langerhans' cell histiocytosis (LCH)

This rare disease (a prevalence of 1 per 50 000) is characterized histologically by proliferation of LCH cells identified by the presence of Birbeck granules on electron-microscopy or the CD_{1a} antigen on the surface of the cells. There is a wide variation in clinical presentation, from unifocal bone lesions in older children (which may regress spontaneously), to more disseminated disease in younger children (with a high mortality). Chest X-rays show multiple small cysts (honeycomb lung), fibrosis or widespread nodular shadows. Etoposide treatment is justified for advanced progressive disease. ■■ .■ .

PULMONARY VASCULITIS AND GRANULOMATOSIS

The classification of pulmonary vasculitis and granulomatous disorders is unsatisfactory. In broad terms it is reasonable to consider two main groups: the respiratory manifestations of systemic connective tissue diseases, and disorders associated with the presence of ant ineutrophil cytoplasmic antibodies (ANCAs). ---*.■v- ■■;■•;■

Pulmonary vasculitis with connective tissue disease

Rheumatoid disease (see also p. 559)

The features of respiratory involvement in rheumatoid disease are illustrated in Figure 14.40.

Pleural adhesions, thickening and effusion are the most common lesions. The effusion is often unilateral and

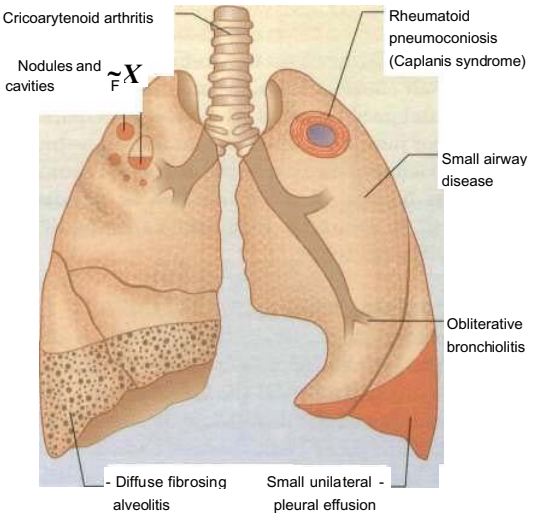

Fig. 14.40 Respiratory manifestations of rheumatoid disease.

tends to be chronic. It has a low glucose content but this can occur in any chronic pleural effusion. Several forms of parenchymal disease can occur in patients with rheumatoid arthritis. These include fibrosing alveolitis, rheumatoid nodules, cryptogenic organizing pneumonia, and lymphoid interstitial pneumonia. Moreover, some patients will have modified presentations because they are already on disease-modifying drugs such as prednisolone or methotrexate for their arthritis.

Fibrosing alveolitis occurring in rheumatoid arthritis can be considered as a variant of the cryptogenic form of the disease (see p. 941). The clinical features and gross appearance are the same but the disease is often more chronic. Rheumatoid nodules appear on the chest X-ray as single or multiple nodules ranging in size from a few millimetres to a few centimetres. The nodules frequently cavitate. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.

Obliterative disease of the small bronchioles is rare. It is characterized by progressive breathlessness and irreversible airflow limitation. Corticosteroids may prevent progression. Cricoarytenoid joint involvement by rheumatoid arthritis gives rise to dyspnoea, stridor, hoarseness and occasionally severe obstruction necessitating tracheostomy. *Caplan's syndrome* is due to a combination of dust inhalation and the disturbed immunity of rheumatoid arthritis. It occurs particularly in coal-worker's pneumoconiosis but it can occur in individuals exposed to other dusts, such as silica and asbestos. Typically the lesions appear as rounded nodules 0.5-5.0 cm in diameter, though sometimes they become incorporated into large areas of fibrosis that are indistinguishable radiologically from progressive massive fibrosis. There may not be much evidence of simple pneumoconiosis prior to the development of the nodule. These lesions may precede the development of the arthritis. Rheumatoid factor is always present in the serum.

Systemic lupus erythematosus (see also p. 575)

Pleurisy is the most common respiratory manifestation of this disease, occurring in up to two-thirds of cases, with or without an effusion. Effusions are usually small and bilateral. Basal pneumonitis is often present, perhaps as a result of poor movement of the diaphragm, or restriction of chest movements because of pleural pain. Pneumonia also occurs, because of either infection or the disease process itself. In contrast to rheumatoid arthritis, diffuse pulmonary fibrosis is rare.

Systemic sclerosis (see pp. 577 and 1343) Autopsy studies have indicated that there is almost always some diffuse fibrosis of alveolar walls and obliteration of capillaries and the alveolar space. Severe changes result in nodular then streaky shadowing on the chest X-ray, followed by cystic changes, ending up with a honeycomb lung. Lung function tests reveal a restrictive defect and poor gas transfer. Pneumonia may occur owing to aspiration from the dilated oesophagus (see p. 927). Breathlessness may be worsened by restriction of chest wall movement owing to thickening and contraction of the skin and trunk.

Granulomatous vasculitides

Antineutrophil cytoplasmic antibodies

(see also pp. 534 and 633)

Antineutrophil cytoplasmic antibodies (ANCAs) are found in the acute phase of vasculitides, particularly Wegener's granulomatosis, Churg-Strauss syndrome and microscopic polyangiitis (polyarteritis) associated with neutrophil infiltration of the vessel wall.

Two major ANCA reactivities are recognized: proteinase-3 (PR3) ANCA and myeloperoxidase (MPO) ANCA.

About 10% of all vasculitis patients are ANCA-negative: this is more common in Wegener's granulomatosis limited to the upper respiratory tract. Ten to fifteen per cent of cases of progressive glomerulonephritis with anti-glomerular basement membrane (GBM) antibodies are MPO ANCA-positive and these are the most likely to suffer pulmonary haemorrhage.

Wegener's granulomatosis

This granulomatous disease of unknown aetiology is one of the primary systemic vasculitides in which the small arteries are predominantly affected (the other is the Churg-Strauss syndrome, see below). It is characterized by lesions involving the upper respiratory tract, the lungs and the kidneys. Often the disease starts with severe rhinorrhoea with subsequent nasal mucosal ulceration followed by cough, haemoptysis and pleuritic pain. Occasionally there may be involvement of the skin and nervous system. A chest X-ray usually shows single or multiple nodular masses or pneumonic infiltrates with cavitation. The most remarkable radiographic feature is the migratory pattern, with large lesions clearing in one area and new lesions appearing in another. The typical histological changes are usually best seen in the kidneys, where there is a necrotizing microvascular glomerulonephritis. This disease responds well to treatment with cyclophosphamide 150-200 mg daily. A variant of Wegener's granulomatosis called 'midline granuloma' affects the nose and paranasal sinuses and is particularly mutilating; it has a poor prognosis.

The Churg-Strauss syndrome

This condition occurs in patients, usually males in their fourth decade, who have a triad of rhinitis and asthma, eosinophilia and systemic vasculitis. The aetiology is uncertain, with some believing that it represents an unusual progression of allergic disease in a subset of predisposed individuals. Others believe it is a primary vasculitis which presents like asthma because of the involvement of eosinophils.

The pathology of this condition is dominated by an eosinophilic infiltration with a characteristic high blood eosinophil count, vasculitis of small arteries and veins, and extravascular granulomas. Typically it involves the lungs, peripheral nerves and skin but kidney involvement is uncommon. Transient patchy pneumonia-like shadows may occur, but sometimes these can be massive and bilateral. Skin lesions include tender subcutaneous nodules as well as petechial or purpuric lesions. ANCA is usually positive. The disease responds well to corticosteroids. Occasionally Churg-Strauss syndrome may be revealed when oral steroids are withdrawn in patients being treated for asthma. There is no reason to think that other anti-asthma drugs precipitate the condition.

Microscopic vasculitis (polyangiitis)

This involves the kidneys and the lungs where it results in recurrent haemoptysis. ANCA is usually positive. In the early literature there was confusion between this condition, the Churg-Strauss syndrome and polyarteritis nodosa. The latter, however, is ANCA-negative and rarely involves the lungs.

PULMONARY INFILTRATION WITH JEOSINOPHILIA

The common types and characteristics of these diseases are shown in Table 14.14. They range from very mild, simple, pulmonary eosinophilias to the often fatal hypereosinophilic syndrome.

Simple and prolonged pulmonary eosinophilia

Simple pulmonary eosinophilia is a relatively mild illness with a slight fever and cough and usually lasting for less than 2 weeks. Occasionally, the disease becomes more prolonged, with a high fever lasting for over a month. There is usually an eosinophilia in the blood and this condition is then called prolonged pulmonary eosinophilia. In both conditions the chest X-ray shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated, including *Ascaris lumbricoides,*

^^^^^^H *Table 14.14* **Common types and characteristics of pulmonary infiltration with eosinophilia**

Disease	Symptoms	Blood eosinophils (%)	Multisystem involvement	Duration	Outcome
Simple pulmonary eosinophilia	Mild	10	None	< 1 month	Good
Prolonged pulmonary eosinophilia	Mild/moderate	>20	None	> 1 month	Good
Asthmatic bronchopulmonary eosinophilia	Moderate/severe	5-20	None	Years	Fair
Tropical pulmonary eosinophilia	Moderate/severe	>20	None	Years	Fair
Hypereosinophilic syndrome	Severe	**>20**	Always	Months/years	Poor

Ankylostoma, Trichuris, Trichinella, Taenia and *Strongyloides.* Drugs such as aspirin, penicillin, nitrofurantoin and sulphonamides have been implicated. Often, no allergen is identified. The disease is self-limiting and no treatment is required, apart from treating the cause. In the more chronic form all unnecessary treatment should be withdrawn and where appropriate, worms are treated. Corticosteroid therapy is indicated, with resolution of the disease over the ensuing weeks.

Asthmatic bronchopulmonary eosinophilia

This is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause world-wide is allergy to *A. fumigatus* (see below), although *Candida albicans* and other mycoses may be the allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain.

Diseases caused by *Aspergillus fumigatus*

The various types of lung disease caused by *A. fumigatus* are illustrated in Figure 14.41.

The spores of *A. fumigatus* (diameter 5 mm) are readily inhaled and are present in the atmosphere throughout the year, though they are at their highest concentration in the late autumn. They can be grown from the sputum in up to 15% of patients with chronic lung disease in whom they do not produce disease. They are a cause of extrinsic asthma in atopic individuals.

Allergic bronchopulmonary aspergillosis

In this rare disease, *Aspergillus* actually grows in the walls of the bronchi and eventually produces proximal bronchiectasis. There are episodes of eosinophilic pneumonia throughout the year, particularly in late autumn and winter. The episodes present with a wheeze, cough, fever and malaise. They are associated with expectoration of firm sputum plugs containing the fungal mycelium, which results in the clearing of the pulmonary infiltrates on the chest X-ray. Occasionally the large mucus plugs obliterate the bronchial lumen, causing collapse of the lung.

Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis

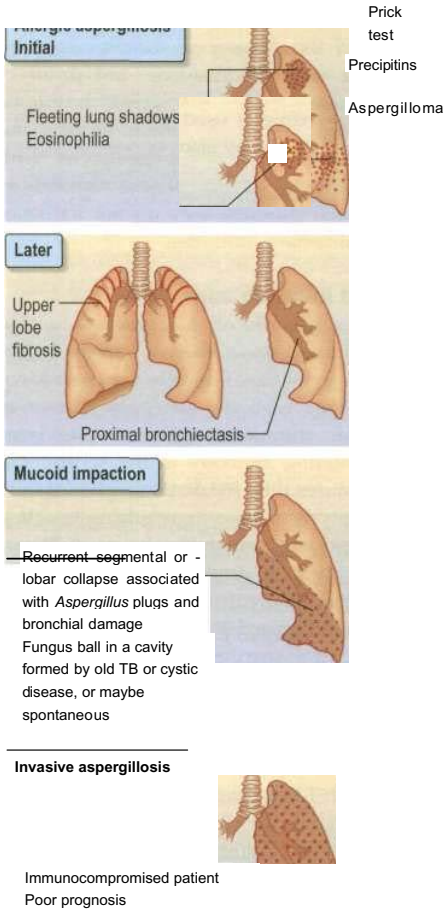

Fig. 14.41 **Diseases caused by *Aspergillus fumigatus*.**

that usually affects the upper zones and can give rise to a chest X-ray appearance similar to that produced by tuberculosis.

The peripheral blood eosinophil count is usually raised, and total levels of IgE are usually extremely high

(both that specific to *Aspergillus* and non-specific). Skin-prick testing to protein allergens from *A. fumigatus* gives rise to positive immediate skin tests. Sputum may show eosinophils and mycelia, and precipitating antibodies are usually, but not always, found in the serum.

Lung function tests show a decrease in lung volumes and gas transfer in more chronic cases, but evidence of reversible airflow limitation can be demonstrated in all cases.

Treatment is with prednisolone 30 mg daily, which causes rapid clearing of the pulmonary infiltrates. Frequent episodes of the disease can be prevented by long-term treatment with prednisolone, but doses of 10-15 mg daily are usually required. Several antifungal agents have been tried in the past without success, but there is now some evidence that treatment with itraconazole helps. The asthma component responds to inhaled corticosteroids, although they do not influence the occurrence of pulmonary infiltrates.

Aspergilloma and invasive aspergillosis

Aspergilloma is the growth of *A. fumigatus* within previously damaged lung tissue where it forms a ball of mycelium within lung cavities. Typically the chest X-ray shows a round lesion with an air 'halo' above it. Continuing antigenic stimulation gives rise to large quantities of precipitating antibody in the serum. The aspergilloma itself causes little trouble, though occasionally massive haemoptysis may occur, requiring resection of the area of damaged lung containing the aspergilloma. Antifungal agents, such as amphotericin, have been tested in aspergilloma, but with little success. Invasive aspergillosis is a well-recognized complication of immunosuppression and requires aggressive antifungal therapy usually with i.v. amphotericin (250 (ig/kg daily). Itraconazole or variconazole is used if amphotericin is ineffective, and caspofungin may also work.

Tropical pulmonary eosinophilia

This term is reserved for an allergic reaction to microfilaria from *Wuchereria bancrofti*. The condition is seen in the Asian subcontinent and presents with cough and wheeze together with fever, lassitude and weight loss. The typical appearance of the chest X-ray is of bilateral hazy mottling that is often uniformly distributed in both lung fields. Individual shadows may be as large as 5 mm or may become more confluent, giving the appearance of pneumonia.

The disease is characterized by a very high eosinophil count in peripheral blood. The filarial complement fixation test is positive in almost every case, although the microfilaria are seldom found. The treatment of choice is diethylcarbamazine (see p. 108 for details).

The hypereosinophilic syndrome

This disease is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases. Typical features are fever, weight loss, recurrent abdominal pain, persistent non-productive cough and congestive cardiac failure. Corticosteroid treatment may be of value in some cases.

GOODPASTURE'S SYNDROME AND IDIOPATHIC PULMONARY HAEMOSIDEROSIS

Goodpasture's syndrome (see also p. 632)

The disease often starts with symptoms of an upper respiratory tract infection followed by cough and intermittent haemoptysis, tiredness and eventually anaemia, although massive bleeding may occur. The chest X-ray shows transient blotchy shadows that are due to intrapulmonary haemorrhage. These features usually precede the development of an acute glomerulonephritis by several weeks or months. The course of the disease is variable: some patients spontaneously improve while others proceed to renal failure.

The disease usually occurs in individuals over 16 years of age. It is due to a type II cytotoxic reaction driven by antibodies directed against the basement membrane of both kidney and lung. It has been proposed that there may be a shared antigen. ANCA may be positive. An association with influenza A2 virus has been reported.

Treatment is with corticosteroids, but in some cases dramatic improvement has been seen with plasmapheresis to remove the autoantibodies.

Idiopathic pulmonary haemosiderosis

This is clinically similar to Goodpasture's syndrome, but there are no anti-basement-membrane antibodies and the kidneys are less frequently involved. Most cases occur in children under 7 years of age. The child develops a chronic cough and anaemia and the chest X-ray shows diffuse shadows that are due to intrapulmonary bleeding, and eventually miliary nodulation. Characteristically, haemosiderin-containing macrophages are found in the sputum. There is an association with a sensitivity to cow's milk, and an appropriate diet is usually tried.

The prognosis in general is poor and treatment with corticosteroids or azathioprine is usually given.

PULMONARY FIBROSIS AND HONEYCOMB LUNG

Pulmonary fibrosis is the end result of many diseases of the respiratory tract. It may be:

- localized (e.g. following unresolved pneumonia)
- bilateral (e.g. in tuberculosis)

Table 14.15 The main causes of honeycomb lung

Localized	Diffuse
Systemic sclerosis	Cryptogenic fibrosing alveolitis
Sarcoidosis	Rheumatoid lung Langerhans' cell
Tuberculosis	histiocytosis Tuberous sclerosis
Asbestosis	Neurofibromatosis
Berylliosis	

- widespread (e.g. in cryptogenic fibrosing alveolitis, in industrial lung disease, or due to drugs such as busulfan, bleomycin and cyclophosphamide).

Sometimes a typical radiological appearance is seen that is known as 'honeycomb lung'. This reflects the presence diffusely in both lungs of thick-walled cysts 0.5-2.0 cm diameter. These cystic air spaces probably represent dilated and thickened terminal and respiratory bronchioles. The main causes are shown in Table 14.15.

Cryptogenic fibrosing alveolitis (CFA)

This relatively rare disorder, known in the USA as *idiopathic pulmonary fibrosis,* causes diffuse fibrosis throughout the lung fields, usually in late middle age. The cause is unknown, but in a few cases it may be the result of occupational exposure to metal or wood dust, while many patients show features of autoimmunity.

Pathogenesis

The pathogenesis of damage and fibrosis is complex and several factors are thought to be involved (Fig. 14.42). Macrophages and alveolar epithelial cells are activated by several mechanisms (see p. 799) and produce growth factors including fibronectin, platelet-derived growth factor, transforming growth factor-p", and insulin-like growth factor-1. These stimulate the deposition of type I and III collagens. Histologically there are two main features:

- cellular infiltration with T lymphocytes and plasma cells and thickening and fibrosis of the alveolar walls
- alveolitis - increased cells within the alveolar space (mainly macrophages and type II pneumocytes shed from the alveolar walls).

Clinical features

The main features are progressive breathlessness and cyanosis, which eventually lead to respiratory failure, pulmonary hypertension and cor pulmonale. Gross finger clubbing occurs in two-thirds of cases and fine bilateral end-inspiratory crackles are heard on auscultation. An

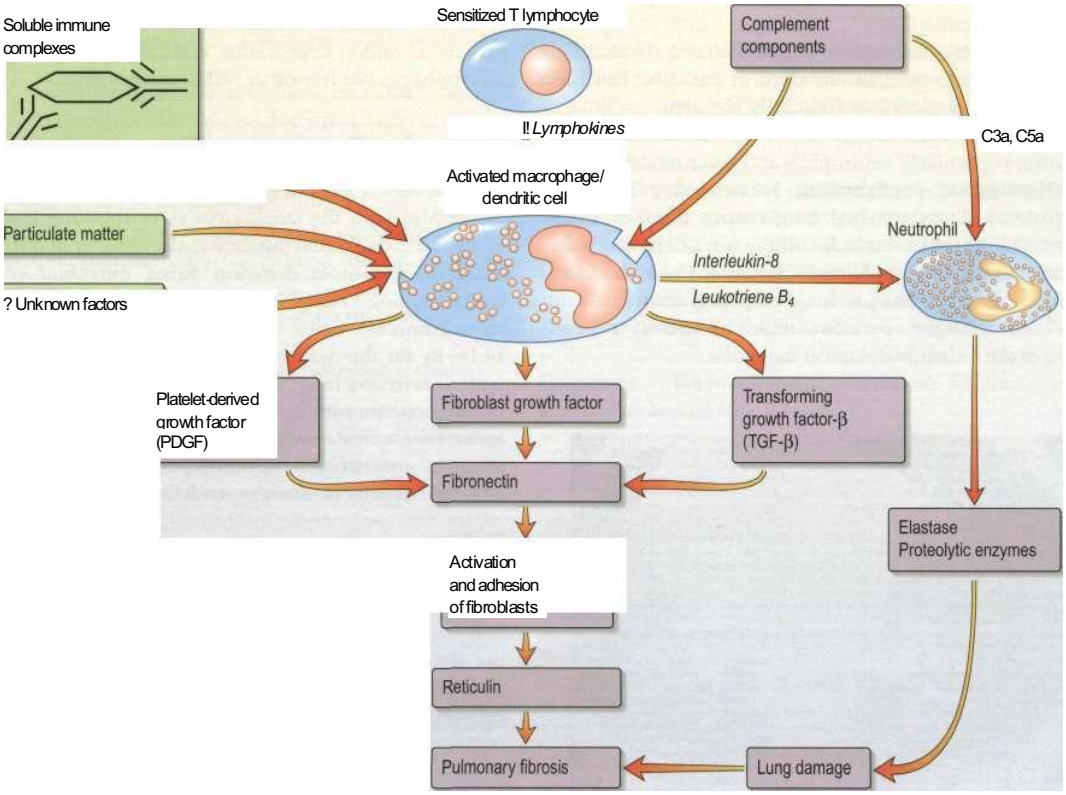

Fig. 14.42 **Pathogenesis of pulmonary fibrosis.** Macrophages can be activated by several factors, such as soluble immune complexes and sensitized T lymphocytes, resulting in the release of various cytokines leading to fibrosis.

acute form known as the *Hamman-Rich syndrome* occurs in a small proportion of cases. The chest X-ray is initially of ground-glass appearance, progressing to obvious small nodular shadows with streaky fibrosis and finally a honeycomb lung. A number of autoimmune diseases are seen in association with this condition. For example, autoimmune hepatitis occurs in 5-10% of cases. Similar lung changes are also seen in rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, systemic sclerosis and Sjogren's syndrome, often associated with Raynaud's phenomenon. CFA has also been reported in association with coeliac disease, ulcerative colitis and renal tubular acidosis.

Investigations

- **Chest X-ray** shows irregular reticulonodular shadowing, often maximal in the lower zones.
- **High-resolution CT scan** shows characteristic changes of peripheral reticular and ground-glass opacification, seen best in the basal regions but extending all over the lungs (Fig. 14.43).
- **Respiratory function tests** show a restrictive ventilatory defect - the lung volumes are reduced, the FEV_1 to FVC ratio is normal to high (with both values being reduced), and carbon monoxide gas transfer is reduced. Peak flow rates may be normal.
- **Blood gases** show an arterial hypoxaemia caused by a combination of alveolar-capillary block and ventilation-perfusion mismatch with normal or low P_aCO_2 owing to hyperventilation.
- **Blood tests.** Antinuclear antibodies and rheumatoid factors are present in one-third of patients. The ESR and immunoglobulins are mildly elevated.
- **Bronchoalveolar lavage** shows increased numbers of cells, particularly neutrophils and macrophages.
- **Histological confirmation** is necessary in some patients. Transbronchial lung biopsy is rarely diagnostic, but can exclude other conditions such as sarcoidosis or lymphangitis carcinomatosa. A video-assisted thoracoscopic lung biopsy is performed to obtain a larger specimen, which is usually needed to make a clear histological diagnosis.

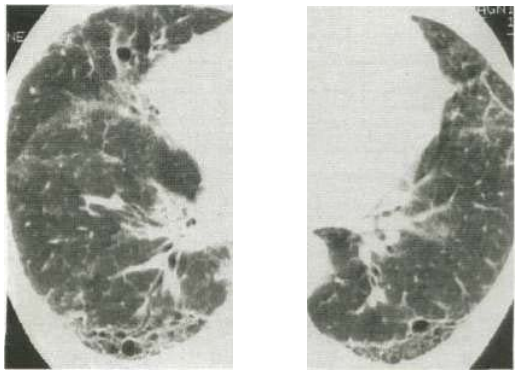

Fig. 14.43 CT scan showing cryptogenic fibrosing alveolitis.

Differential diagnosis

The diagnosis of CFA is usually made in a patient presenting with the above signs and characteristic CT changes. The differential diagnosis of the chest X-ray appearance includes extrinsic allergic alveolitis, bronchiectasis, chronic left heart failure, sarcoidosis, industrial lung disease and lymphangitis carcinomatosa.

Prognosis and treatment

The median survival time for patients with CFA is approximately 5 years, although mortality is very high in the acute form. Treatment with prednisolone (30 mg daily) is usually prescribed for disabling disease, though its benefit has still to be proved by appropriate controlled trials. Azathioprine or cyclophosphamide may be added if there is no response. Supportive treatment includes domiciliary oxygen therapy. In severe disease, single lung transplantation can be offered.

Pulmonary alveolar proteinosis

This is a rare disease in which there is accumulation of lipoproteinaceous material within the alveoli. It can be congenital, but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against the cytokine GM-CSF. The disease mostly affects men and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in about 50%, and the condition is thus different from fibrosing alveolitis. Diagnosis is made by bronchial lavage, which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells.

Extrinsic allergic alveolitis

In this disease there is a widespread diffuse inflammatory reaction in both the small airways of the lung and the alveoli. It is due to the inhalation of a number of different antigens, the most common being microbial spores contaminating vegetable matter (e.g. straw, hay, mushroom compost). Some examples are illustrated in Table 14.16. By far the most common of these diseases worldwide is farmer's lung, which affects up to 1 in 10 of the farming community in disadvantaged, wet communities around the world. In the West the incidence is declining as more mechanized farming procedures and better informed animal husbandry are introduced.

Pathogenesis

Histologically there is an initial infiltration of the small airways and alveolar walls with neutrophils followed by T lymphocytes and macrophages, leading to the development of small non-caseating granulomas. These comprise multinucleated giant cells, occasionally containing the inhaled antigenic material. The allergic response to the inhaled antigens involves both cellular immunity and the deposition of immune complexes causing foci of inflammation through the activation of complement via the classical pathway. Some of the inhalant materials may also lead to inflammation by

Table 14.16 **Extrinsic allergic (bronchiolar) alveolitis - some causes**

Disease	Situation	Antigens
Farmer's lung	Forking mouldy hay or any other mouldy vegetable material	Thermophilic actinomycetes, e.g. *Micropolyspora faeni*
Bird fancier's lung	Handling pigeons, cleaning lofts or budgerigar cages	Fungi, e.g. *Aspergillus umbrasus* Proteins present in the 'bloom' on the feathers and in excreta
Maltworker's lung	Turning germinating barley	*Aspergillus clavatus* Possibly a variety of bacteria or amoeba (e.g. *Naegleha gruberi)*
Humidifier fever	Contaminated humidifying systems in air conditioners or humidifiers in factories (especially in printing works)	Thermoactinomyces
Mushroom workers	Turning mushroom compost	Thermophilic actinomycetes
Cheese washer's lung	Mouldy cheese	*Penicillin casei Aspergillus clavatus* Botrytis
Wine maker's lung	Mould on grapes	

directly activating the alternative complement pathway. These mechanisms attract and activate alveolar and interstitial macrophages, so that continued antigenic exposure results in the progressive development of pulmonary fibrosis.

Clinical features

Typically fever, malaise, cough and shortness of breath come on several hours after exposure to the causative antigen. Thus, a farmer forking hay in the morning may notice symptoms during the late afternoon and evening with resolution by the following morning. On examination, the patient may have a fever, tachypnoea, and coarse end-inspiratory crackles and wheezes throughout the chest. Cyanosis caused by ventilation-perfusion mismatch may be severe even at rest. Continued exposure leads to a chronic illness characterized by severe weight loss, effort dyspnoea and cough as well as the features of fibrosing alveolitis (see p. 941).

Investigations

- **Chest X-ray** shows fluffy nodular shadowing with the subsequent development of streaky shadows, particularly in the upper zones. In very advanced cases, honeycomb lung occurs.
- **Lung function tests** show a restrictive ventilatory defect with a decrease in carbon monoxide gas transfer.
- **Polymorphonuclear leucocyte count** is raised in acute cases. Eosinophilia is not a feature.
- **Precipitating antibodies** are present in the serum. One-quarter of pigeon fanciers have precipitating IgG-antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are evidence of exposure, not disease.
- **Bronchoalveolar lavage** shows increased T lymphocytes and granulocytes.

Differential diagnosis

Although extrinsic allergic alveolitis due to inhalation of the spores of *Micropolyspora faeni* is common among farmers, it is probably more common for these individuals to suffer from asthma related to inhalation of antigens from a variety of mites that infest stored grain and other vegetable material. These include *Lepidoglyphus domesticus, L. destructor* and *Acarus siro.* Symptoms of asthma resulting from inhalation of these allergens are often mistaken for farmer's lung. Lung function tests will effectively discriminate between the disorders. Pigeon fancier's lung is quite common, but alveolitis from budgerigars, parrots and parakeets is very rare.

Management

Prevention is the aim. This can be achieved by changes in work practice, with the use of silage for animal fodder and the drier storage of hay and grain. Pigeon fancier's lung is more difficult to control since affected individuals remain strongly attached to their hobby. Prednisolone, initially in large doses of 30-60 mg daily, may achieve regression during the early stages of the disease. Established fibrosis will not resolve and in some patients the disease may progress inexorably to respiratory failure in spite of intensive therapy. Farmer's lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending upon their degree of disability.

Humidifier fever (Table 14.16)

Humidifier fever, one cause of building-related illnesses (p. 1033), may present with the typical features of extrinsic allergic alveolitis without any radiographic changes. This disease has occurred in outbreaks in factories in the UK, particularly in printing works. In North America it is more commonly found in office blocks with contaminated air-conditioning systems. Humidifier fever may be effectively prevented by sterilization of the re-circulating water used in large humidifying plants.

Drug-induced respiratory reactions (Table 14.17)

Drugs may produce a wide variety of disorders of the respiratory tract. The mechanisms are varied and include direct toxicity (e.g. bleomycin), immune complex

Table 14.17 **Some drug-induced respiratory reactions**

Disease	Drugs
Bronchospasm	Penicillins, cephalosporins Sulphonamides Aspirin/NSAIDs Monoclonal antibodies, e.g. infliximab Iodine-containing contrast media fi-Adrenoceptor-blocking drugs, (e.g. propranolol) Non-depolarizing muscle relaxants Intravenous thiamine Adenosine
Diffuse parenchymal damage and/or fibrosis	Amiodarone Anakinra (IL-1 receptor antagonist) Nitrofurantoin Paraquat Continuous oxygen Cytotoxic agent (many, particularly busulfan, CCNU, bleomycin, methotrexate)
Pulmonary eosinophilia	Antibiotics: Penicillin Tetracycline Sulphonamides, e.g. sulfasalazine NSAIDs Cytotoxic agents
Acute lung injury	Paraquat
Pulmonary hypertension	Fenfluramine
SLE-like syndrome including pulmonary infiltrates, effusions and fibrosis	Hydralazine Procainamide Isoniazid Phenytoin ACE inhibitors Monoclonal antibodies

CCNU, chloroethyl-cyclohexyl-nitrosourea (lomustine); NSAIDs, non-steroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus

formation with arteritis, hypersensitivity (involving both T cell and IgE mechanisms) and autoimmunity.

Pulmonary infiltrates with fibrosis may result from the use of a number of cytotoxic drugs used in the treatment of cancer. The most common cause of these reactions is bleomycin. The pulmonary damage is dose-related, occurring when the total dosage is greater than 450 mg, but will regress in some cases if the drug is stopped. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution. Drugs affecting the respiratory system are shown in Table 14.17, together with the types of reaction they produce. Anaphylaxis with bronchospasm can occur with many drugs. The list is not exhaustive; for example, over 20 different drugs are known to produce a systemic lupus erythematosus-like syndrome, sometimes complicated by pulmonary infiltrates and fibrosis. Paraquat ingestion (see p. 1018) causes severe pulmonary oedema and death, and pulmonary fibrosis develops in many of those who survive.

Radiation damage

Irradiation of the lung during radiotherapy can cause a radiation pneumonitis. Patients complain of breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

OCCUPATIONAL LUNG DISEASE

Exposure to dusts, gases, vapours and fumes at work can cause several different types of lung disease:

- acute bronchitis and even pulmonary oedema from irritants such as sulphur dioxide, chlorine, ammonia or the oxides of nitrogen
- pulmonary fibrosis due to mineral dust
- occupational asthma (see Table 14.12) - this is now the commonest industrial lung disease in the developed world
- extrinsic allergic alveolitis (see Table 14.16)
- bronchial carcinoma due to industrial agents (e.g. asbestos, poly cyclic hydrocarbons, radon in mines).

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis) and tin (stannosis) lead to dramatic dense nodular shadowing on the chest X-ray, their effect on lung function and symptoms is minimal. Exposure to silica or asbestos, on the other hand, leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and used to account **for** 90% of all compensated industrial lung diseases in the UK. The term 'pneumoconiosis' means the accumulation of dust in the lungs and the reaction of the tissue to its presence. The term is not wide enough to encompass all occupational lung disease and is now

generally used only in relation to coal dust and its effects on the lung.

Coal-worker's pneumoconiosis

Improved conditions and the progressive contraction of the coal industry in the UK have led to a considerable reduction in the number of cases of pneumoconiosis. The disease is caused by dust particles approximately 2-5 |im in diameter that are retained in the small airways and alveoli of the lung. The incidence of the disease is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Two very different syndromes result from the inhalation of coal.

Simple pneumoconiosis

This simply reflects the deposition of coal dust in the lung. It produces fine micronodular shadowing on the chest X-ray and is by far the most common type of pneumoconiosis. It is graded on the chest X-ray appearance according to standard categories set by the International Labour Office (see below). Considerable dispute remains about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases the symptoms are due to COPD related to cigarette smoking, but this is not always the case. Changes to UK workers' compensation legislation means that coal miners who develop COPD may be compensated for their disability regardless of their chest X-ray appearance. Categories of simple pneumoconiosis are as follows:

1. small round opacities definitely present but few in number
2. small round opacities numerous but normal lung markings still visible
3. small round opacities very numerous and normal lung markings partly or totally obscured.

Simple pneumoconiosis may lead to the development of progressive massive fibrosis (PMF) (see below). PMF virtually never occurs on a background of category 1 simple pneumoconiosis but occurs in about 7% of those with category 2 and in 30% of those with category 3. Miners with category 1 pneumoconiosis are unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes may be compensated solely on the basis of their X-ray appearances.

Progressive massive fibrosis

In PMF, patients develop round fibrotic masses several centimetres in diameter, almost invariably in the upper lobes and sometimes having necrotic central cavities. The pathogenesis of PMF is still not understood, though it seems clear that some fibrogenic promoting factor is present in individuals developing the disease. At one time this was thought to be *M. tuberculosis,* but it is more probably due to immune complexes, analogous to the development of large fibrotic nodules in coal miners with rheumatoid arthritis (Caplan's syndrome). Rheumatoid factor and antinuclear antibodies are both often present in the serum of patients with PMF, and also in those suffering from asbestosis or silicosis. Pathologically there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive ventilatory defect with loss of lung volume, irreversible airflow limitation and reduced gas transfer.

The patient with PMF suffers considerable effort dyspnoea, usually with a cough. The sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

Silicosis

This disease is uncommon though it may still be encountered in stonemasons, sand-blasters, pottery and ceramic workers and foundry workers involved in fettling (removing sand from metal castings made in sand-filled moulds). Silicosis is caused by the inhalation of silica (silicon dioxide). This dust is highly fibrogenic. For example, a coal miner can remain healthy with 30 g of coal dust in his lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis (see Fig. 14.42). The chest X-ray appearances and clinical features of silicosis are similar to those of PMF, but distinctive thin streaks of calcification may be seen around the hilar lymph nodes ('eggshell' calcification).

Asbestosis

Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to heat, acid and alkali, and has been widely used for roofing, insulation and fireproofing. Asbestos has been mined in southern Africa, Canada, Australia and eastern Europe. Several different types of asbestos are recognized: about 90% of asbestos is chrysotile, 6% crocidolite and 4% amosite. Chrysotile or white asbestos is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite. Crocidolite (blue asbestos) is particularly resistant to chemical destruction and exists in straight fibres up to 50 mm in length and 1-2 |a,m in width. Crocidolite is the most likely type of asbestos to produce asbestosis and mesothelioma. This may be due to the fact that it is readily trapped in the lung. Its long, thin shape means that it can be inhaled, but subsequent rotation against the long axis of the smaller airways, particularly in turbulent airflow during expiration, causes the fibres to impact. Crocidolite is also particularly resistant to macrophage and neutrophil enzymatic destruction.

Exposure to asbestos occurred particularly in shipbuilding yards and in power stations, but its ubiquitous use meant that low levels of exposure were common. Up to 50% of urban dwellers have been found to have asbestos bodies (asbestos fibre covered in protein secretions) in

their lungs at post-mortem. Regulations in the UK prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem. Workers continue to be exposed to blue asbestos in the course of demolition or in the replacement of insulation, and it should be remembered that there is a considerable time lag between exposure and development of disease, particularly mesothelioma (20-40 years).

A synergistic relationship exists between asbestosis and cigarette smoking and the development of bronchial carcinoma, usually adenocarcinoma; the risk is multiplied fivefold above the risk attributable to smoking. The risk of lung cancer is also increased in non-smokers, especially in those who have parenchymal asbestosis but also in those with pleural plaques without parenchymal fibrosis.

The diseases caused by asbestos are summarized in Table 14.18. Bilateral diffuse pleural thickening, asbestosis, mesothelioma and asbestos-related carcinoma of the bronchus are all eligible for industrial injuries benefit in the UK, but account for only one-quarter of the number of cases of compensation compared with coal-worker's pneumoconiosis.

Asbestosis is defined as fibrosis of the lungs caused by asbestos dust, which may or may not be associated with fibrosis of the parietal or visceral layers of the pleura. It is a progressive disease characterized by breathlessness and accompanied by finger clubbing and bilateral basal end-inspiratory crackles. Fibrosis, not detectable on chest X-ray, may be revealed on CT scan. No treatment is known to alter the progress of the disease, though corticosteroids are often prescribed.

Mesothelioma

The number of cases of mesothelioma has increased progressively since the mid-1980s and has now reached over 1000 cases per year. Pleural effusions are the most common presentation of mesothelioma, typically with persistent chest wall pain, which should raise the index of suspicion even if the initial pleural fluid or biopsy samples are non-diagnostic. Often a video-assisted thoracoscopic

Table 14.18 **The effects of asbestos on the lung**

	Exposure	Chest X-ray	Lung function	Symptoms	Outcome
Asbestos bodies	Light	Normal	Normal	None	Evidence of asbestos exposure only
Pleural plaques	Light	Pleural thickening (parietal pleura) and calcification (also in diaphragmatic pleura)	Mild restrictive ventilatory defect	Rare, occasional mild effort dyspnoea	No other sequelae
Effusion	First two decades following exposure	Effusion	Restrictive	Pleuritic pain, dyspnoea	Often recurrent
Bilateral diffuse pleural thickening	Light/moderate	Bilateral diffuse thickening (of both parietal and visceral pleura) more than 5 mm thick and extending over more than one-quarter of the chest wall	Restrictive ventilatory defect	Effort dyspnoea	May progress in absence of further exposure
Mesothelioma	Light (interval of 20-40 years from exposure to disease)	Pleural effusion, usually unilateral	Restrictive ventilatory defect	Pleuritic pain, increasing dyspnoea	Median survival 2 years
Asbestosis	Heavy (interval of 5-10 years from exposure to disease)	Diffuse bilateral streaky shadows, honeycomb lung	Severe restrictive ventilatory defect and reduced gas transfer	Progressive dyspnoea	Poor, progression in some cases after exposure cases
Asbestos-related carcinoma of the bronchus	The features of asbestosis, bilateral diffuse pleural thickening or bilateral pleural plaques plus those of bronchial carcinoma				Fatal

lung biopsy is needed to obtain sufficient tissue for diagnosis. In the event of a positive pleural biopsy diagnosis, local radiotherapy should be given to prevent the seeding of mesothelioma cells down the needle track. No treatment influences the universally fatal outcome.

Byssinosis

This disease occurs world-wide but is declining rapidly in areas where the numbers of people employed in cotton mills are falling. In the UK the disease used to occur in areas of Lancashire and Northern Ireland but is now a historical footnote. The symptoms start on the first day back at work after a break (Monday sickness) with improvement as the week progresses. Tightness in the chest, cough and breathlessness occur within the first hour in dusty areas of the mill, particularly in the blowing and carding rooms where raw cotton is cleaned and the fibres are straightened.

The exact nature of the disease and its aetiology remain disputed. Two important features are that pure cotton does not cause the disease, and that cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly badly affected by exposure to cotton dust. The most likely aetiology is endotoxins from bacteria present in the raw cotton causing constriction of the airways of the lung. There are no changes on the chest X-ray and there is considerable dispute as to whether the progressive airflow limitation seen in some patients with the disease is due to the cotton dust or to other factors such as cigarette smoking or co-existent asthma.

Berylliosis

Beryllium-copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature and corrosion. It is used in the aerospace industry, in atomic reactors and in many electrical devices.

When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to sarcoidosis. The major chronic problem is that of progressive dyspnoea with pulmonary fibrosis. However, strict control of levels in the working atmosphere have made the disease a rarity.

Beckett WS (2000) Occupational respiratory disorders. *New England Journal of Medicine* 342: 406-413. Parker C, Neville E (2003) Management of malignant mesothelioma. *Thorax* 58: 809-813.

LUNG CYSTS

These may be congenital, bronchogenic cysts or may result from a sequestrated pulmonary segment. Hydatid disease causes fluid-filled cysts. Thin-walled cysts are due to lung abscesses, which are particularly found in staphylococcal pneumonia, tuberculous cavities, septic pulmonary infarction, primary bronchogenic carcinoma, cavitating metastatic neoplasm, or paragonimiasis caused by the lung fluke *Pamgonimus ivestermani.*

TUMOURS OF THE RESPIRATORYTRA

Bronchial carcinoma accounts for 95% of all primary tumours of the lung. Alveolar cell carcinoma accounts for 2% of lung tumours, and other less malignant or benign tumours account for the remaining 3%.

MALIGNANT TUMOURS

Bronchial carcinoma

This is the most common malignant tumour in the West and is the third most common cause of death in the UK after heart disease and pneumonia. Mortality rates worldwide are highest in Scotland, closely followed by England and Wales. In the UK, 32 000 people die each year from bronchial carcinoma, with a male-to-female ratio of 3 : 1. Although the mortality rate from this disease has levelled off in men, it continues to rise in women, and now causes more deaths from malignant disease in women than any other tumour.

The strength of the association between cigarette smoking and bronchial carcinoma overshadows any other aetiological factors (Table 14.19), but there is a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Passive smoking (the frequent inhalation of other people's smoke by non-smokers) increases the risk of bronchial carcinoma by a factor of 1.5. Occupational factors include exposure to asbestos, and an association is also claimed for workers in contact with arsenic, chromium, iron oxide, petroleum products and oils, coal tar, products of coal combustion, and radiation. Tumours associated with occupational factors are mostly adenocarcinomas and appear to be less related to cigarette smoking.

Cell types

Based on the characteristics of the disease and its response to treatment bronchial carcinoma maybe divided into small-cell carcinoma and non-small-cell

Table 14.19 **Death rates from lung cancer (age standardized) per 100 000 according to smoking habits in male British doctors**

Death rate		Number of cigarettes per day	Death rate
Non-smokers	10	1-14	**78**
Ex-smokers	**43**	15-24	127
Continuing smokers		25 or more	251
Any tobacco	104		
Pipe/cigar	58		
Cigarettes	**140**		

carcinoma. Studies of mean doubling times of carcinomas indicate that development from the initial malignant change to presentation takes about 15 years for adenocarcinoma, 8 years for squamous carcinoma and 3 years for small-cell carcinoma. ■

Non-small-cell carcinoma

Squamous or *epidermoid carcinoma* is the commonest type, accounting for approximately 40% of all carcinomas. Most present as obstructive lesions of the bronchus leading to infection. It occasionally cavitates (10%) at presentation. The cells are usually well differentiated but occasionally anaplastic. Local spread is common but widespread metastases occur relatively late.

Adenocarcinoma arises from mucous cells in the bronchial epithelium. Invasion of the pleura and the mediastinal lymph nodes is common, as are metastases to the brain and bones. Adenocarcinoma accounts for approximately 10% of all bronchial carcinomas. It is the most common bronchial carcinoma associated with asbestos and is proportionally more common in non-smokers, in women, in the elderly, and in the Far East.

Large cell carcinomas are less-differentiated forms of squamous cell and adenocarcinomas. These account for about 25% of all lung cancers and metastasize early.

Bronchoalveolar cell carcinoma (also termed bronchiolar carcinoma) accounts for only 1-2% of lung tumours and occurs either as a peripheral solitary nodule or as diffuse nodular lesions of multicentric origin. Occasionally this tumour is associated with expectoration of very large volumes of mucoid sputum.

Small-cell carcinoma

This tumour, often called oat-cell carcinoma, accounts for 20-30% of all lung cancers. It arises from endocrine cells (Kulchitsky cells). These cells are members of the APUD system, which explains why many polypeptide hormones are secreted by these tumours. Some of these polypeptides act in an autocrine fashion: they feed back on the cells and cause cell growth. Small-cell carcinoma spreads early and is almost always inoperable at presentation. The tumour is rapidly growing and highly malignant. It responds to chemotherapy but the prognosis remains poor.

Clinical features

The frequencies of the common symptoms of lung cancer on presentation are shown in Table 14.20. Chest pain and discomfort are often described as fullness and pressure in the chest. Sometimes the pain may be pleuritic owing to invasion of the pleura or ribs.

Often there are no abnormal physical signs. Enlarged supraclavicular lymph nodes may be present. There may be signs of a pleural effusion or of lobar collapse. Signs of an unresolved pneumonia or of associated underlying disease (e.g. diffuse pulmonary fibrosis in asbestosis) may be present.

Direct spread

The tumour may directly involve the pleura and ribs. Carcinoma in the apex of the lung can erode the ribs and involve the lower part of the brachial plexus (C8, Tl and T2), causing severe pain in the shoulder and down the inner surface of the arm (Pancoast's tumour). The sympathetic ganglion can also be involved, producing Horner's syndrome. Hilar tumours may involve the recurrent laryngeal nerve, causing unilateral vocal cord paresis with hoarseness and a bovine cough.

Bronchial carcinoma can also directly invade the phrenic nerve, causing paralysis of the ipsilateral hemidiaphragm. It can involve the oesophagus, producing progressive dysphagia, and the pericardium, producing pericardial effusion and malignant dysrhythmias. *Superior vena caval obstruction* causes early morning headache, facial congestion and oedema involving the upper limbs; the jugular veins are distended, as are the veins on the chest that form a collateral circulation with veins arising from the abdomen.

Table 14.20 **The frequency of the common presenting symptoms of bronchial carcinoma**

Symptom	Frequency (%)
Cough	41
Chest pain	22
Cough and pain	15
Coughing blood	7
Chest infection	<5
Malaise	<5
Weight loss	<5
Shortness of breath	<5
Hoarseness	<5
Distant spread	<5
No symptoms	<5

Metastatic complications

Bony metastases are common, giving rise to severe pain and pathological fractures. There is frequent involvement of the liver. Secondary deposits in the brain present as a change in personality, epilepsy or as a focal neurological lesion. Spinal cord compression is not uncommon and requires urgent treatment (p. 492). Secondary deposits in the adrenal gland are a very frequent post-mortem finding but are often asymptomatic.

Non-metastatic extrapulmonary manifestations

Although approximately 10% of small-cell tumours produce ectopic hormones at some stage, clinical extrapulmonary manifestations are relatively rare apart from finger clubbing (Table 14.21).

Hypertrophic pulmonary osteoarthropathy (HPOA) (see p. 588) occurs in approximately 3% of all bronchial carcinomas, particularly squamous-cell carcinomas and adenocarcinomas. Symptoms include joint stiffness and severe pain in the wrists and ankles, sometimes associated with gynaecomastia. X-rays show a characteristic proliferative periostitis at the distal ends of long bones, which have an onion-skin appearance. HPOA is invariably associated with clubbing of the fingers. It may regress after resection of the lung tumour or as a result of vagotomy at thoracotomy.

Table 14.21 **Non-metastatic manifestations of bronchial c all cases)**

Metabolic (universal at some stage) Loss of weight Lassitude Anorexia

Endocrine (10%) (usually small-cell carcinoma) Ectopic adrenocorticotrophin syndrome Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) Hypercalcaemia (usually squamous cell carcinoma) Rarer: hypoglycaemia, thyrotoxicosis, gynaecomastia

Neurological (2-16%) Encephalopathies - including subacute cerebellar degeneration Myelopathies - motor neurone disease Neuropathies - peripheral sensorimotor neuropathy Muscular disorders - polymyopathy, myasthenic syndrome (Eaton-Lambert syndrome)

Vascular and haematological (rare) Thrombophlebitis migrans Non-bacterial thrombotic endocarditis Microcytic and normocytic anaemia Disseminated intravascular coagulopathy Thrombotic thrombocytopenic purpura Haemolytic anaemia

Skeletal Clubbing (30%) Hypertrophic osteoarthropathy (± gynaecomastia) (3%)

Cutaneous (rare) Dermatomyositis Acanthosis nigricans Herpes zoster

Investigations

Chest X-ray

By the time the lung cancer is causing symptoms, it will almost always be visible on chest X-rays. Asymptomatic tumours may be seen on chest X-ray if they are more than 1 cm in diameter. Lateral views are useful to assess the hilum and masses behind the heart. CT scanning will detect smaller masses and is being evaluated for screening. A minority of tumours are confined to the central airways and mediastinum without obvious change on the plain chest X-ray. These will be readily seen at bronchoscopy or on CT scanning. Although investigation of isolated haemoptysis with a normal chest X-ray is often negative, a normal chest X-ray should not deter from further investigation, especially in smokers over the age of 40. About 70% of all primary lung cancers present with a mass, including virtually all small-cell lung cancers and most squamous cell carcinomas. Adenocarcinoma occurs more often in the periphery than the other cell types.

Carcinomas causing partial obstruction of a bronchus interrupt the mucociliary escalator, and bacteria are retained within the affected lobe. This gives rise to the so-called secondary pneumonia that is commonly seen on the chest X-ray.

Bronchial carcinoma can also appear as round shadows on a chest X-ray (see p. 886). Characteristically the edge of the tumour has a fluffy or spiked appearance, though sometimes it may be entirely smooth with cavitation.

The hilar lymph nodes on the side of the tumour are frequently involved. Bronchial carcinoma is also a common cause of large pleural effusions. Carcinoma can spread through the lymphatic channels of the lung to give rise to lymphangitis carcinomatosa; in bronchial carcinoma this is usually unilateral and associated with striking dyspnoea. The chest X-ray shows streaky shadowing throughout the lung. Bilateral lymphangitis carcinomatosa is more often due to metastatic spread, usually from tumours below the diaphragm (the stomach and colon) or from breast cancers.

Computed tomography

CT is useful for identifying disease in the mediastinum, such as enlarged lymph nodes (see Fig. 14.12, p. 887) or local spread of the tumour, and for identifying secondary spread of carcinoma to the opposite lung by detecting masses too small to be seen on the chest X-ray. CT is a poor guide to whether nodes are involved by tumour but a normal CT scan prior to surgery excludes the need for mediastinoscopy and node biopsy. CT scanning should include the liver, adrenal glands and the brain since these are common sites for metastases.

Other imaging modalities

MRI is not useful for the diagnosis of primary lung tumours. PET scanning is now the investigation of choice for assessment of the mediastinum (see p. 887).

Fibreoptic bronchoscopy (see also p. 891, Fig. 14.44) This technique is used to define the bronchial anatomy

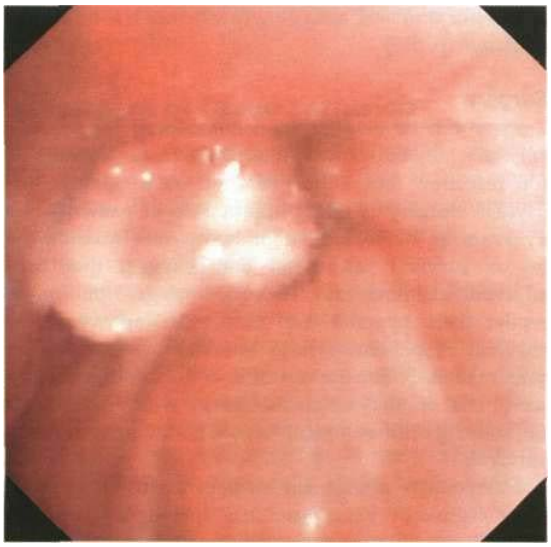

Fig. 14.44 **Bronchoscopic view of a bronchial carcinoma obstructing a large bronchus.**

and to obtain biopsy and cytological specimens. If the carcinoma involves the first 2 cm of either main bronchus, the tumour is inoperable as there would be insufficient resection margins for pneumonectomy. Widening and loss of the sharp angle of the carina indicates the presence of enlarged mediastinal lymph nodes, either malignant or reactive. These can be biopsied by passage of a needle through the bronchial wall. Vocal cord paresis on the left indicates involvement of the recurrent laryngeal nerve and inoperability.

Percutaneous aspiration and biopsy
Peripheral lung lesions cannot be seen by fibreoptic bronchoscopy and samples may be obtained by direct aspiration or biopsy through the chest wall under appropriate X-ray or CT screening. Fine-needle aspiration samples can be obtained from 75% of peripheral lesions that could not be biopsied transbronchially. Pneumothorax is common (25% of patients), occasionally requiring drainage. Mild haemoptysis occurs in 5%. Implantation metastases do not occur. Although useful if positive, negative FNA is not very helpful. Biopsies obtained with Trucut needles are usually diagnostic.

Other investigations
These include a full blood count for the detection of anaemia, biochemistry for liver involvement, hypercalcaemia and hyponatraemia.

Treatment (see also p. 518)

Treatment of lung cancer involves several different modalities and is best planned by a multidisciplinary team. Treatment decisions need to reflect the poor overall survival rates: only 20% of patients are alive 1 year after diagnosis and only 6-8% after 5 years (cf. 50% for breast or cervix). Patients are staged according to the TNM classification (p. 490) for non-small-cell cancer but small-cell cancer is treated according to whether it is limited or extensive (p. 519).

Surgery
Surgery can be curative in non-small-cell lung cancer (T1, NO, MO) but only 5-10% of all cases are suitable for resection and about 70% of these survive for 5 years. Surgery is rarely appropriate in patients over 65 years as the operative mortality rate exceeds the 5-year survival rate. Trial data suggest that neo-adjuvant chemotherapy may downstage tumours to render them operable and may also improve 5-year survival in patients whose tumours are operable at presentation. Following resection of adenocarcinomas, a recent trial of adjuvant chemotherapy with uracil-tegafir (a pro-drug of fluorouracil) has shown improvements in survival.

Preoperative assessment includes exclusion of metastatic disease by blood tests and imaging as described above. Lung function tests, including walking oximetry, are used to predict postoperative potential. An active life after pneumonectomy is unlikely if the gas transfer is reduced below 50%.

Radiation therapy for cure
In patients who are fit and who have a slowly growing squamous carcinoma, high-dose radiotherapy (65 Gy or 6500 rads) can produce good results. It is the treatment of choice if surgery is declined. Poor lung function is a relative contraindication for radiotherapy. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10-15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases. These complications usually cause no problems.

Radiation treatment for symptoms
Bone pain, haemoptysis and superior vena cava obstruction respond favourably to irradiation in the short term.

Chemotherapy is discussed on page 519. Adjuvant chemotherapy with radiotherapy improves response rate and extends median survival in non-small-cell cancer.

Laser therapy, endobronchial irradiation and tracheobronchial stents
These techniques are used in the palliation of inoperable lung cancer in selected patients with tracheobronchial narrowing from intraluminal tumour or extrinsic compression causing disabling breathlessness, intractable cough and complications, including infection, haemoptysis and respiratory failure.

A neodytnium-Yag (Nd-Yag) laser passed through a fibreoptic bronchoscope can be used to vaporize inoperable fungating intraluminal carcinoma involving short segments of trachea or main bronchus. Benign tumours, strictures and vascular lesions can also be treated effectively with immediate relief of symptoms.

Endobronchial irradiation (brachytherapy) is useful for the treatment of both intraluminal tumour and malignant extrinsic compression. A radioactive source is afterloaded into a catheter placed adjacent to the carcinoma under fibreoptic bronchoscope control. Radiation dose falls rapidly with distance from the source, minimizing damage to adjacent normal tissue. Reduction in endoscopically assessed tumour size occurs in 70-95% of cases.

Tracheobronchial stents made of silicone or as expandable metal springs are available for insertion into strictures caused by tumour or from external compression or when there is weakening and collapse of the tracheobronchial wall.

Palliative care (see **p.** 524)

Patients dying of cancer of the lung need attention to their overall well-being. Palliative care must not be ignored simply because the patient cannot be cured. Much can be done to make the patient's remaining life symptom-free and as active as possible. As compared to patients with fatal cancers at other sites, patients with lung cancer tend to remain relatively independent and pain-free, but die more rapidly once they reach the terminal phase.

Daily treatment with prednisolone (up to 15 mg daily) may improve appetite. Morphine or diamorphine are

given regularly for pain, either in the form of a sustained-release morphine sulphate tablet twice daily or else as regular elixirs or injections. Many patients benefit from a continuous subcutaneous injection of opiates given by a pump. Candidiasis and other infections in the mouth are common and must be looked for and treated. Patients taking opiates are frequently constipated, so regular laxatives should be prescribed. Short courses of palliative radiotherapy are helpful for bone pain, severe cough or haemoptysis.

Both the patient and the relatives may require counselling, a task that should be shared between the respiratory teams, the primary care team and the nurses, social workers, hospital chaplains and doctors, who make up the palliative care team.

Tracheal carcinoma

Primary tumours of the trachea are rare - their incidence relative to laryngeal and bronchial tumours is 1 : 75 and 1 :180 respectively. The majority are malignant and cause severe and rapidly progressive dyspnoea and stridor. Flow-volume curves show typical and dramatic reductions in inspiratory flow (extrathoracic tracheal tumours) (see p. 879). Diagnosis is confirmed by bronchoscopy. Rapid and effective destruction of tumour (p. 950) by laser provides temporary relief of symptoms. Radiotherapy is often given and occasionally surgery may be possible but the prognosis is very poor.

Secondary tumours

Metastases in the lung are very common and usually present as round shadows (1.5-3.0 cm diameter). They may be detected on chest X-ray in patients already diagnosed as having carcinoma. *Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.*

Metastases nearly always develop in the parenchyma and are often relatively asymptomatic even when the chest X-ray shows extensive pulmonary metastases. Rarely metastases may develop in the bronchi, when they may present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. On the chest X-ray, bilateral lymphadenopathy is seen together with streaky basal shadowing fanning out over both lung fields.

Occasionally a pulmonary metastasis may be detected as a *solitary round shadow* on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- primary bronchial carcinoma
- tuberculoma
- benign tumour of the lung
- hydatid cyst.

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases undetected on chest X-ray, surgery is seldom performed.

SCREENING FOR LUNG CANCER

Screening programmes (yearly chest X-ray, 4-monthly sputum cytology) have been tried in high-risk groups but the success rate is minimal, underlining the need for prevention. CT screening is currently being evaluated.

BENIGN TUMOURS

Pulmonary hamartoma

This is the most common benign tumour of the lung and is usually seen on the X-ray as a very well-defined round lesion 1-2 cm in diameter in the periphery of the lung. Growth is extremely slow, but the tumour may reach several centimetres in diameter. Rarely it arises from a major bronchus and causes obstruction.

Bronchial carcinoid

This rare tumour resembles intestinal carcinoid tumour and is locally invasive, eventually spreading to mediastinal lymph nodes and finally to distant organs. It is a highly vascular tumour that projects into the lumen of a major bronchus causing recurrent haemoptysis. It grows slowly and eventually blocks the bronchus, leading to lobar collapse. As foregut derivatives, bronchial carcinoids may produce ACTH but do not usually produce the 5-hydroxytryptamine that is seen in midgut or hindgut carcinoid tumours.

Cylindroma, chondroma and lipoma

These are extremely rare tumours that may grow in the bronchus or trachea, causing obstruction.

Tracheal tumours

Benign tumours include squamous papilloma, leiomyoma, haemangiomas and tumours of neurogenic origin.

DISORDERS OF THE CHEST WALL AND PLEURA

Trauma

Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.

Rib fractures

Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in patients with osteoporosis. Pathological rib fractures are due to metastatic spread from carcinoma of the bronchus, breast, kidney, prostate or thyroid. Ribs can also become involved by a mesothelioma. Fractures may not be readily visible on a PA chest X-ray, so lateral X-rays and oblique views may be necessary.

Pain prevents adequate chest expansion and coughing and this can lead to pneumonia.

Treatment is with adequate oral analgesia, by local infiltration or an intercostal nerve block.

Two fractures in one rib can lead to a flail segment with paradoxical movement, i.e. part of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

Rupture of the trachea or a major bronchus

Rupture of the trachea or even a major bronchus can occur during deceleration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also occur after the insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

Rupture of the oesophagus (p. 279) Rupture of the oesophagus leads to mediastinitis usually with mixed bacterial infections. This is a serious complication of external injury, endoscopic procedures, bougienage or necrotic carcinoma, and requires vigorous antibacterial chemotherapy.

Lung contusion

This causes widespread fluffy shadows on the chest X-ray owing to intrapulmonary haemorrhage. This may give rise to acute respiratory distress syndrome (see p. 986).

Kyphoscoliosis

Kyphoscoliosis may be congenital, owing to disease of the vertebrae such as tuberculosis or osteomalacia, or due to neuromuscular disease such as Friedreich's ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the fourth or fifth decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure (see p. 985).

Ankylosing spondylitis (see also p. 564)

Limitation of chest wall movement is often well compensated by diaphragmatic movement, and so the respiratory effects of this disease are relatively mild. It is occasionally associated with upper lobe fibrosis.

Pectus excavatum and carinatum

Pectus excavatum causes few problems other than embarrassment about the deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on the chest X-ray. Pectus carinatum (pigeon chest) is often the result of rickets but is rarely seen in the West. No treatment is required.

Pleurisy

This is the term used to describe pain arising from any disease of the pleura. The localized inflammation produces sharp localized pain, made worse on deep inspiration, coughing and occasionally on twisting and bending movements. Pleurisy occurs with pneumonia, pulmonary infarct and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

Epidemic myalgia (Bornholm disease) is due to infection by Coxsackie B virus. This illness is common in young adults in the late summer and autumn and is characterized by an upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest X-ray remains normal and the illness clears within a week.

Mesothelioma (see p. 946)

Pleural effusion

A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on X-ray when 300 mL or more of fluid is present and clinically when 500 mL or more is present. The chest X-ray appearances (Fig. 14.45) range from the obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in the fissures may resemble an intrapulmonary mass. The physical signs are shown in Table 14.1 (p. 883).

Diagnosis

This is by pleural aspiration (see p. 892). The fluid that accumulates may be a transudate or an exudate.

Transudates

Effusions that are transudates can be bilateral, but are often larger on the right side. The protein content is less than 30g/L and the lactic dehydrogenase is less than 200 IU/L. Causes include:

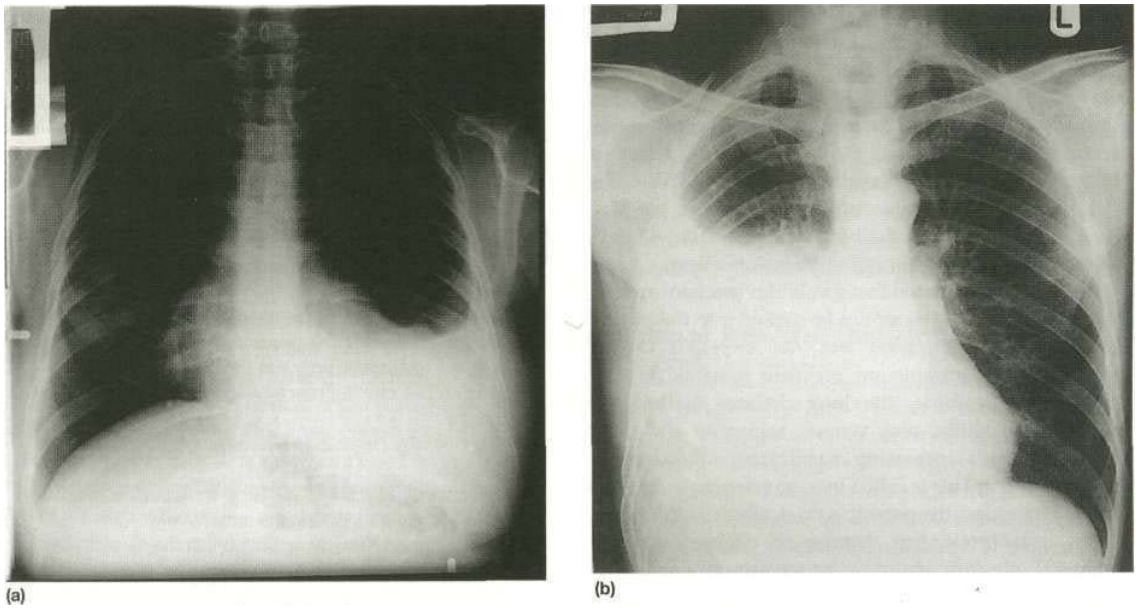

Fig. 14.45 Radiographs showing (a) small and (b) large pleural effusions.

heart failure
hypoproteinaemia (e.g. nephrotic syndrome)
constrictive pericarditis
hypothyroidism
ovarian tumours producing right-sided pleural effusion - Meigs' syndrome. ,

Exudates

The protein content of exudates is > 30 g/L and the lactic dehydrogenase is > 200 IU/L. Causes include:

bacterial pneumonia (common)
carcinoma of the bronchus and pulmonary infarction - fluid may be blood-stained (common) tuberculosis
connective-tissue disease post-myocardial
infarction syndrome (rare) acute pancreatitis (high amylase content) (rare) mesothelioma (rare)
sarcoidosis (very rare)
yellow-nail syndrome (effusion due to lymphoedema) (very rare) ■ familial Mediterranean fever (rare).

Pleural biopsy (see p. 891) may be necessary if the diagnosis has not been established by simple aspiration.

Treatment is of the underlying condition unless the fluid is purulent (empyema) in which case drainage is mandatory.

Management of malignant pleural effusions

Malignant pleural effusions that reaccumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as tetracycline or bleomycin. Effusions should be drained slowly since rapid shift of the mediastinum causes severe pain and occasionally shock. This treatment produces only temporary relief.

Chylothorax

This is due to the accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

Empyema

This is the presence of pus in the pleural space and can be a complication of pneumonia (see p. 929).

Pneumothorax

'Pneumothorax' means air in the pleural space. It may be spontaneous or occur as a result of trauma to the chest. Spontaneous pneumothorax is commonest in young males, the male-to-female ratio being 6 :1. It is caused by the rupture of a pleural bleb, usually apical, and is thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency. Often these patients are tall and thin. In patients over 40 years of age, the usual cause is underlying COPD. Rarer causes include bronchial asthma, carcinoma, a lung abscess breaking down and leading to bronchopleural fistula, and severe pulmonary fibrosis with cyst formation.

Pneumothorax may be localized if the visceral pleura has previously become adherent to the parietal pleura, or generalized if there are no pleural adhesions. Normally the pressure in the pleural space is negative but this is

lost once a communication is made with atmospheric pressure; the elastic recoil pressure of the lung then causes it to partially deflate. If the communication between the airways and the pleural space remains open, a bronchopleural fistula is created. Once the communication between the lung and the pleural space is obliterated, air will be reabsorbed at a rate of 1.25% of the total radiographic volume of the hemithorax per day. Thus, a 50% collapse of the lung will take about 40 days to reabsorb completely once the air leak is closed.

It has been postulated that a valvular mechanism may develop through which air can be sucked into the pleural space during inspiration but not expelled during expiration. The intrapleural pressure remains positive throughout breathing, the lung deflates further, the mediastinum shifts, and venous return to the heart decreases, with increasing respiratory and cardiac embarrassment. This is called tension pneumothorax and is very rare unless the patient is on positive ventilation.

The usual presenting features are sudden onset of unilateral pleuritic pain or progressively increasing breathlessness. If the pneumothorax enlarges, the patient becomes more breathless and may develop pallor and tachycardia. There may be few physical signs if the pneumothorax is small.

The characteristic features and management are shown in Figure 14.46. The main aim is to get the patient back to active life as soon as possible.

The procedure for simple aspiration is shown in Practical box 14.6.

DISORDERS OF THE DIAPHRAGM

Diaphragmatic fatigue

The diaphragm can become fatigued if the force of contraction during inspiration exceeds 40% of the force it can develop in a maximal static effort. When this occurs acutely in patients with exacerbations of COPD or cystic fibrosis or in quadriplegics, positive-pressure ventilation is required. Further rehabilitation requires exercises to increase the strength and endurance of the diaphragm by breathing against a resistance for 30 minutes a day.

Unilateral diaphragmatic paralysis

This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed when a sniff causes the paralysed diaphragm to rise, the unaffected diaphragm to descend. Causes include:

surgery ■
carcinoma of the bronchus with involvement of the phrenic nerve
neurological, including poliomyelitis, herpes zoster
trauma to cervical spine, birth injury, subclavian vein puncture
infection: tuberculosis, syphilis, pneumonia.

Practical Box 14.6
Simple aspiration

1. Explain the nature of the procedure.
2. Infiltrate 2% lidocaine down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3-4 cm 16 French gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and 50 ml_ syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat chest X-ray (in expiration) in the X-ray department.

Bilateral diaphragmatic weakness or paralysis

This causes breathlessness in the supine position and is a cause of sleep apnoea leading to daytime headaches and somnolence. Tidal volume is decreased and respiratory rate increased. Vital capacity is substantially reduced when lying down, and sniffing causes a paradoxical inward movement of the abdominal wall best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neurone disease, poliomyelitis, Guillain-Barre syndrome, quadriplegia after trauma, and rare muscle diseases. Treatment is either diaphragmatic pacing or night-time assisted ventilation.

Complete eventration of the diaphragm

This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on X-ray.

Diaphragmatic hernias

These are most commonly through the oesophageal hiatus, but occasionally occur anteriorly, through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tears.

Hiccups

Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g. subphrenic abscess) or a metabolic cause (e.g. uraemia). Treatment for persistent hiccups is with chlorpromazine 50 mg three times daily, or diazepam 5 mg three times daily. The cause should be treated, if known.

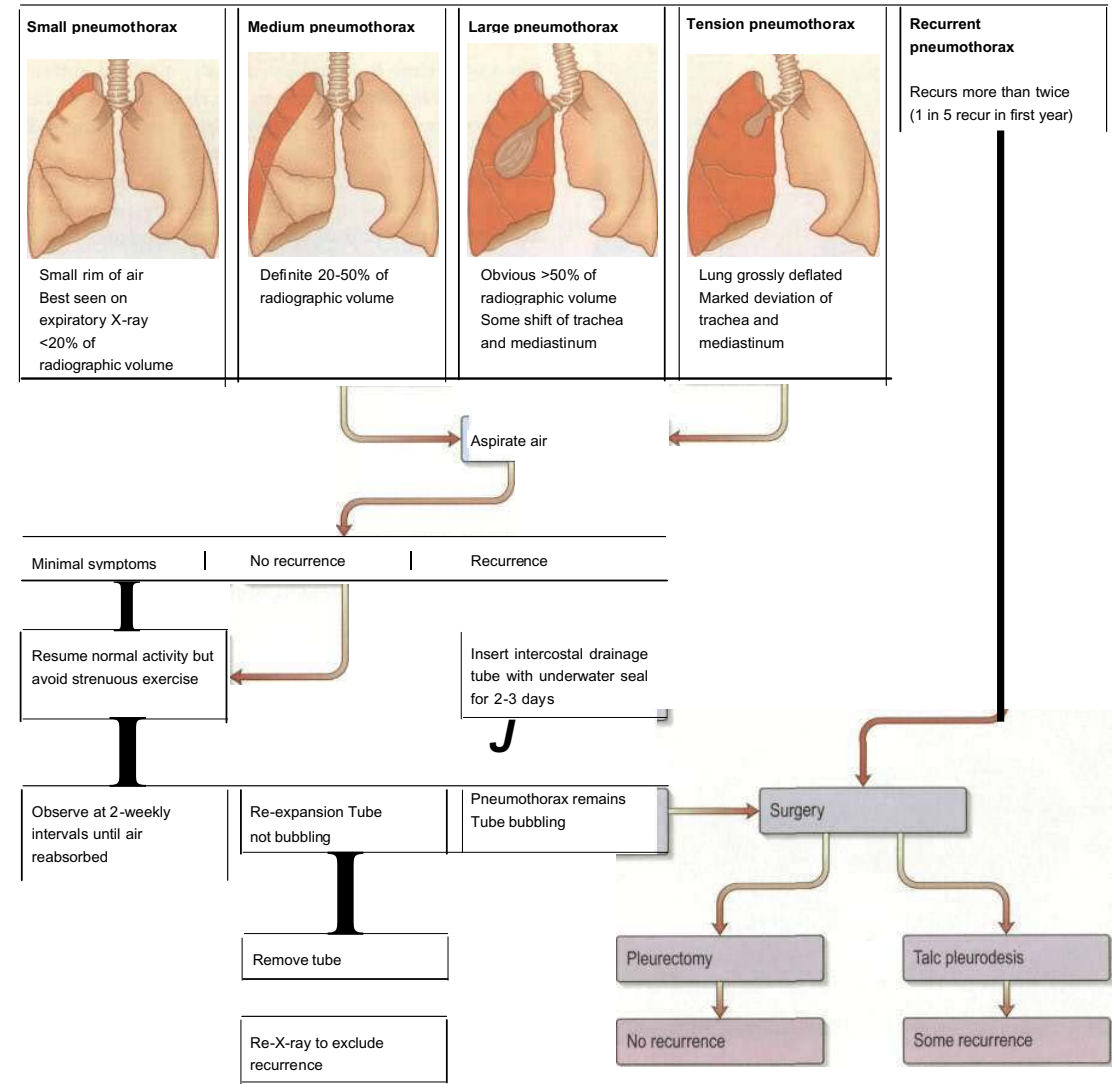

Fig. 14.46 **Pneumothorax: an algorithm for management.**

MEDIASTINAL LESIONS

The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in Figure 14.47. Tumours affecting the mediastinum are rare. Masses are detected very accurately on CT or MR scan (Fig. 14.48).

Retrosternal or intrathoracic thyroid

The most common mediastinal tumour is a retrosternal or intrathoracic thyroid, which is nearly always an extension of the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre, malignant disease or rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before producing the cardinal feature of dyspnoea. Very occasionally an intrathoracic thyroid may be the cause of dysphagia and, rarely, of hoarseness of the voice and vocal cord paralysis from stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

Thymic tumours

The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours, which may cause myasthenia gravis or lead to compression of the trachea or, rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of the patients presenting with a thymic tumour have myasthenia gravis.

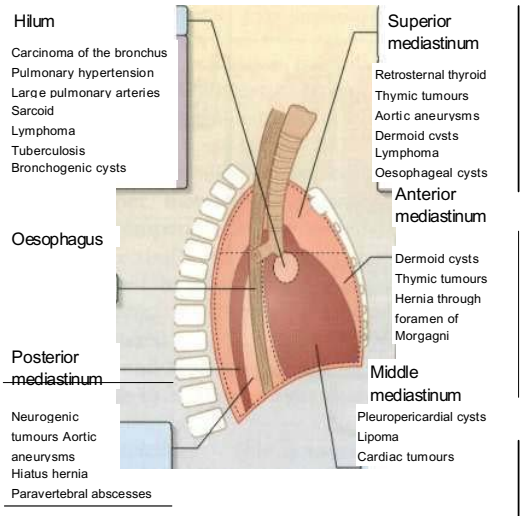

Fig. 14.47 Subdivisions of the mediastinum and mass lesions.

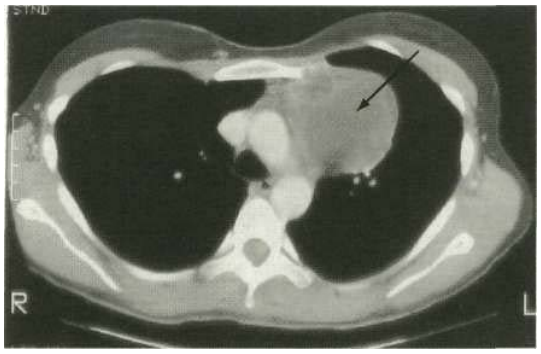

Fig. 14.48 CT scan of a dermoid cyst in the mediastinum.

Pleuropericardial cysts

These cysts, which may be up to 10 cm in diameter, are filled with clear fluid and are usually situated anteriorly in the cardiophrenic angle on the right in 70% of cases. Infection only rarely occurs; malignant change does not occur. The diagnosis is usually made by needle aspiration. No treatment is required, but these patients should be followed up as an increase in cyst size suggests an alternative pathology; surgical excision is then advisable.

Intensivecare medicine

15

Intensive care medicine (or 'critical care medicine') is concerned predominantly with the management of patients with acute life-threatening conditions ('the critically ill') in specialized units. As well as emergency cases, such units admit high-risk patients electively after major surgery (Table 15.1). Intensive care medicine also encompasses the resuscitation and transport of those who become acutely ill, or are injured, either elsewhere in the hospital (e.g. in coronary care units, acute admissions wards, postoperative recovery areas, or accident and emergency units) or in the community. Management of seriously ill patients throughout the hospital, including critically ill patients who have been discharged to the ward ('outreach care') is also undertaken. Teamwork and a multidisciplinary approach are central to the provision of intensive care and are most effective when directed and coordinated by committed specialists. An example of guidelines for involving the critical care team in the management of an acutely ill patient is shown in Box 15.1. Intensive care units (ICUs) are usually reserved for patients with established or potential organ failure and must therefore provide facilities for the diagnosis, prevention and treatment of multiple organ failure. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory (or 'near patient testing'

Table 15.1 **Some common indications for admission to intensive care**

Surgical emergencies
Acute intra-abdominal catastrophe
Ruptured/leaking abdominal aortic aneurysm Perforated viscus, especially with faecal soiling of peritoneum (often complicated by septic shock) *Trauma* (often complicated by hypovolaemic and later septic shock) Multiple injuries Massive blood loss Severe head injury

Obstetric emergencies
Severe pre-eclampsia/ eclampsia Haemorrhage
Amniotic fluid embolism

Medical emergencies
Respiratory failure
Exacerbation of chronic obstructive pulmonary disease (COPD) Acute severe asthma Severe pneumonia (may be complicated by septic shock) Meningococcal infection Status epilepticus
Severe diabetic ketoacidosis
Coma

Elective surgical
Extensive/prolonged procedure (e.g. oesophagogastrectomy)
Cardiothoracic surgery
Major head and neck surgery Coexisting cardiovascular or respiratory disease

Sox *15.1* Guidance for involving a Medical Emergency or 'Patient at Risk' team

This system should be activated if the following criteria are fulfilled and the patient is being actively treated:

- Heart rate below 40 b.p.m.
- Heart rate above 120 b.p.m.
- Systolic blood pressure above 200 mmHg
- Systolic blood pressure below 80 mmHg
- Urine output less than 0.5 mL/kg/h for 2 consecutive hours
- Respiratory rate above 30 breaths per minute
- Respiratory rate below 8 breaths per minute
- Oxygen saturation less than 90% whilst receiving supplemental oxygen
- Glasgow coma scale less than 8
- Core temperature greater than 39°C
- Core temperature less than 35°C

Modified from Lee A et al. (1995) The medical emergency team. *Anaesthesia and Intensive Care* 23: 183-186.

devices) for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and blood lactate levels. Patients can receive continuous expert nursing care and the constant attention of appropriately trained medical staff. High dependency units (HDUs) offer a level of care intermediate between that available on the general ward and that provided in an ICU. They provide monitoring and support for patients with acute (or acute-on-chronic) single organ failure and for those who are at risk of developing organ failure; facilities include short-term ventilatory support and those for immediate resuscitation. They can also provide a 'step-down' facility for patients being discharged from intensive care. These units also provide a more comfortable environment for less severely ill patients who are often conscious and alert. Intermediate care units should not be used for patients requiring multiple organ support or prolonged, sophisticated mechanical ventilation.

The provision of staff and the level of technical support must match the needs of the individual patient and resources are used more efficiently when they are combined in a single critical care facility rather than being divided between physically and managerially separate units.

In the UK only around 2.6% of hospital beds are designated for intensive care, but elsewhere in the developed world the proportion is often much higher.

GENERAL ASPECTS OF INTENSIVE CARE MANAGEMENT

Critically ill patients require multidisriplinary care with:

- Intensive skilled nursing care (usually 1:1 nurse/patient ratio in the UK).
- Regular physiotherapy.
- Careful management of pain and distress with analgesics and sedation as necessary.
- Constant reassurance and support (critically ill patients easily become disorientated and psychologically disturbed).
- Nutritional support (enteral nutrition should always be used if possible). Studies have shown various nutrients to have positive immunomodulatory effects (immunonutrition) including glutamine, polyunsaturated fatty acids and nucleotides. Confirmatory randomized studies are awaited. Growth hormone should not be used.
- The use of insulin infusions (if necessary in high doses) to normalize blood sugar appears to improve outcome from critical illness.
- H_2-receptor antagonists in selected cases to prevent stress-induced ulceration.
- TED stockings and subcutaneous heparin to prevent venous thrombosis.
- Care of the mouth, prevention of constipation and of pressure sores.

In many critically ill patients the underlying diagnosis is initially unclear, but in all cases the *immediate objective* is to preserve life and prevent, reverse or minimize damage to vital organs such as the brain, liver and kidneys. This involves a rapid assessment of the physiological derangement followed by prompt institution of measures to support cardiovascular and respiratory function in order to restore perfusion of vital organs, improve delivery of oxygen to the tissues and encourage the removal of carbon dioxide and other waste products of metabolism. The patient's condition and response to treatment should be closely monitored throughout. The underlying diagnosis can then be established as the results of investigations become available, a more detailed history is obtained and a more thorough physical examination is performed.

Discharge of patients from intensive care should normally be planned in advance and should ideally take place during normal working hours. Planned discharge may involve a period in a 'step-down' intermediate care area. Premature or unplanned discharge, especially during the night, has been associated with higher hospital mortality rates. A summary including 'points to review' should be included in the clinical notes and there should be a detailed handover to the receiving team (medical and nursing). The intensive care team should continue to review the patient, who may deteriorate following discharge, on the ward and should be available at all times for advice on further management (e.g. tracheostomy care, nutritional support). In this way deterioration and readmission to intensive care (which is associated with a particularly poor outcome) or even cardiorespiratory arrest may be avoided.

This chapter concentrates on cardiovascular and respiratory problems. Many patients also have failure of other organs such as the kidney and liver; treatment of these is dealt with in more detail in the appropriate chapters.

APPLIED CARDIORESPIRATORY

OXYGEN DELIVERY AND CONSUMPTION

Oxygen delivery (oxygen **dispatch) is defined** as the total amount of oxygen delivered to the tissues per unit time. It is dependent on the volume of blood flowing through the microcirculation per minute (i.e. the total cardiac output, Q,) and the amount of oxygen contained in that blood (i.e. the arterial oxygen content, C_ao_2). Oxygen is transported both in combination with haemoglobin and dissolved in plasma. The amount combined with haemoglobin is determined by the oxygen capacity of the haemoglobin (usually taken as 1.34 mL of oxygen per gram of haemoglobin) and its percentage saturation with oxygen (So_2), while the volume dissolved in plasma depends on the partial pressure of oxygen (Po_2). Except when hyperbaric oxygen is administered, the amount of dissolved oxygen in plasma is insignificant.

Clinically, however, the utility of this global concept of oxygen dispatch is limited because it fails to account for changes in the relative flow to individual organs and its distribution through the microcirculation (i.e. the efficiency with which oxygen delivery is matched to the metabolic requirements of individual tissues or cells). Furthermore, some organs (such as the heart) have high oxygen requirements relative to their blood flow and may become hypoxic even if the overall oxygen delivery is apparently adequate.

Cardiac output

Cardiac output is the product of heart rate and stroke volume, and is affected by changes in either (Fig. 15.2).

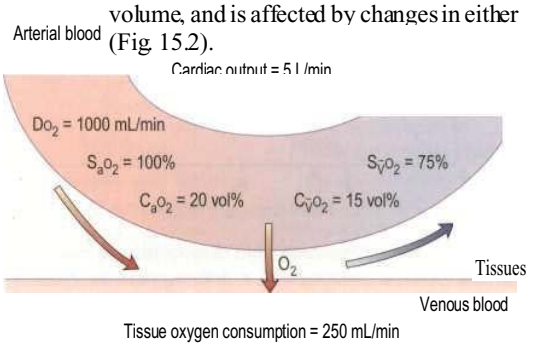

Fig. 15.1 **Tissue oxygen delivery and consumption.** *Oxygen delivery* (Do_2) = cardiac output x (haemoglobin concentration x oxygen saturation (S_ao_2) x 1.34). In normal adults it is roughly 1000 mL/min, of which 250 mL is taken up by tissues. Mixed venous blood is thus 75% saturated with oxygen. $C\hat{}o_2$, mixed venous oxygen content; $S\hat{}o_2$, mixed venous oxygen saturation. From Singer M, Grant I (eds) (1999) *ABC of Intensive Care*. London: BMJ Books, with permission.

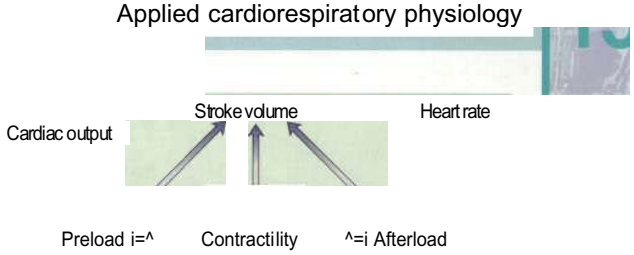

Fig. 15.2 **The determinants of cardiac output.**

Heart rate

When heart rate increases, the duration of systole remains essentially unchanged, whereas diastole, and thus the time available for ventricular filling, becomes progressively shorter, and the stroke volume eventually falls. In the normal heart this occurs at rates greater than about 160 beats per minute, but in those with cardiac pathology, especially when this restricts ventricular filling (e.g. mitral stenosis), stroke volume may fall at much lower heart rates. Furthermore, tachycardias cause a marked increase in myocardial oxygen consumption (V_mO_2) and this may precipitate ischaemia in areas of the myocardium that have reduced coronary perfusion. When the heart rate falls, a point is reached at which the increase in stroke volume is insufficient to compensate for bradycardia and again cardiac output falls.

Alterations in heart rate are often caused by disturbances of rhythm (e.g. atrial fibrillation, complete heart block) in which ventricular filling is not augmented by atrial contraction and stroke volume therefore falls.

Stroke volume

The volume of blood ejected by the ventricle in a single contraction is the difference between the ventricle end-diastolic volume (VEDV) and end-systolic volume (VESV) (i.e. stroke volume = VEDV - VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e. ejection fraction = (VEDV - VESV)/VEDV x 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume: preload, myocardial contractility and afterload (see p. 728).

Preload

This is defined as the tension of the myocardial fibres at the end of diastole, just before the onset of ventricular contraction, and is therefore related to the degree of stretch of the fibres. As the end-diastolic volume of the ventricle increases, tension in the myocardial fibres is increased and stroke volume rises (Fig. 15.3). V_mo_2 increases only slightly with an increase in preload and this is therefore the most efficient way of improving cardiac output.

Myocardial contractility

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in intensive care patients, as

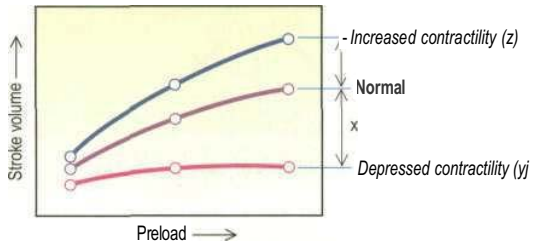

Fig. 15.3 **Ventricular function (Starling curve).** As the preload is increased, the stroke volume rises. If the ventricle is overstretched, the stroke volume will fall (x). In myocardial failure, the curve is depressed and flattened (y). Increasing contractility shifts the curve upwards and to the left (z).

a result of either pre-existing myocardial damage (e.g. ischaemic heart disease), or the acute disease process itself (e.g. sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; the resulting worsening ventricular performance is manifested as a depressed, flattened curve (Fig. 15.3 and Figs 13.0 and 13.0).

Afterload

This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilatation, an increase in intraventricular pressure or a reduction in ventricular wall thickness.

Decreasing the afterload can increase the stroke volume achieved at a given preload (Fig. 15.4), whilst reducing V_mo_2. The reduction in wall tension may also lead to an increase in coronary blood flow, thereby improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will cause hypotension.

Increasing the afterload, on the other hand, can cause a fall in stroke volume and is a potent cause of increased V_mo_2. Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is very low.

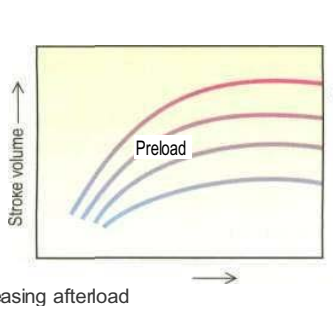

Fig. 15.4 **The effect of changes in the afterload on ventricular function curve.** At any given preload, decreasing afterload increases the stroke volume.

Oxygenation of the blood

Oxyhaemoglobin dissociation curve

The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen (Po_2) in the blood, the relationship between the two being described by the oxyhaemoglobin dissociation curve (Fig. 15.5). The sigmoid shape of this curve is significant clinically for a number of reasons:

- Modest falls in the partial pressure of oxygen in the arterial blood (P_ao_2) may be tolerated (since oxygen content is relatively unaffected) provided that the percentage saturation remains above 90%.
- Increasing the P_ao_2 to above normal has only a minimal effect on oxygen content unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- Once on the steep 'slippery slope' of the curve (percentage saturation below about 90%), a small decrease in P_ao_2 can cause large falls in oxygen content, while increasing P_ao_2 only slightly, e.g. by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content.

The P_ao_2 is in turn influenced by the alveolar oxygen tension *(PA°2),* the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood

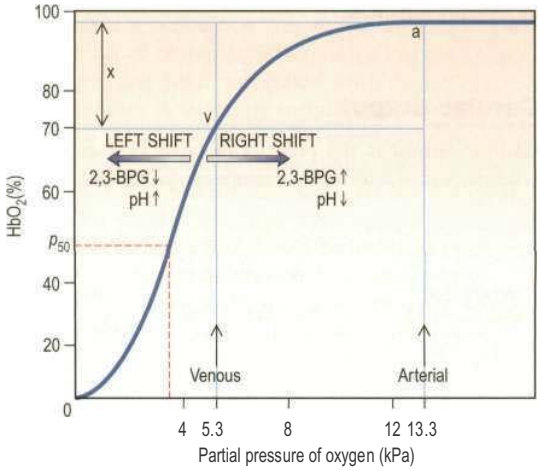

Fig. 15.5 **The oxyhaemoglobin dissociation curve.** a, arterial point; v, venous point; x, arteriovenous oxygen content difference. HbO_2 (%) is the percentage saturation of haemoglobin with oxygen. The curve will move to the right in the presence of acidosis (metabolic or respiratory), pyrexia or an increased red cell 2,3-BPG concentration. For a given arteriovenous oxygen content difference, the mixed venous Po_2 will then be higher. Furthermore, if the mixed venous Po_2 is unchanged, the arteriovenous oxygen content difference increases and more oxygen is offloaded to the tissues (see p. 423). P_{50} (the Po_2 at which haemoglobin is half saturated with O_2) is a useful index of these shifts - the higher the P_{50} (i.e. shift to the right), the lower the affinity of haemoglobin for O_2.

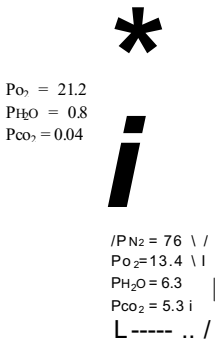

Fig. 15.6 The partial pressures of inspired and alveolar gas. Values given in kiloPascals.

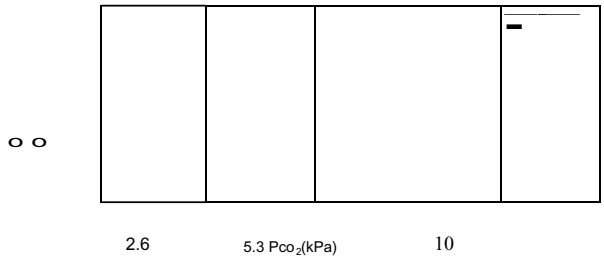

Fig. 15.7 The carbon dioxide dissociation curve. Note that in the physiological range the curve is essentially linear.

Alveolar oxygen tension ($P_A°2$)

The partial pressures of inspired gases are shown in Figure 15.6. By the time the inspired gases reach the alveoli they are fully saturated with water vapour at body temperature (37°C), which has a partial pressure of 6.3 kPa (47 mmHg), and contain CO_2 at a partial pressure of approximately 5.3 kPa (40 mmHg). The P_AO_2 is thereby reduced to approximately 13.4 kPa (100 mmHg).

The clinician can influence P_Ao_2 by administering oxygen or by increasing the barometric pressure. Because of the reciprocal relationship between the partial pressures of oxygen and carbon dioxide in the alveoli, a small increase in P_ao_2 can be produced by lowering the P_Aco_2 (e.g. by using mechanical ventilation).

Pulmonary gas exchange

In *normal* subjects there is a small alveolar-arterial oxygen difference (PA-a°2)- This is due to:

- a small (0.133 kPa, 1 mmHg) pressure gradient across the alveolar membrane
- a small amount of blood (2% of total cardiac output) bypassing the lungs via the bronchial and thebesian veins
- a small degree of ventilation/perfusion mismatch.

Pathologically there are three possible causes of an increased $P^{\wedge}{}_ao_2$ difference, as follows:

Diffusion defect

This is not a major cause of hypoxaemia even in conditions such as fibrosing alveolitis, in which the alveolar-capillary membrane is considerably thickened. Carbon dioxide is not affected, as it is more soluble than oxygen.

Right-to-left shunts

In certain congenital cardiac lesions, such as Fallot's tetralogy and when a segment of lung is completely unventilated, a considerable amount of blood bypasses the lungs and causes arterial hypoxaemia. This hypoxaemia cannot be corrected by administering oxygen to increase the P_Ao_2, because blood leaving normal alveoli is already fully saturated and further increases in Po_2 will not significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (Fig. 15.7), the high Pco_2 of the shunted blood can be compensated for by overventilating patent alveoli, thus lowering the CO_2 content of the effluent blood. Indeed, many patients with acute right-to-left shunts hyperventilate in response to the hypoxia or stimulation of mechanoreceptors in the lung, so that the P_aco_2 is normal or low.

Ventilation/perfusion mismatch (see Ch. 14) Diseases of the lung parenchyma result *inV/Q* mismatch, producing an increase in alveolar deadspace and hypoxaemia. The increased deadspace can be compensated by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low *V/Q* can be partially corrected by administering oxygen and thereby increasing the P_AO_2 even in poorly ventilated areas of lung.

Mixed venous oxygen tension ($P^{\wedge}o_2$) and saturation ($S;O_2$)

The $Py\ o_2$ is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed during its passage through the heart. Assuming P_ao_2 remains constant, $Py\ o_2$ and $S^{\wedge}\ o_2$ will fall if more oxygen has to be extracted from each unit volume of blood arriving at the tissues. A low $P^{\wedge}\ o_2$ therefore indicates either that oxygen delivery has fallen or that tissue oxygen requirements have increased without a compensatory rise in cardiac output. If PyO_2 falls, the effect of a given degree of pulmonary shunting on arterial oxygenation will be exacerbated. Thus, worsening arterial hypoxaemia does not necessarily indicate a deterioration in pulmonary function but may instead reflect a fall in cardiac output and/or a rise in oxygen consumption.

Conversely, a rise in PyO_2 and $S^{\wedge}o_2$ may reflect impaired tissue oxygen extraction (due to microcirculatory dysfunction) and/or a reduced oxygen uptake utilization (due, for example, to a mitochondrial defect) as may be seen in severe sepsis (see below).

Monitoring the oxygen saturation in central venous, rather than pulmonary artery blood is less invasive and has been shown to be a valuable guide to the resuscitation of critically ill patients (see p. 968).

DISTURBANCES OF ACID-BASE BALANCE

The physiology of acid-base control is discussed on page 716. Acid-base disturbances can be described in relation to the diagram illustrated in Figure 12.14, which shows P_aco_2 plotted against arterial $[H^+]$.

Both acidosis and alkalosis can occur, each of which may be either metabolic (primarily affecting the bicarbonate component of the system) or respiratory (primarily affecting P_aCO_2). Compensatory changes may also be apparent. In clinical practice, arterial $[H^+]$ values outside the range 18-126 nmol/L (pH 6.9-7.7) are very rarely encountered.

Blood gas and add-base values (normal ranges) are shown in Table 15.2. For blood gas analysis, see p. 980.

Respiratory acidosis. This is caused by retention of carbon dioxide. The P_aco_2 and $[H^+]$ rise. A chronically raised P_aco_2 is compensated by renal retention of bicarbonate, and the $[H^+]$ returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2-5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis (see p. 716). Common causes of respiratory acidosis include ventilatory failure and COPD (type II respiratory failure where there is a high P_aco_2 and a low P_ao_2 - see Ch. 14).

Respiratory alkalosis. In this case the reverse occurs and there is a fall in P_aco_2 and $[H^+]$, often with a small reduction in bicarbonate concentration. If hypocarbia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice this is unusual. A respiratory alkalosis is often produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen with hypoxaemic (type I) respiratory failure (see Ch. 14), spontaneous hyperventilation and in those living at high altitudes.

Metabolic acidosis (p. 716). This may be due to excessive acid production, most commonly lactate and H^+ (lactic acidosis) as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest. A metabolic acidosis may also develop in chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut, for example, or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis is usually slightly delayed because the blood-brain barrier initially prevents the respiratory centre from sensing the increased blood $[H^+]$. Following this short delay, however, the patient hyperventilates and 'blows off carbon dioxide to produce a compensatory respiratory alkalosis. There is a limit to this respiratory compensation, since in practice values for P_aco_2 less than about 1.4 kPa (11 mmHg) are never achieved. It should also be noted that spontaneous respiratory compensation cannot occur if the patient's ventilation is controlled or if the respiratory centre is depressed, for example by drugs or head injury.

Metabolic alkalosis. This can be caused by loss of acid, for example from the stomach with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable alkali. Overzealous treatment with intravenous sodium bicarbonate is frequently implicated. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a P_aco_2 above 6.5 kPa (50 mmHg), even with severe alkalosis.

Table 15.2 **Arterial blood gas and acid-base values (normal ranges)**

H^+	35-45 nmoi/L	pH 7.35-7.45
Po₂	10-13.3 kPa	(75-100 mmHg)
Pco_2	4.8-6.1 kPa	(36-46 mmHg)
Base deficit	±2.5	
Plasma HCCV	22-26 mmol/L	
O_2 saturation	95-100%	

SHOCK AND ACUTE DISTURBANCES OF HAEMODYNAMIC FUNCTION

Shock is difficult to define. The term is used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion resulting in generalized cellular hypoxia.

Causes of shock

Abnormalities of tissue perfusion may result from:

- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in Table 15.3. Often shock can result from a combination of these factors (e.g. in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).

Table 15.3 **Causes of shock**

Hypovolaemic
Exogenous losses
(e.g. haemorrhage, burns)
Endogenous losses

Cardiogenic
(e.g. ischaemic cardiac damage)

Obstructive
Obstruction to outflow (e.g. pulmonary embolus)
Restricted cardiac filling (e.g. cardiac tamponade, tension pneumothorax)

Distributive
(e.g. sepsis, anaphylaxis) Vascular dilatation Sequestration
Arteriovenous shunting
Maldistribution of flow
Myocardial depression

PATHOPHYSIOLOGY

The sympatho-adrenal response to Shock (Fig. 15.8)

Hypotension stimulates the baroreceptors, and to a lesser extent the chemoreceptors, causing increased sympathetic nervous activity with 'spill-over' of norepinephrine (noradrenaline) into the circulation. Later this is augmented by the release of catecholamines (predominantly epinephrine (adrenaline)) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, help to restore blood pressure and cardiac output. Reduction in perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which is in turn converted in the lungs and by the vascular endothelium to the potent vasoconstrictor angiotensin II. Angiotensin II also stimulates secretion of aldosterone by the adrenal cortex, causing sodium and water retention (p. 1096). This helps to restore the circulating volume (see p. 690).

Neuroendocrine response

- There is *release of pituitary hormones* such as adrenocorticotrophic hormone (ACTH), vasopressin (antidiuretic hormone, ADH) and endogenous opioid peptides.
- There is *release of cortisol,* which causes fluid retention and antagonizes insulin.

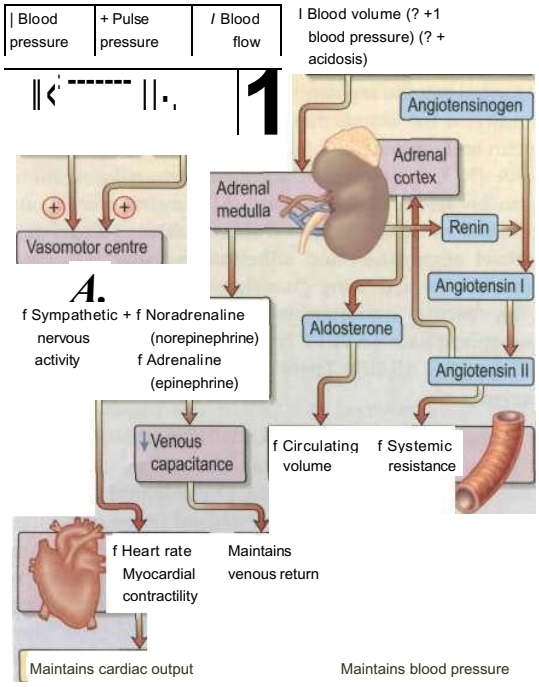

Fig. 15.8 The sympatho-adrenal response to shock.

- There is *release of glucagon,* which raises the blood sugar level.

Although absolute adrenocortical insufficiency (due, for example, to bilateral adrenal haemorrhage or necrosis) is rare, there is evidence that patients with septic shock have blunted response to exogenous ACTH (so-called 'relative' or 'occult' adrenocortical insufficiency) and that this may be associated with an impaired pressor response to norepinephrine (noradrenaline) and a worse prognosis.

Release of pro- and anti-inflammatory mediators (see also Ch. 4)

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g. following trauma or extensive surgery) or prolonged/repeated episodes of hypoperfusion can trigger an exaggerated inflammatory response with systemic activation of leucocytes and release of a variety of potentially damaging 'mediators'. Although beneficial when targeted against local areas of infection or necrotic tissue, dissemination of this 'innate immune' response can produce shock and widespread tissue damage. Characteristically the initial episode of overwhelming inflammation is followed by a period of immune suppression, which in some cases may be profound and during which the patient is at increased risk of developing secondary infections.

Microorganisms and their toxic products

In sepsis/septic shock the inflammatory cascade is triggered by the presence in the bloodstream of microorganisms, their cell wall components (e.g. endotoxin) and/or exotoxins (antigenic proteins produced by bacteria such as staphylococci, streptococci and pseudomonas). Endotoxin is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria which is a potent trigger of the inflammatory response. The lipid A portion of LPS can be bound by a protein normally present in human serum known as lipopolysaccharide binding protein (LBP). The LBP/LPS complex attaches to the cell surface marker CD14 and, combined with a secreted protein, this complex then binds to a member of the toll-like receptor family (probably TLR4), which transduces the activation signal into the cell. Another mechanism in this complex area involves TREM-I (triggering receptor expressed in myeloid cells) (see p. 202). Specific kinases then phosphorylate IκB, releasing the nuclear transcription factor NFκB, which passes into the nucleus where it binds to DNA and promotes the synthesis of a wide variety of inflammatory mediators. Cell wall components from Gram-positive bacteria, some of which are similar in structure to LPS (e.g. lipoteichoic acid), can also trigger a systemic inflammatory response, probably through similar, but not identical pathways (see Fig. 15.9).

Activation of complement cascade (see p. 201)
One of the many functions of the complement system is to attract and activate leucocytes, which then marginate

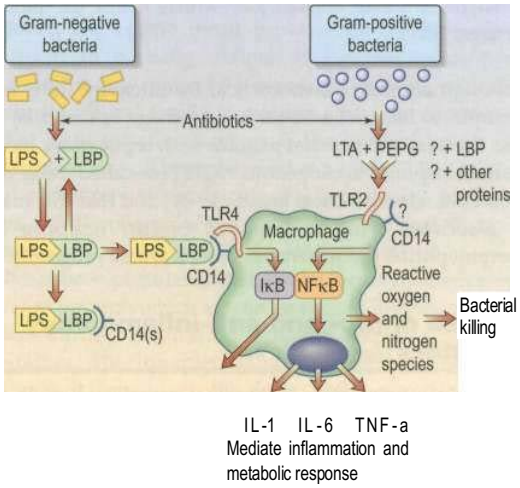

Fig. 15.9 **Induction of synthesis of cytokines, free radicals and nitric oxide by bacterial cell wall components.** LPS, lipopolysaccharide; LPB, lipopolysaccharide binding protein; LTA, lipoteichoic acid; NFκB, nuclear factor kappa B; IκB inhibitory factor kappa B; PEPG, peptidoglycan-G; TLR, toll-like receptors.

on to endothelium and release inflammatory mediators such as proteases and toxic free radicals of oxygen and other reactive oxygen and nitrogen species (see below).

Cytokines (see also p. 202)
Pro-inflammatory cytokines such as the interleukins (ILs) and tumour necrosis factor (TNF) are also mediators of the systemic inflammatory response. TNF-a release initiates many of the responses to endotoxin, for example, and acts synergistically with IL-1, in part through induction of cyclo-oxygenase, platelet-activating factor (PAF) and nitric oxide synthase (see below). The cytokine network is extremely complex, with many endogenous self-regulating mechanisms. For example, naturally occurring soluble TNF receptors are shed from cell surfaces during the inflammatory response, binding to TNF and thereby reducing its biological activity. An endogenous inhibitory protein that binds competitively to the IL-1 receptor has also been identified.

In addition to pro-inflammatory mediators such as TNF, anti-inflammatory cytokines, e.g. IL-10, are released. The ratio of IL-10 to TNF, and of TNF to TNF receptors, has been shown to be related to mortality in severe sepsis/septic shock. When excessive, this compensatory anti-inflammatory response syndrome (CARS) may be associated with an inappropriate immune hyporesponsiveness.

Platelet-activating factor (PAF)
This vasoactive lipid is released from various cell populations, such as leucocytes and macrophages, in shock. Its effects, which are caused both directly and through the secondary release of other mediators, include hypotension, increased vascular permeability and platelet aggregation.

Products of arachidonic acid metabolism
(see Fig. 14.32)
Arachidonic acid, derived from the breakdown of membrane phospholipid, is metabolized to form prostaglandins and leukotrienes, which are key inflammatory mediators (see p. 198).

Lysosomal enzymes
These can cause myocardial depression and coronary vasoconstriction. Furthermore, lysosomal enzymes can convert inactive kininogens to vasoactive kinins such as bradykinins. These substances cause vasodilatation and increased capillary permeability, as well as myocardial depression. They can also activate clotting mechanisms.

Adhesion molecules (see also p. 198) Adhesion of activated leucocytes to the vessel wall and their subsequent extravascular migration is a key component of the sequence of events leading to endothelial injury, tissue damage and organ dysfunction. This process is mediated by inducible intercellular adhesion molecules (ICAMs) found on the surface of leucocytes and endothelial cells. Expression of these molecules can be induced by endotoxin and pro-inflammatory cytokines such as IL-1 and TNF-a. Several families of molecules are involved in promoting leucocyte-endothelial interaction. The selectins are 'capture' molecules and initiate the process of leucocyte rolling on vascular endothelium, whilst members of the immunoglobulin superfamily (ICAM-1 and vascular cell adhesion molecule-1) are involved in the formation of a more secure bond which leads to leucocyte migration into the tissues (see Fig. 4.1).

Endothelium-derived vasoactive mediators
Endothelial cells synthesize a number of mediators which contribute to the regulation of blood vessel tone and the fluidity of the blood; these include nitric oxide, prostacyclin and endothelin-1 (a potent vasoconstrictor). Nitric oxide (NO) is synthesized from the terminal guanidino-nitrogen atoms of the amino acid L-arginine under the influence of nitric oxide synthase (NOS). NO inhibits platelet aggregation and adhesion and produces vasodilatation by activating guanylate cyclase in the underlying vascular smooth muscle to form cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) (Fig. 15.10). There are several distinct NOS enzymes.

- *Constitutive or endothelial NOS* (cNOS or eNOS) present in endothelial cells is responsible for the basal release of NO and is involved in the physiological regulation of vascular tone, blood pressure and tissue perfusion.
- *Neuronal NOS* (nNOS). The role of nerves containing nNOS is uncertain but they probably provide neurogenic vasodilator tone. In the central nervous system nNOS may be a regulator of local cerebral blood flow as well as fulfilling a number of other physiological functions, such as the acute modulation of neuronal firing behaviour.

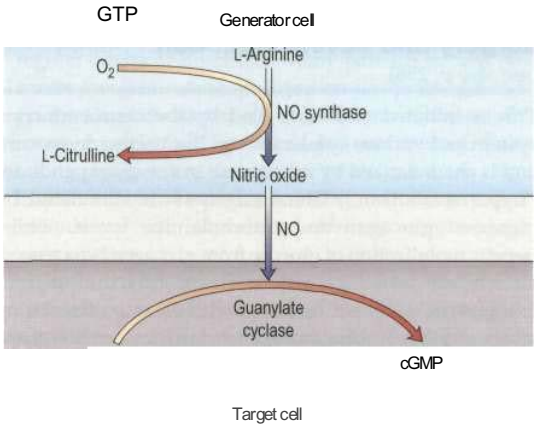

Fig. 15.10 Synthesis and biochemical action of nitric oxide.

- *Inducible NOS* (iNOS) is induced in vascular endothelial smooth muscle cells and monocytes within 4-18 hours of stimulation with certain cytokines, such as TNF-oc, and endotoxin. The resulting prolonged increase in NO formation is believed to be a cause of the sustained vasodilatation, hypotension and reduced reactivity to adrenergic agonists (Vasoplegia') that characterizes septic shock. This mechanism may also be involved in severe prolonged haemorrhage/ traumatic shock. The NO generated by macrophages contributes to their role as highly effective killers of intracellular and extracellular pathogens, in part as a consequence of its ability to bind to cytochrome oxidase and inhibit electron transport, but also via the production of the highly reactive radical peroxynitrite.

Redox imbalance

In health the balance between reducing and oxidizing conditions (redox) is controlled by antioxidants which may either prevent radical formation (e.g. transferrin and lactoferrin which bind iron, a catalyst for radical formation) or remove/inactivate reactive oxygen and nitrogen species (e.g. enzymes such as superoxide dismutases, vitamins C and E, and sulphydryl group donors such as glutathione). There are also mechanisms to remove and repair oxidatively damaged molecules and in particular to preserve DNA integrity. In severe systemic inflammation the uncontrolled production of oxygen-derived free radicals and reactive nitrogen species, e.g. superoxide (O_2*~), hydroxyl radicals (OH*), hydrogen peroxide (H_2O_2) and peroxynitrite (ONOO~) particularly by activated polymorphonuclear leucocytes can overwhelm these defensive mechanisms and cause:

lipid and protein peroxidation
damage to cell membranes
increased capillary permeability
impaired mitochondrial respiration
DNA strand breakage apoptosis (p. 162).

Haemodynamic and microcirculatory changes

The dominant haemodynamic feature of septic shock is peripheral vascular failure with:

- vasodilatation
- maldistribution of regional blood flow
- abnormalities in the microcirculation:
  - arteriovenous shunting
  - 'stop-flow' capillaries (flow is intermittent)
  - 'no-flow' capillaries (capillaries are obstructed)
  - failure of capillary recruitment
  - increased capillary permeability with interstitial oedema.

Although these *vascular and microvascular abnormalities* may partly account for the reduced oxygen extraction often seen in septic shock, there is also a *primary defect of cellular oxygen utilization* owing to mitochondrial dysfunction (see above). Initially, before hypovolaemia supervenes, or when therapeutic replacement of circulating volume has been adequate, *cardiac output is usually high and peripheral resistance is low.* These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased SyO_2 and a lactic acidosis (so-called 'tissue dysoxia'). Vasodilatation and increased permeability also occur in anaphylactic shock.

In the initial stages of other forms of shock, and sometimes when hypovolaemia and myocardial depression supervene in sepsis and anaphylaxis, cardiac output is low and increased sympathetic activity causes constriction of both precapillary arterioles and, to a lesser extent, the postcapillary venules. This helps to maintain the systemic blood pressure. In addition, the hydrostatic pressure within the capillaries falls and fluid is mobilized from the extravascular space into the intravascular compartment.

Activation of the coagulation system

The production of PGI_2 by the capillary endothelium may be impaired, cell damage (for example to the vascular endothelium) leads to the release of tissue factor (p. 466), which triggers coagulation. In severe cases these changes are compounded by elevated levels of plasminogen activation inhibitor type 1 which impairs fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S and tissue factor-pathway inhibitor). Antithrombin and protein C have a number of anti-inflammatory properties, whereas thrombin is pro-inflammatory.

Ultimately, unregulated activation of the coagulation cascade can progress to disseminated intravascular coagulation (DIC), which is characterized by widespread microvascular thrombosis, inadequate tissue perfusion and organ failure (p. 475).

The inflammatory response to shock, tissue injury and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation and widespread thrombosis. Plasminogen is converted to

plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products (FDPs). Circulating levels of FDPs are therefore increased, the thrombin time, PTT and PT are prolonged and platelet and fibrinogen levels fall. Activation of the coagulation cascade can be confirmed by demonstrating increased plasma levels of 'D' dimers. The development of DIC often heralds the onset of multiple organ failure. Because clotting factors and platelets are consumed in DIC, they are unavailable for haemostasis elsewhere and a coagulation defect results - hence the alternative name for DIC is 'consumption coagulopathy'. In some cases a microangiopathic haemolytic anaemia develops. DIC is particularly associated with septic shock, especially when due to meningococcal infection (see p. 75). Management of the underlying cause is most important. Supportive treatment includes infusions of fresh frozen plasma, platelets and occasionally factor VIII concentrates.

Reperfusion injury

Restoration of flow to previously hypoxic tissues can exacerbate cell damage through the generation of large quantities of reactive oxygen species and activation of polymorphonuclear leucocytes (see above) (Fig. 15.11). The gut mucosa seems to be especially vulnerable to this 'ischaemia-reperfusion injury'.

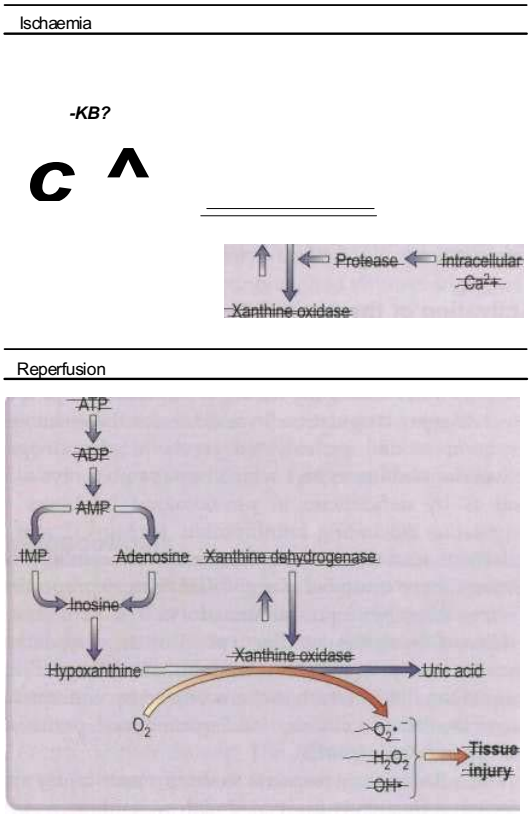

Fig. 15.11 **Generation of reactive oxygen species following ischaemia and reperfusion.**

Metabolic response to trauma, major surgery and severe infection

(see also p. 236)

This is initiated and controlled by the neuroendocrine system and various cytokines (e.g. IL-6) acting in concert, and is characterized by an increase in energy expenditure ('hypermetabolism'). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, whilst hepatic mobilization of glucose from glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol, these changes ensure that the majority of patients are hyperglycaemic ('insulin resistance'). Later hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the 'acute phase reactants' (see p. 200). The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leucocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation and delaying mobilization. Tissue repair, wound healing and immune function may also be compromised.

CLINICAL FEATURES OF SHOCK

Although many clinical features are common to all types of shock, there are certain aspects in which they differ (Box 15.2).

Hypovolaemic shock

- Inadequate tissue perfusion:
  - (a) Skin - cold, pale, blue, slow capillary refill, 'clammy'
  - (b) Kidneys - oliguria, anuria
  - (c) Brain - drowsiness, confusion and irritability
- Increased sympathetic tone:
  - (a) Tachycardia, narrowed pulse pressure, 'weak' or 'thready' pulse
  - (b) Sweating
  - (c) Blood pressure - may be maintained initially (despite up to a 25% reduction in circulating volume if the patient is young and fit), but later hypotension supervenes
- Metabolic acidosis - compensatory tachypnoea.

Extreme hypovolaemia may be associated with bradycardia. *Additional clinical features* may occur in the following types of shock.

OSox *15.2* Haemodynamic changes in shock

Hypovolaemic shock
Low central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) Low cardiac output Increased systemic vascular resistance

Cardiogenic shock
Signs of myocardial failure
Increased systemic vascular resistance
CVP and PAOP high (except when hypovolaemic)

Cardiac tamponade
Parallel increases in CVP and PAOP
Low cardiac output
Increased systemic vascular resistance

Pulmonary embolism
Low cardiac output
High CVP, high pulmonary artery pressure but low PAOP
Increased systemic vascular resistance

Anaphylaxis
Low systemic vascular resistance
Low CVP and PAOP High cardiac output

Septic shock
Low systemic vascular resistance
Low CVP and PAOP
Cardiac output usually high
Myocardial depression - low ejection fraction
Stroke volume maintained by ventricular dilatation
Cardiac output maintained or increased by tachycardia

Cardiogenic shock (see p. 797)

Signs of myocardial failure, e.g. raised jugular venous pressure (JVP), pulsus alternans, 'gallop' rhythm, basal crackles, pulmonary oedema.

Obstructive shock

- Elevated JVP
- Pulsus paradoxus and muffled heart sounds in cardiac tamponade
- Signs of pulmonary embolism (see p. 844).

Anaphylactic shock (see p. 997)

- Signs of profound vasodilatation:
  (a) Warm peripheries
  (b) Low blood pressure
  (c) Tachycardia
- Erythema, urticaria, angio-oedema, pallor, cyanosis
- Bronchospasm, rhinitis
- Oedema of the face, pharynx and larynx
- Pulmonary oedema
- Hypovolaemia due to capillary leak
- Nausea, vomiting, abdominal cramps, diarrhoea.

Sepsis, severe sepsis and septic shock

- Pyrexia and rigors, or hypothermia (unusual)
- Nausea, vomiting
- Vasodilatation, warm peripheries
- Bounding pulse
- Rapid capillary refill
- Hypotension (septic shock)
- Occasionally signs of cutaneous vasoconstriction
- Other signs:
  (a) Jaundice
  (b) Coma (rare)
  (c) Bleeding due to coagulopathy (e.g. from vascular puncture sites, GI tract and surgical wounds)
  (d) Rash and meningism
  (c) Hyper-, and in more severe cases hypoglycaemia.

The diagnosis of sepsis is easily missed, particularly in the elderly when the classical signs may not be present. Mild confusion, tachycardia and tachypnoea may be the only clues, sometimes associated with unexplained hypotension, a reduction in urine output, a rising plasma creatinine and glucose intolerance.

The clinical signs of sepsis are not always associated with bacteraemia and can occur with non-infectious processes such as pancreatitis or severe trauma. The term 'systemic inflammatory response syndrome' (SIRS) has been suggested to describe the disseminated inflammation that can complicate this diverse range of disorders (Box 15.3). The usefulness of this terminology has, however, been questioned.

MONITORING CRITICALLY ILL PATIENTS

As well as allowing immediate recognition of changes in the patient's condition, monitoring can also be used to establish or confirm a diagnosis, to gauge the severity of the condition, to follow the evolution of the illness and to assess the response to treatment. Invasive monitoring is generally indicated in the more seriously ill patients and in those who fail to respond to initial treatment. These techniques are, however, associated with a small, but significant, risk of complications and should therefore only be used when the potential benefits outweigh the dangers. Likewise, invasive devices should be removed as soon as possible.

Assessment of tissue perfusion

- *Pale, cold skin,* delayed capillary refill and the absence of visible veins in the hands and feet indicate poor perfusion. (Peripheral skin temperature measurements can help clinical evaluation as vasoconstriction is an early compensatory response.)
- *Urinary flow* is a sensitive indicator of renal perfusion and haemodynamic performance.
- *Metabolic acidosis with raised lactate concentration* may suggest that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with a very poor prognosis. In many critically ill patients, especially those with sepsis, however, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and may be exacerbated by reduced clearance owing to hepatic or renal dysfunction.

***Box 15.3* Terminology used in systemic inflammation and sepsis**

Infection
Invasion of normally sterile host tissue by microorganisms

Bacteraemia
Viable bacteria in blood

Systemic inflammatory response syndrome (SIRS)
The systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following:

Temperature > 38°C or < 36°C
Heart rate > 90 beats/min
Respiratory rate > 20 breaths/min or P_aco_2 < 4.3 kPa:
White cell count > 12 x 10^9/L, < 4 x 10^9/L or > 10% immature forms

Compensatory anti-inflammatory response syndrome (CARS)
Release of anti-inflammatory mediators which downregulate the inflammatory response. If excessive, may lead to inappropriate immune hyporesponsiveness

Sepsis
SIRS resulting from documented infection

Severe sepsis
Sepsis associated with organ dysfunction, hypoperfusion or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria or an acute alteration in mental state

Septic shock
Severe sepsis with hypotension (systolic BP < 90 mmHg or a reduction of > 40 mmHg from baseline) in the absence of other causes for hypotension and despite adequate fluid resuscitation
(Patients receiving inotropic or vasopressor agents may not be hypotensive when perfusion abnormalities are documented)

Refractory shock
Shock unresponsive to conventional therapy (intravenous fluids and inotropic/vasoactive agents) within 1 hour

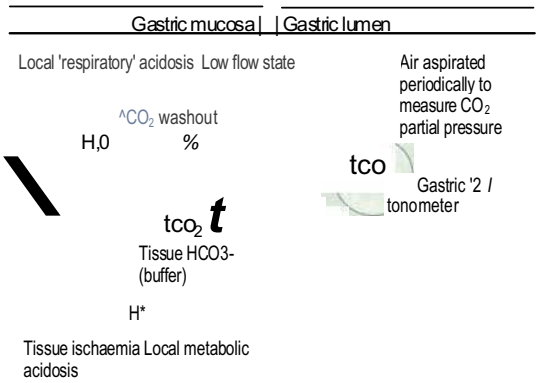

Fig. 15.12 **Gastric tonometry.** A Silastic balloon is passed into the stomach. Equilibration of carbon dioxide partial pressure between mucosa and balloon takes up to 30 minutes. Low flow states and tissue ischaemia are associated with a rise in carbon dioxide partial pressure. From Singer M, Grant I (eds) (1999) *ABC of Intensive Care.* London: BMJ Books, with permission.

■ *Gastric tonometry* (Fig. 15.12). The earliest compensatory response to hypovolaemia or a low cardiac output, and the last to resolve after resuscitation is splanchnic vasoconstriction. In sepsis, gut mucosal ischaemia may be precipitated by disturbed microcirculatory flow combined with increased oxygen requirements. Mucosal acidosis is therefore an early sign of shock. Changes in intramucosal pH or Pco_2 have been suggested as a guide to the adequacy of resuscitation, although the clinical value of this technique is questionable.

Blood pressure

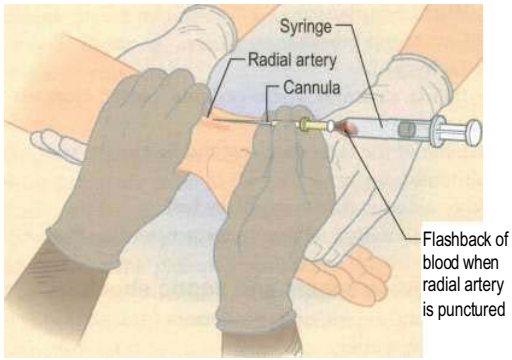
Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal, even when the cardiac output is reduced. Conversely, the vasodilated patient may be hypotensive despite a very high cardiac output.

Hypotension may jeopardize perfusion of vital organs. The adequacy of blood pressure in an individual patient must always be assessed in relation to the premorbid value. Blood pressure is traditionally measured using a sphygmomanometer but if rapid alterations are anticipated, continuous monitoring using an intra-arterial cannula is indicated (Practical box 15.1, Fig. 15.13).

Central venous pressure (CVP)

This provides a fairly simple but appropriate method of assessing the adequacy of a patient's circulating volume and the contractile state of the myocardium. The absolute value of the CVP is not as useful as its response to a fluid challenge (the infusion of 100-200 mL of fluid over a few

***Fig. 15.13* Cannulation of the radial artery.**



minutes) (Fig. 15.14). The hypovolaemic patient will initially respond to transfusion with little or no change in CVP, together with some improvement in cardiovascular function (falling heart rate, rising blood pressure and increased peripheral temperature). As the normovolaemic state is approached, the CVP usually rises slightly and stabilizes, while other cardiovascular values normalize. At this stage, volume replacement should be slowed, or even stopped, in order to avoid overtransfusion (indicated by an abrupt and sustained rise in CVP, often accompanied by some deterioration in the patient's condition). In cardiac failure the venous pressure is usually high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP.

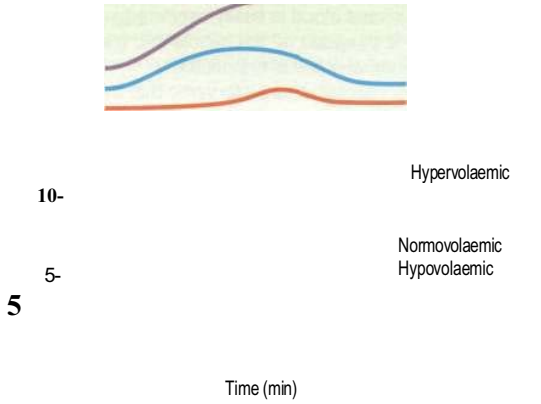


***Fig. 15.14* The effects of rapid administration of a 'fluid challenge' to patients with a central venous pressure within the normal range.** From Sykes MK (1963) Venous pressure as a clinical indication of adequacy of transfusion. *Annals of the Royal College of Surgeons of England* 33: 185-197.

***Practical Box 15.1* Radial artery cannulation**

Technique

1 The procedure is explained to the patient and if possible consent obtained.
2 The arm is supported, with the wrist extended, by an assistant. (Gloves should be worn.)
3 The skin should be cleaned with chlorhexidine.
4 The radial artery is palpated where it arches over the head of the radius.
5 In conscious patients, local anaesthetic is injected to raise a weal over the artery, taking care not to puncture the vessel or obscure its pulsation.
6 A small skin incision is made over the proposed puncture site.
7 A small parallel-sided cannula (20 gauge for adults, 22 gauge for children) is used in order to allow blood flow to continue past the cannula.
8 The cannula is inserted over the point of maximal pulsation and advanced in line with the direction of the vessel at an angle of approximately 30°.
9 'Flashback' of blood into the cannula indicates that the radial artery has been punctured.
10 To ensure that the shoulder of the cannula enters the vessel the needle and cannula are lowered and advanced a few millimetres into the vessel.
11 The cannula is threaded off the needle into the vessel and the needle withdrawn.
12 The cannula is connected to a non-compliant manometer line filled with heparinized saline. This is then connected via a transducer and continuous flush device to a monitor, which records the arterial pressure.

Complications

- Thrombosis
- Loss of arterial pulsation
- Distal ischaemia, e.g. digital necrosis (rare)
- Accidental injection of drugs - can produce vascular occlusion
- Disconnection - rapid blood loss.

The central venous catheter is usually inserted via a percutaneous puncture of a subclavian or internal jugular vein (Practical box 15.2, Fig. 15.15). Techniques using a guidewire are generally safer and more reliable than the catheter over needle devices (Fig. 15.16). They can also be used in conjunction with a vein dilator for inserting introducers of pulmonary artery catheters, multilumen catheters and double lumen cannulae for haemofiltration.

The CVP may be read intermittently using a manometer system (Fig. 15.17) or continuously using a transducer and bedside monitor. It is essential that the pressure recorded always be related to the level of the right atrium. Various landmarks are advocated (e.g. sternal notch with the patient supine, sternal angle or mid-axilla when patient at 45 degrees), but which is chosen is largely immaterial provided it is used consistently in an individual patient. Pressure measurements should be obtained at end-expiration.

The following are common pitfalls in interpreting central venous pressure readings:

Blocked catheter. This results in a sustained high reading, with a damped or absent waveform which often does not correlate with clinical assessment.

Manometer or transducer wrongly positioned. Failure to level the system is a common cause of erroneous readings.

Catheter tip in right ventricle. If the catheter is advanced too far, an unexpectedly high pressure with pronounced oscillations is recorded. This is easily recognized when the waveform is displayed.

Left atrial pressure

In uncomplicated cases, careful interpretation of the CVP provides a reasonable guide to the filling pressures of both sides of the heart. In many critically ill patients, however, this is not the case and there is a disparity in function between the two ventricles. Most commonly, left ventricular performance is worst, so that the left ventricular function curve is displaced downward and to the right (Fig. 15.18). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but may occur with right ventricular dysfunction and in situations where the pulmonary vascular resistance (i.e. right ventricular afterload) is raised, such as in acute respiratory failure and pulmonary embolism.

Practical Box 15.2
Internal jugular vein cannulation

Technique

1 The procedure is explained to the patient and if possible consent obtained.
2 The patient is placed head-down to distend the central veins (this facilitates cannulation and minimizes the risk of air embolism but may exacerbate respiratory distress and is dangerous in those with raised intracranial pressure).
3 The skin is cleaned with an anaesthetic solution such as chlorhexidine. Sterile precautions are taken throughout the procedure.
4 Local anaesthetic (1 % plain lidocaine) is injected intradermally to raise a weal at the apex of a triangle formed by the two heads of sternomastoid with the clavicle at its base.
5 A small incision is made through the weal.
6 The cannula or needle is inserted through the incision and directed laterally downwards and backwards in the direction of the nipple until the vein is punctured just beneath the skin and deep to the lateral head of sternomastoid. *Ultrasound-guided puncture has been recommended, at least for difficult cases, and to reduce the incidence of complications.*
7 Check that venous blood is easily aspirated.
8 The cannula is threaded off the needle into the vein.
9 The CVP manometer line is connected.
10 A chest X-ray should be taken to verify that the tip of the catheter is in the superior vena cava and to exclude pneumothorax.

Possible complications

Haemorrhage
Accidental arterial puncture (carotid or subclavian)
Pneumothorax
■ Damage to thoracic duct on left
■ Air embolism
5* Thrombosis
Catheter-related sepsis

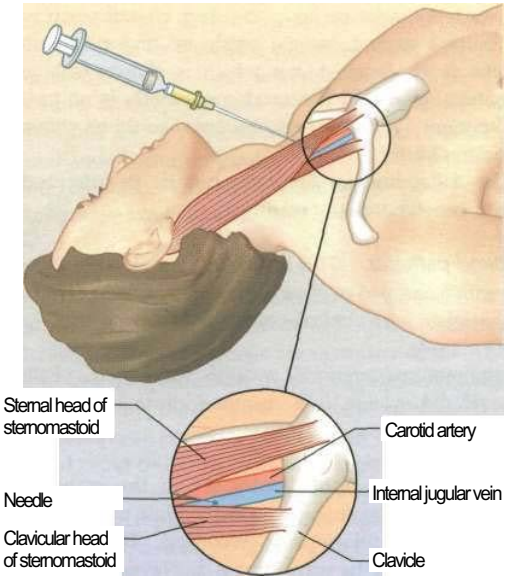

Fig. 15.15 **Cannulation of right internal jugular vein with a catheter over the needle device.** , . , . „ . . , <

If there is a disparity in ventricular function after cardiac surgery, then the left atrium can be cannulated directly. If the chest is not open, however, some other means of determining left ventricular filling pressure must be devised. .. ■ „ - ;; >, • - ... . - ; . ■ .. , ■ _ , , ■

Pulmonary artery pressure

A 'balloon flotation catheter' enables prompt and reliable catheterization of the pulmonary artery. These 'Swan-Ganz' catheters can be inserted centrally (see Fig. 15.16) or through the femoral vein, or via a vein in the antecubital fossa. Passage of the catheter from the major veins, through the chambers of the heart, into the pulmonary artery and into the wedged position is monitored and guided by the pressure waveforms recorded from the distal lumen (Fig. 15.19 and Practical box 15.3). A chest X-ray should always be obtained to check the final position of the catheter. In difficult cases screening with an image intensifier may be required.

Once in place, the balloon is deflated and the pulmonary artery mean, systolic and end-diastolic pressures (PAEDP) can be recorded. The pulmonary artery occlusion pressure (PAOP, otherwise known as pulmonary artery wedge pressure - PAWP) is measured by reinflating the

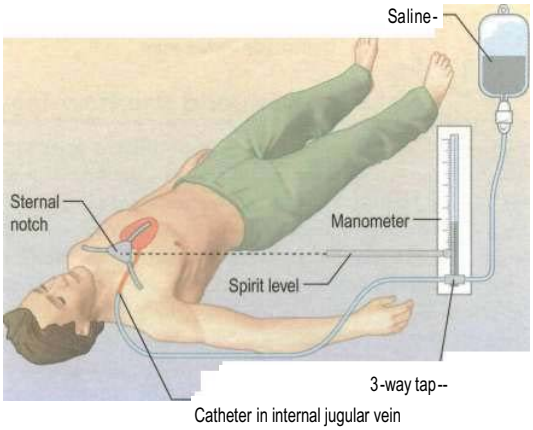

Fig. 15.17 **Central venous pressure measurement using a manometer system.** The reading must be referred to the level of the right atrium (indicated by the axillary fold or, provided the patient is supine, the sternal notch) using a spirit level.

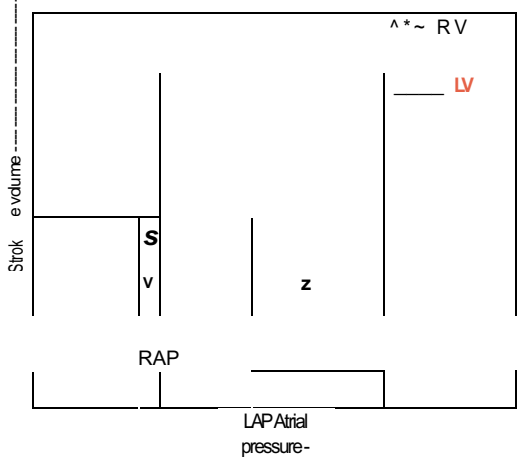

Fig. 15.18 **Left ventricular (LV) and right ventricular (RV) function curves in a patient with left ventricular dysfunction.** Since the stroke volume of the two ventricles must be the same (except perhaps for a few beats during a period of circulatory adjustment), left atrial pressure (LAP) must be higher than right atrial pressure (RAP). Moreover, an increase in stroke volume (x) produced by expanding the circulatory volume may be associated with a small rise in RAP (v) but a marked increase in LAP (z).

Passage of a pulmonary artery balloon flotation catheter through the chambers of the heart into the 'wedged' position

A balloon flotation catheter is inserted through the femoral vein or a vein in the ante-cubital fossa. Once in the thorax, marked respiratory oscillations are seen. The catheter should be advanced further towards the lower superior vena cava/right atrium, where oscillations become more pronounced. The balloon should then be inflated and the catheter advanced. When the catheter is in the right ventricle, there is no dicrotic notch and the diastolic pressure is close to zero. The patient should be returned to the horizontal, or slightly head-up, position before advancing the catheter further.

When the catheter reaches the pulmonary artery a dicrotic notch appears and there is elevation of the diastolic pressure. The catheter should be advanced further with the balloon inflated.
Reappearance of a venous waveform indicates that the catheter is 'wedged'. The balloon is deflated to obtain the pulmonary artery pressure. The balloon is inflated intermittently to obtain the pulmonary capillary artery occlusion (also known as pulmonary artery, or capillary, 'wedge') pressure.

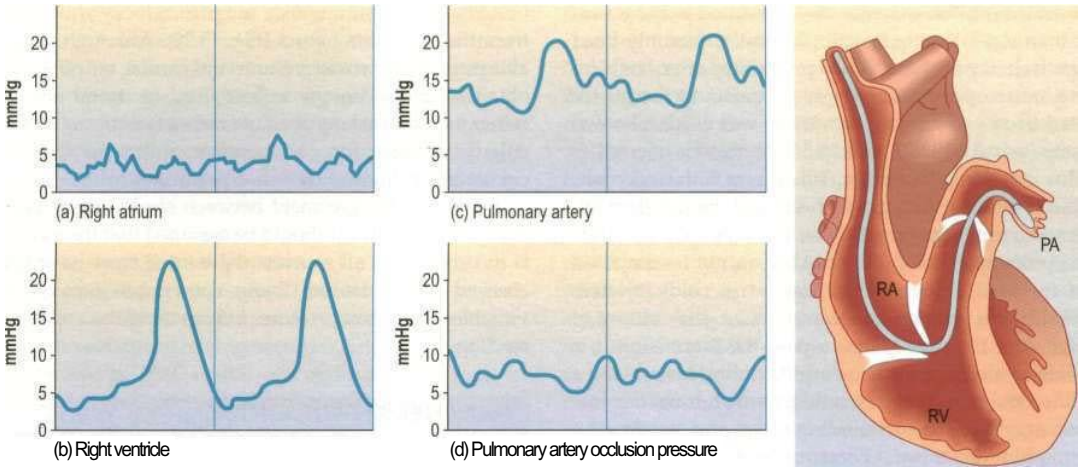

Fig. 15.19 **Passage of pulmonary artery balloon flotation catheter through the chambers of the heart into the 'wedged' position to measure the pulmonary artery occlusion pressure.** See Practical box 15.3.

***Table 15.4* Balloon flotation pulmonary artery catheters: some complications in addition to those associated with central venous cannulation**

Complication	Comments
Arrhythmias	Occur during passage of catheter through right ventricle Usually benign Can often be prevented with lidocaine
Sepsis	Occurs at insertion site Bacteraemia or endocarditis may develop
Knotting	Occurs when catheter coils in right ventricle and is then withdrawn
Valve trauma	Occurs if catheter is withdrawn with balloon inflated, also tricuspid and pulmonary valves repeatedly open and close on the catheter
Thrombosis/embolism	
Pulmonary infarction	Occurs if catheter remains in 'wedged' position
Pulmonary artery rupture	Usually fatal May occur if balloon is inflated when catheter already 'wedged'
Balloon rupture/leak/ embolism	Rare

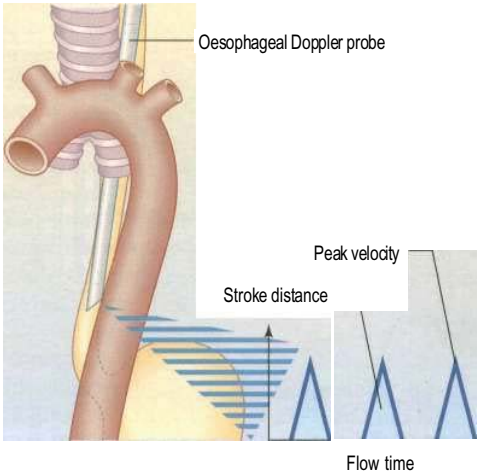

***Fig. 15.20* Doppler ultrasonography.** An oesophageal Doppler probe continuously measures velocity waveforms from the descending thoracic aorta. With a nomogram, stroke distance (area under waveform) provides an estimate of stroke volume. Acceleration and peak velocity indicate myocardial performance, while flow time is related to circulating volume and peripheral resistance. From Singer M, Grant I (eds) (1999) *ABC of Intensive Care*. London: BMJ Books, with permission.

balloon, thereby propelling the catheter distally until it impacts in a medium-sized pulmonary artery. In this position there is a continuous column of fluid between the distal lumen of the catheter and the left atrium, so that PAOP is usually a reflection of left atrial pressure.

The technique is generally safe - the majority of complications are related to user inexperience. Pulmonary artery catheters should preferably be removed within 72 hours, since the incidence of complications, especially infection, then increases progressively (Table 15.4).

Cardiac output

The thermodilution technique is most commonly used clinically. In the past a modified pulmonary artery catheter with a lumen opening in the right atrium and a thermistor located a few centimetres from its tip was used. A known volume (usually 10 mL) of cold 5% dextrose is injected as a bolus into the right atrium. This mixes with, and cools, the blood passing through the heart and the transient fall in temperature is continuously recorded by the thermistor in the pulmonary artery. The cardiac output is computed from the total amount of indicator (i.e. cold) injected, divided by the average concentration, i.e. the amount of cooling, and the time taken to pass the thermistor. It is possible to measure cardiac output continuously using a modified pulmonary artery catheter which transmits low heat energy into the surrounding blood and constructs a 'thermodilution curve'. These catheters also optically measure and continuously display $S\bar{v}O_2$.

In general, pulmonary artery catheters enable the clinician to optimize cardiac output and oxygen delivery, while minimizing the risk of pulmonary oedema. They can also be used to guide the rational use of inotropes and vasoactive agents. There is increasing evidence however, which suggests that the use of this monitoring device may not lead to improved outcomes and less invasive techniques are increasingly preferred.

Non-invasive techniques for assessing cardiac function

One of the most useful techniques for determining cardiac output and myocardial function non-invasively is Doppler ultrasonography. A probe is passed into the oesophagus to continuously monitor velocity waveforms from the descending aorta (Fig. 15.20). Although reasonable estimates of stroke volume and cardiac output can be obtained, the technique is best used for trend analysis rather than for making absolute measurements. It is particularly valuable for perioperative optimization of the circulating volume and cardiac performance.

If there is disagreement between clinical signs and a monitored variable it should be assumed that the monitor is incorrect until all sources of potential error have been checked and eliminated. Changes and trends in monitored variables are always more informative than a single reading.

MANAGEMENT OF SHOCK (see Fig. 15.21)

Delays in making the diagnosis and in initiating treatment, as well as inadequate resuscitation, contribute to the development of multiple organ failure (MOF) and must be avoided (see p. 978).

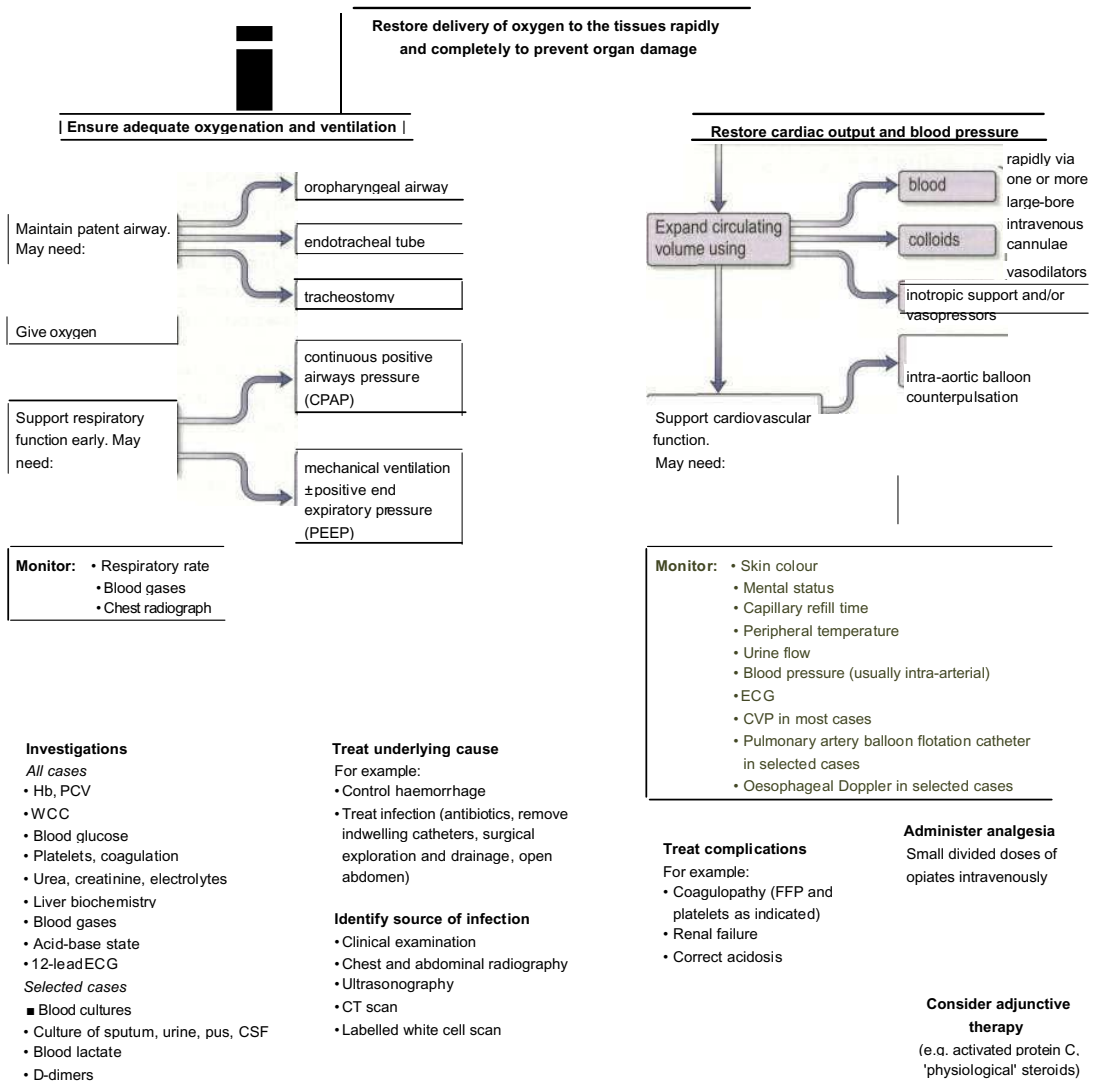

Fig. 15.21 Management of shock. Patients require intensive nursing care.

A patent airway must be maintained and oxygen must be given. If necessary, an oropharyngeal airway or an endotracheal tube is inserted. The latter has the advantage of preventing aspiration of gastric contents. Very rarely, emergency tracheostomy is indicated (see below). Some patients may require mechanical ventilation.

The underlying cause of shock should be corrected - for example, haemorrhage should be controlled or infection eradicated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. As well as a thorough history and clinical examination, X-rays, ultrasonography, CT scanning or a labelled white cell scan may be required to locate the origin of the infection. Appropriate samples (urine, sputum, cerebrospinal fluid, pus drained from abscesses) should be sent to the laboratory for microscopy, culture and sensitivities. Several blood cultures should be performed and 'blind', broad-spectrum antibiotic therapy (p. 30) should be commenced within the first hour of recognition of sepsis. If an organism is isolated later, therapy can be adjusted appropriately. The choice of antibiotic depends on the likely source of infection, previous antibiotic therapy and known local resistance patterns, as well as on whether it was acquired in hospital or in the community. Abscesses must be drained and infected indwelling catheters removed.

Whatever the aetiology of the haemodynamic abnormality, tissue blood flow must be restored by achieving and maintaining an adequate cardiac output, as well as ensuring that arterial blood pressure is sufficient to maintain perfusion of vital organs. Traditionally a mean arterial pressure (MAP) > 60 mmHg, or a systolic blood pressure

> 80 mmHg, has been considered adequate but recently published guidelines suggest that initial resuscitation should aim at achieving a MAP > 65 mmHg.

Preload and volume replacement

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilatation, sequestration of blood and loss of circulating volume because of capillary leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasions, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures may be markedly elevated, often benefit from measures to reduce preload (and afterload) - such as the administration of diuretics and vasodilators (see below). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

The circulating volume must be replaced quickly (in minutes not hours) to reduce tissue damage and prevent acute renal failure. Fluid is administered via wide-bore intravenous cannulae to allow large volumes to be given quickly, and the effect is continuously monitored.

Care must be taken to prevent volume overload, which leads to cardiac dilatation, a reduction in stroke volume, and a rise in left atrial pressure with a risk of pulmonary oedema. Pulmonary oedema is more likely in very ill patients because of a low colloid osmotic pressure (usually due to a low serum albumin) and disruption of the alveolar-capillary membrane (e.g. in acute lung injury). As a general rule, left ventricular filling pressures should therefore not be allowed to rise to more than 15-18 mmHg in most critically ill patients. Overall, however, many more patients are undertransfused rather than overtransfused.

Choice of fluid for volume replacement

Blood

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, cross-match can be performed in about 30 minutes and is as safe as the standard procedure (see p. 459).

Although red cell transfusion will augment oxygen-carrying capacity, and hence global oxygen delivery, tissue oxygenation is also dependent on microcirculatory flow. This is influenced by the viscosity of the blood and hence the packed cell volume (PCV). Conventionally a PCV of 30-35% has been considered to provide the optimal balance between oxygen-carrying capacity and tissue flow, although it is well recognized that previously fit patients with haemorrhagic shock can tolerate extremely low Hb concentrations provided their circulating volume and cardiac output are maintained. Transfusion of old stored red cells, which are poorly deformable, may be associated with microvascular occlusion and worsening tissue hypoxia.

Complications of blood transfusion are discussed on page 460. Special problems arise when large volumes of stored blood are transfused rapidly. These include:

Temperature changes. Bank blood is stored at 4°C and transfusion may result in hypothermia, peripheral vasoconstriction (which slows the rate of the infusion) and arrhythmias. If possible, blood should therefore be warmed during massive transfusion and in those at risk of hypothermia (e.g. during prolonged major surgery with open body cavity).

Coagulopathy. Stored blood has virtually no effective platelets and is deficient in clotting factors. Large transfusions can therefore produce a coagulation defect. This may need to be treated by replacing clotting factors with fresh frozen plasma and administering platelet concentrates. Occasionally cryoprecipitate may be required.

Metabolic acidosis/alkalosis. Stored blood is preserved in citrate/phosphate/dextrose (CPD) solution, and metabolic acidosis attributable solely to blood transfusion is rare and in any case seldom requires correction. A metabolic alkalosis often develops 24—48 hours after a large blood transfusion, probably mainly owing to metabolism of the citrate. This will be exacerbated if any preceding acidosis has been corrected with intravenous sodium bicarbonate.

Hypocalcaemia. Stored blood is anticoagulated with citrate, which binds calcium ions. This can reduce total body ionized calcium levels and cause myocardial depression. This is uncommon in practice, but can be corrected by administering 10 mL of 10% calcium chloride intravenously. Routine treatment with calcium is not recommended.

Increased oxygen affinity. In stored blood, the red cell 2,3-bisphosphoglycerate (2,3-BPG) content is reduced, so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. This effect is less marked with CPD blood. Red cell levels of 2,3-BPG are substantially restored within 12 hours of transfusion.

Hyperkalaemia. Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem as rewarming of the blood increases red cell metabolism - the sodium pump becomes active and potassium levels fall.

Microembolism. Microaggregates in stored blood may be filtered out by the pulmonary capillaries. This process is thought by some to contribute to acute lung injury (ALI) (see p. 460).

Red cell concentrates

Nutrient additive solutions - saline, adenine, glucose and mannitol (SAGM) - are available which allow red cell storage in the absence of plasma (see p. 463).

Concern about the supply, cost and safety of blood, including the risk of disease transmission and immune suppression, has encouraged a conservative approach to transfusion. There is some evidence to suggest that in normovolaemic critically ill patients a restrictive strategy

of red cell transfusion (Hb maintained at 7.0-9.0 g/dL) is at least as effective, and may be safer than a liberal transfusion strategy (Hb maintained at 10-12 g/dL). However, in some groups of patient (e.g. the elderly and those with significant cardiac or respiratory disease) it may be preferable to maintain Hb at the higher level.

Blood substitutes

Attempts to develop an effective and safe oxygen-carrying blood substitute have so far been unsuccessful.

Crystalloids and colloids

The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids has long been controversial. Crystalloid solutions such as saline are cheap, convenient to use and free of side-effects, although they are rapidly lost from the circulation into the extravascular spaces. It has been generally accepted that volumes of crystalloid several times that of colloid are required to achieve an equivalent haemodynamic response and that colloidal solutions produce a greater and more sustained increase in circulating volume, with associated improvements in cardiovascular function and oxygen transport.

Nevertheless, a recent large, prospective, randomized, controlled trial has demonstrated that in a heterogeneous group of critically ill patients the use of either physiological saline or 4% albumin for fluid resuscitation resulted in similar outcomes. Moreover the ratio of administered albumin to saline was only 1:4.

Polygelatin solutions (Haemaccel, Gelofusin) have an average molecular weight of 35 000, which is iso-osmotic with plasma. They are cheap and do not interfere with crossmatching. Large volumes can be administered, as clinically significant coagulation defects are unusual and renal function is not impaired. However, because they readily cross the glomerular basement membrane, their half-life in the circulation is only approximately 4 hours and they can promote an osmotic diuresis. Allergic reactions can occur. These solutions are particularly useful during the acute phase of resuscitation, especially when volume losses are continuing; but colloids with a longer half-life are often used later to achieve haemodynamic stability.

Hydroxyethyl starch (HES) has a mean molecular weight of approximately 450 000 and a half-life of about 12 hours. Volume expansion is equivalent to, or slightly greater than, the volume infused. The incidence of allergic reactions is approximately 0.1%. Esterified starch is more expensive than gelatins, but is a useful volume expander.

Dextrans are polymolecular polysaccharides which have a powerful osmotic effect. They interfere with crossmatching and have a small rate of allergic reactions (0.1-1%) which may be life-threatening. Normally a dose of 1.5 g dextran per kilogram of bodyweight (as Dextran 70) should not be exceeded because of the risk of renal damage. In practice, dextrans are rarely used in the UK because of the availability of other agents.

Human albumin solution (HAS) is a natural colloid which has been used for volume replacement in shock and burns, and for the treatment of hypoproteinaemia. HAS is not generally recommended for routine volume replacement, because supplies are limited and other cheaper solutions are equally effective. Controversially a systematic review suggested that the administration of human albumin to patients with hypovolaemia, burns or hypoalbuminaemia might increase mortality. Recent evidence (see above) has, however, demonstrated the safety of 4% albumin when used for fluid resuscitation in such patients.

Myocardial contractility and inotropic agents

Myocardial contractility can be impaired by many factors such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g. beta-blockers, antiarrhythmics, angiotensin-converting enzyme inhibitors and sedatives).

Severe lactic acidosis can depress myocardial contractility and may limit the response to inotropes. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance. Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should only be administered to correct *extreme persistent metabolic acidosis* (see p. 719).

If the signs of shock persist despite adequate volume replacement, and perfusion of vital organs is jeopardized, pressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial oxygen supply and demand, with the development or extension of ischaemic areas. For this reason inotropes should be used with caution, particularly in cardiogenic shock following myocardial infarction and in those known to have ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to 'downregulation' of adrenergic receptors and NO-induced 'vasoplegia' (p. 964).

All inotropic agents should be administered via a large central vein, and their effects monitored. Some of the currently available inotropes are considered here (see also p. 793 and Table 15.5).

Adrenaline (epinephrine)

Epinephrine stimulates both a- and (3-adrenergic receptors, but at low doses p effects seem to predominate. This

Table 15.5 **Receptor actions of sympathomimetic and dopaminergic agents**

				Dose dependence
Adrenaline (epinephrine) Low dose Moderate dose High dose	±	+		
Noradrenaline (norepinephrine)	++	+		
Isoprenaline	+++	+		
Dopamine Low dose Moderate dose High dose	0	0		
Dopexamine	±	?	0	0
Dobutamine				

Receptor	Action
p! - postsynaptic	Positive inotropism and chronotropism
	Renin release
p_2 - presynaptic	Stimulates noradrenaline (norepinephrine) release
P_2 - postsynaptic	Positive inotropism and chronotropism
	Vascular dilatation
	Relaxes bronchial smooth muscle
a, - postsynaptic	Constriction of peripheral, renal and coronary vascular smooth muscle
	Positive inotropism
	Antidiuresis
$<x_2$ - presynaptic	Inhibition of noradrenaline (norepinephrine) release, vasodilatation
a_2 - postsynaptic	Constriction of coronary arteries
	Promotes salt and water excretion
D-, - postsynaptic	Dilates renal, mesenteric and coronary vessels
	Renal tubular effect (natriuresis, diuresis)
D_2 - presynaptic	Inhibits adrenaline (epinephrine) release

increases heart rate, cardiac index and reduces peripheral resistance. At higher doses, a-mediated vasoconstriction develops. If this produces a useful increase in perfusion pressure and an increase in urine output, renal failure can be avoided. However, epinephrine can cause excessive vasoconstriction, with worrying reductions in splanchnic flow, particularly at higher doses. Cardiac output may fall, prolonged high-dose administration can cause peripheral gangrene and metabolic acidosis is common. For these reasons the minimum effective dose should be used for as short a time as possible.

Noradrenaline (norepinephrine)

This is predominantly an oc-adrenergic agonist. It is particularly useful in those with severe hypotension associated with a low systemic vascular resistance, for example in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload. Noradrenaline administration should normally therefore be accompanied by comprehensive full haemodynamic monitoring, including invasive or non-invasive determination of cardiac output (see p. 972) and calculation of the peripheral resistance.

Dopamine

Dopamine is a natural precursor of adrenaline (epinephrine) which acts on P receptors and a receptors, as well as dopaminergic D, and D_2 receptors.

In low doses (e.g. l-3(ig/kg/min), dopaminergic vasodilatory receptors in the renal, mesenteric, cerebral and coronary circulations are activated. Dj receptors are located on postsynaptic membranes and mediate vasodilatation, whilst D_2 receptors are presynaptic and potentiate these vasodilatory effects by preventing the release of adrenaline (epinephrine). Renal and hepatic flow increase and urine output is improved. The value of the renal vasodilator effect of dopamine has, however, been questioned and it has been suggested that the increased urine output is largely attributable to the rise in cardiac output, combined with a decrease in aldosterone concentration and inhibition of tubular sodium reabsorption mediated via D_3 stimulation.

In moderate doses (e.g. 3-10 ug/kg/min), dopamine increases heart rate, myocardial contractility and cardiac output. In some patients the dose of dopamine is limited by fi-receptor effects such as tachycardia and arrhythmias.

In higher doses (e.g. > lOug/kg/min) the increased noradrenaline (norepinephrine) produced is associated

with vasoconstriction. This increases afterload and raises ventricular filling pressures.

Dopexamine

Dopexamine is an analogue of dopamine which activates P_2 receptors as well as D] and D_2 receptors. Dopexamine is a very weak positive inotrope, but is a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. In septic shock, dopexamine can increase cardiac index and heart rate, but causes further reductions in peripheral resistance. It is most useful in those with low cardiac output and peripheral vasoconstriction and has been used as an adjunct to the perioperative management of high-risk patients (see below).

Dobutamine

Dobutamine is closely related to dopamine and has predominantly fij activity. Dobutamine has no specific effect on the renal vasculature but urine output often increases as cardiac output and blood pressure improve. It reduces systemic resistance, as well as improving cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic shock and cardiac failure. In septic shock, dobutamine increases cardiac output and oxygen delivery.

Phosphodiesterase inhibitors (e.g. milrinone, enoximone)

These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the (i-adrenergic receptor they do not cause tachycardia and are less arrhythmogenic than P agonists. They may be useful in patients with receptor 'downregulation', those receiving beta-blockers, for weaning patients from cardiopulmonary bypass and for patients with cardiac failure. In vasodilated septic patients, however, they may precipitate or worsen hypotension.

Vasopressin

Patients with septic shock have low circulating levels of vasopressin and are hypersensitive to the pressor effects of exogenous vasopressin. Low-dose vasopressin increases blood pressure and systemic vascular resistance in patients with vasodilatory septic shock resistant to catecholamines. A fixed low dose of vasopressin can be used in severe, refractory septic shock, but the results of randomized controlled trials are awaited. . .. .

Guidelines for use of inotropic and vasopressor agents

Many still consider dopamine in low to moderate doses to be the first-line agent for restoring blood pressure, although others favour dopexamine as a means of increasing cardiac output and organ blood flow. High-dose dopamine is usually best avoided. Dobutamine is particularly indicated in patients in whom the vasoconstriction caused by dopamine could be dangerous (i.e. patients with cardiac disease and septic patients with fluid overload or myocardial failure). The combination of dobutamine and norepinephrine (noradrenaline) is popular for the management of patients who are *shocked with a low systemic resistance* (e.g. septic shock). Dobutamine is given to achieve an optimal cardiac output, while noradrenaline (norepinephrine) is used to restore an adequate blood pressure by reducing vasodilatation. In some *vasodilated septic patients* with a high cardiac output, noradrenaline (norepinephrine) is used alone.

Adrenaline (epinephrine), because of its potency, remains a useful agent in patients with *refractory hypotension,* although adverse effects are common. This agent is preferred by some as a cheap, effective agent for the management of septic shock, especially when haemodynamic monitoring is not available. :

Targeting 'supranormal' values for oxygen delivery (Do_2) and oxygen consumption (l/oj

Although resuscitation has conventionally aimed at achieving normal haemodynamics, survival of many critically ill patients is associated with raised values for cardiac output, Do_2 and Vo_2. However, elevation of Do_2 and Vo_2 to these 'supranormal' levels following admission to intensive care produces no benefit and may be harmful. By contrast, *early* goal-directed therapy in the emergency room, aimed at maintaining central venous oxygen saturation at more than 70%, significantly improves outcome in patients with severe sepsis or septic shock.

Box 15.4 **Patients at risk of developing perioperative multiorgan failure**

Patients with jeopardized cardiorespiratory function Patients with trauma to two body cavities requiring multiple blood transfusions Patients undergoing surgery involving extensive tissue dissection, e.g. oesophagectomy, pancreatectomy, aortic aneurysm surgery Patients undergoing emergency surgery for **intra-**abdominal or intrathoracic catastrophic states, e.g. faecal peritonitis, oesophageal perforation

Modified from Shoemaker WC et al. (1988) *Chest* 94: 1176-1178.

High-risk surgical patients (Box 15.4)

These patients benefit from intensive perioperative monitoring and circulatory support, in particular maintenance of an adequate circulating volume, and postoperative admission to ICU/HDU. In such cases volume replacement and administration of inotropes or vasopressors should be guided by an oesophageal Doppler probe or, in selected cases, pulmonary artery catheterization.

The value of preoperative admission to ICU/HDU for optimization of Do_2, the targeting of survivor values for Do_2 and Vo_2 and the routine use of inodilators such as dopexamine remains unclear.

In condusion, early resuscitation, aimed especially at achieving an adequate circulating volume, combined with the rational use of inotropes and/or vasoactive

agents to maintain blood pressure and cardiac output is essential.

Vasodilator therapy (see p. 792)

In selected cases, afterload reduction may be used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilatation also decreases heart size and the diastolic ventricular wall tension so that coronary blood flow is improved. The relative magnitude of the falls in preload and afterload depends on the pre-existing haemodynamic disturbance, concurrent volume replacement and the agent selected (see below).

Vasodilator therapy is most beneficial in patients with cardiac failure in whom the ventricular function curve is flat (see Fig. 15.3) and falls in preload have only a limited effect on stroke volume.

This form of treatment, often combined with inotropic support, may therefore be useful in cardiogenic shock and in the management of patients with pulmonary oedema associated with low cardiac output. Vasodilators may also be valuable in shocked patients who remain vasoconstricted and oliguric despite restoration of an adequate blood pressure.

The agents used most commonly to achieve vasodilatation in the critically ill are those which act directly on the vessel wall.

Nitroglycerine (NTG) and *isosorbide dinitrate* (ISDN) are both predominantly venodilators. They are of most value in those with cardiac failure in whom preload reduction may reduce ventricular wall tension and improve coronary perfusion without adversely affecting cardiac performance. Furthermore, these agents may reverse myocardial ischaemia by increasing and redistributing coronary blood flow. They are therefore often used in preference to sodium nitroprusside (see below) in patients with cardiac failure and/or myocardial ischaemia. Both NTG and ISDN reduce pulmonary vascular resistance, an effect that can occasionally be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

Hydralazine predominantly affects arterial resistance vessels. It therefore reduces afterload and blood pressure, while cardiac output and heart rate usually increase. Hydralazine is usually given as an intravenous bolus to control acute increases in blood pressure.

Sodium nitroprusside (SNP) dilates arterioles and venous capacitance vessels, as well as the pulmonary vasculature by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. On the other hand, it has been suggested that SNP can exacerbate myocardial ischaemia by producing a 'steal' phenomenon in the coronary circulation. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. A large overdose of SNP can cause cyanide poisoning, with intracellular hypoxia caused by inhibition of cytochrome oxidase, the terminal enzyme of the respiratory chain. This is manifested as a metabolic acidosis and a fall in the arteriovenous oxygen content difference.

Mechanical support of the myocardium

Intra-aortic balloon counterpulsation (IABCP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed on page 763.

Sepsis and multiple organ failure (MOF)

(also known as multiple organ dysfunction syndrome - MODS)

Sepsis is being diagnosed with increasing frequency and is now the commonest cause of death in non-coronary adult intensive care units. The in-hospital incidence of severe sepsis is conservatively in the order of two cases per 100 admissions and length of stay is dramatically longer than for those without sepsis. Mortality rates are high (between 20-70%) and are closely related to the number of organs which fail and the duration of organ dysfunction. Those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension and failure of several organs.

Sequential failure of vital organs occurs progressively over weeks, although the pattern of organ dysfunction is variable. In most cases the lungs are the first to be affected (acute lung injury - ALI; acute respiratory distress syndrome - ARDS; see p. 986) in association with cardiovascular instability and deteriorating renal function. Damage to the mucosal lining of the gastrointestinal tract as a result of reduced splanchnic flow followed by reperfusion, allows bacteria within the gut lumen, or their cell wall components, to gain access to the circulation. The liver defences, which are often compromised by poor perfusion, are overwhelmed and the lungs and other organs are exposed to bacterial toxins and inflammatory mediators released by liver macrophages. Some have therefore called the gut the 'motor of multiple organ failure'. Secondary pulmonary infection, complicating ALI/ARDS also frequently acts as a further stimulus to the inflammatory response. Later, renal failure and liver dysfunction develop (see p. 979). Gastrointestinal failure, with an inability to tolerate enteral feeding and paralytic ileus, is common. Ischaemic colitis, acalculous cholecystitis, pancreatitis and gastrointestinal haemorrhage may also occur. Features of central nervous system dysfunction include impaired consciousness and disorientation, progressing to coma. Characteristically, these patients initially have a hyperdynamic circulation with vasodilatation and a high cardiac output, associated with an increased metabolic rate. Eventually, however, cardiovascular collapse supervenes and is the usual terminal event.

Adjunctive treatment

Initial attempts to combat the high mortality associated with sepsis concentrated on cardiovascular and respiratory support in the hope that survival could be prolonged until surgery, antibiotics and the patient's own

Table 15.6 **Some of the therapeutic strategies tested in randomized, controlled phase II or III trials in human sepsis**

High-dose steroids
Endotoxin antibodies
Bactericidal permeability-increasing protein
TNF antibodies
Soluble TNF receptors
Interleukin-1 receptor antagonists
Platelet-activating factor antagonists
A/-acetyl cysteine
Nitric oxide synthase inhibition
Antithrombin
Activated protein C

defences had eradicated the infection and injured tissues were repaired. Despite some success, mortality rates remained unacceptably high. So far, attempts to improve outcome by modulating the inflammatory response (including high-dose steroids) or neutralizing endotoxin (Table 15.6) or inhibiting nitric oxide synthesis (e.g. with N-monomethyl-L-arginine) have also proved disappointing and in some cases may even have been harmful.

Recently, however, administration of recombinant human activated protein C (rhAPC), an endogenous anti-coagulant with anti-inflammatory properties, has been shown to improve survival in patients with sepsis-induced organ dysfunction. Also, it seems that the administration of relatively low, 'stress' doses of hydro-cortisone to patients with vasopressor dependent septic shock, may improve outcome. Careful control of the blood sugar level to within the normal range with insulin ('tight glycaemic control') may also reduce mortality rates in critically ill patients.

RENAL FAILURE

Acute renal failure is a common and serious complication of critical illness which adversely affects the prognosis. The importance of preventing renal failure by rapid and effective resuscitation, as well as the avoidance of nephrotoxic drugs (especially NSAIDs), and control of infection cannot be overemphasized. Shock and sepsis are the most common causes of acute renal failure in the critically ill, but diagnosis of the cause of renal dys-function is necessary to exclude reversible pathology, especially obstruction (see Ch. 11).

Oliguria is usually the first indication of renal impair-ment and immediate attempts should be made to optimize cardiovascular function, particularly by expanding the circulating volume and restoring blood pressure. Restoration of the urine output is a good indicator of successful resuscitation. Evidence now suggests that dopamine is not an effective means of preventing or reversing renal impairment and this agent should not be used for renal protection in sepsis (p. 976). If these measures fail to reverse oliguria, administration of diuretics such as furosemide (frusemide), or less often mannitol, may be indicated. Currently furosemide infusions are most frequently employed (see Ch. 11), but mannitol is specifically indicated in rhabdomyolysis. If oliguria persists, it is necessary to reduce fluid intake and review drug doses.

Intermittent haemodialysis has a number of dis-advantages in the critically ill. In particular it is fre-quently complicated by hypotension and it may be difficult to remove sufficient volumes of fluid. Peritoneal dialysis is also frequently unsatisfactory in these patients and is contraindicated in those who have undergone intra-abdominal surgery. The use of continuous veno-venous haemofiltration, usually with dialysis (CWHD), is therefore preferred (see Ch. 11) and is indicated for fluid overload, electrolyte disturbances (especially hyperkalaemia), severe acidosis and, to a lesser extent, uraemia.

If the underlying problems resolve, renal function almost invariably recovers within a few days to several weeks later.

RESPIRATORY FAILURE

Types and causes

The respiratory system consists of a gas-exchanging organ (the lungs) and a ventilatory pump (respiratory

muscles/ thorax), either or both of which can fail and precipitate respiratory failure. Respiratory failure occurs when pulmonary gas exchange is sufficiently impaired to cause hypoxaemia with or without hypercarbia. In practical terms, respiratory failure is present when the P_ao_2 is < 8 kPa (60 mmHg) or the P_aco_2 is > 7 kPa (55 mmHg). It can be divided into:

- type I respiratory failure, in which the P_aO_2 is low and the P_aCO_2 is normal or low
- type II respiratory failure, in which the P_ao_2 is low and the P_aco_2 is high.

Type I or *'acute hypoxaemic'* respiratory failure occurs with diseases that damage lung tissue. Hypoxaemia is due to right-to-left shunts or *V/Q* mismatch. Common causes include pulmonary oedema, pneumonia, acute lung injury and, in the chronic situation, fibrosing alveolitis.

Type II or *'ventilatory failure'* occurs when alveolar ventilation is insufficient to excrete the volume of carbon dioxide being produced by tissue metabolism. Inadequate alveolar ventilation is due to reduced ventilatory effort, inability to overcome an increased resistance to ventilation, failure to compensate for an increase in deadspace and/or carbon dioxide production, or a combination of these factors. The most common cause is chronic obstructive pulmonary disease (COPD). Other causes include chest-wall deformities, respiratory muscle weakness (e.g. Guillain-Barre syndrome) and depression of the respiratory centre (e.g. overdose).

Deterioration in the mechanical properties of the lungs and/ or chest wall increases the work of breathing and the oxygen consumption/carbon dioxide production of the respiratory muscles. The concept that respiratory muscle fatigue (either acute or chronic) is a major factor in the pathogenesis of respiratory failure is controversial.

MONITORING OF RESPIRATORY FAILURE

A clinical assessment of respiratory distress should be made on the following criteria (those marked with an asterisk may be indicative of respiratory muscle fatigue):

the use of accessory muscles of respiration
intercostal recession
tachypnoea*
tachycardia
sweating
pulsus paradoxus (rarely present)
inability to speak, unwillingness to lie flat
agitation, restlessness, diminished conscious level
asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)*
paradoxical respiration (abdominal and thoracic compartments move in opposite directions)*
respiratory alternans (breath-to-breath alteration in the relative contribution of intercostal/accessory muscles and the diaphragm).*

Blood gas analysis should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure. The *most sensitive clinical* indicator of increasing respiratory difficulty is a rising respiratory rate. *Measurement of tidal volume* is a less sensitive indicator.

Vital capacity is often a better guide to deterioration and is particularly useful in patients with respiratory inadequacy that is due to neuromuscular problems - such as the Guillain-Barre syndrome, in which the vital capacity decreases as weakness increases.

Pulse oximetry

Lightweight oximeters which measure the changing amount of light transmitted through pulsating arterial blood and provide a continuous, non-invasive assessment of S_ao_2 can be applied to an ear lobe or finger. These devices are reliable, easy to use and do not require calibration, although remember that pulse oximetry is not a very sensitive guide to *changes* in oxygenation. An S_ao_2 within normal limits in a patient receiving supplemental oxygen in no way excludes the possibility of hypoventilation. Readings may be inaccurate in those with poor peripheral perfusion.

Blood gas analysis

Errors can result from malfunctioning of the analyser or incorrect sampling of arterial blood.

- The sample should be analysed immediately or the syringe should be immersed in iced water (the end having first been sealed with a cap) to prevent the continuing metabolism of white cells causing a reduction in Po_2 and a rise in Pco_2.
- The sample must be adequately anticoagulated to prevent clot formation within the analyser. However, excessive dilution of the blood with heparin, which is acidic, will significantly reduce its pH. Heparin (lOOOi.u./mL) should just fill the deadspace of the syringe, i.e. approximately 0.1 mL. This will adequately anticoagulate a 2 mL sample.
- Air almost inevitably enters the sample. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the Pco_2 and usually raising the Po_2 of the sample. However, provided the bubbles are ejected immediately by inverting the syringe and expelling the air that rises to the top of the sample, their effect is insignificant.

Disposable pre-heparinized syringes are available for blood gas analysis.

Normal values of blood gas analysis are shown in Table 15.2. Interpretation of the results of blood gas analysis can be considered in two separate parts:

- disturbances of acid-base balance (see pp. 715 and 962)
- alterations in oxygenation.

Correct interpretation requires a knowledge of the history, the age of the patient, the inspired oxygen

concentration, any other relevant treatment (e.g. the administration of sodium bicarbonate, and the ventilator settings for those on mechanical ventilation). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the P_aO_2 is determined by the oxyhaemoglobin dissociation curve (Fig. 15.5).

Capnography

Continuous breath-by-breath analysis of expired carbon dioxide concentration can be used to:

- confirm tracheal intubation
- continuously monitor end-tidal Pco_2, which approximates to $P_a^{co}2^m$ normal subjects (may be useful when transporting critically ill patients, for example)
- detect apparatus malfunction
- detect alterations in lung function.

MANAGEMENT OF RESPIRATORY FAILURE

Standard management of patients with respiratory failure includes:

administration of supplemental oxygen
treatment for airways obstruction
measures to limit pulmonary oedema
control of secretions treatment of
pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics. Correction of abnormalities which may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.

Oxygen therapy

Methods of oxygen administration

Oxygen is initially given via a face mask. In the majority of patients (except patients with COPD and chronically elevated P_aco_2) the concentration of oxygen given is not vital and oxygen can therefore be given by a 'variable performance' device such as a simple face mask or nasal cannulae (Fig. 15.22).

With these devices the inspired oxygen concentration varies from about 35-55%, with oxygen flow rates of between 6-10L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but they can cause ulceration of the nasal or pharyngeal mucosa. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (Fig. 15.22c). Figure 15.22 should be compared with the fixed-performance mask shown in Figure 14.26, with which the oxygen concentration can be controlled. This latter type of mask is used in patients with COPD and chronic type II failure, although the dangers of reducing hypoxic drive have been overemphasized - hypoxaemia is more dangerous than hypercapnia.

Oxygen toxicity

Experimentally, mammalian lungs have been shown to be damaged by continuous exposure to high concentrations of oxygen, but oxygen toxicity in humans is less well proven. Nevertheless, it is reasonable to assume that high concentrations of oxygen might damage the lungs, and so the lowest inspired oxygen concentration compatible with adequate arterial oxygenation should be used. Dangerous hypoxia should never be tolerated through a fear of pulmonary oxygen toxicity.

Respiratory support

If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (Table 15.7). For non-invasive support, see pp 985.

Intermittent positive-pressure ventilation (IPPV) is achieved by intermittently inflating the lungs with a positive pressure delivered by a ventilator via an endotracheal tube or a tracheostomy. A number of refinements and modifications of IPPV have been introduced over the years (Table 15.7). *Controlled mechanical ventilation* (CMV) with the abolition of spontaneous breathing rapidly leads to atrophy of respiratory muscles so that assisted modes that are triggered by the patient's inspiratory efforts (see below) are preferred.

Table 15.7 Techniques for respiratory support

Technique	Comment
Invasive respiratory support	
Intermittent positive-pressure ventilation (IPPV)	May be given with positive end-expiratory pressure (PEEP)
Continuous positive airway pressure (CPAP)	Given via endotracheal tube
Synchronized intermittent mandatory ventilation (SIMV) (volume or pressure controlled)	May be given with pressure support and CPAP
Pressure support ventilation (PSV)	Usually given with CPAP
'Lung-protective' ventilatory strategies to minimize ventilator-associated lung injury	Low tidal volume, reduced airway pressures. Can use with SIMV, PEEP and prolonged inspiratory phase
High-frequency jet ventilation (HFJV)	May be useful in those with lung leak (e.g. bronchopleural fistula)
Extracorporeal techniques	May be useful in severe acute respiratory failure
Non-invasive respiratory support	All given by tight-fitting nasal or facial masks Inspiratory and expiratory pressures the same ±CPAP
Continuous positive airway pressure (CPAP) Non-invasive positive support ventilation Bilevel positive airway pressure (BiPAP)	Inspiratory and expiratory pressures set separately

The rational use of mechanical ventilation depends on a clear understanding of its potential beneficial effects, as well as its dangers.

Beneficial effects of mechanical ventilation

m Improved carbon dioxide elimination. By increasing the tidal volume of ventilation, the P_aco_2 can be controlled.

- *Relief from exhaustion.* Mechanical ventilation reduces the work of breathing, 'rests' the respiratory muscles and relieves the extreme exhaustion that may be present in patients with respiratory failure. In some cases, if ventilation is not instituted, this exhaustion may culminate in respiratory arrest.

Effects on oxygenation. Application of positive pressure can prevent or reverse atelectasis. In those with severe pulmonary parenchymal disease, the lungs may be very stiff and the work of breathing is therefore greatly increased. Under these circumstances the institution of respiratory support may significantly reduce total body oxygen consumption; consequently PyO_2 and thus P_ao_2 may improve. Because ventilated patients are connected to a leak-free circuit, it is possible to administer high concentrations of oxygen (up to 100%) accurately and to apply a positive end-expiratory pressure (PEEP). In selected cases the latter may reduce shunting and increase P_ao_2 (see below).

Indications for mechanical ventilation ;

Acute respiratory failure, with signs of severe respiratory distress (e.g. respiratory rate > 40/min, inability to speak, patient exhausted) persisting despite maximal therapy. Confusion, restlessness, agitation, a decreased conscious level, a rising P_aco_2 (> 8 kPa) and extreme hypoxaemia (< 8 kPa), despite oxygen therapy, are further indications.

Acute ventilatory failure due, for example, to myasthenia gravis or Guillain-Barre syndrome. Mechanical ventilation should usually be instituted when the vital capacity has fallen to lOmL/kg or less. This will avoid complications such as atelectasis and infection as well as preventing respiratory arrest. The tidal volume and respiratory rate are relatively insensitive indications of respiratory failure in the above conditions and change late in the course of the disease. A high P_aco_2 (particularly if rising) is an indication for urgent mechanical ventilation.

Other indications include:

- prophylactic postoperative ventilation in high-risk patients
- head injury - to avoid hypoxia and hypercarbia which increase cerebral blood flow and intracranial pressure
- trauma - chest injury and lung contusion
- severe left ventricular failure with pulmonary oedema
- coma with breathing difficulties, e.g. following drug overdose. , . . ■ ..

Institution of invasive respiratory support

This requires tracheal intubation. If the patient is conscious the procedure must be fully explained before anaesthesia is induced. The complications of tracheal intubation are given in Table 15.8.

Intubating patients in severe respiratory failure is an extremely hazardous undertaking and should only be performed by experienced staff. In extreme emergencies it may be preferable to ventilate the patient by hand using an oropharyngeal airway, a face mask and a self-inflating bag with added oxygen until experienced help arrives.

The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias and even cardiac arrest. Except in an extreme emergency, therefore, the ECG and oxygen saturation should be monitored, and the patient preoxygenated with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before attempting intubation. In some cases it may be appropriate to establish intra-arterial and central venous pressure monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients, no sedation may be required, but in the majority of patients a short-acting intravenous anaesthetic agent followed by muscle relaxation will be necessary.

Tracheostomy

Tracheostomy may be required for the long-term control of excessive bronchial secretions, particularly in those

Table 15.8 **Complications of endotracheal intubation**

Complication	Comments
Immediate	
Tube in one or other (usually the right) bronchus	Avoid by checking both lungs are being inflated; i.e. both sides of the chest move and air entry is heard on auscultation Obtain chest X-ray to check position of tube and to exclude lung collapse
Tube in oesophagus	Gives rise to hypoxia and abdominal distension Detected by capnography
Early	
Migration of the tube out of the trachea	
Leaks around the tube	
Obstruction of tube because of kinking or secretions	*A dangerous complication* The patient becomes distressed, cyanosed and has poor chest expansion The following should be performed immediately: Manual inflation with 100% oxygen Endotracheal suction Check position of tube Deflate cuff Check tube for 'kinks' If no improvement, remove tube, ventilate with face mask and then insert new endotracheal tube
Late	
Sinusitis	
Mucosal oedema and ulceration	
Laryngeal injury	
Tracheal narrowing and fibrosis	
Tracheomalacia	

with a reduced conscious level, and/ or to maintain an airway and protect the lungs in those with impaired pharyngeal and laryngeal reflexes. Tracheostomy is also performed when intubation is likely to be prolonged, for patient comfort and to facilitate weaning from mechanical ventilation.

Tracheostomy can be performed at the bedside in an ICU. A percutaneous dilatational technique, which is quick and economical, is the technique of choice in critically ill patients and can be used in an emergency. Alternatively, the trachea can be opened through the second, third and fourth tracheal rings via a transverse skin incision in theatre.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can be relieved by a *cricothyroidotomy,* which is safer, quicker and easier to perform than a formal tracheostomy.

Tracheostomy has a small but significant mortality rate. Complications of tracheostomy are shown in Table 15.9. With any tracheostomy, care should be taken to ensure that the tube is not blocked by secretions.

Minitracheostomy involves inserting a small-diameter uncuffed tube percutaneously into the trachea via the cricothyroid membrane using a guidewire. It can be performed under local anaesthesia. This technique facilitates the clearance of copious secretions in those who are unable to cough effectively, although, because these tubes have no cuff, patients must be able to protect their airway.

Table 15.9 **Complications of tracheostomy**

As for tracheal intubation (Table 15.8), plus:

Early
Death
Pneumothorax
Haemorrhage
Hypoxia
Hypotension
Cardiac arrhythmias
Tube misplaced in pretracheal subcutaneous tissues
Subcutaneous emphysema

Intermediate
Mucosal ulceration
Erosion of tracheal cartilages (may cause tracheo-oesophageal fistula) Erosion of innominate artery (may lead to fatal haemorrhage)
Stomal infection
Pneumonia

Late
Failure of stoma to heal
Tracheal granuloma
Tracheal stenosis at level of stoma, cuff or tube tip
Collapse of tracheal rings at level of stoma
Cosmetic

Dangers of mechanical ventilation

Airway complications. There may be complications with tracheal intubation with additional local complications of a tracheostomy (see above) (Tables 15.8 and 15.9).

Disconnection, failure of gas or power supply, mechanical faults. These are unusual but dangerous. A method of manual ventilation, such as a self-inflating bag, and oxygen must always be available by the bedside.

Cardiovascular complications. The application of positive pressure to the lungs and thoracic wall impedes venous return and distends alveoli, thereby 'stretching' the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both these mechanisms can produce a fall in cardiac output.

Respiratory complications. Mechanical ventilation can be complicated by a deterioration in gas exchange because of *V/Q* mismatch and collapse of peripheral alveoli. Traditionally the latter was prevented by using high tidal volumes (10-12 mL/kg) but high inflation pressures, with overdistension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar-capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators leading to *'ventilator-associated lung injury'.* Extreme overdistension of the lungs during mechanical ventilation with high tidal volumes and PEEP can rupture alveoli and cause air to dissect centrally along the perivascular sheaths. This *'barotrauma'* may be complicated by pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, pneumothorax, and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g. necrotizing pneumonia, emphysema), asthma or fractured ribs.

A *tension pneumothorax* can be rapidly fatal in ventilated patients. Suggestive signs include the development or worsening of hypoxia, hypercarbia, respiratory distress, an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift (deviated trachea, displaced apex beat) and a hyperresonant hemithorax. Although, traditionally, breath sounds are diminished over the pneumothorax, this sign can be extremely misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray.

Ventilator-associated pneumonia. Nosocomial pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and may be associated with a significant increase in mortality. It can be difficult to diagnose. Leakage of infected oropharyngeal secretions past the tracheal cuff is largely responsible. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid and the risk of nosocomial pneumonia can be reduced by nursing patients in the semi-recumbent, rather than the supine, position.

Gastrointestinal complications. Initially, many ventilated patients will develop abdominal distension associated with an ileus. The cause is unknown, although the use of opiates may in part be responsible.

Salt and water retention. Mechanical ventilation, particularly with PEEP, causes increased ADH secretion and possibly a reduction in circulating levels of atrial narriuretic peptide. Combined with a fall in cardiac output and a reduction in renal blood flow, these can cause salt and water retention.

Positive end-expiratory pressure (PEEP)

A positive airway pressure can be maintained at a chosen level throughout expiration by attaching a threshold resistor valve to the expiratory limb of the circuit. PEEP re-expands underventilated lung units, and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing the P_aO_2. Unfortunately, however, the inevitable rise in mean intrathoracic pressure that follows the application of PEEP may further impede venous return, increase pulmonary vascular resistance and thus reduce cardiac output. This effect is probably least when the lungs are stiff. The fall in cardiac output can be ameliorated by expanding the circulating volume, although in some cases inotropic support may be required. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

PEEP should be considered if it proves difficult to achieve adequate oxygenation of arterial blood (more than 90% saturation) without raising the inspired oxygen concentration to potentially dangerous levels (conventionally 50%). Many use lower levels of PEEP (5-7 cmH_2O) in the majority of mechanically ventilated patients in order to maintain lung volume.

Other techniques for respiratory support

Continuous positive airway pressure (CPAP)

The application of CPAP achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy or a tightly fitting face mask (non-invasive ventilation). Not only can this improve oxygenation, but the lungs become less stiff, and the work of breathing is reduced.

Pressure support ventilation (PSV)

Spontaneous breaths are augmented by a pre-set level of positive pressure (usually between 5 and 20cmH_2O) triggered by the patient's spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient's effort and pulmonary mechanics. The level of pressure support can be reduced progressively as the patient improves.

Intermittent mandatory ventilation (IMV)

This technique allows the patient to breathe spontaneously between the 'mandatory' tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient's own inspiratory effort (synchronized IMV, or SIMV). SIMV can be used with or without CPAP and spontaneous breaths may be assisted with pressure support.

'Lung-protective' ventilatory strategies

These are designed to avoid exacerbating or perpetuating lung injury by avoiding overdistension of alveoli, minimizing airway pressures and preventing the repeated opening and closure of distal airways. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 6mL/kg predicted bodyweight in order to achieve a plateau airway pressure of 30 cmH_2O or less. Peak airway pressures should not exceed 35-40 cmH_2O. An alternative is to deliver a constant pre-set inspiratory pressure for a prescribed time in order to generate a low tidal volume at reduced airway pressures ('pressure-limited' mechanical ventilation). Respiratory rate can be increased to improve CO_2 removal and avoid severe acidosis (pH < 7.2), but hypercarbia is frequent and should be accepted ('permissive hypercarbia'). Both techniques can be used with SIMV. Ventilation with low tidal volumes has been shown to improve outcome in patients with acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS) (see p. 986).

Extracorporeal gas exchange (ECGE)

In patients with severe refractory respiratory failure veno-venous bypass through a membrane lung (extracorporeal membrane oxygenation - ECMO, or extracorporeal carbon dioxide removal - $ECCO_2R$) has been used to reduce ventilation requirements, thereby minimizing further ventilation-induced lung damage and encouraging resolution of the lung injury. Although randomized controlled trials have indicated that this technique does not improve outcome in adults, some authorities remain convinced that, when used by experienced teams in specialist centres, extracorporeal gas exchange can significantly reduce the high mortality associated with severe ARDS.

Non-invasive ventilation (NIV)

NIV is used as a therapeutic trial with a view to tracheal intubation if it fails. It is also used as the ceiling of treatment in patients who are not candidates for intubation. It is only suitable for patients who are conscious, cooperative and able to protect their airway; they must also be able to expectorate effectively. Positive pressure is applied to the airways using a tight-fitting full-face or nasal mask so that tracheal intubation is avoided. Techniques include CPAP, and/or bilevel positive airway pressure (BiPAP). With the latter technique, inspiratory and expiratory pressure levels and times are set independently and unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech and swallowing which allows better nutrition. Spontaneous coughing and expectoration are not hampered, allowing good physiotherapy, and sedation is unnecessary. Institution of non-invasive respiratory support can rest the respiratory muscles, reduce respiratory acidosis and breathlessness, improve clearance of secretions and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay and, in some categories of patient, mortality may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD, provided the patient is not profoundly hypoxic. NIV may also be useful as a means of avoiding tracheal intubation in immunocompromised patients with acute respiratory failure. Box 15.5 shows some indications for the use of NIV when standard medical treatment has failed. Remember NIV should not be used as a substitute for invasion ventilation when the latter is clearly more appropriate.

***Box 15.5* Some indications for the use of non-invasive ventilation (NIV)**

Acute exacerbation of COPD (ph <7.35)
Cardiogenic pulmonary oedema
Chest wall deformity/neuromuscular disease (hypercapnic respiratory failure)
Obstructive sleep apnoea
Severe pneumonia (see Box 14.4)
Asthma (occasionally)
Weaning patients from invasive ventilation (p. 985)

Contraindications include facial or upper airway surgery, upper gastrointestinal surgery, inability to protect the airway.

Modified from BTS guidelines after 1997. http://www.british thoracic society.co.uk

Weaning

Weakness and wasting of respiratory muscles is an inevitable consequence of the catabolic response to critical illness and may be exacerbated by the reduction in respiratory work during mechanical ventilation. Often abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming spontaneous ventilation. In a significant proportion of patients who have undergone a prolonged period of respiratory support the situation is further complicated by the development of a neuropathy, a myopathy or both.

Critical illness polyneuropathy and myopathy

Polyneuropathies have most often been described in association with persistent sepsis and multiple organ failure (see below). Polyneuropathy is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically the initial mani-

festation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent. Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The cerebrospinal fluid (CSF) protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain-Barre syndrome, in which nerve conduction studies show evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1-6 months but muscle weakness and fatigue frequently persist.

Myopathies can also occur. A severe quadriplegic myopathy has been particularly associated with the administration of steroids and muscle relaxants to mechanically ventilated patients with acute, severe asthma.

Often the most severely ill patients will have a combined neuropathy and myopathy.

Criteria for weaning patients from mechanical ventilation

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. The patient's conscious level, psychological state, metabolic function, the effects of drugs and cardiovascular performance must all be taken into account. A subjective evaluation of the patient's response to a short period of spontaneous ventilation by an experienced clinician (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics and muscular strength.

Techniques for weaning

Patients who have received mechanical ventilation for less than 24 hours - for example, after elective major surgery - can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfil objective criteria for weaning. Methods of weaning include:

- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is reinstituted. The periods of spontaneous breathing are gradually increased and the periods of respiratory support are reduced. Initially it is usually advisable to ventilate the patient throughout the night. This method can be stressful and tiring for both patients and staff, although this approach is sometimes successful when other methods have failed.
  SIMV has been used as a gradual, controlled method of weaning.
- Gradual reduction of the level of pressure support, with no mandatory breaths is currently considered by many to be the preferred technique.
- CPAP can prevent the alveolar collapse, hypoxaemia and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore often used during weaning with SIMV/pressure support and in spontaneously breathing patients prior to extubation.
- Non-invasive ventilation via tightly fitting facial or nasal masks (BiPAP, CPAP).
- Tracheostomy is used frequently in critically ill patients to facilitate weaning from mechanical ventilation (see above).

Extubation

This should not be considered until patients can cough, swallow, protect their own airway and are sufficiently alert to be cooperative. Patients who fulfil these criteria can be extubated provided their respiratory function has improved sufficiently to sustain spontaneous ventilation indefinitely.

ACUTE LUNG INJURY/ACUTE RESPIRATORY DISTRESS SYNDROME

Definition and causes (see Table 15.10)

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are diagnosed in an appropriate clinical setting with one or more recognized risk factors. ALI/ARDS can be defined as follows:

- Respiratory distress.
- Stiff lungs (reduced pulmonary compliance resulting in high inflation pressures).
- Chest radiograph: new bilateral, diffuse, patchy or homogeneous pulmonary infiltrates.
- Cardiac: no apparent cardiogenic cause of pulmonary oedema (pulmonary artery occlusion pressure < 18 mmHg if measured or no clinical evidence of left atrial hypertension).
- Gas exchange abnormalities: ALI - arterial oxygen tension/fractional inspired oxygen *(P^/F^)* ratio <40kPa (< 300 mmHg); ARDS $P_aO_2/F,O_2$ (<26.6kPa)

Table 15.10 Disorders associated with acute lung injury/acute respiratory distress syndrome

Indirect (non-pulmonary)
Sepsis/septic shock
Systemic inflammatory response (e.g. pancreatitis, cardiopulmonary bypass, severe non-thoracic trauma, severe burns)
Haematological:
Massive blood transfusion
Transfusion-associated lung injury
Disseminated intravascular coagulation
Obstetric:
Eclampsia
Drug overdose:
Heroin
Barbiturates
Miscellaneous:
High altitude
Direct (pulmonary)
Pneumonia Pulmonary aspiration:
Gastric contents
Near drowning
Inhalation injury:
Smoke
Corrosive gases Lung contusion Blast injury Fat embolism Amniotic fluid embolism

(< 200 mmHg) (in both cases despite normal arterial carbon dioxide tension and regardless of positive end-expiratory pressure). The criterion for arterial oxygen tension/fractional inspired oxygen is arbitrary and the value of differentiating ALI from ARDS has been questioned.

ALI/ARDS can occur as a non-specific reaction of the lungs to a wide variety of direct pulmonary and indirect non-pulmonary insults. By far the commonest predisposing factor is sepsis, and 20^10% of patients with severe sepsis will develop ALI/ ARDS (Table 15.10).

PATHOGENESIS AND PATHOPHYSIOLOGY OF ALI/ARDS

Acute lung injury can be considered as the earliest manifestation of a generalized inflammatory response with endothelial dysfunction and is therefore frequently associated with the development of MODS.

Non-cardiogenic pulmonary oedema

This is the cardinal feature of ALI and is the first and clinically most evident sign of a generalized increase in vascular permeability caused by the microcirculatory changes and release of inflammatory mediators described previously (see p. 963), with activated neutrophils playing a particularly key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production and lowering the threshold for alveolar flooding.

Pulmonary hypertension

This is a common feature. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, whilst local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines, serotonin, thromboxane and complement. Those vessels supplying alveoli with low oxygen tensions constrict (the 'hypoxic vasoconstrictor response'), diverting pulmonary blood flow to better oxygenated areas of lung, thus limiting the degree of shunt.

Haemorrhagic intra-alveolar exudate

This exudate is rich in platelets, fibrin, fibrinogen and clotting factors and may inactivate surfactant and stimulate inflammation, as well as promoting hyaline membrane formation and the migration of fibroblasts into the air spaces.

Fibrosis

Within days of the onset of lung injury, formation of a new epithelial lining is underway and activated fibroblasts accumulate in the interstitial spaces. Subsequently, interstitial fibrosis progresses, with loss of elastic tissue and obliteration of the lung vasculature, together with lung destruction and emphysema. In those who recover, the lungs are substantially remodelled.

Physiological changes

Shunt and deadspace increase, compliance falls, and there is evidence of airflow limitation. Although the lungs in ALI and ARDS are diffusely injured, the pulmonary lesions, when identified as densities on a CT scan, are predominantly located in dependent regions. This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse.

CLINICAL PRESENTATION OF ALI/ARDS

The first sign of the development of ALI/ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia, with central cyanosis, and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms that may then progress to the picture of complete 'white-out' (Fig. 15.23). The differential diagnosis includes cardiac failure and pneumonia.

MANAGEMENT OF ALI/ARDS

This is based on treatment of the underlying condition (e.g. eradication of sepsis), avoidance of complications such as ventilator-associated pneumonia, and supportive measures.

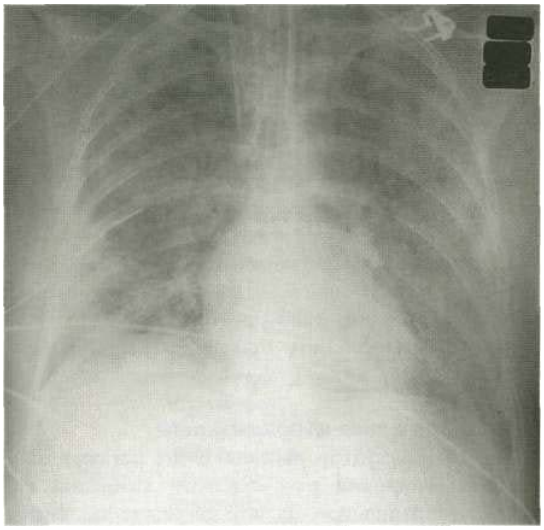

Fig. 15.23 Chest radiograph appearances in acute respiratory distress syndrome. Bilateral diffuse alveolar shadowing with air bronchograms and no cardiac enlargement.

Mechanical ventilation

Strategies designed to minimize ventilator-induced lung injury and encourage lung healing should be used (see p.985).

Pulmonary oedema limitation. Pulmonary oedema formation should be limited by minimizing left ventricular filling pressure with fluid restriction, the use of diuretics and, if these measures fail, preventing fluid overload by haemofiltration. The aim should be to achieve a consistently negative fluid balance. Some recommend that plasma oncotic pressure should be maintained by using colloidal solutions to expand the intravascular volume. In patients with ALI/ARDS, however, colloids are unlikely to be retained within the vascular compartment; once they enter the interstitial space, the transvascular oncotic gradient is lost and the main determinants of interstitial oedema formation become the microvascular hydrostatic pressure and lymphatic drainage. There is therefore some controversy concerning the relative merits of colloids or crystalloids for volume replacement in patients likely to develop ALI/ARDS, or in whom the condition is established. Cardiovascular support and the reduction of oxygen requirements are also necessary.

Prone position. When the patient is changed from the supine to the prone position lung densities in the dependent region are redistributed and shunt fraction is reduced. A reduced pleural pressure gradient, more uniform alveolar ventilation, caudal movement of the diaphragm, redistribution of perfusion and recruitment of collapsed alveoli may all contribute to the improvement in gas exchange. Body position changes can be achieved with minimal complications despite the presence of multiple indwelling vascular lines. Repeated position changes between prone and supine may allow reductions in airway pressures and the inspired oxygen fraction. The response to prone positioning is, however, variable and it seems that this strategy may not improve overall outcome and, until further trials are performed, should be reserved for those with severe hypoxaemia.

Inhaled nitric oxide. This vasodilator, when inhaled, can improve *V/Q* matching by increasing perfusion of ventilated lung units, as well as reducing pulmonary hypertension. It has been shown to improve oxygenation in so-called responders with ALI/ARDS but so far has not been shown to increase survival. Its administration requires specialized monitoring equipment, as products of its combination with oxygen include toxic nitrogen dioxide.

Aerosolized prostacyclin. This appears to have similar effects to inhaled NO and is easier to monitor and deliver. As with inhaled NO, the response to aerosolized prostacyclin is, however, variable and although it has been shown to improve oxygenation its effect on outcome has yet to be established.

Aerosolized surfactant. Surfactant replacement therapy reduces morbidity and mortality in neonatal respiratory distress syndrome and is beneficial in animal models of ALI/ARDS. In adults with ARDS, however, the value of surfactant administration remains uncertain.

High-dose Steroids. Administration of high-dose steroids to patients with established ALI/ARDS does not appear to improve outcome, and current evidence suggests that prophylactic administration to those at risk is of no value. There is, however, some anecdotal evidence that the administration of corticosteroids to patients in the fibroproliferative stage of the disease (e.g. 10-14 days after the onset) may reduce mortality, provided there is no evidence of infection.

Prognosis

Mortality from ALI/ ARDS has fallen over the last decade, from around 60% to between 30% and 40%, perhaps as a consequence of improved general care, the increasing use of management protocols, and attention to infection control and nutrition, as well as the introduction of novel treatments and lung-protective strategies for respiratory support. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality rates are to be expected in those with 'primary' ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

PATIENT SELECTION - WITHHOLDING AND WITHDRAWING TREATMENT

For many critically ill patients, intensive care is undoubtedly life-saving and resumption of a normal lifestyle is to be expected. In the most seriously ill patients, however, immediate mortality rates are high, a significant number die soon after discharge from the intensive care unit, and the quality of life for some of those who do survive may be poor. Moreover, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases treatment may simply prolong the process of dying, or sustain life of dubious quality, and in others the risk of interventions may outweigh the potential benefits.

Both for a humane approach to the management of critically ill patients and to ensure that limited resources are used appropriately, it is necessary to avoid admitting patients who cannot benefit from intensive care and to limit further aggressive therapy when the prognosis is clearly hopeless. Such decisions can be extremely difficult and every case must be assessed individually, taking into account the patient's previous health and quality of life, the primary diagnosis, the medium- and long-term prognosis of the underlying condition (both in terms of survival and quality of life) and the survivability of the acute illness. Age alone should not be a consideration. When in doubt, active measures should continue but should be reviewed regularly in the light of response to treatment and any further information which may become available. Decisions to limit therapy, not to resuscitate in the event of cardiorespiratory arrest, or to withdraw treatment should be made jointly by the medical staff of the unit, the primary physician or surgeon, the nurses and if possible the patient, normally in consultation with the patient's family. Withdrawal or limitation of active treatment should not be viewed negatively as the cessation of all medical or nursing care. Rather, a positive approach should be adopted to ensuring that the patient dies with dignity, free of pain and distress, and that family and friends receive support and comfort.

Scoring systems

A variety of scoring systems have been developed that can be used to evaluate the severity of a patient's illness. Some have included an assessment of the patient's previous state of health and the severity of the acute disturbance of physiological function (acute physiology, age, chronic health evaluation - APACHE, and simplified acute physiology score - SAPS). Other systems have been designed for particular categories of patient (e.g. the injury severity score for trauma victims).

The APACHE and SAPS scores are widely applicable and have been extensively validated. They can quantify accurately the severity of illness and predict the overall mortality for large groups of critically ill patients, and are therefore useful for defining the 'casemix' of patients when auditing a unit's clinical activity, for comparing results nationally or internationally, and as a means of characterizing groups of patients in clinical studies. Although the APACHE and SAPS methodologies can also be used to estimate risks of mortality, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

The Therapeutic Intervention Scoring System (TISS) scores interventions and nursing activities for each day of admission. Such information may provide estimates of resource consumption and indices of nursing dependency. This may not only be related to prognosis but can also be used to estimate costs. Current estimates of daily costs of intensive care in the UK vary from £800 to £1600; high dependency and ward care costs are approximately 50% and 20% of intensive care costs respectively.

BRAIN DEATH

Brain death means 'the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe'. Both these are essentially functions of the brainstem. Death, if thought of in this way, can arise either from causes outside the brain (i.e. respiratory and cardiac arrest) or from causes within the cranial cavity. With the advent of artificial ventilation it became possible to support such a dead patient temporarily, although in all cases cardiovascular failure eventually supervenes and progresses to asystole.

Before considering a diagnosis of brainstem death it is essential that certain preconditions and exclusions be fulfilled.

Preconditions

m The patient must be in apnoeic coma (i.e. unresponsive and on a ventilator, with no spontaneous respiratory efforts).

- Irremediable structural brain damage due to a dis order that can cause brainstem death must have been diagnosed with certainty (e.g. head injury, intracranial haemorrhage).

Exclusions

- The possibility that unresponsive apnoea is the result of poisoning, sedative drugs or neuromuscular block ing agents must be excluded.
- Hypothermia must be excluded as a cause of coma. The central body temperature should be more than 35°C.
- There must be no significant metabolic or endocrine disturbance that could produce or contribute to coma or cause it to persist.
- There should be no profound abnormality of the plasma electrolytes, acid-base balance, or blood glucose levels.

Diagnostic tests for the confirmation of brain death

All brainstem reflexes are absent in brain death.

Tests

The following tests should not be performed in the presence of seizures or abnormal postures.

- Oculocephalic reflexes should be absent: when the head is rotated from side to side, the eyes move with the head and therefore remain stationary relative to the orbit. In a comatose patient whose brainstem is intact, the eyes will rotate relative to the orbit (i.e. doll's eye movements will be present).
- The pupils are fixed and unresponsive to bright light. Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often they will be dilated.
- Corneal reflexes are absent.
- There are no vestibulo-ocular reflexes on caloric testing (see p. 1189).
- There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.
- There is no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation.
- Spontaneous respiration is absent. The patient should be ventilated with 5% CO_2 in 95% O_2 for 10 minutes and then temporarily disconnected from the ventilator for up to 10 minutes. Oxygenation is maintained by insufflation with 100% oxygen via a catheter placed in the endotracheal tube. The patient is observed for any signs of spontaneous respiratory efforts. A blood gas sample should be obtained during this period to ensure that the P_aco_2 is sufficiently high to stimulate spontaneous respiration (> 6.7 kPa (50mmHg)).

The examination should be performed and repeated by two senior doctors.

In the UK it is not considered necessary to perform confirmatory tests such as EEG and carotid angiography.

The primary purpose of establishing a diagnosis of brainstem death is to demonstrate beyond doubt that it is futile to continue mechanical ventilation and other life-supporting measures.

In suitable cases, and provided the assent of relatives has been obtained (easier if the patient was carrying an organ donor card), the organs of those in whom brainstem death has been established may be used for transplantation. In the UK each region has a transplant coordinator who can help with the process, as well as providing information, training and advice about organ donation. They should be informed of all potential donors. In all cases in the UK the coroner's consent must be obtained.

16 Drugtherapyand poisoning

DRUG THERAPY

Introduction

This chapter provides an introduction to the principles of rational therapeutics whose cardinal features are encompassed within the 1984 'Nairobi Declaration'. This emphasizes the importance of prescribing:

- to the right patient
- the right drug
- at the right dose
- and at an affordable cost.

THE PATIENT

The prerequisite of any form of therapeutic intervention is a reliable diagnosis or, at least, assessment of clinical need. An accurate diagnosis ensures that a patient is not exposed, unnecessarily, to the hazards or costs of a particular intervention. Nevertheless there are some circumstances when treatment is used in the absence of a clear diagnosis. Examples include:

- the symptomatic treatment of severe pain
- the initiation of 'blind' antimicrobial therapy where delay would expose a patient to hazard, or discomfort (e.g. parenteral antimicrobial therapy to a patient in the community with suspected meningococcal menin gitis; antimicrobial therapy to a patient with a suspected lower urinary tract infection).

In some instances a particular medicine is only effective in subgroups of patients with a particular disorder. Trastuzumab, for example, is only effective in women with advanced breast cancer whose malignant cells express the HER2 epidermal growth factor receptor. It is likely, in the future, that there will be fragmentation of many diseases we currently consider as single entities, with a more precise definition of sites against which drugs can be targeted.

Medicines are also given to otherwise healthy individuals. In such circumstances there must be a very clear imperative to ensure that the benefits to the individual outweigh the harm. Examples include:

- immunization against serious microbial infections (e.g. influenza vaccination)
- the reduction of individual risk factors for overt disease (e.g. the use of antihypertensive, or lipid-lowering, agents)
- the use of oral contraceptives in sexually active women who wish to avoid pregnancy.

Co-morbidity may also significantly alter the way in which conditions are managed, particular in the elderly. Some examples are shown in Table 16.1.

Prescribing in neonates, infants and children

The use of drugs in the newborn, infants and children poses special problems, as the doses are extrapolated from adult experience (e.g. by adjusting doses solely on the basis of body index). This is rarely wise and may be inappropriate because:

- Dosages are difficult to calculate and precise dosing is often impossible in babies who spit out unpleasant-tasting syrups.
- Percutaneous absorption of topical drugs and dis infecting agents is increased in premature babies (e.g. steroids, iodine or topical aminoglycosides).

Table 16.1 Examples of drugs to be avoided in patients with co-morbidity

Co-morbidity	Avoid	Effect
Parkinson's disease	Neuroleptics Non-steroidal anti-inflammatory drugs	Exacerbates Parkinson's disease Sodium retention
Asthma	Beta-blockers, adenosine	Bronchospasm
Respiratory failure	Morphine, diamorphine	Respiratory depression
Atrioventricular block	Digoxin, digitoxin	Heart block
Renovascular disease	Beta-blockers ACE inhibitors/ antagonists	Reduction in glomerular filtration
Epilepsy	Tricyclic antidepressants	Lower convulsive threshold

- Premature babies have approximately 1% of their bodyweight as fat (compared to 20% in adults) causing a marked increase in plasma drug concentrations of fat-soluble drugs when doses are extrapolated from those in adults, even when adjusted for differences in total body mass.
- Hepatic metabolism and renal excretion of drugs are reduced in neonates and infants. Extrapolation from adult dosage regimens, merely adjusted for weight, leads to excessive (and potentially toxic) plasma drug concentrations.

Prescri^

The use of drugs in the elderly is often a problem because:

- Compliance with treatment regimens is especially poor if there is cognitive impairment, and is worse with increasing numbers of different prescribed medicines.
- Co-morbidity and the inevitable tendency for poly-pharmacy lead to increased opportunities for drug interactions.
- Changes in drug distribution, associated with a reduction in body mass and changes in body composition, may increase plasma concentrations (especially following intravenous administration).
- Ageing is accompanied by changes in the distribution of cardiac output. In particular, a relatively higher pro portion of the stroke volume reaches the brain. This, at least in part, explains why elderly people are so vulnerable to the effects of drugs acting on the central nervous system.

Exaggerated pharmacodynamic effects of drugs acting on cardiovascular and gastrointestinal systems are also common.

Some of the commoner problems that may occur with the use of drugs in the elderly are shown in Table 16.2.

Table 16.2 Common adverse effects of drugs in the elderly

Drug	Effect
Beta-blockers Digoxin Nitrates a-Adrenoceptor-blockers Diuretics	Bradycardia Postural hypotension
Diuretics (thiazides)	Glucose intolerance Gout
Anti-muscarinic drugs Tricyclic antidepressants Neuroleptics Minor tranquillizers Anticonvulsants Hypnotics Opioids	Confusion, cognitive dysfunction
Bisphosphonates (mainly alendronic acid)	Oesphageal ulceration and stricture formation
NSAIDs	Gastric erosions Upper gastrointestinal bleeding
Drug	**Effect**
ACE inhibitors/antagonists Retinoids, e.g. acitretin Amiodarone Carbimazole	Perforated peptic ulcer Renal impairment

Drug use in pregnancy

Clinicians should be extremely cautious about prescribing drugs to pregnant women, and only essential treatments should be given. When a known teratogen is needed during pregnancy (e.g. an anticonvulsant drug or lithium) the potential adverse effects should be discussed with the parents preferably before conception. If they decide to go ahead with the pregnancy, they should be offered an appropriate ultrasound scan to assess whether there is any fetal damage. Some known human teratogens are shown in Table 16.3.

Table 16.3 Some human teratogens

	Effect
Warfarin	Oligohydramnios Multiple abnormalities Neonatal goitre
Antiepileptics (see p. 1223) Carbamazepine Phenytoin Valproate	Neonatal hypothyroidism Dysmorphia Abnormalities of bone growth
NSAIDs	
Cytotoxic drugs	Cleft palate
Lithium	Neural tube defects Delayed closure of the ductus arteriosus Most are presumed teratogens Ebstein's anomaly

NB: All drugs should be avoided in pregnancy unless benefit clearly outweighs the risk

Breast-feeding

Although most drugs can be detected in breast milk, the quantity is generally small. This is because, for most drugs, the concentration in milk is in equilibrium with plasma water (i.e. the non-protein-bound fraction). A few drugs (e.g. aspirin, carbimazole) may, however, cause harm to the infant if ingested in breast milk. Relevant drug literature should be consulted when prescribing to a nursing mother.

THE DRUG

Selecting the right drug involves three elements:

- the drug's clinical efficacy for the proposed use
- the balance between the drug's efficacy and safety
- patient preference.

The 'gold standard' approach (see p. 998) to demonstrating the clinical efficacy of a drug is the randomized controlled trial (RCT) although other approaches (p. 999) can be informative. The demonstration of absolute efficacy (against placebo) may, itself, be insufficient. Where there is more than one treatment for the same indication consideration has to be given as to how they compare with one another, taking account the magnitude of their benefits, their individual adverse reaction profiles, and their costs. Comparative randomized controlled trials are particularly useful in this respect.

The preferences of patients themselves should also, wherever possible, be sought. Such discussions should enable them to be equal partners in decision-making about whether and how they wish to undergo treatment. A full understanding of the reasons for considering treatment, the likely benefits, and the possible adverse reactions, has repeatedly been shown to improve 'concordance' with treatment regimens.

THE DOSE

Appropriate drug dosages will have usually been determined from the results of so-called 'dose-ranging' studies during the original development programme. Such studies are generally conducted as RCTs covering a range of potential doses. Drug doses and dosage regimens may be fixed or adjusted.

Fixed dosage regimens

Drugs suitable (in adults) for prescribing at fixed doses for all patients share common features. Efficacy is optimal in virtually all patients; and the risks of dose-related (type A) adverse reactions (see p. 996) are normally low. These drugs have a high 'therapeutic ratio' (i.e. the ratio between the toxic and therapeutic doses). Examples of drugs prescribed at a fixed dose are shown in Table 16.4.

Titrated dosage regimens

For many drugs there are wide interindividual variations in response. As a consequence, whilst a particular dose may in one person lack any therapeutic effect, the same dose in another may cause serious toxicity. The reasons for such variability are partly due to pharmacokinetic factors (differences in the rates of drug absorption, distribution or metabolism) and partly due to pharmacodynamic factors (differences in the sensitivity of target organs).

Table 16.4 **Examples of fixed dose prescribing**

Drug	Indication
Aspirin	Secondary prevention of myocardial infarction
Bendroflumethiazide (bendrofluazide)	Hypertension
Amoxicillin	Lower urinary tract infection Upper and lower respiratory tract infection
Ferrous sulphate	Iron-deficiency anaemia Oral
Oral contraceptives	contraception

Pharmacokinetics

The intensity of a drug's action, immediately after parenteral administration, is largely a function of its volume of distribution. This, in turn, is predominantly governed by body composition and regional blood flow. Dosage adjustments, for bodyweight or surface area, are therefore common, for example in cancer chemotherapy in order to optimize treatment.

For drugs taken repeatedly, the main determinants of their plasma concentrations (and the intensity of their effects) are the extent of presystemic hepatic metabolism after absorption (Box 16.1), and the rate of systemic clearance (by hepatic metabolism or renal excretion).

Liver drug metabolism occurs in two stages:

- *Phase I* is the modification of a drug, by oxidation, reduction or hydrolysis. Of these, oxidation is the most frequent route and is largely undertaken by a family of isoenzymes known as the cytochrome P450 system (p. 994). Inhibition or induction of cytochrome P450 isoenzymes is a major cause of drug interaction (Table 16.5).
- *Phase II* involves conjugation with glucuronic acid, sulphate, acetate or other substances to render it more soluble and therefore able to be excreted in the urine.

Box 16.1 **Some drugs undergoing extensive presystemic (first pass) hepatic metabolism**

Clomethiazole
Glyceryl trinitrate*
Isosorbide dinitrate
Lidocaine*
Morphine
Pethidine
Propanolol
Verapamil

* For these drugs presystemic metabolism is virtually complete and oral dosing ineffective. Sublingual administration (e.g. glyceryl trinitrate) avoids presystemic metabolism.

Table 16.5 **Some inducers and inhibitors of cytochrome P450**

Inducers	Barbiturates (esp. phenobarbital) Carbamazepine Phenytoin Rifampicin Griseofulvin Non-nucleoside reverse transcriptase inhibitors (NNRTI) Allopurinol Isoniazid Protease inhibitors
Inhibitors	Cimetidine Quinolones Erythromycin Imidazoles Sulphonamides Allopurinol Grapefruit juice

Genetic causes of altered pharmacokinetics

Both presystemic hepatic metabolism, and the rate of systemic hepatic clearance, may vary markedly between healthy individuals, because of genetic factors governing the expression of drug-metabolizing enzymes (Table 16.6). The best-known genetic cause of altered drug handling is acetylator phenotype. Certain drugs are metabolized by acetylation in the liver and individuals can be classified as slow acetylators or fast acetylators. Most populations show a distinct bimodal distribution in their acetylator status (see Fig. 16.1), which is likely to be due to a single gene variation. Those who acetylate slowly will have higher plasma concentrations of drug for any given dose and will tend to develop adverse effects more readily. The antituberculous drug isoniazid will cause a polyneuropathy more commonly in patients with slow acetylator status; inhibition of metabolism of the anticonvulsant phenytoin when prescribed concurrently with isoniazid is also more common in slow acetylators. Rapid acetylators may, conversely, be more likely to relapse because of inadequate plasma concentrations of isoniazid. SLE is more likely to develop with procainamide and hydralazine in slow acetylators.

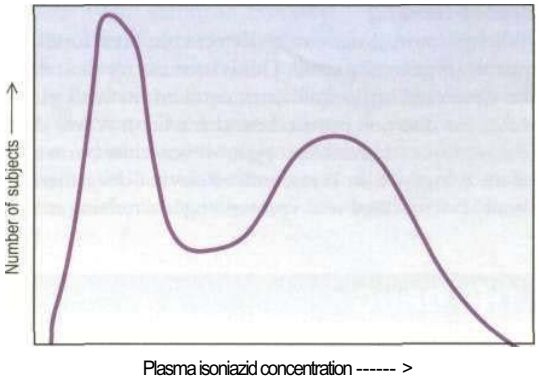

Fig. 16.1 **Bimodal distribution of acetylator status.** Plasma isoniazid concentration shows two distinct groups. Modified from Evans DAP et al. (1960) *British Medical Journal* **2:** 485.

Debrisoquine hydroxylation is also markedly deficient is certain individuals (about 8% of the British population), and such deficiency shows autosomal dominant inheritance. Debrisoquine is rarely used in the treatment of hypertension, not least because almost 1 in *10* patients will have defective metabolism resulting in enhanced adrenergic blockade with the risk of severe hypotension. The same hydroxylase enzyme is involved in metabolism of several beta-blockers and the antidepressant nortriptyline, although it is not clear whether hydroxylation status predicts adverse effects with these drugs.

The rare failure to metabolize suxamethonium resulting in prolonged muscular paralysis is due to a genetic defect in the production of plasma pseudocholinesterase. The condition is autosomal recessive and affects about 1 in 2500 patients.

Other causes of altered pharmacokinetics

Rates of hepatic drug clearance can also be influenced by environmental factors including diet, alcohol consumption and concomitant therapy with drugs capable of inducing or inhibiting (Table 16.6) drug metabolism. Hepatic drug clearance also decreases with age. By contrast, renal drug clearance does not show substantial

Table 16.6 **Genetic polymorphisms involving drug metabolism**

Enzyme	Drug
P450 Cytochrome	
CYP1A2	Amitriptyline Clozapine
Cytochrome CYP3A4	Quinidine Ciclosporin Lidocaine Verapamil Statins Protease inhibitors
Cytochrome CYP2C9	Warfarin Tolbutamide Phenytoin Glipizide Losartan
Cytochrome CYP2D6	Amitriptyline Venlafaxine SSRIs Codeine Beta-blockers Flecainide
Cytochrome CYP2C19	Diazepam Omeprazole/lansoprazole
Plasma pseudocholinesterase	Succinylcholine Mivacurium
Thiopurine methyltransferase	Mercaptopurine Azathioprine
UDP-glucuronosyl transferase	Irinotecan
W-acetyl transferase	Procainamide Isoniazid Hydralazine

Table 16.7 **Some pharmacodynamic genetic polymorphisms**

	Drug	Drug effect
ACE	ACE inhibitors, e.g. ranipril	Blood pressure reduction
Bradykinin B_2 receptor	ACE inhibitors	Cough
p_2-Adrenoceptor	Salbutamol	Bronchodilatation
Dopamine receptors (D_2, D_3, D_4)	Haloperidol Clozapine Risperidone	Antipsychotic response Tardive dyskinesia Akathisia
Serotonin transporter	Fluoxetine Paroxetine	Antidepressant response
Oestrogen receptor-a	Oestrogens	Bone mineral density

variation between healthy individuals although it declines with age and in patients with intrinsic renal disease.

Pharmacodynamics

Pharmacodynamic sources of variability in the intensity of drug action are in part due to drug receptor polymorphisms (Table 16.7).

Monitoring the effects of treatment

The combination of pharmacokinetic and pharmacodynamic causes of variability makes careful monitoring of the effects of treatment essential. Three approaches are used.

Pre-treatment dose selection

In patients with known, or suspected, impaired renal function it is usually possible to predict their dose requirements from the serum creatinine concentration. If treatment needs to be started before the serum creatinine concentration is available, or in patients with very advanced renal impairment, or if renal function is fluctuating then start with conventional doses but be prepared to make adjustments within 24 hours. Frequent assessments of renal function, coupled with measurements of plasma drug concentrations, may be necessary.

Measuring plasma drug concentrations

For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations (Table 16.8). This technique is only useful, however, if both the following criteria are fulfilled:

- There is a reliable and available drug assay.
- Plasma concentrations correlate well with therapeutic efficacy and toxicity.

Measuring drug effects

For many drugs, dosage adjustments are made in line with patients' responses. Monitoring can involve dose titration against a therapeutic end-point or a toxic effect. Objective measures (such as monitoring antihypertensive therapy by measuring blood pressure, or cytotoxic therapy with serial white blood cell counts) are most helpful, but subjective ones are necessary in many instances (as with antipsychotic therapy in patients with schizophrenia).

In the future, drug selection and dose requirements may become largely predictable from a knowledge of an individual's pharmacogenetic characteristics (including both drug metabolism and drug receptor polymorphisms) coupled with relevant demographic and clinical data. Currently, only two pharmacogenetic tests are used routinely:

- HER2 expression in patients with advanced breast cancer before treatment with trastuzumab (see p. 520)
- thiopurine methyltransferase activity in children with acute lymphatic leukaemia and patients with Crohn's disease who are to undergo treatment with mercaptopurine and/or azathioprine.

AFFORDABILITY

The money available for healthcare varies widely across the world and there are marked differences even between developed countries (Fig. 16.2). All healthcare systems try to provide their populations with the highest standards of care within the resources they have at their disposal. The expenditure of large sums on a few people may deprive many of cost-effective remedies — a phenomenon known as the 'opportunity cost'.

Table 16.8 **Drugs for which therapeutic drug monitoring is used**

Drug	Therapeutic plasma concentration range	Toxic level	Optimum post-dose sampling time (hours)
Carbamazepine	20-50 umol/L	50 umol/L	>8
Digoxin	1.3-2.6 nmol/L	2.6 nmol/L	>8
Gentamicin	Trough < 2 mg/L	14 mg/L	Pre-dose
	Peak 5-10 mg/L	12 mg/L	> 1
Lithium	0.6-1.0 mmol/L	1.5 mmol/L	> 10
Phenytoin	40-80 umol/L	80 umol/L	> 10
Theophylline	55-110 umol/L	110 |jmol/L	>4
Ciclosporin	50-200 ug/L	200 ug/L	Pre-dose

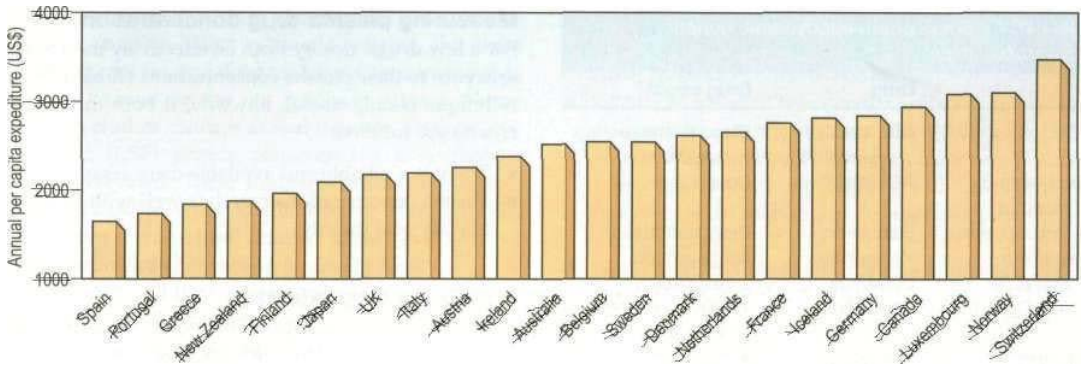

Fig. 16.2 **Annual expenditure on healthcare in US $, per head of population, in some developed countries.**

In all countries it is therefore inevitable that cost-containment measures will be encouraged (or mandated). For example, to reduce costs all drugs should be prescribed by their generic (approved) names rather than their 'brand' ones because, once their patents have expired, they are cheaper. Despite occasional claims to the contrary, generic products are required to go through the same stringent regulatory processes as their branded counterparts.

ADVERSE DRUG REACTIONS

Adverse drug reactions (ADRs), defined as 'the unwanted effects of drugs occurring under normal conditions of use', are a significant cause of morbidity and mortality. Around 5% of acute medical emergencies are admitted with ADRs; and around 10-20% of hospital inpatients suffer an ADR during their stay. Unwanted effects of drugs are five to six times more likely in the elderly, compared to young adults; and the risk of an ADR rises sharply with the number of drugs administered.

Classification

Two types of ADR are recognized.

Type A (augmented) reactions (Table 16.9) are:

- qualitatively normal, but quantitatively abnormal, manifestations of a compound's pharmacological or toxicological properties
- predictable from a compound's known pharmacological or toxicological actions
- generally dose-dependent
- usually common
- only occasionally serious.

Whilst some such as hypotension with ACE inhibitors may occur after a single dose, others may develop only after months (pulmonary fibrosis with amiodarone) or years (second cancers with cytotoxic drugs).

Type B (idiosyncratic) reactions (Table 16.9) have no resemblance to the recognized pharmacological or toxicological effects of the drug. They are:

qualitatively abnormal responses to the drug unpredictable from a compound's known pharmacological or toxicological actions generally dose-independent usually rare often serious.

Table 16.9 **Examples of ADRs**

Drug	Adverse reaction
Type A	
Anticoagulants	Bleeding
Insulin	Hypoglycaemia
Angiotensin-converting enzyme inhibitors/ antagonists	Hypotension
Antipsychotics	Acute dystonia and dyskinesia Parkinson's disease Tardive dyskinesia
Tricyclic antidepressants	Dry mouth
Amiodarone	Hyperthyroidism Hypothyroidism Pulmonary fibrosis
Cytotoxic agents	Bone marrow dyscrasias Cancer
Glucocorticoids	Osteoporosis
TypeB	
Benzylpenicillin Radiological contrast media	Anaphylaxis
Amoxicillin	Maculopapular rash
Gold salts	Bone marrow dyscrasias
Sulphonamides	Toxic epidermal necrolysis
Lamotrigine	
Halothane plus suxamethonium	Malignant hyperthermia
Diclofenac Halothane Isoniazid Rifampicin Phenytoin	Hepatotoxicity

Diagnosis

All ADRs mimic some naturally occurring disease, and the distinction between an iatrogenic aetiology and an event unrelated to the drug is often difficult. Although some effects are obviously iatrogenic (e.g. acute anaphylaxis occurring a few minutes after intravenous penicillin), many are less so. There are six characteristics that can help distinguish an adverse reaction from an event due to some other cause:

- *Appropriate time interval.* The time interval between the administration of a drug and the suspected adverse reaction should be appropriate. Acute anaphylaxis usually occurs within a few minutes of administration, whilst aplastic anaemia will only become apparent after a few weeks (because of the life-span of erythrocytes). Drug-induced malignancy, however, will take years to develop.
- *Nature of the reaction.* Some conditions (maculopapular rashes, angio-oedema, fixed drug eruptions, toxic epidermal necrolysis) are so typically iatrogenic that an adverse drug reaction is very likely.
- *Plausibility.* Where an event is a manifestation of the known pharmacological property of the drug, its recognition as a type A adverse drug reaction can be made (e.g. hypotension with an antihypertensive agent, or hypoglycaemia with an antidiabetic drug). Unless there have been previous reports in the literature, the recognition of type B reactions may be very difficult. The first cases of depression with isotretinoin, for example, were difficult to recognize as an adverse drug reaction even though a causal association is now acknowledged.
- *Exclusion of other causes.* In some instances, particularly suspected hepatotoxicity, an iatrogenic diagnosis can only be made after the exclusion of other causes of disease.
- *Results of laboratory tests.* In a few instances, the diagnosis of an adverse reaction can be inferred from the plasma concentration (Table 16.8). Occasionally, an ADR produces diagnostic histopathological features. Examples include putative reactions involving the skin and liver.
- *Results of dechallenge and rechallenge.* Failure of remission when the drug is withdrawn (i.e. 'dechallenge') is unlikely to be an ADR. The diagnostic reliability of dechallenge, however, is not absolute: if the ADR has caused irreversible organ damage (e.g. malignancy) then dechallenge will result in a false negative response. Rechallenge, involving re-institution of the suspected drug to see if the event recurs, is often regarded as an absolute diagnostic test. This is, in many instances, correct but there are two caveats. First, it is rarely ethically justified to subject a patient to further hazard. Second, some adverse drug reactions develop because of particular circumstances which may not necessarily be replicated on rechallenge (e.g. hypoglycaemia with an antidiabetic agent).

Management

As a general rule, type A reactions can usually be managed by a reduction in dosage whilst type B reactions almost invariably require the drug to be withdrawn (and never re-instituted).

Specific therapy is sometimes required for ADRs such as bleeding with warfarin (vitamin K), acute dystonias (benzatropine), or acute anaphylaxis (Emergency box 16.1).

Emergency Box 16.1 **Treatment of acute anaphylaxis**

Acute anaphylaxis can occur after insect bites and nut ingestion as well as drugs.

Clinical features

Bronchospasm
Facial and laryngeal oedema
Hypotension
Nausea, vomiting and diarrhoea

Management

Position the patient lying flat with feet raised.
Ensure the airway is free.
Give oxygen.
Monitor BP.
Establish venous access.
Administer 0.5 mg intramuscular epinephrine (adrenaline) and repeat every 5 min if shock persists.

- Administer intravenous antihistamine (e.g. 10-20 mg chlorphenamine) slowly.
- Administer 100 mg intravenous hydrocortisone.

If hypotension persists, give 1-2 L of intravenous fluid.

If hypoxia is severe, assisted ventilation may be required.

EVIDENCE-BASED MEDICINE

There is now general acceptance that, in so far as is possible, clinical practice should be based on scientific evidence of benefit rather than theoretical speculation, anecdote or pronouncement.

One of the main applications of 'evidence-based medicine' is in therapeutics. From this it is axiomatic that treatments should be introduced into, and used in, routine clinical care only if they have been demonstrated to be effective in formal clinical trials. Three approaches have been used:

randomized controlled trials
- controlled observational trials
- uncontrolled observational studies.

Randomized controlled trials

*Parallel **group design.*** In this type of study, patients with a particular condition are given, prospectively, one of two (or more) treatments. Treatments are usually allocated randomly (a 'randomized' controlled trial). In order to reduce patient bias, the patients themselves are generally unaware of their treatment allocations (a 'single-blind' trial); and in order to reduce doctor bias the treatment allocation is also withheld from the investigators (a 'double-blind' trial). In order to recruit sufficient numbers of patients, and to examine the effects of treatment in different settings, it is often necessary to conduct the trial at several locations (a 'multicentre' trial). The 'gold standard' for demonstrating the efficacy of a treatment is, thus, the *prospective, randomized, double-blind, multicentre, controlled trial.*

Prospective randomized controlled trials are designed either to show that one treatment is better than another (a 'superiority' trial); or that one treatment is similar to another (an 'equivalence' trial). In a *superiority trial* the study treatment is usually compared to placebo, no treatment, or to current standard practice. With drugs, the comparators may include different doses of the study ('active') drug in order to define the optimum treatment regimen. In an *equivalence trial* the treatment under study is usually compared to another treatment for the same condition.

Although randomized controlled trials were originally introduced to investigate the efficacy of drugs, the methodology can encompass surgical procedures and medical devices.

Cross-over design. In some circumstances patients can receive both the active and the comparator, in a random sequence, thus acting as their own control. Cross-over trials have the advantage that, since each patient is his/her own control, fewer numbers are required to demonstrate efficacy. Such designs, however, are usually only appropriate in circumstances where the drug is intended to produce improvement in a chronic condition. Examples include hypnotics, bronchodilators and antihypertensive agents.

Assessing randomized controlled trials

In assessing the relevance and reliability of an RCT a number of features need to be taken into account.

- *Was ethical approval obtained?* All clinical trials should have received approval, before the start of the study, from a properly constituted research ethics committee. In particular, patients taking part should have given their full and informed consent to participate.
- *Randomization.* In any randomized controlled trial the method of randomization should be robust. In particular, the investigator should be unaware of which treatment a patient about to enter a trial will receive. This avoids selection bias.

Maintaining blindness. Although, ideally, in RCTs neither the investigator nor the patient is aware of the treatment allocation until the end of the study, this is not always possible. Adverse drug reactions, for example, may make it obvious which treatment a patient has been given. Nevertheless maintaining blindness is necessary where the outcome is subjective (e.g. relief of pain, alleviation of depression) if bias is to be avoided.

Were the treated and control groups comparable? Were the treated and control groups similar in their 'baseline' characteristics? Were they, for example, of similar age, severity and duration of illness? If not, are the differences likely to bias the results? Or has the statistical analysis (using analysis of covariance, or Cox's proportional hazards model) tried to adjust for them? Table 16.10 shows an RCT where the baseline characteristics were comparable.

Outcomes. There are two ways to look at the outcomes of an RCT. One is to include only those who completed the study ('per protocol analysis') and the other is to include all patients from the time of randomization ('intention-to-treat analysis'). Ideally there should be no difference but in reality the results of a per protocol analysis are usually more advantageous to a treatment than an intention-to-treat analysis. The reason is that the intention-to-treat analysis will take account of patients who have withdrawn from the trial because of intolerance of the treatment or adverse drug reactions. It is therefore a much more robust approach. Table 16.10 shows the baseline characteristics and results of an 'intention-to-treat' analysis in an RCT comparing magnesium sulphate and diazepam in the treatment of eclamptic fits. The superiority of magnesium sulphate in this study has resulted in its nearly uniform use.

Are the results generalizable? Were the patients enrolled into the study a reasonable reflection of those likely to be treated in routine clinical practice (a so-called pragmatic trial)? Or were they a selected population that excluded significant patient groups (such as the elderly)? If the latter, view the results with caution.

Analysis of a superiority trial. The aim of a superiority trial is to determine whether one treatment (or dose) is better (or more effective) than another. It is usual to estimate the probability that there is 'no difference' between the treatments; if this is less than 1 in 20 ($p < 0.05$) it is regarded as 'statistically significant'. There are two caveats. First, any difference may still be due to chance and it is better to await the results of two independent studies before adopting a new treatment. Secondly, a trial may show no 'statistically significant' difference when one in fact exists because too few patients have been included. The 'power' of a study (the number of patients needed in each treatment group to detect a predefined difference) should have been defined at the outset. If not, the results of the study should be interpreted with extreme care.

Table 16.10 **Randomized comparative trial of parenteral magnesium sulphate and diazepam in the treatment of eclamptic fits**

	Baseline characteristics		
	$MgSO_4$ (n = 453)	Diazepam (n = 452)	
Mean age (years)	22.1	22.3	
Primiparous	293	302	
Twins/triplets	**14**	**16**	
Previous epileptic history	**9**	**8**	
Blood pressure at start of treatment:			
diastolic > 110	238	228	
systolic > 170	**161**	166	
Gestational age (weeks):			
<34	119	103	
34-37	110	107	
>37	168	180	
not known	**56**	**62**	
	Results		
	$MgSO_4$ (n = 453)	Diazepam (n = 452)	**Relative risk (95% CI)**
Further fits	**60**	126	0.48 (0.36-0.63)
Death	**17**	**23**	0.74 (0.40-1.36)
Respiratory depression	**35**	33	
Pneumonia	**9**	**14**	
Renal failure	**28**	**29**	
Stroke	13	**17**	

Collaborative Eclampsia Trialists (1995) Which anticonvulsant for women with eclampsia? Reprinted with permission from Elsevier. *Lancet* 345: 1455-1462

Effect size. The size of a difference in a superiority trial (the so-called 'effect size') may (or may not) be clinically relevant even if statistically significant. For example, if a trial of a new analgesic for mild pain showed that a new treatment relieved pain in 94% of patients compared to 92% of patients with an older treatment, few clinicians would be impressed even if the effect size (2%) was statistically significant. On the other hand, a reduction in the 30-day mortality after acute myocardial infarction from 8% to 6%, by giving streptokinase, is of real clinical advantage even though the effect size is 2%. *Analysis of an equivalence trial.* The aim in this trial is to determine whether two (or possibly more) treatments produce similar benefits. During the design of such trials, it is necessary to decide what difference is unimportant and then to calculate the number of patients needed in order to have an 80% or 90% chance of showing this. In equivalence trials such power calculations show that the number of patients required is invariably greater than those needed for superiority trials. The results of equivalence trials are usually reported as a 'hazard ratio' (the ratio of the response rate to the study treatment to that of the comparator) with its 95% confidence intervals. A hazard ratio of around unity (and with a confidence interval of - say - 0.9-1.1) would indicate that the two treatments were indeed likely to be equivalent. A hazard ratio of 0.5 (confidence interval 0.3-0.7) would suggest inequivalence, and superiority of the study treatment. By contrast, a hazard ratio of 2.0 (confidence interval 1.7-2.3) would suggest that the new treatment was inferior. In equivalence trials, it should be obvious that the comparator itself must have been shown to be effective.

- Meto-analysis. An analysis of all controlled trials that have been performed in a particular area can minimize random errors in the assessment of treatment effects because more patients and treatments are included than in any individual trial. Meta-analysis should be performed (and interpreted) carefully because of the heterogeneity of studies.

Controlled observational trials

Three types of observational study have been used to test the clinical effectiveness of therapeutic interventions - historical controlled trials, case-control studies and before and after studies.

Historical controlled trials. Despite the pre-eminence of the prospective randomized controlled trial there are many treatments that have never been subjected to this technique, yet their efficacy is unquestioned. Examples include insulin in the treatment of diabetic ketoacidosis, thyroxine for hypothyroidism, vitamin B_{12} in pernicious anaemia, and defibrillation for ventricular fibrillation.

In a historical controlled trial the outcome in patients treated with the study drug is compared to that of previously untreated patients with the same disease. The

circumstances when it is legitimate for a treatment to be accepted into routine use on the basis of favourable comparisons with historical controls are generally limited to the following:

- There should be a biologically plausible reason why the treatment might be effective. From a knowledge of the underlying nature of the condition, and the properties of the treatment, it should be reasonable to infer likely benefit.
- There should be no other effective form of treatment. If there is, then the study treatment should be compared with the alternative in a prospective, randomized controlled trial.
- The disease, if untreated, should result in death or permanent disability.
- The condition should have a known, and predictable, natural history.

New treatments that fulfil these stringent criteria are uncommon. Historical controlled trials are most frequently (though inappropriately) used in the assessment of, for example, new anticancer treatments; in most instances prospective, comparative, randomized, and controlled trials would be more informative.

***Case-control** Studies.* This type of study design compares patients with a particular condition (the 'cases') with those without (the 'controls'). The approach has predominantly been used to identify 'risk factors' for specific conditions such as lung cancer (smoking), sudden infant death syndrome (lying prone), or deep venous thrombosis (oral contraceptives). Such a study allows an estimation of the odds ratio:

	Cases	Controls
Risk factor present	*a*	*c*
Risk factor absent	*b*	*d*

The odds ratio (OR) = $a + b/c + d$.

An OR that is significantly greater than unity indicates a statistical association that may be causal. The OR for deep venous thrombosis and current use of oral contraceptives equals 2-4 (depending on the preparation): this indicates that the risk of developing a deep venous thrombosis on oral contraceptives is between 2 and 4 times greater than the background rate.

In some studies, the OR for a particular observation has been found to be significantly less than unity, suggesting 'protection' from the condition under study. Some studies of women with myocardial infarction indicated protection in those using hormone-replacement therapies but it has been subsequently shown that the result was due to bias. On the other hand, case-control studies have consistently shown that aspirin and other non-steroidal anti-inflammatory drugs are associated with a reduced risk of colon cancer. This seems to be a causal effect.

Case-control studies claiming to demonstrate the efficacy of a drug need to be interpreted with great care: the possibility of bias and confounding is substantial as was seen in the studies of hormone-replacement therapy and myocardial infarction. Confirmation from one or more RCTs is usually essential.

Before-and-after studies. **It** has sometimes been inferred that observed improvements seen in patients before, and after, the application of a particular treatment is evidence of efficacy. Such an approach is fraught with difficulties: the combination of a placebo effect, as well as regression to the mean, is likely to negate most studies using this type of design. Nevertheless there are some circumstances where genuine efficacy can be confidently observed with such designs: the consequences of hip replacement, and cataract surgery, are good examples. Such instances can be regarded as special examples of the use of implicit historical controls.

Uncontrolled observational studies

Uncontrolled case series cannot be considered as providing primary evidence of efficacy unless they are undertaken in circumstances that are virtually those of historical controlled trials. When used in this way to demonstrate clinical effectiveness their validity relies on the use of implicit historical trials. Case series can, however, sometimes be of value in demonstrating the generalizability of the results of RCTs.

Dangers

Drug trials are carried out in specific groups of selected patients under strict supervision. The results, particularly when dramatic, are often used outside these strict criteria. The dramatic effect of spironolactone in heart failure (30% reduction in all-cause mortality) has not been replicated in clinical practice because the wrong patients have been treated, often with higher doses, leading to hyperkalaemia and death.

Evaluation of new drugs

New drugs are subjected to a vigorous programme of preclinical and clinical testing before they are licensed for general use (Table 16.11) and are also monitored for safety following licensing. Doctors are recommended to fill in yellow cards when they suspect an adverse reaction has taken place.

Table 16.11 Evaluation of new drugs

Phase I
Healthy human subjects (usually men)
First use in man
Evaluation of safety and toxicity
Pharmacokinetic assessment
Sometimes pharmacodynamic assessment
Approximately 100 subjects

Phase II
First assessment in patients
Safety and toxicity evaluated
Dose range identified
Pharmacokinetic and pharmacodynamic monitoring
Approximately 500 subjects

Phase III
Use *in wider patient population*
Efficacy main objective
Safety and toxicity also carefully monitored
Often multicentre trials
Approximately 2000 patients involved

Phase IV
Postmarketing surveillance
All patients prescribed drug monitored Efficacy, safety and toxicity measured Quantification of unusual drug adverse effects Yellow card and Prescription Event Monitoring Often very large numbers of patients observed

STATISTICAL ANALYSES

The relevance of statistics is not confined to those who undertake research but also to anyone who wants to understand the relevance of research studies to their clinical practice.

The average

Clinical studies may describe, quantitatively, the value of a particular variable (e.g. height, weight, blood pressure, haemoglobin) in a sample of a defined population. The 'average' value (or 'central tendency' in statistical parlance) can be expressed as the mean, median or mode depending on the circumstances:

- The *mean* is the average of a distribution of values that are grouped symmetrically around the central tendency.
- The *median* is the middle value of a sample. It is used, particularly, where the values in a sample are asymmetrically distributed around the central tendency.
- The *mode* is the interval, in a frequency distribution of values, that contains more values than any other.

In a symmetrically distributed population the mean, median and mode are the same.

The average value of a sample, on its own, is of only modest interest. Of equal (and often greater) relevance is the confidence we can place on the sample average as truly reflecting the average value of the population from which it has been drawn. This is most often expressed as a *confidence interval,* which describes the probability of a sample mean being a certain distance from the population mean. If, for example, the mean systolic blood pressure of 100 undergraduates is 124 mmHg, with a 95% confidence interval of + 15 mmHg, we can be confident that if we replicated the study 100 times the value of the mean would be within the range 109-139 mmHg on 95 occasions. It is intuitively obvious that the larger the sample the less will be the size of the confidence interval.

Correlation

In clinical studies two, or more, variables may be measured in the same individuals in a sample population (e.g. weight and blood pressure). The degree of correlation between the two can be investigated by calculating the *correlation coefficient* (often abbreviated to V). The correlation coefficient measures the degree of association between the two variables and may range from 1 to -1. If $r = 1$, there is complete and direct concordance between the two variables: if $r = -1$, there is complete but inverse concordance; and where $r = 0$ there is no concordance.

Statistical tables are available to inform investigators as to the probability that r is due to chance. As in other areas of statistics, if the probability is less than 1 in 20 ($p < 0.05$) then by custom and practice it is regarded as 'statistically significant'. There are, however, two caveats. First, the 1 in 20 rule is a convention and does not exclude the possibility that a presumed association is due to chance. Second, the fact that there is an association between two variables does not necessarily mean that it is causal. A correlation between blood pressure and weight, with $r = 0.75$ and $p < 0.05$, does not mean that weight has a direct effect on blood pressure (or vice versa).

Correlation analyses can become complicated. The simplest (least squares regression analysis) presumes a straight-line relationship between the two variables. More complicated techniques can be used to estimate r where a non-linear relationship is presumed (or assumed); where the distributions deviate from normal; where the scales of one or both variables are intervals or ranks; or where a correlation between three or more variables is sought.

Hypothesis testing

Much of statistics is concerned with testing hypotheses. The basic assumption - known as the *'null hypothesis'* - is that there is no difference between two variables in one (or more) groups. The reason for this confusing terminology is that statistical techniques are designed to assess the extent to which a zero difference might be due to the play of chance (such as a sampling 'error'). In the analysis of an RCT (p. 998) the null hypothesis asserts that there is no difference between the results in patients treated with placebo and those on active treatment. Statistical tests are used to determine the probability that the observed

difference is due to chance. Where this is less than 1 in 20 ($p < 0.05$) it is described as 'statistically significant'. Again, the 1 in 20 rule is arbitrary but is a convention that is widely adopted.

The choice of statistical test to examine the null hypothesis is a complicated one. It is dependent on the type of data collected (whether it is ordinal, cardinal or categorical); and whether it conforms to a normal (parametric) or other (non-parametric) distribution. Those most commonly used include Student's *t* test (parametric) and $\%^2$ test, analysis of variance and various tests for non-parametric data. In some circumstances it is possible to use the confidence intervals of the means of two (or more) groups to test the null hypothesis.

When the results of a statistical test indicate that it is reasonable to reject the null hypothesis, and that the probability of the results being due to chance is less than 1 in 20 ($p < 0.05$), it means that 95 times out of a 100 we will be right, but that 5 times out of a 100 we will be wrong. Statisticians call erroneous rejection of the null hypothesis a *type 1 error*. In this situation the null hypothesis is actually true, although we believe it to be false. Erroneous acceptance of the null hypothesis when there is indeed a difference is known as a *type 2 error*. Type 1 errors can be reduced by requiring a higher level of significance (e.g. $p < 0.01$ or $p < 0.005$) but can never be absolutely excluded. Type 2 errors are usually the result of too few participants in the study and can be avoided by estimating the numbers needed to examine specific levels of difference before the trial is started. Such estimates are known as 'power calculations'.

Other statistical techniques

Statisticians have developed a range of sophisticated methods to handle a wide variety of biomedical problems. Unless an investigator is supremely (and usually unwisely) confident it is wise to seek professional advice in analysing numerical data that look complicated. In doing so, it is invariably wiser to do so at the time the study is being designed rather than after the results have been generated!

INFORMATION

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Details of current prescribing advice can be found in:

- The Summary of Product Characteristics (SmPCs) produced by manufacturers but vetted by the UK drug regulatory authority (the Medicines and Healthcare products Regulatory Agency)
- The British National Formulary (BNF) produced, jointly, by the British Medical Association and the Royal Pharmaceutical Society
- The Technology Appraisals Guidance series from the National Institute for Clinical Excellence (NICE).

Advice on the management of individual conditions, in the form of clinical guidelines (systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances) can be accessed from:

- the National Institute for Clinical Excellence (NICE): http://www.nice-org.uk
- the Scottish Intercollegiate Guidelines Network (SIGN): http://www.sign.ac.uk/
- the National Guidelines Clearing House in the USA: http://www.guideline.gov.

POISONING

The nature of the problem

In many hospitals all over the world, acute poisoning is one of the most common reasons for acute admission to a medical ward. Poisoning is usually by self-administration of prescribed and over-the-counter medicines, or illicit drugs. Poisoning in children aged less than 6 months is most commonly iatrogenic and involves overtreatment with, for example, paracetamol (acetaminophen). Children between 8 months and 5 years of age also ingest poisons accidentally. Drugs may be administered deliberately to cause harm, as in Miinchausen's syndrome by proxy, or for financial or sexual gain. L Occupational poisoning as a result of dermal or inhalational exposure to chemicals is a common occurrence in the developing world and still occurs in the developed world. Sometimes, inappropriate prescribing by a doctor is responsible for the development of poisoning, for example digoxin intoxication.

In adults, self-poisoning is commonly a 'cry for help'. Those involved are most often females under the age of 35 who are in good physical health. They take an overdose in circumstances where they are likely to be found, or in the presence of others. In those older than 55 years of age, men predominate and the overdose is usually taken in the course of a depressive illness or because of poor physical health.

Box 16.2 **Prevention of self-poisoning**

Patients usually take what is readily available at home.

Small amounts only of drugs should be bought. & Foil-wrapped drugs are less likely to be taken. * Keep drugs in a safe place. ► Keep drugs and liquids in their original containers. K Child-resistant drug containers should be used. » Doctors should be careful in prescribing all drugs. K Prescriptions for any susceptible patient (e.g. the depressed) must be monitored carefully. » Household products should be labelled and kept safely, away from children.

SELF-POISONING CAN KILL

All people must be aware of the dangers of drugs and chemicals. Education on safe storage and careful handling of household and workplace chemicals is necessary on a continual basis.

A third of self-poisoning patients state that they are unaware of the toxic effects of the substance involved; the majority take whatever drug is easily available at their home (Box 16.2). Studies of the agents involved reveal that:

- Acute overdoses usually involve more than one agent.
- Alcohol is the most commonly implicated second agent in mixed self-poisonings - 60% of men and 45% of women consume some alcohol at the same time as the drug.
- There is often a poor correlation between the drug history and the toxicological analytical findings. There fore, a patient's statement about the type and amount of drug ingested cannot always be relied upon.

In England and Wales there are some 100 000 hospital admissions each year for self-poisoning. The most common agents involved are paracetamol, benzodiazepines, antidepressants and NSAIDs. A similar pattern exists in other developed countries. In contrast, in the developing world, pesticide poisoning is far commoner with some 1 million cases of serious unintentional pesticide poisonings annually and 2 million hospitalized deliberate pesticide ingestions. In addition, ingestion of heating fuels (e.g. petroleum distillates), antimalarials, antituberculous drugs and traditional medicine is reported frequently.

The majority of cases of self-poisoning do not require intensive medical management, but all patients require a sympathetic and caring approach, a psychiatric and social assessment and, sometimes, psychiatric treatment. However, as the majority of patients ingest relatively non-toxic agents, all that is required is good supportive care and, when appropriate, the administration of specific antidotes, such as N-acetylcysteine for paracetamol poisoning. The in-hospital mortality in most developed countries is now < 0.5%. Most deaths from poisoning *(80%* of some 4500 in the UK) occur outside hospital; the commonest causes are carbon monoxide, tricyclic antidepressants, paracetamol, and analgesic combinations containing paracetamol and an opioid.

Box 16.3 **Diagnostic process in acute poisoning**

Obtain history if possible from the patient or a relative/friend/paramedic.
Is there circumstantial evidence of an overdose?
Are the circumstances in which the patient has been found suggestive of an overdose?
Was a suicide note left?
Are the symptoms suggestive of an overdose?
Do the physical signs suggest an overdose? (Table 16.12)
Identify the tablets if available with the help of pharmacy and poison information centres. TICTAC is a computer-aided tablet and capsule identification system available in the UK to authorized users. TOX BASE is available over the Internet to registered users (http://www.spib.axl.co.uk).

THE APPROACH TO THE PATIENT

History

Eighty per cent of adults are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history (Box 16.3). It should be emphasized that in any patient with an altered level of consciousness, drug overdose must always be considered in the differential diagnosis.

Examination

On arrival at hospital the patient must be assessed urgently in the A&E department. Check:

Airways
:
Breathing
Circulation.

Then:

- *Level of consciousness* - the Glasgow Coma Scale should be used (see p. 1206).
- *Ventilation* - pulse oximetry can be used to measure oxygen saturation. The displayed reading may be inaccurate when the saturation is below 70%, there is poor peripheral perfusion and in the presence of carboxyhaemoglobin and methaemoglobin. Arterial blood gases measure CO_2 as well as oxygenation and is also usually measured.
- *Blood pressure and pulse rate.*
- *Pupil size and reaction to light.*
- Evidence of intravenous drug abuse.
- *A head injury* complicating poisoning.

If the patient is unconscious the following should also be checked:

- *Cough and gag reflex* - present or absent
- *Temperature* - measured with a low-reading rectal thermometer.

Some of the physical signs that may aid identification of the agents responsible for poisoning are shown in Table 16.12.

Table 16.12 **Some physical signs of poisoning**

Features	Likely poisons
Constricted pupils	Opioids Organophosphorus insecticides Nerve agents
Dilated pupils	Tricyclic antidepressants Amfetamines Cocaine Antimuscarinic drugs
Convulsions	Tricyclic antidepressants Theophylline Opioids Mefenamic acid Isoniazid Amfetamines
Dystonic reactions	Metoclopramide Phenothiazines
Delirium and hallucinations	Antimuscarinic drugs Amfetamines Cannabis Recovery from tricyclic antidepressant overdose
Loss of vision	Methanol Quinine
Divergent strabismus	Tricyclic antidepressants
Papilloedema	Carbon monoxide Methanol
Nystagmus	Phenytoin Carbamazepine
Hypertonia and hyperreflexia	Tricyclic antidepressants Antimuscarinic drugs
Tinnitus and deafness	Salicylates Quinine
Hyperventilation	Salicylates Phenoxyacetate herbicides Theophylline
Hyperthermia	MDMA (Ecstasy)
Blisters	Usually occur in comatose patients

PRINCIPLES OF MANAGEMENT

Most patients with self-poisoning require only general care and support of the vital systems. However, for a few drugs additional therapy is required.

Toxicological investigations

On admission, or at an appropriate time post-overdose, a timed blood sample should be taken if the agents shown in Table 16.13 have been ingested. The determination of the concentrations of these drugs will be valuable in management and is sometimes useful in medicolegal cases. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. Poison Information Services will advise.

Box 16.4 **Management strategy in acute poisoning**

Provide supportive treatment.
Reduce poison absorption?
Take blood for drug levels (Table 16.13).
Will any other investigations help? (Table 16.14)
Should urine alkalinization, multiple-dose activated charcoal, or haemodialysis be employed to increase poison elimination?
Is an antidote helpful? (Table 16.16)

Table 16.13 **Agents for which emergency measurement of blood concentrations is appropriate**

Aspirin (salicylate)
Digoxin

Methanol Paracetamol Theophylline

Non-toxicological investigations

(Table16.14)

Some routine investigations are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia and hepatic renal failure or of acid-base disturbances (Table 16.15). Measurement of carboxyhaemoglobin, methaemoglobin and RBC cholinesterase activity are of assistance in the diagnosis and management respectively of cases of poisoning due to carbon monoxide, methaemoglobin-inducing agents such as nitrites, and organophosphorus insecticides and nerve agents.

CARE OF THE UNCONSCIOUS PATIENT

(see also p. 1206)

In all cases the patient should be nursed in the lateral position with the lower leg straight and the upper leg flexed; in this position the risk of aspiration is reduced. A clear passage for air should be ensured by the removal of any obstructing object, vomit or dentures, and by backward pressure on the mandible. Nursing care of the mouth and pressure areas should be instituted. Immediate catheterization of the bladder in unconscious patients is usually unnecessary as it can be emptied by gentle suprapubic pressure. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary

Table 16.14 Relevant non-toxicological investigations

Serum sodium (e.g. hyponatraemia in MDMA* poisoning) and potassium (e.g. hypokalaemia in theophylline poisoning and hyperkalaemia in digoxin poisoning) concentrations
Serum creatinine concentration (e.g. renal failure in ethylene glycol poisoning)
Acid-base disturbances, including metabolic acidosis (Table 16.15)
Blood glucose concentration (e.g. hypoglycaemia in insulin poisoning or hyperglycaemia in salicylate poisoning)
Serum calcium concentration (e.g. hypocalcaemia in ethylene glycol poisoning)
Liver function (e.g. in paracetamol poisoning)
Serum phosphate (e.g. hypophosphataemia in paracetamol-induced renal tubular damage)
Serum creatine kinase (rhabdomyolysis)
Carboxyhaemoglobin concentration (in carbon monoxide poisoning)
Methaemoglobinaemia (e.g. in nitrite poisoning)
RBC cholinesterase activity (e.g. organophosphorus insecticide and nerve agent poisoning)
ECG (e.g. wide QRS in tricyclic antidepressant poisoning) X-ray for ingestion/injection of radiopaque substances

*MDMA, 3,4-methylenedioxy-methamfetamine (Ecstasy)

unless the patient has been unconscious for more than 12 hours or is hypotensive.

Respiratory support

If respiratory depression is present, as determined by pulse oximetry or preferably by arterial blood gas analysis, an oropharyngeal airway should be inserted, and supplemental oxygen should be administered. Pulse oximetry alone will not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. The gag reflex can be assessed by positioning the patient on one side and making him or her gag using a suction tube. In many severely poisoned patients the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants. The complications of endotracheal tubes are discussed on page 983.

If ventilation remains inadequate after intubation, as shown by hypoxaemia and hypercapnia, intermittent positive-pressure ventilation (IPPV) should be instituted.

Cardiovascular support

Although hypotension (systolic blood pressure below 80 mmHg) is a recognized feature of acute poisoning, the classic features of shock - tachycardia and pale cold skin - are observed only rarely. In patients with marked hypotension, volume expansion with saline, gelatins or etherified starches (e.g. hetastarch, hexastarch) should be used, guided by monitoring of central venous pressure (CVP). Urine output (aiming for 35-50 mL/h) is also a useful guide to the adequacy of the circulation.

If a patient fails to respond to the above measures, more intensive therapy is required (see p. 975).

Arrhythmias are observed occasionally in poisoned patients, for example after the ingestion of a tricyclic antidepressant or theophylline. All such patients and those with shock should have ECG monitoring. Known arrhythmogenic factors such as hypoxia, acidosis and hypokalaemia should be corrected.

Other problems

Body temperature

Hypothermia - a rectal temperature below 35°C - is a recognized complication of poisoning, especially in older patients or those who are comatose. The patient should be covered with a 'space blanket' and, if necessary, given intravenous and intragastric fluids at normal body temperature. Inspired gases should also be warmed to 37°C.

Hyperthermia can develop with CNS stimulant ingestion. Removal of clothing and sponging with tepid water will promote evaporation.

Rhabdomyolysis

Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate, for example, MDMA (Ecstasy, p. 1012) abuse in the absence of coma. Patients with rhabdomyolysis are at risk of developing firstly, renal failure from myoglobinaemia, particularly if they are hypovolaemic and have an acidosis, and, secondly, wrist or ankle drop from the development of a compartment syndrome (see p. 547).

Convulsions

These may occur, for example, in poisoning due to tricyclic antidepressants, mefenamic acid or opioids. Usually the fits are short-lived but, if they are prolonged, diazepam 10-20 mg i.v. should be administered. Per-

sistent fits must be controlled rapidly to prevent severe hypoxia, brain damage and laryngeal trauma.

If diazepam in repeated doses is ineffective, the patient should also receive a loading dose of phenytoin (15 mg/kg) administered intravenously at a rate of not more than 50 mg/min, with blood pressure and ECG monitoring.

Stress ulceration and bleeding

Medication to prevent stress ulceration of the stomach should be started on admission in all patients who are unconscious and require intensive care. An H_2-receptor antagonist or a proton pump inhibitor should be administered intravenously.

SPECIFIC MANAGEMENT

Antidotes

Specific antidotes are available for only a small number of poisons (Table 16.16).

Antidotes may exert a beneficial effect by:

- forming an inert complex with the poison (e.g. desferrioxamine, dicobalt edetate, dimercaprol, DMSA, DMPS, digoxin-specific antibody fragments, hydroxocobalamin, pralidoxime, protamine, Berlin (Prussian) blue, sodium calcium edetate)
- accelerating the detoxification of the poison (e.g. N-acetylcysteine, sodium thiosulphate)
- reducing the rate of conversion of the poison to a more toxic compound (e.g. ethanol, fomepizole)
- competing with toxic substances for essential receptor sites (e.g. oxygen, naloxone, vitamin K-i)
- blocking essential receptors through which the toxic effects are mediated (e.g. atropine)
- bypassing the effect of the poison (e.g. oxygen).

Table 16.16 **Antidotes of value in poisoning**

Poison	Antidote
Aluminium	Desferrioxamine
Anticoagulants (oral)	Vitamin K,
Arsenic	Dimercaprol (BAL)
Benzodiazepines	Flumazenil
(3-Adrenoceptor blocking drugs	Atropine Glucagon
Carbon monoxide	Oxygen
Copper	D-penicillamine A/-acetylcysteine DMPS
Cyanide	Oxygen Dicobalt edetate Hydroxocobalamin Sodium nitrite Sodium thiosulphate
Digoxin	Digoxin-specific antibody fragments
Ethylene glycol	Ethanol Fomepizole
Iron salts	Desferrioxamine
Lead (inorganic)	Sodium calcium edetate DMSA
Methaemoglobinaemia	Methylthioninium chloride (methylene blue)
Methanol	Ethanol Fomepizole
Mercury (inorganic)	DMPS
Opioids	Naloxone
Organophosphorus compounds	Atropine Pralidoxime
Paracetamol	W-acetylcysteine
Thallium	Berlin (Prussian) blue

DMSA, dimercaptosuccinic acid (succimer); DMPS, dimercaptopropanesulphonate (unithiol)

Reduction of poison absorption

Inhaled

To reduce poison absorption through the lungs, the casualty should be removed from the toxic atmosphere, without the rescuers themselves being put at risk.

Skin

If clothing is contaminated this should be removed to reduce dermal absorption. In addition, contaminated skin should be washed thoroughly with soap and water.

Gut decontamination

The efficacy of current methods to remove unabsorbed drug from the gastrointestinal tract remains unproven. The two major international societies of clinical toxicology, the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists have produced Position Statements on each method.

Gastric lavage

Gastric lavage involves the insertion of a large-bore orogastric tube into the stomach. Small amounts (200-300 mL in an adult) of warm (38°C) fluid (water or 0.9% saline) are introduced and removed by suction. Lavage is continued until the recovered solution is clear of particulate matter.

Gastric lavage *should not be employed routinely in the management of poisoned patients.* The amount of marker removed by gastric lavage is highly variable and diminishes with time. There is no certain evidence that its use improves clinical outcome and it may cause significant morbidity. Gastric lavage should only be *used,* therefore, if a patient has ingested a potentially life-threatening amount of a poison and the procedure can be undertaken within 1 hour of ingestion. Gastric lavage is contraindicated if airway-protective reflexes are lost (unless the patient is intubated) and also if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

Syrup of ipecacuanha

Syrup of ipecacuanha contains two alkaloids, emetine and cephaeline, which induce vomiting by a central action and by a local action (emetine).

Syrup of ipecacuanha *should not be administered to poisoned patients.* The amount of marker removed in

studies was highly variable and diminished with time. There is no evidence that it improves the clinical outcome and therefore its administration, even in children, should be abandoned.

Single-dose activated charcoal

Activated charcoal has a highly developed internal pore structure which is able to adsorb a wide variety of compounds and drugs, e.g. aspirin, carbamazepine, aminophylline, digoxin, barbiturates, phenytoin, paracetamol. It does not absorb strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury and methanol.

Single-dose activated charcoal *should not be administered routinely in the management of poisoned patients.* Based on volunteer studies, the effectiveness of activated charcoal decreases with time; the greatest benefit is within 1 hour of ingestion. The administration of activated charcoal should only be *used* if a patient (with an intact or protected airway) has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 hour previously. There is no evidence that activated charcoal improves the clinical outcome.

For multiple-dose activated charcoal use, see below.

Cathartics

The administration of a cathartic alone has *no role in the management of the poisoned patient* and is not recommended as a method of gut decontamination. Experimental data are conflicting regarding the use of cathartics in combination with activated charcoal. No clinical studies have been published to investigate the ability of a cathartic, with or without activated charcoal, to reduce the bioavailability of drugs or to improve the outcome of poisoned patients. Based on available data, the routine use of a cathartic in combination with activated charcoal is not recommended.

Whole bowel irrigation

Whole bowel irrigation (WBI) requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500-2000 mL/h in an adult. WBI is continued until the rectal effluent is clear. *WBI should not be used routinely in the management of the poisoned patient.* Although some volunteer studies have shown substantial decreases in the bioavailability of ingested drugs, no controlled clinical trials have been performed and there is no conclusive evidence that WBI improves the outcome of the poisoned patient. Based on volunteer studies, WBI should be *used* for potentially toxic ingestions of sustained-release or enteric-coated drugs. There are insufficient data to support or exclude the use of WBI for potentially toxic ingestions of iron, lead, zinc, or packets of illicit drugs; WBI remains a theoretical option for these ingestions. WBI is contraindicated in patients with bowel obstruction, perforation, ileus, and in patients with haemodynamic instability or compromised unprotected airways. WBI should be used cautiously in debilitated patients, or in patients with medical conditions that may be further compromised by its use.

Increasing poison elimination

Treatments that speed poison elimination are urine alkalinization, multiple-dose activated charcoal, dialysis and haemoperfusion.

Urine alkalinization

In practice, urine alkalinization is only employed in salicylate and chlorophenoxy herbicide poisoning. (The methodology employed is described under aspirin poisoning p. 1009) There is some controversy regarding the mechanism by which urine alkalinization increases elimination. Most drugs, particularly unionized, lipid-soluble molecules, are largely reabsorbed by the renal tubules. With alkalinization the drug becomes fully ionized and there is a reduction in reabsorption and enhanced elimination. This alkalinization is achieved by increasing urine pH to approximately 7.5 by the administration of intravenous sodium bicarbonate.

Multiple-dose activated charcoal

Multiple doses of activated charcoal aid the elimination of some drugs from the circulation by interrupting their enterohepatic circulation and also by adsorbing the drug that has diffused into the intestinal juices. The adsorptive capacity of charcoal is such that as zero concentrations of free drug are present in luminal fluid, the diffusion gradient still remains as high as possible. The process has been termed 'gut dialysis' since, in effect, the intestinal mucosa is being used as a semipermeable membrane.

Although many studies have demonstrated that multiple-dose activated charcoal increases drug elimination significantly, this therapy has not yet been shown to reduce morbidity and mortality. Multiple-dose activated charcoal should be *used* only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline. In all of these cases there are data to confirm enhanced elimination, though no controlled studies have demonstrated clinical benefit. Adults should receive 50-100 g initially, followed by 50 g 4-hourly or 25 g 2-hourly until charcoal appears in the faeces or recovery occurs.

Haemodialysis

Haemodialysis in acute poisoning is most commonly indicated for the treatment of acute renal failure and only infrequently to increase the elimination of poisons. Haemodialysis is indicated in patients with severe clinical features and high plasma concentrations of ethanol, ethylene glycol, isopropanol, lithium, methanol or salicylate. Haemodialysis is of little value in patients who have ingested poisons with large volumes of distribution, e.g. tricyclic antidepressants, because the plasma contains only a small proportion of the total amount of drug in the body.

Peritoneal dialysis increases the elimination of poisons such as ethylene glycol and methanol but is much less efficient than haemodialysis.

SPECIFIC POISONS

DRUGS AND CHEMICALS

In this section only specific treatment regimens will be discussed and are in alphabetical order. The general principles of management of self-poisoning will always be required. *All drug doses relate to adults.*

Aluminium and zinc phosphides

Aluminium and zinc phosphides, which are used as rat poison in India and South East Asia, react with moisture in the air and the gastrointestinal tract to produce phosphine, a gas with a garlic-like odour.

Clinical features

Ingestion causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, and renal failure in addition to the features induced by phosphine. Exposure to phosphine causes lacrimation, rhinorrhoea, productive cough, breathlessness, chest tightness, dizziness, headache nausea, and drowsiness. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions and jaundice have been described in severe cases. Ataxia, intention tremor, and diplopia may be found on examination.

Treatment

Treatment is symptomatic and supportive. Gastric lavage should be avoided as it might increase the rate of disintegration of the product ingested and increase toxicity. Activated charcoal is also contraindicated as it will not bind metal phosphides. The value of steroids in preventing pulmonary damage (which may be delayed) has not been established. The mortality is very high despite supportive care.

Amfetamines

Amfetamines are CNS and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of epinephrine (adrenaline) and dopamine. Poisoning is usually the result of their use for pleasurable purposes.

Clinical features

These drugs cause euphoria, extrovert behaviour, a lack of desire to eat or sleep, tremor, dilated pupils, tachycardia and hypertension. More severe intoxication is associated with agitation, paranoid delusions, hallucinations and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia and cardiac arrhythmias may develop in severe intoxication. Rarely, intracerebral and subarachnoid haemorrhage occur and can be fatal. There is evidence that long-term neuronal damage is present in abstinent methamfetamine users.

Treatment

Agitation is controlled by diazepam 10-20 mg i.v. or chlorpromazine 50-100 mg i.m. The peripheral sympathomimetic actions of amfetamines may be antagonized by fl-adrenoceptor blocking drugs.

FURTHER READING

Ernst T, Chang L, Leonido-Yee M, Speck O (2000) Evidence for long-term neurotoxicity associated with methamphetamine abuse. *Neurology* 54: 1344-1349.

Antidiabetic agents

In all cases of poisoning with insulin and sulphonylureas, prompt diagnosis and treatment are essential if death or cerebral damage from neuroglycopenia is to be prevented. Metformin overdose rarely causes hypoglycaemia, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication.

Clinical features

Features include drowsiness, coma, twitching, convulsions, depressed limb reflexes, extensor plantar responses, hyperpnoea, pulmonary oedema, tachycardia, and circulatory failure. Hypoglycaemia is to be expected, and hypokalaemia, cerebral oedema, and metabolic acidosis might occur. Neurogenic diabetes insipidus and persistent vegetative states are possible long-term complications. Cholestatic jaundice has been described as a late complication of chlorpropamide poisoning.

Treatment

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given.

Giucagon may be ineffective. If the blood sugar is normal, gastric lavage should be considered if the patient has presented within 1 hour of the substantial ingestion of an oral preparation. Recurring hypoglycaemia is highly likely. A continuous infusion of glucose together with carbohydrate-rich meals are required in cases of severe insulin poisoning, though there may be difficulty in maintaining normoglycaemia. In the case of sulphonylurea poisoning, however, further glucose (although its administration may be unavoidable) only serves to increase already high circulating insulin concentrations. Diazoxide 1.25 mg/kg body weight intravenously over 1 hour, repeated at 6-hourly intervals if necessary, has therefore been recommended, since it increases blood glucose concentrations and raises circulating catecholamine concentrations while blocking insulin release.

Aspirin

Aspirin is metabolized to salicylic acid (salicylate) by hydrolases present in many tissues, especially the liver, and subsequently to salicyluric acid and salicyl phenolic glucuronide (Fig. 16.3); these two pathways become saturated in overdose, with the following consequences:

- The plasma salicylate concentration increases more than proportionately expected with increasing dose.
- The time needed to eliminate a given fraction of a dose increases with increasing dose.
- Renal excretion of salicylic acid becomes increasingly significant after overdose; this excretion pathway is extremely sensitive to changes in urinary pH, e.g. increasing urinary pH from 7 to 8 (urine alkalinization) increases the renal excretion of salicylates by a factor of10.

Salicylates stimulate the respiratory centre, increase the depth and rate of respiration, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat and protein metabolism, disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate and ketone bodies, all of which contribute to the acidosis.

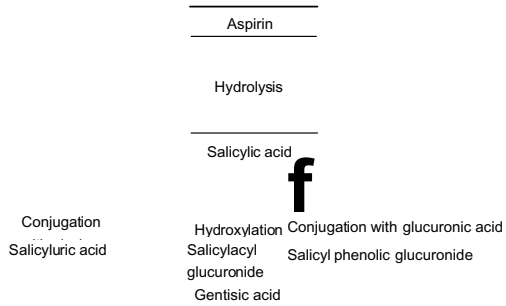

Fig. 16.3 The metabolism of aspirin.

Clinical features

After an overdose, symptoms including hyperventilation, sweating, nausea, vomiting, epigastric pain, tinnitus, and deafness can develop. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid-base disturbance is commonly observed. Rarely, in severe cases, non-cardiogenic pulmonary oedema, renal failure, tetany, coma and convulsions ensue.

Management

For all cases (patients must be assessed in hospital):

- Plasma salicylate concentration. The severity of salicylate poisoning can only be assessed accurately by measurement of the salicylate concentration and acid-base status, though the clinical features will also act as a guide. Initial and repeat salicylate levels after 2 hours should be performed.
- Arterial blood gases.
- Serum urea and electrolytes.
- Intravenous fluids and electrolytes to correct any dehydration or electrolyte imbalance.
- Gastric lavage or activated charcoal (50-100 g) is used in patients who have taken a large amount of aspirin less than 1 hour previously, though there is no evidence that lavage and activated charcoal improve the clinical outcome.

Moderate cases - plasma salicylate concentration 500-700 mg/L (3.62-5.07 mmol/L) - should receive *urine alkalinization:* 225 mL of an 8.4% (1 mmol bicarbonate/mL) solution of sodium bicarbonate is infused intravenously over 1 hour to ensure a urine pH (measured by narrow-range indicator paper or pH meter) of more than 7.5; additional boluses are given to maintain alkalinization.

Urine alkalinization is a metabolically invasive procedure requiring frequent biochemical monitoring and medical and nursing expertise. As administration of sodium bicarbonate will exacerbate pre-existing hypokalaemia, this should be corrected before commencing alkalinization.

Severe cases - plasma salicylate concentration > 700 mg/L (5.07 mmol/L) - particularly those with coma and metabolic acidosis, require haemodialysis.

(i-Adrenoceptor blocking drugs

Clinical features

In mild poisoning sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions and hypotension develop. Less commonly, delirium, hallucinations and cardiac arrest supervene.

Treatment

Atropine 0.6-1.2 mg i.v. may be given but it is usually less effective than giucagon 50-150 Hg/kg (typically 5-10 mg

in an adult) followed by an infusion of 1-5 mg/h. Glucagon acts by bypassing the blocked p-receptor thus activating adenyl cyclase and promoting formation of cyclic AMP from ATP; cyclic AMP in turn exerts a direct P-stimulant effect on the heart.

FURTHER READING

Lip GYH, Ferner RE (1995) Poisoning with anti-hypertensive drugs: beta-adrenoreceptor blocker drugs. *Journal of Human Hypertension* 9: 213-221.

Batteries (disc)

Children occasionally ingest disc button batteries, less commonly larger batteries. In the past there was concern that disc batteries might leak and release mercuric oxide but this metal has now been removed in Europe as a result of legislation. Most disc batteries **will** pass through the gut in 2 or 3 days. If they lodge in the oesophagus, removal by endoscopy is performed.

Benzodiazepines

Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning except in the elderly or those with chronic respiratory disease.

Clinical features

Benzodiazepines produce drowsiness, ataxia and dysarthria. Coma and respiratory depression develop in severe intoxication.

Treatment

If respiratory depression is present, flumazenil 0.5 mg i.v. should be administered in an adult and this dose may be repeated, if necessary.

Cannabis (marijuana)

Cannabis is usually smoked but may be ingested as a 'cake', made into a tea or injected intravenously. It is the drug (other than alcohol) most widely abused in developed countries. The major psychoactive constituent is delta-9-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid and cannabinoid receptors.

Clinical features

Initially there is euphoria followed by drowsiness. A tachycardia is often present. High doses (and chronic use) may lead to psychosis. Intravenous injection leads to watery diarrhoea, tachycardia, hypotension and arthralgia. Whether chronic cannabis abuse causes brain damage remains controversial, though there is increasing evidence that this is the case (p. 1306). Heavy users often become apathetic and suffer impairment of memory and attention. Cannabis use also confers an overall twofold increase in the relative risk for later schizophrenia. Cannabis smoke is carcinogenic.

Treatment

Reassurance is usually the only treatment required, though sedation with intravenous diazepam 10-20 mg i.v. or chlorpromazine 50-100 mg i.m. in adults may be required.

Carbamate insecticides

Carbamate insecticides inhibit acetylcholinesterase but the duration of this effect is comparatively short-lived since the carbamate-enzyme complex tends to dissociate spontaneously.

Clinical features

The features are similar to those of organophosphorus insecticide poisoning (see p. 1016).

Treatment

Occasionally atropine 0.6-2 mg i.v. is required but recovery invariably occurs within 24 hours.

Carbon monoxide

The commonest source of carbon monoxide is an improperly maintained and poorly ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning as methylene chloride is metabolized in vivo to carbon monoxide. The affinity of haemoglobin for carbon monoxide is some 240 times greater than that for oxygen. Carbon monoxide combines with haemoglobin to form carboxyhaemoglobin, thereby reducing the total oxygen-carrying capacity of the blood and increasing the affinity of the remaining haem groups for oxygen. This results in tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase a_3.

Clinical features

Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness. A peak carboxyhaemoglobin (COHb) concentration of less than 10% is not normally associated with symptoms, and peak COHb concentrations of 10-30% may result only in headache and mild exertional dyspnoea. Higher concentrations of COHb are associated with coma, convulsions and cardiorespiratory arrest. Neuropsychiatric features can occur after apparent recovery from carbon monoxide intoxication.

Treatment

In addition to removing the patient from carbon monoxide exposure, high-flow oxygen should be administered using a tightly fitting face mask (p. 985). Endotracheal intubation and mechanical ventilation may be required in those who are unconscious. A recent study using hyperbaric oxygen (HBO) is suggestive of long-term benefit and patients should be referred if they have been unconscious, have a blood carboxyhaemoglobin concentration of > 40% or are pregnant with COHb >20%.

Chloroquine

Chloroquine poisoning is common in Africa, the Far East and West Pacific.

Clinical features

Hypotension is often the first clinical manifestation of poisoning. It may progress to cardiogenic shock, pulmonary oedema and cardiac arrest. Agitation and acute psychosis, convulsions and coma may ensue. Hypokalaemia is common and is due to chloroquine-induced potassium channel blockade.

Treatment

Severe hypokalaemia (p. 707) should be at least partially corrected (severe hyperkalaemia has been reported in the recovery phase). Adrenaline (epinephrine) is the drug of choice for severe hypotension. The use of high doses of diazepam is controversial but may reduce morbidity and mortality. Multiple-dose activated charcoal may enhance chloroquine elimination.

Cocaine (p. 1306)

Cocaine may be abused by smoking, ingestion, injection or snorting it intranasally. Cocaine blocks the reuptake of biogenic amines. Inhibition of dopamine reuptake is responsible for the psychomotor agitation which commonly accompanies cocaine use. Blockade of norepinephrine (noradrenaline) reuptake produces tachycardia, and inhibition of serotonin reuptake may induce hallucinations. Cocaine also enhances CNS arousal by potentiating the effects of excitatory amino acids.

Clinical features

After initial euphoria, cocaine produces agitation, tachycardia, hypertension, sweating, hallucinations, convulsions, metabolic acidosis, hyperthermia, rhabdomyolysis, and ventricular arrhythmias. Dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, and cerebral haemorrhage also occur.

Treatment

Diazepam 10-20 mg i.v. is used to control agitation and convulsions. Active external cooling should be used for hyperthermia. (3-Adrenoceptor blockers are contraindicated for treatment of hypertension and severe tachycardia, as propranolol particularly can cause paradoxical hypertension.

Copper

Copper is used for pipes and roofing material, in alloys and as a pigment. Copper sulphate is used as a fungicide, an algicide and in some fertilizers. Approximately one-third of an ingested copper salt is absorbed and in the blood 80% is bound to caeruloplasmin. Most absorbed copper is deposited in the liver and eliminated mainly in bile.

Clinical features

Acute copper poisoning usually results from the ingestion of contaminated foods or from accidental or deliberate ingestion of copper salts. Copper sulphate is a common cause of poisoning in parts of India. Following substantial ingestion of a copper salt, there is profuse vomiting with abdominal pain, diarrhoea, headache, dizziness, and a metallic taste. Gastrointestinal haemorrhage, haemolysis, and hepatorenal failure may ensue and fatalities have occurred. Body secretions may have a green or blue discoloration.

Occupational exposure to copper fumes (during refining or welding) or to copper-containing dust causes 'metal-fume fever' with upper respiratory tract symptoms, headache, fever and myalgia. Chronic occupational copper exposure causes general malaise, anorexia, nausea, vomiting and hepatomegaly. Contact dermatitis, pulmonary granulomata and pulmonary fibrosis have also been described.

Treatment

Although vomiting occurs invariably following the ingestion of many copper salts, gastric lavage may be of value in reducing copper absorption if presentation is early. Blood copper concentrations correlate well with severity of intoxication, a concentration of < 3 mg/L indicating mild to moderate poisoning and a concentration in excess of 8 mg/L severe intoxication. D-penicillamine, N-acetylcysteine and DMPS (unithiol) enhance copper elimination.

FURTHER READING

Barceloux DG (1999) Copper. *Journal of Toxicology-Clinical Toxicology* 37: 217-230.

Cyanide

Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams. Cyanide reversibly inhibits cytochrome oxidase a_3 so that cellular respiration ceases.

Clinical features

Inhalation of hydrogen cyanide gas produces symptoms within seconds and death within minutes. In contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure, initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions and metabolic acidosis may then supervene.

Treatment

Oxygen should be administered and, if available, dicobalt edetate 300 mg should be given i.v.; the dose may be repeated in severe cases. An alternative antidote is hydroxocobalamin 5 g i.v. (although this is not available in all countries at this dosage and is much more expensive) which may be repeated as necessary. If these two preferred antidotes are not available, sodium nitrite 300 mg i.v. and sodium thiosulphate 12.5 g i.v. should be administered.

Dicobalt edetate (and the free cobalt contained in the preparation) complexes free cyanide. Hydroxocobalamin and sodium thiosulphate enhance endogenous cyanide detoxification mechanisms. Sodium nitrite produces methaemoglobinaemia; methaemoglobin combines with cyanide to form cyanmethaemoglobin.

Digoxin

Toxicity occurring during chronic administration is common, though acute poisoning is infrequent.

Clinical features

These include nausea, vomiting, dizziness, anorexia and drowsiness. Rarely, confusion, visual disturbances and hallucinations occur. Sinus bradycardia is often marked and may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats and ventricular tachycardia. Hyperkalaemia occurs owing to the inhibition of the sodium/potassium-activated ATPase pump.

Treatment

Sinus bradycardia, atrioventricular block and sinoatrial standstill are often reduced or even abolished by atropine 0.6-2.4 mg i.v. If cardiac output is compromised, however, digoxin-specific antibody fragments 6-8 mg/kg bodyweight should be administered.

Ecstasy (3,4-methylenedioxymethamfetamine, MDMA) (p• 1305) _____

Ecstasy is often taken in the setting of a rave **where** dancing is fast and prolonged. It is likely that the pharmacological effects of the drug (which are similar to those of the closely related amfetamines) are compounded by physical exertion, dehydration or over-hydration.

Clinical features

Mild abuse is characterized by agitation, tachycardia, hypertension, widely dilated pupils, trismus and sweating. In more severe cases, hyperthermia, disseminated intravascular coagulation, rhabdomyolysis, acute renal failure and hyponatraemia (secondary to inappropriate antidiuretic hormone secretion) predominate.

Treatment

Reassurance and rehydration are all that is required. If necessary, diazepam 5-10 mg i.v. should be given for severe agitation or convulsions. If hyperthermia is present, dantrolene 1 mg/kg bodyweight i.v. should be administered. Deaths occur from hyperpyrexia, renal and liver failure. Self-induced water intoxication also

Ethanol (see p. 262)

Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetate (Box 5.5, p. 262).

Clinical features

Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations; they are shown in Table 22.15 (p. 1303). In children in particular, severe hypoglycaemia may accompany alcohol intoxication, owing to inhibition of gluconeogenesis. Hypoglycaemia is also observed in adults who are malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present and lactic acidosis, ketoacidosis and acute renal failure have been reported.

Treatment

As ethanol-induced hypoglycaemia is not responsive to glucagon, intravenous glucose 25 g (50 mL of 50% dextrose) should be given. Haemodialysis should be considered if the blood ethanol concentration exceeds 5000 mg/L (32.5 mmol/L) and, particularly, if severe metabolic acidosis is present.

Ethylene glycol

Ethylene glycol is a common constituent of antifreeze fluid used in car radiators. Ethylene glycol itself is non-toxic but is metabolized to toxic products (Fig. 16.4).

Clinical features

Initially the features of ethylene glycol poisoning are similar to ethanol intoxication (though there is no ethanol

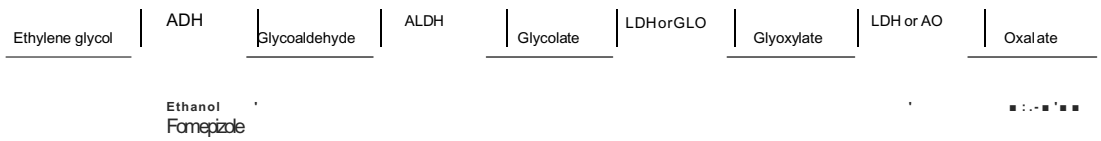

Fig. 16.4 **The metabolism of ethylene glycol.** ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; LDH, lactate dehydrogenase; GLO, glycolic acid oxidase; AO aldehyde oxidase.

on the breath). Coma and convulsions follow and a variety of neurological abnormalities including nystagmus and ophthalmoplegias may be observed. Severe metabolic acidosis, hypocalcaemia and the presence of calcium oxalate crystalluria are well-recognized complications.

Treatment

Supportive measures to combat shock, hypocalcaemia, and metabolic acidosis should be instituted. Inhibitors of alcohol dehydrogenase (either ethanol or fomepizole) should be given to inhibit ethylene glycol metabolism (Fig. 16.4) and, secondly, haemodialysis should be employed to remove ethylene glycol, its aldehyde metabolites and glycolate. A loading dose of ethanol 50 g (conveniently given orally as 125 mL of gin, whisky or vodka) should be administered followed by an intravenous infusion of ethanol 10-12 g/h to produce blood ethanol concentrations of 500-1000 mg/L (11-22 mmol/L). The infusion is continued until ethylene glycol is no longer detectable in the blood. If haemodialysis is employed, the rate of ethanol administration will need to be increased to 17-22 g/h as ethanol is dialysable. Alternatively, fomepizole 15 mg/kg bodyweight can be administered over 30 minutes followed by four 12-hourly doses of 10 mg/kg until ethylene glycol concentrations are less than 200 mg/L. If dialysis is employed the frequency of fomepizole dosing should be increased to 4-hourly during dialysis because fomepizole is dialysable.

Gamma-hydroxybutyric acid (GHB)

Gamma-hydroxybutyric acid is a short-chain fatty acid that occurs naturally in mammalian brain where it is derived metabolically from gamma-aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the brain. In the last 10 years GHB has emerged as a major recreational drug for body building, weight loss and for producing a 'high'. It has many street names, e.g. cherry meth, liquid X, and is taken as a colourless liquid dissolved in water. Several hundred deaths from GHB poisoning have been reported world-wide in recent years.

Clinical features

Poisoning with GHB is characterized by aggressive behaviour, ataxia, amnesia, vomiting, drowsiness, bradycardia, respiratory depression and apnoea, seizures and coma.

Management

In a patient who is breathing spontaneously, the management of GHB poisoning is primarily supportive with oxygen supplementation and the administration of atropine for persistent bradycardia, as necessary. Those who are severely poisoned will require mechanical ventilation, though recovery is usually complete within 6-8 hours.

Household products

The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age. If the ingestion is accidental, adverse features very rarely occur except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension.

Powder detergents, sterilizing tablets, denture-cleaning tablets and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Endotracheal intubation or tracheostomy may be required for life-threatening pharyngeal or laryngeal oedema. Gastric aspiration and lavage and dilution or neutralization of the alkali is contraindicated as it causes further damage and a risk of aspiration. Careful upper GI endoscopy is required to estimate the extent of injury. Oesophageal strictures occur.

Nail polish and nail polish remover contain acetone, which may produce coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

Iron

Unless more than 60 mg of elemental iron per kg bodyweight is ingested (each ferrous sulphate tablet contains 60 mg of iron), adverse features are unlikely to develop. As a result, poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

Clinical features

The initial features are characterized by nausea, vomiting (the vomit may be grey or black in colour), abdominal pain and diarrhoea. Most patients only suffer mild gastrointestinal symptoms. Severely poisoned patients develop haematemesis, hypotension, coma and shock at an early stage. A small minority deteriorate 12-48 hours after ingestion and develop shock, metabolic acidosis, acute renal tubular necrosis and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, intestinal strictures due to corrosive damage occur.

Treatment

Serum iron should be measured approximately 4 hours after ingestion. Desferrioxamine therapy is not required unless the concentration exceeds the predicted normal iron-binding capacity (> 5 mg/L, 90 μmol/L). If a patient develops coma or shock, desferrioxamine should be

given without delay in a dose of 15 mg/kg/h i.v. (total amount of infusion not to exceed 80 mg/kg in 24 hours). If the recommended rate of administration is exceeded, or the therapy is continued for several days, adverse effects including pulmonary oedema have been reported.

Tenenbein M (1996) Benefits of parenteral deferoxamine for acute iron poisoning. *Journal of Toxicology-Clinical Toxicology* 34:485-489.

Lead

Exposure to lead occurs occupationally and the current practice in many countries is to recommend that workers over 18 years of age should cease working with lead when their blood lead concentration is above 600 Hg/L (2.9 umol/L), or 300 (Xg/L (1.45 |imol/L) for a woman of reproductive capacity, or 500 ug/L (2.4 |imol/L) for all employees aged under 18 years. Children who chew on lead-painted items in their homes (pica) may develop lead poisoning. The use of lead-containing cosmetics or 'drugs' has also resulted in lead poisoning.

Clinical features

Even relatively low blood lead concentrations are of concern in children below the age of 5 years. Each increase of 100 (ig/L in lifetime average blood lead concentration is associated with a 4.6 point decrease in IQ. Mild lead intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain, vomiting, constipation and encephalopathy (seizures, delirium, coma) develop in more severe cases. Encephalopathy is more common in children than in adults but is now rare in the developed world. Renal effects include reversible tubular dysfunction and irreversible renal insufficiency leading to hypertension. Typically, though very rarely, lead poisoning results in foot drop attributable to peripheral motor neuropathy. A bluish discoloration of the gum margins owing to the deposition of lead sulphide is observed occasionally.

The characteristic haematological features include:

- *sideroblastic anaemia,* due to inhibition by lead of several enzymes involved in haem synthesis, including ALA synthetase
- *haemolysis,* which is usually mild, resulting from damage to the red cell membrane
- *punctate basophilia* (or basophilic stippling: the blood film shows red cells with small, round, blue particles), due to aggregates of RNA in red cells owing to inhi bition by lead of pyrimidine-5-nucleotidase, which normally disperses residual RNA to produce a diffuse blue staining seen in reticulocytes on blood films (poly chromasia).

Treatment

Children and adults, after treatment, must not be returned to their previous environment (and lead exposure).

The decision to use chelation therapy is based not only on the blood lead concentration but on the presence of symptoms. Although sodium calcium edetate 75 mg/kg bodyweight per day for 5 days is probably more efficient in increasing lead excretion than oral dimercaptosuccinic acid (DMSA) 30 mg/kg bodyweight for 5 days, it has to be given intravenously and may result in increased uptake of lead into the brain and zinc depletion. Oral DMSA, if available, is therefore preferred. However, DMSA did not improve scores on tests of cognition, behaviour and neuropsychological function in children with blood lead concentrations of less than 450 Mg/L.

Canfield RL et al. (2003) Intellectual impairment in children with blood lead concentrations below 10 per deciliter. *New England Journal of Medicine* 348: 1517-1526.

Lithium (see p. 1295)

Lithium toxicity is usually the result of therapeutic overdose (chronic toxicity) rather than deliberate self-poisoning (acute toxicity).

Chronic toxicity is usually associated with serum concentrations above 1.5 mmol/L (10.4 mg/L). Acute massive overdose may produce concentrations of 5 mmol/L (34.7 mg/L) without causing toxic features (see p. 1296).

Treatment

Forced diuresis with sodium chloride 0.9% is effective in increasing elimination of lithium, though haemodialysis is far superior and should be undertaken particularly if neurological features are present, if renal function is impaired and if chronic toxicity or acute on chronic toxicity are the modes of presentation.

Mercury

Metallic mercury is very volatile and when spilled has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus, great care should be taken in clearing up a spillage of mercury if a thermometer or sphygmomanometer is broken. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may be found in the appendix. Mercury salts are well absorbed following ingestion as are organometallic compounds where mercury is covalently bound to carbon.

Clinical features

Inhalation of acute mercury vapour causes headache, nausea, vomiting, cough, chest pain, breathlessness and chemical pneumonitis. Proteinuria and nephrotic syndrome are observed rarely. In addition, a fine tremor and neurobehavioural impairment occur and peripheral nerve involvement has also been observed. Ingestion of inorganic and organic mercury compounds causes an

irritant gastroenteritis with corrosive ulceration, bloody diarrhoea and abdominal cramps and may lead to circulatory collapse and shock.

Mercurous compounds are less corrosive and toxic than mercuric salts.

Treatment

DMPS (dimercaptopropanesulphonate) is the antidote of choice and is given orally in a dose of 30 mg/kg per day. At least 5 days' treatment is usually required.

Methanol

Methanol is used widely as **a** solvent **and** is **found** in antifreeze solutions. Methanol is metabolized to formaldehyde and formate (Fig. 16.5). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions causing metabolic acidosis.

Clinical features

Methanol causes inebriation and drowsiness. After a latent period coma supervenes. Blurred vision and diminished visual acuity occur. The presence of dilated pupils that are unreactive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.63 mmol/L) confirms serious poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neurological sequelae including parkinsonian-like signs as well as blindness.

Treatment

Treatment involves the correction of metabolic acidosis, the inhibition of methanol metabolism by the administration of ethanol or fomepizole and the use of haemodialysis to remove methanol and formate and to correct severe metabolic abnormalities. Either of these components is given as described under ethylene glycol poisoning (p. 1013) until methanol is no longer detectable in the blood.

Folinic acid 30 mg i.v. 6-hourly may protect against ocular toxicity by accelerating formate metabolism.

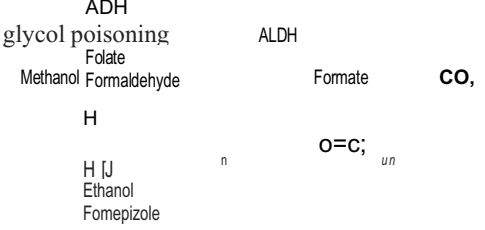

Fig. 16.5 **The metabolism of methanol.** ADH, alcohol dehydrogenase; FDH, formaldehyde dehydrogenase.

Barceloux DG et al. (2002) American Academy of Clinical Toxicology practice guidelines on the treatment of methanol poisoning. *Journal of Toxicology-Clinical Toxicology* 40: 415-446.

Monoamine oxidase inhibitors

These are used less frequently in the treatment of depression because of the dangers of dietary and drug interactions. Moclobemide, which acts by reversible inhibition of monoamine oxidase type A (known as a RIMA), is less toxic in overdose.

Clinical features

Features after overdose may be delayed for 12-24 hours. They include excitement, restlessness, hyperpyrexia, hyperreflexia, convulsions, opisthotonos, rhabdomyolysis and coma. Sinus tachycardia and either hypo- or hypertension are also observed.

Treatment

Treatment is supportive with the control of convulsions and the marked excitement; diazepam 10—20 mg i.v. in an adult should be given as necessary and repeated. Dantrolene 1 mg/kg i.v. should be administered if hyperpyrexia develops. Hypotension should be treated with plasma expansion, and hypertension by the administrationof a P-adrenoceptor blocker such as chlorpromazine.

Nerve agents

Nerve agents are related chemically to organophosphorus insecticides and have a similar mechanism of toxicity, but a much higher mammalian acute toxicity, particularly via the dermal route. Two classes of nerve agent are recognized: G agents (G allegedly stands for Germany where the early agents were first synthesized) and V agents (V allegedly stands for venomous). G agents include tabun, sarin, soman and cyclosarin. The V agents were introduced later, e.g. VX, and were used by Iraq against that country's own Kurdish population. The nerve agent, sarin, was also employed in two terrorist attacks in Japan in 1994 and 1995. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons. Agents used in bioterrorism are described on page 1031.

Clinical features

Systemic poisoning may follow inhalation, ingestion or dermal exposure, though the onset of systemic toxicity is slower by the dermal route.

Systemic features include increased salivation and rhinorrhoea; miosis and eye pain; abdominal pain,

nausea, vomiting and diarrhoea; involuntary micturition and defecation; muscle weakness and fasciculation, tremor, restlessness, ataxia and convulsions. Bradycardia, tachycardia and hypotension may occur, dependent on whether muscarinic or nicotinic effects predominate. Death occurs from respiratory failure within minutes but mild or moderately exposed individuals usually recover completely. EEG abnormalities, however, have been reported in those severely exposed to sarin in Japan.

Treatment

The release of a nerve agent among a civilian population requires the deployment of special measures and personnel to ensure the rescue of casualties and the rapid administration of atropine and an oxime, such as pralidoxime. The parenteral administration of atropine to patients presenting with rhinorrhoea and bronchorrhoea may be life-saving. Alternatively, an infusion of pralidoxime can be given. Intravenous diazepam (adult 10-20 mg; child 1-5 mg) is useful in controlling apprehension, agitation, fasciculation and convulsions; the dose may be repeated as required.

Non-steroidal anti-inflammatory agents (NSAIDs)

Self-poisoning with NSAIDs has increased, as several are now widely available.

Clinical features

In most cases minor gastrointestinal disturbance is the only feature but, in more severe cases, coma, convulsions, metabolic acidosis and renal failure have occurred. Poisoning with mefenamic acid commonly results in convulsions, though these are usually short-lived.

Treatment

Treatment is symptomatic and supportive.

Opiates and opioids

Clinical features

Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate and coma. Hypothermia, hypoglycaemia and convulsions are occasionally observed in severe cases. In severe heroin overdose, non-cardiogenic pulmonary oedema (ARDS) has been reported.

Treatment

Naloxone 0.8-1.2 mg i.v. in an adult (5-10 |J,g per kg bodyweight in a child) will reverse severe respiratory depression and coma at least partially. In severe poisoning, larger initial doses or repeat doses will be required, as the duration of action of naloxone is often less than that of the drug taken in overdose, e.g. methadone, which has a very long half-life. For this reason an infusion of naloxone may be required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

Management of the 'body packer'

'Body-packing' is the practice of smuggling drugs in small packets (condoms, foil and cellophane are commonly used) that are swallowed for later retrieval from vomit or faeces, or are inserted into the vagina or rectum. Acute intestinal obstruction may result, and overdose is a hazard if a packet bursts.

Suspected individuals should have abdominal radiography (preferably CT of the abdomen) and a urine screen for drugs. Screens should be repeated daily, or immediately if the patient develops features of intoxication, in case the package is leaking, to confirm the diagnosis.

Packets in the stomach should not be removed by endoscopy or by inducing emesis, as these are potentially dangerous. Packets in the vagina can usually be removed manually. With packets in the small bowel (if there is no clinical, analytical or radiological evidence to support leakage), sorbitol or lactulose to encourage transit through the gut is appropriate. Alternatively, for faster results, whole-bowel irrigation using polyethylene glycol electrolyte solutions can be used. Liquid paraffin should not be used because it can weaken the rubber, leading to bursting of the packets. Activated charcoal is contradicted as it induces constipation when used in substantial doses. Packets in the colon or rectum are probably best managed by giving sorbitol or lactulose and allowing them to pass spontaneously, with least risk of rupture.

Immediate surgery is indicated if acute intestinal obstruction develops, or when packets can be seen radiologically and there is radiological, clinical or analytical evidence to suggest leakage, particularly if the drug involved is a CNS stimulant (e.g. cocaine).

Organophosphorus insecticides

Organophosphorus (OP) insecticides are used widely throughout the world and are a major cause of death in the developing world e.g. rural Bangladesh. Organophosphorus insecticides inhibit acetylcholinesterase, causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions.

Clinical features

Poisoning may follow ingestion, inhalation or dermal absorption. As many OP insecticides require biotransformation before becoming active, the features of intoxication are delayed. Poisoning is characterized by anxiety, restlessness, tiredness, headache, and muscarinic features such as nausea, vomiting, abdominal colic, diarrhoea, tenesmus, swearing, rhinorrhoea, bronchorrhoea, and chest tightness. Miosis may be present. Nicotinic effects include muscle fasciculation and flaccid paresis of limb, respiratory, and, occasionally, extraocular muscles. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchorrhoea and pulmonary oedema. Coma and convulsions occur in severe poisoning. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed.

Treatment

Mild cases require no specific treatment other then the removal of soiled clothing; contaminated skin should be washed with soap and water to prevent further absorption. In patients presenting with systemic features, atropine 0.6-2 mg i.v. should be given to reduce bronchorrhoea and rhinorrhoea, together with an oxime, such as pralidoxime, which reactivates phosphorylated acetylcholinesterase. Pralidoxime may either be administered by slow i.v. injection (30 mg/kg every 4-6 hours) or as an infusion (8-10 mg/kg/h).

Paracetamol (acetaminophen)

Paracetamol is the most common form of poisoning encountered in the UK (48% of all overdoses, cf. USA 7%).

Mechanism of toxicity

In therapeutic dose, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed function oxidase enzymes to form a highly reactive compound (N-acetyl-p-benzoquinoneimine, NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates. In overdose, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate the toxic metabolite (NAPQI). Paracetamol-induced renal damage probably results from a mechanism similar to that which is responsible for hepatotoxicity.

The severity of paracetamol poisoning is dose-related. There is, however, some variation in individual susceptibility to paracetamol-induced hepatotoxicity. Patients with pre-existing liver disease, those with a high alcohol intake and poor nutrition, those receiving enzyme-inducing drugs, those suffering from anorexia nervosa and other eating disorders and HIV infection are at greater risk and are given treatment at lower plasma paracetamol concentrations (Fig. 16.6).

Clinical features

After an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours or, at the most, develop anorexia, nausea and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 hours after ingestion of the drug. Liver damage usually reaches a peak, as assessed by measurement of aminotransferase (ALT/AST) activity and prothrombin time (INR), at 72-96 hours after ingestion. Without treatment, a small percentage of patients will develop fulminant hepatic failure. Renal failure due to acute tubular necrosis occurs in 25% of patients with severe hepatic damage and in a few without evidence of serious disturbance of liver function.

Treatment

N-acetylcysteine (NAC) is an effective protective agent provided it is administered within 8-10 hours of ingestion of the overdose. It acts by replenishing cellular glutathione stores and may also repair oxidation damage caused by NAPQI. As oral NAC induces vomiting (as does paracetamol ingestion), the intravenous route is preferred. The main treatment regimens used internationally are shown in Box 16.5. Some 5% of patients treated with intravenous NAC develop rash, *angio-*

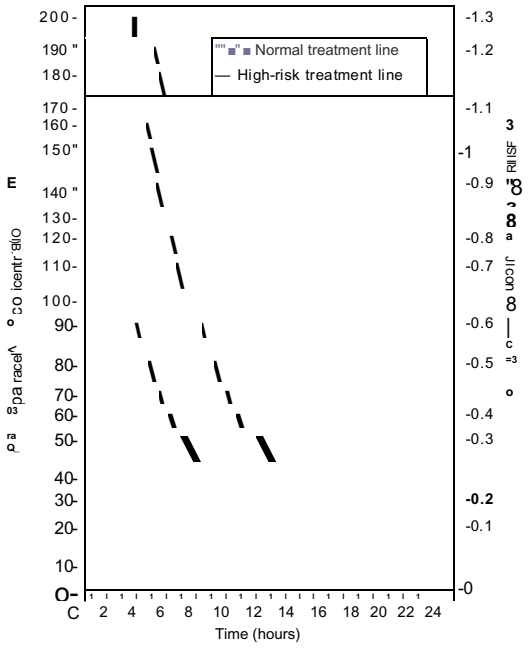

Fig. 16.6 **Nomogram of paracetamol.** From *British National Formulary* (1998) with permission. For definition of 'High-risk patients', see text.

***Box 16.5* Antidote regimens for paracetamol poisoning**

W-acetylcysteine (intravenously in 5% glucose)
150 mg/kg in 200 ml_ over 15 min, then 50 mg/kg in 500 ml_ over the next 4 hours and 100 mg/kg in 1000 mL of 5% glucose over the ensuing 16 hours.

Total dose: 300 mg/kg over 20.15 hours

Note: A 48-hour regimen is used in some US centres: Patients receive a loading dose of 140 mg/kg, followed by 70 mg/kg every 4 hours for 12 doses, all infused over 1 hour.

A/-acetylcysteine (orally)
140 mg/kg initially, then 60 mg/kg every 4 hours for 17 additional doses.

Total dose: 1330 mg/kg over 72 hours.

Methionine
Oral 2.5 g followed by three similar doses every 4 hours if unable to give A/-acetylcysteine.

oedema, hypotension and bronchospasm. These adverse effects, which are related to the initial bolus, are seldom serious and discontinuing the infusion is usually all that is required. In more severe cases, chlorphenamine 10-20 mg i.v. in an adult is given. The overall treatment strategy is to:

- Admit the patient to hospital.
- Take blood for urgent estimation of the plasma paracetamol concentration as soon as 4 hours or more have elapsed since ingestion. Check INR, plasma creatinine and ALT.
- Assess whether the patient is at increased risk of liver damage.
- Give treatment (below) if needed (Fig. 16.6).

The treatment protocol is dependent on the time of presentation.

< 8 hours after ingestion

- If the plasma paracetamol concentration is not available within 8 hours of the overdose and, if 10-15 g or > 150 mg/kg paracetamol has been ingested, treatment should be started at once and stopped if the plasma paracetamol concentration subsequently indicates that treatment is not required.
- Check INR, plasma creatinine and ALT on the completion of treatment and before discharge.

8-15 hours after ingestion

- Urgent action is required because the efficacy of treatment declines progressively from 8 hours after overdose. If > 150 mg/kg paracetamol has been ingested, start treatment immediately.
- In patients already receiving treatment, only discontinue if the plasma paracetamol concentration is below the relevant treatment line (Fig. 16.6) and there is no abnormality of the INR, plasma creatinine or ALT and the patient is asymptomatic. Do not discontinue the infusion if there is any doubt as to the timing of the overdose.
- At the end of treatment, measure INR, plasma creatinine and ALT. If any test is abnormal or the patient is symptomatic, further monitoring is required and expert advice should be sought.
- Patients with normal INR, plasma creatinine and ALT and who are asymptomatic may be discharged.

15-24 hours after ingestion

- Urgent action is required because the efficacy of treatment is limited more than 15 hours after overdose. Start treatment immediately if > 150 mg/kg paracetamol has been ingested.
- The prognostic accuracy of the '200 mg/L line' after 15 hours is uncertain but a plasma paracetamol concentration above the extended treatment line should be regarded as carrying serious risk of severe liver damage.
- At the end of treatment, check INR, plasma creatinine and ALT. If any test is abnormal or the patient is symptomatic, further monitoring is required and expert advice should be sought.
- If liver or renal failure ensues, this should be treated conventionally though there is evidence that a continuing infusion of NAC (continue 16-hour infusion until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients with paracetamol-induced fulminant hepatic failure (p. 368).

FURTHER READING

Vale JA, Proudfoot AT (1995) Paracetamol (acetaminophen) poisoning. *Lancet* **346:** 547-552.

Paraquat

Poisoning with paraquat is very uncommon in the UK but is a common cause of morbidity and mortality in the developing world.

Clinical features

Following ingestion, ulcers in the mouth and oesophagus develop, accompanied by vomiting and diarrhoea, which are induced by paraquat and partly by the co-formulants. In severe cases of poisoning multiple organ failure develops. The prognosis may be determined by measurement of the plasma paraquat concentration.

Treatment

Treatment is supportive.

Phenothiazines

Phenothiazines have varying antimuscarinic, extrapyramidal and sedative effects.

Clinical features

In overdose, impairment of consciousness, hypotension and respiratory depression develop. These effects are less likely to be observed in those who are taking the drug therapeutically.

Treatment

Benzatropine 2 mg i.v. in an adult is occasionally required for the treatment of dyskinesia and oculogyric crisis.

Quinine

Quinine poisoning is relatively common in some countries because of its use for the treatment of leg cramps. It is also ingested in overdose in the developing world where it is employed as an antimalarial.

Clinical features

In addition to the development of tinnitus and deafness, a substantial number of patients develop oculotoxicity including blindness which may be irreversible. Ventricular arrhythmias, convulsions and coma are observed in severe cases.

Treatment

Treatment is supportive. There is evidence that multiple-

dose activated charcoal increases quinine elimination (see p. 1007).

Selective serotonin reuptake inhibitors (SSRIs)

Citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline are antidepressants that inhibit serotonin reuptake; venlafaxine additionally inhibits norepinephrine (noradrenaline) reuptake. They lack the antimuscarinic actions of tricyclic antidepressants.

Clinical features

Even large overdoses appear to be relatively safe, unless potentiated by ethanol, though there is some evidence that venlafaxine is more toxic than other SSRIs. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea, and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures, and hypertension have been encountered and influenza-like symptoms may develop.

Treatment

Supportive measures are all that are required.

Theophylline

Poisoning may complicate therapeutic use as well as being the result of deliberate self-poisoning. If a slow-release preparation is involved, peak plasma concentrations may not be attained until 6-12 hours after overdosage and the onset of toxic features is correspondingly delayed.

Clinical features

Nausea, vomiting, hyperventilation, haematemesis, abdominal pain, diarrhoea, sinus tachycardia, supraventricular and ventricular arrhythmias, hypotension, restlessness, irritability, headache, hyperreflexia, tremors, and convulsions have been observed. Hypokalaemia probably results from activation of Na^+/K^+-ATPase. A mixed acid-base disturbance is common. Most symptomatic patients have plasma theophylline concentrations in excess of 25 mg/L (430 |imol/L). Convulsions are seen more commonly when concentrations are > 50 mg/L (> 860 |j,mol/L). Plasma potassium concentrations of < 2.6 mmol/L, acidaemia, hypotension, seizures and arrhythmias are indicators of severe poisoning.

Treatment

There is good evidence that multiple-dose activated charcoal enhances the elimination of theophylline (p. 1007). However, protracted theophylline-induced vomiting may mitigate the benefit of this therapy, unless vomiting is suppressed by ondansetron 8 mg i.v. in an adult. Correction of hypokalaemia to prevent or treat tachyarrhythmias is of great importance. A non-selective p-adrenoceptor blocking drug, such as propranolol, is also useful in the treatment of tachyarrhythmias secondary to hypokalaemia but should only be given to those without a history of respiratory disease. Convulsions should be treated with diazepam 10-20 mg i.v. in an adult.

FURTHER READING

Shannon M (1999) Life-threatening events after theophylline overdose - a 10-year prospective analysis. *Archives of Internal Medicine* 159: 989-994.

Tricyclic antidepressants

Tricyclic antidepressants block the reuptake of norepinephrine (noradrenaline) into peripheral and intracerebral neurones, thereby increasing the concentration of monoamines in these areas. These drugs also have antimuscarinic actions and class 1 antiarrhythmic (quinidine-like) activity.

Clinical features

Features of poisoning usually appear within 1 hour after ingestion. Drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention, increased reflexes, and extensor plantar responses are the most common features of mild poisoning. Severe intoxication leads to coma, often with divergent strabismus and convulsions. Plantar, oculocephalic, and oculovestibular reflexes may be temporarily abolished. An ECG will often show a wide QRS interval and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

Treatment

The majority of patients recover with supportive therapy alone though a small percentage of patients will require mechanical ventilation for 24-48 hours. The onset of supraventricular tachycardia and ventricular tachycardia should be treated with sodium bicarbonate (8.4%) 50 mmol (50 mL) intravenously over 20 minutes, even if there is no acidosis present. In addition, adequate oxygenation, control of convulsions and correction of acidosis should be undertaken. If ventricular tachycardia is compromising cardiac output, lidocaine 50-100 mg i.v. should be administered.

Kerr GW, McGuffie AC, Wilkie S (2001) Tricyclic antidepressant overdose: a review. *Emergency Medicine Journal* 18: 236-241.

Volatile substance abuse (p. 1305)

Volatile substances are either 'bagged' (sprayed into a plastic bag and then inhaled until the subject passes out) or 'huffed' (sprayed on to a cloth held to the mouth). Volatile substances abused in this way include organic solvents, hydrocarbon mixtures such as petrol, and aerosol propellants. Glues (containing toluene) are most

often sniffed from a plastic bag, and repeated abuse in this manner leads to the development of erythematous spots around the mouth and nose ('glue-sniffer's rash').

Clinical features

The clinical features are similar to those of alcohol intoxication with initial CNS stimulation followed by depression. Thus, euphoria, blurring of vision, tinnitus, slurring of speech, ataxia, feelings of omnipotence, impaired judgement, irritability and excitement are observed commonly. Convulsions and coma, which is usually short-lived, may occur. Some chronic abusers report psychotic symptoms, listlessness and anorexia. Chronic abuse of toluene-containing glues has also resulted in muscle weakness, gastrointestinal complaints (abdominal pain and haematemesis) and neuropsychiatric disorders (altered mental status, cerebellar abnormalities, polyneuropathy). In addition, hypokalaemia, hypophosphataemia and hyperchloraemia have been reported. Rhabdomyolysis occurs in a substantial minority of these patients.

MARINE ANIMALS

Ciguatera fish poisoning

Over 400 fish species have been reported as ciguatoxic *(Cigua* is Spanish for poisonous snail), though barracuda, red snapper, amberjack and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin and scaritoxin, which are lipid-soluble, heat-stable compounds that are derived from ingested dinoflagellates such as *Gambierdiscus toxicus.* The mechanisms of toxicity in man appear to involve more than just inhibition of acetylcholinesterase activity, which has been found in vitro.

Clinical features

The onset of symptoms may occur from a few minutes to 30 hours after ingestion of toxic fish. Typically, features appear between 1 and 6 hours and include abdominal cramps, nausea, vomiting and watery diarrhoea. In some cases, numbness and paraesthesiae of the lips, tongue and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia and transient blindness. In more severe cases, hypotension, cranial nerve palsies and respiratory paralysis have been reported. The mortality in severe cases may be as high as 12%. Recovery takes from 48 hours to 1 week in the mild form and from 1 to several weeks in the severe form.

Treatment

Treatment is symptomatic, although atropine has occasionally lessened some of the cardiovascular and gastrointestinal manifestations. Gabapentin may be useful in lessening persistent paraethesiae.

Jelly fish

Most of the jelly fish found in North European coastal waters are non-toxic as their stings cannot penetrate human skin. A notable exception is the 'Portuguese man-o'-war' *(Physalia physalis),* whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor.

Clinical features

Local pain occurs followed by myalgia, nausea, griping abdominal pain, dyspnoea and even death.

Treatment

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local analgesia and antihistamine creams provide symptomatic relief.

Paralytic shell fish poisoning

This is uncommon and is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by the toxic dinoflagellates, *Gonyaulax catenella* and *Gonyaulax tamarensis.*

Clinical features

Symptoms develop within 30 minutes of ingestion. The illness is characterized by paraesthesiae of the mouth, lips, face and extremities and is often accompanied by nausea, vomiting and diarrhoea. In more severe cases, dysphonia, dysphagia, muscle weakness, paralysis, ataxia and respiratory depression occur.

Treatment

Treatment is symptomatic and supportive.

Scrombrotoxic fish poisoning

This is due to the action of bacteria such as *Proteus morgani* and *Klebsiella pneumoniae* in decomposing the flesh of fish such as tuna, mackerel, bonito and skipjack if the fish are stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

Clinical features

The mean incubation period is 30 minutes. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting and diarrhoea and is usually short-lived; the mean duration is 4 hours.

Treatment

Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

Stings from marine animals

Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cottus, spiny dogfish and the stingray. Bathers and fishermen may be stung if they tread on or handle these species.

Clinical features

The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis and, if the poisoned spine is not removed, chronic sepsis (though this is uncommon). Occasionally, systemic symptoms including vomiting, diarrhoea, hypotension and tachycardia occur.

Treatment

Immersing the affected part in hot water may relieve local symptoms as this denatures the thermolabile toxin.

VENOMOUS ANIMALS

Insect stings and bites

Clinical features

Insect stings from wasps and bees and bites from ants produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm or oropharyngeal oedema.

Treatment

The onset of anaphylaxis requires urgent treatment (see p. 997). Prophylactic immunotherapy has been demonstrated to be of value.

Scorpions

Scorpion stings are a serious problem in North Africa, the Middle East and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines causing both cholinergic and adrenergic symptoms.

Clinical features

Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic, diarrhoea. In some cases, depending on the species, shock, respiratory depression and pulmonary oedema may develop.

Treatment

Local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon possible.

Spiders

The black widow spider *(Latrodectus mactans)* is found in North America and the tropics and occasionally in Mediterranean countries.

Clinical features

The bite quickly becomes painful, and generalized muscle pain, sweating, headache and shock may occur.

Treatment

No systemic treatment is required except in cases of severe systemic toxicity, when specific antivenom should be given, if this is available.

FURTHER READING

Brown SGA et al. (2003) Ant venom immunotherapy: a double-blind, placebo-controlled, crossover trial. *Lancet* **361:** 1001-1006.

Venomous snakes

Approximately 15% of the 3000 species of snake found worldwide are considered to be dangerous to humans. Snake bite is common in some tropical countries. For example, in Sri Lanka there are some 6 bites per 100 000 population and 900 deaths per year. In Nigeria there are some 500 bites per 100 000 population with a 12% mortality. In Myanmar there are 15 deaths per 100 000 population from snake bites. In the USA (population 250 million) there are some 45 000 bites per year (8000 by venomous species) with some 6 deaths annually. In the UK (population 50 million) approximately 100 people are admitted to hospital annually but no deaths have occurred since 1970. In Australia there are 2-3 deaths annually.

There are three main groups of venomous snakes, representing some 200 species, which have in their upper jaws a pair of enlarged teeth (fangs) that inject venom into the tissues of their victim. These are Viperidae (with two subgroups: Viperinae - European adders and Russell's vipers; and Crotalinae - American rattlesnakes, moccasins, lanceheaded vipers and Asian pit vipers), Elapidae (cobras, kraits, mambas, coral snakes, Australian venomous snakes), and Hydrophiidae (sea snakes). In addition, some members of the family Colubridae are mildly venomous (mongoose snake).

Clinical features

Viperidae

Russell's viper causes most of the snake-bite mortality in India, Pakistan and Burma. There is local swelling at the site of the bite (Fig. 16.7) which may become massive. Local tissue necrosis may occur, particularly with cobra bites. Evidence of systemic involvement occurs within 30 minutes, including vomiting, evidence of shock and hypotension. Haemorrhage due to incoagulable blood can be fatal.

Fig. 16.7 **Snake bite showing swelling at site.**

Elapidae

There is not usually any swelling at the site of the bite, except with Asian cobras and African spitting cobras - here the bite is painful and is followed by local tissue necrosis. Vomiting occurs first followed by shock and then neurological symptoms and muscle weakness, with paralysis of the respiratory muscles in severe cases. Cardiac muscle can be involved.

Hydrophiidae

Systemic features are muscle involvement, myalgia and myoglobinuria, which can lead to acute renal failure. Cardiac and respiratory paralysis may occur.

Management

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized. This may delay the spread of the venom. Arterial tourniquets should *not* be used, and incision or excision of the bite area should not be performed. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Antitetanus prophylaxis must be given. The type of snake should be identified if possible.

In about 50% of cases no venom has been injected by the bite. Nevertheless, careful observation for 12-24 hours is necessary in case systemic features (envenomation) develop. General supportive measures should be given, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac and renal failure is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required. As antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.

Allergic reactions are frequent, and epinephrine (adrenaline) (1 in 1000 solution) should be available. In severe cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of epinephrine being given as necessary.

Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

PLANTS

Many plants are known to be poisonous, but it is unusual for severe poisoning to occur in practice. In some regions of the world, however, plant poisonings cause substantial morbidity and mortality. While deaths do occur after unintentional poisoning with plants such as *Atractylis gummifera* (bird-lime or blue thistle) and *Blighia sapida* (ackee tree), the majority of deaths globally occur following intentional self-poisoning with plants such as *Thevetia peruviana* (yellow oleander).

Cicuta species

Cicuta spp. (water hemlock) and the related genus *Oenanthe* contain cicutoxin, a potent central nervous system (CNS) stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of GABA. Severe gastrointestinal symptoms, diaphoresis, salivation and skeletal muscle stimulation may precede the seizure activity.

Conium maculatum

Conium maculatum (poison hemlock) contains a variety of volatile pyridine alkaloids, including coniine, *N*-methylconiine and gamma-coniceine. Coniceine is significantly more toxic than coniine and is thought to be the precursor to coniine. The toxic activity of the alkaloids is similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade which may result in respiratory depression and death.

Datura stramonium

Datura stramonium (jimsonweed) and other *Datura* species contain the tropane alkaloids, L-hyoscyamine and scopolamine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures and/or arrhythmias.

Atropa belladonna

Atropa belladonna (deadly nightshade) contains hyoscyamine and causes antimuscarinic effects - a dry mouth, nausea and vomiting - leading to blurred vision, hallucinations, confusion and hyperpyrexia.

Digitalis purpurea, Nerium oleander, Thevetia peruviana

Ingestion of *Digitalis purpurea,* or the common *(Nerium oleander)* or yellow *(Thevetia peruviana)* oleander can produce a syndrome similar to digoxin poisoning. A randomized controlled trial has shown that digoxin-specific antibody fragments rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm, and rapidly reverse bradycardia and hyperkalaemia.

FURTHER READING

Eddleston M et al. (2000) Anti-digoxin Fab fragments in cardiotoxicity induced by ingestion of yellow oleander: a randomised controlled trial. *Lancet* 355: 967-971.

MUSHROOMS

Most mushrooms and edible fungi are not poisonous, but transient nausea, vomiting and diarrhoea can occur after ingestion of some varieties. There are a few species which are toxic.

Amanita muscaria, Amanita pantherina

Amanita muscaria (fly agaric) and *Amanita pantherina* (false blusher) contain isoxazoles (y-aminobutyric acid agonists) which cause inebriation, visual disturbances, hallucinations, myoclonic jerks, muscle fasciculation, convulsions and coma.

Amanita phalloides

Amanita phalloides (death cap mushroom) contains amatoxins which inhibit transcription from DNA to mRNA by blockade of nuclear RNA polymerase II, resulting in impaired protein synthesis and cell death. Amatoxins are not inactivated by cooking. Hepatocellular necrosis follows 72 hours after ingestion and some varieties cause renal failure. Treatment is with gastric aspiration and general support; haemodialysis and liver/renal transplantation may be necessary. The value of silibinin and N-acetylcysteine is unproven.

Coprinus atramentarius

Coprinus atramentarius (ink cap) contains coprin, an acetaldehyde dehydrogenase inhibitor with a disulfiram-like effect, causing flushing and rash.

Cortinarius orellanus, Cortinarius speciossimus

Cortinarius orellanus and *Cortinarius speciossimus* contain orellanin, a potent nephrotoxin.

'Magic' mushrooms

'Magic' mushrooms, such as *Psilocybe, Panaeolus, Conocybe, Gymnopilus, Stropharia, Pluteus* and *Panaeolina* spp., contain the hallucinogen, psilocybin.

Environmental medicine

HEAT

In health, the body core temperature is maintained at 37°C by the hypothalamic thermoregulator centre.

Heat is produced by cellular metabolism, and lost through the skin by both vasodilatation and sweating and through the lungs in expired air. Profuse sweating occurs when the ambient temperature is greater than 32.5°C and during exercise. Evaporation of sweat is the vital mechanism cooling the body.

Heat acclimatization

Acclimatization to hot climates takes several weeks. Sweat volume increases and its salt content falls. Increased evaporation cools down the body.

Heat cramps

Painful muscle (usually leg) cramps often occur in well-acclimatized fit young people when they exercise in hot weather. Cramps are probably the result of low extracellular sodium caused by replenishment of water but not salt during prolonged sweating. They can be prevented by increasing dietary salt and respond to combined salt and water replacement.

Heat illness (heat exhaustion)

In high environmental temperatures, particularly with high humidity, vigorous exercise in clothing which inhibits heat loss can provoke a sudden elevation in core temperature. Weakness/exhaustion, dizziness and syncope, with a core temperature > 37°C define heat *illness* (exertional heat illness after exercise). Temperature elevation is more critical than water and sodium loss. Heat *illness* may progress to heat *injury,* a serious medical emergency.

Management

Remove the patient from any heat source. Cool with cold sponging and fans. Give oxygen by mask. Other causes of hyperpyrexia, e.g. malaria, should be considered.

Oral rehydration with both salt and water (25 g of sodium chloride per 5 L of water) is given in the first 24 hours, with adequate replacement thereafter. In severe heat illness, intravenous fluids are needed. Isotonic saline is usually given, depending on serum sodium. Careful monitoring is required. Secondary potassium loss must be corrected.

Heat injury (heat stroke)

Heat *injury* is an acute life-threatening situation when core temperature rises above 41 °C. There is headache; nausea, vomiting and weakness. The skin is hot. Sweating is often absent, but this is not invariable, even in severe heat injury. Brain involvement leads to confusion, delirium and coma.

Heat injury develops in unacclimatized people in hot, humid windless climates, even without exercise. Sweating may be limited by prickly heat. Excessive exercise in inappropriate clothing, e.g. exercising on land in a wetsuit, can lead to heat injury in temperate climates. Old age, diabetes, drugs (e.g. alcohol, antimuscarinics, diuretics and phenothiazines) are all further precipitating factors. The pathogenesis of heat injury is a fall in cardiac output, lactic acidosis and intravascular coagulation. *Diagnosis* is clinical.

Management

- Remove the patient from the hot area immediately.
- Cool with sponging and icepacks.
- Manage in intensive care (monitor biochemistry, clotting and muscle enzymes).
- Give fluids with caution: hypovolaemia is often absent. -

Prompt treatment is essential and can lead to rapid and complete recovery. Delay may be fatal. Prevention is by acclimatization, fluids and common sense.

Complications

These are hypovolaemia (shock), intravascular coagulation, cerebral oedema, rhabdomyolysis, and renal and hepatic failure. Their management is described in appropriate chapters.

Malignant hyperpyrexia (see p. 1271)

FURTHER READING
Simon H (1993) Hyperthermia. *New England Journal of Medicine* 329: 483-487.

COLD

Hypothermia is defined as a core (i.e. rectal) temperature below 35°C. It is frequently lethal when core temperature falls below 32°C.

Frostbite is local cold injury when tissue freezes.

Hypothermia occurs in many settings.

At home

Hypothermia occurs in cold climates when there is poor heating, inadequate clothing and poor nutrition. Depressant drugs (e.g. hypnotics), alcohol, hypothyroidism or intercurrent illness also contribute. Hypothermia is commonly seen in the poor and elderly, the latter having a diminished ability to sense cold and often loss of insulating fat. Infants and neonates become hypothermic rapidly at room temperature because of their relatively large surface area and lack of subcutaneous fat.

During exposure to extremes of temperature

Hypothermia is a prominent cause of death in climbers, skiers, polar travellers and in wartime. Wet, cold conditions with wind chill, physical exhaustion, injuries and inadequate clothing are contributory.

Following immersion in cold water

Dangerous hypothermia can develop after 1 hour's immersion at water temperatures of 15-20°C. Below 12°C limbs rapidly become numb and paralysed. Recovery takes some hours after rescue.

Clinical features

Mild hypothermia (core 32-35°C) causes shivering and initially quite intense cold. Though alert the subject may not act appropriately to rewarm (e.g. huddling, extra clothing or exercise). As core temperature falls below 32°C, severe hypothermia causes impaired judgement (including awareness of cold), drowsiness and coma. Death follows, usually from ventricular fibrillation.

Diagnosis

If a thermometer (low-reading) is available, diagnosis is straightforward. If not, a rapid clinical assessment is reliable. A person who *feels* icy to touch - the abdomen, groin and axillae - is hypothermic. If clammy and uncooperative, sleepy or in a coma, core temperature is almost certainly below 32°C - a medical emergency.

Sequelae

Pulse rate and volume fall; respiration becomes shallow and slow. Muscle stiffness develops and tendon reflexes become sluggish. Systemic blood pressure falls. As coma ensues, pupillary and other brainstem reflexes are lost (pupils are fixed and may be dilated in severe hypothermia).

Metabolic changes are variable, either metabolic acidosis or alkalosis developing. Arterial oxygen tension may appear normal since it is measured at room temperature, but the measurement is falsely high as arterial Po_2 falls 7% for each degree Celsius (C) fall in temperature.

Ventricular arrhythmias (tachycardia/fibrillation) or asystole is the usual cause of death. 'J' waves - rounded waves above the isoelectric line immediately after the QRS complex - are pathognomonic of hypothermia. Prolongation of PR, QT intervals and QRS complex occurs.

Principles of management

- Rewarm gradually.
- Correct metabolic abnormalities.
- Anticipate and treat dysrhythmias.
- Check for hypothyroidism (see p. 1072).

If the patient is awake, with core temperature above 32°C, place them in a warm room, use a 'space blanket', and give warm fluids orally. Outdoors, add extra dry clothing, huddle together and use a warmed sleeping bag. Rewarming may take several hours. Avoid alcohol: it may add to confusion, boost confidence factitiously, cause peripheral vasodilatation (and further heat loss), or precipitate hypoglycaemia.

Severe hypothermia

In severe hypothermia, people look dead. Always exclude hypothermia before diagnosing brain death (p. 989). Warm gradually, aiming at a 1°C per hour increase in core temperature. Cover with a 'space blanket' and place in a warm room. Direct surface heat from an electric blanket is also helpful. Treat any underlying condition promptly, e.g. sepsis. Monitor all vital functions. Correct dysrhythmias. Drug screening is essential.

Give warm i.v. fluids slowly. Correct metabolic abnormalities. Hypothyroidism, if present, should be treated with triiodothyronine 10 μg i.v. 8-hourly. Various methods of artificial rewarming exist - inhaled humidified air, gastric or peritoneal lavage, and haemodialysis. These are rarely used.

Prevention

Hypothermia prevention is especially necessary in the elderly. Improved home heating and insulation, central heating in bedrooms and electric blankets are helpful. Finance is often needed. Supervision should be given during cold spells; warm food and extra blankets must be provided.

Frostbite

Ice crystals form within skin and superficial tissues when the tissue temperature falls to -3°C: ambient temperatures generally must be below -6°C.

Recognition

Frostbitten tissue is pale, greyish and initially doughy to touch. Later it freezes hard, when it looks and feels like meat taken from a deep freeze. Frostbite can easily occur when working or exercising in low temperatures. Typically it develops without the patient's knowledge. Below -5°C, hands or feet that have lost their feeling are at risk of frostbite.

Management

The frostbitten patient should, if possible, be transported (or walk, even on frostbitten feet) to a place of safety before treatment commences. Warm with a companion's body or by immersion in water at 39^2°C (hand hot). Continue until obvious thawing occurs. This may be painful. Blisters form within several days and, depending on the degree of frostbite, a blackened carapace or shell develops as the blisters regress or burst. Dry, non-adherent dressings and strict aseptic precautions are essential. Frostbitten tissues are anaesthetic and at risk from infection and further trauma. Recovery takes place over many weeks. Surgery may be required, but should be avoided in the early stages.

FURTHER READING

Lazar HL (1997) Editorial: The treatment of hypothermia. *New England journal of Medicine* 337: 1545-1547.

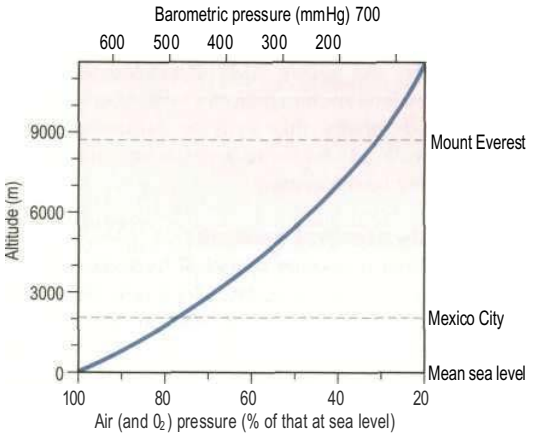

Fig. 17.1 **The decrease in oxygen and barometric pressure with increasing altitude.**

Table 17.1 **Conditions caused by sustained hypoxia**

Condition	Incidence (%)	Usual altitude (m)
Acute mountain sickness	70	3500-4000
Acute pulmonary oedema	2	4000
Acute cerebral oedema	1	4500
Retinal haemorrhage	50	5000
Deterioration	100	6000
Chronic mountain sickness	Rare	4500

Acclimatization takes several weeks and enables humans to live (permanently if necessary) up to about 5600 m. At greater heights, although people can survive for days or weeks, deterioration due to chronic hypoxia is inevitable.

Ascent of the world's highest summits is possible without the use of supplementary oxygen. At the summit of Everest (nearly 9000 m) the barometric pressure is 34 kPa (253 mmHg). An acclimatized mountaineer has an alveolar Po_2 of *4.0-4.7* kPa (30-35 mmHg) - near man's absolute physiological limit.

HIGH ALTITUDES

The partial pressure of ambient (and hence alveolar and arterial) oxygen falls in a near-linear relationship to altitude (Fig. 17.1).

Below 3000 m there are few clinical effects. Commercial aircraft are pressurized to 2750 m. The resulting hypoxia causes breathlessness only in those with severe cardiorespiratory disease. The incidence of thrombo-embolism is slightly greater in (sedentary) travellers on long flights than in a similar population at sea level. Above 3000-3500 m hypoxia causes a spectrum of related clinical syndromes that affect visitors to high altitudes, principally climbers, trekkers, skiers and troops (Table 17.1). These occur largely during acclimatization.

Acute mountain sickness (AMS)

This describes malaise, nausea, headache and lassitude common for a few days above 3500 m. Following arrival at this altitude there is usually a latent interval of 6-36 hours before symptoms begin. Treatment is rest, with analgesics if necessary. Recovery is usually spontaneous.

Prophylactic treatment with acetazolamide, a carbonic anhydrase inhibitor and a respiratory stimulant is of some value in preventing AMS. Acclimatizing, i.e. ascending gradually, is the best prophylaxis.

In the minority, more serious sequelae of high-altitude pulmonary oedema and high-altitude cerebral oedema develop.

High-altitude pulmonary oedema

Predisposing factors include youth, rapidity of ascent, heavy exertion and severe AMS. Breathlessness, with frothy blood-stained sputum indicates established oedema. Unless treated rapidly this leads to cardiorespiratory failure and death. Milder forms are common, presenting with less severe breathlessness.

High-altitude cerebral oedema

Cerebral oedema is another sequel of hypoxia. It is the result of abrupt increase in cerebral blood flow that occurs even at modest altitudes of 3500^4000 m. Headache is usual, and is accompanied by drowsiness, ataxia, and papilloedema. Coma and death follow if the condition progresses.

Treatment

Any but the milder forms of AMS require urgent treatment. Oxygen should be given if available, and descent to a lower altitude should take place as quickly as possible. Nifedipine reduces pulmonary hypertension and is used in the treatment of pulmonary oedema. Dexamethasone is effective in reducing brain oedema. Portable pressure bags, in which the patient is inserted, are helpful in increasing barometric pressure; these are widely used.

Retinal haemorrhages

Small 'flame' haemorrhages in the retinal nerve fibre layer are common above 5000 m. They are usually symptomless. Rarely they cover the macula, causing painless loss of central vision. Recovery is usual.

Deterioration

Prolonged residence between 6000 and 7000 m leads to weight loss, anorexia and listlessness after several weeks. Above 7500 m, deterioration develops more quickly, although it is possible to survive for a week or more at altitudes over 8000 m.

Chronic mountain sickness

This rare syndrome occurs in long-term residents at high altitudes after several decades. It has been described in the Andes and in central Asia.

Polycythaemia, drowsiness, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement occur. It is gradually progressive.

By way of contrast, coronary artery disease and hypertension are rare in high-altitude native populations.

DIVING

Ambient pressures at various depths are shown in Table 17.2.

Various methods are used to supply air to a diver. With the simplest (e.g. a snorkel), the limiting factor which occurs below 0.5 m, is respiratory effort sucking air into the lungs. At greater depths this 'forced negative-pressure ventilation' causes pulmonary capillary damage and haemorrhagic oedema. Scuba divers - the usual sports diving down to 50 m - carry bottled compressed air.

Divers who work at great depths for commercial purposes or exploration breathe helium-oxygen or nitrogen-oxygen mixtures delivered by hose from the surface.

Complex problems can affect divers at all depths.

Compression problems (descent)

Middle ear barotrauma ('squeeze') is common and caused by inability to equalize pressure in the middle ear - usually the result of Eustachian tube blockage. Deafness occurs and eventual tympanic membrane rupture, with acute vertigo.

Sinus barotrauma ('squeeze') - is due to blockage of the nasal and paranasal sinus ostia, with intense local pain.

Treatment is with decongestants. Avoid diving with any respiratory infection.

Nitrogen narcosis

When compressed air is breathed below 30 m, narcotic effects of nitrogen impair brain function. Changes of mood and performance may be hazardous. These reverse rapidly on ascent.

Nitrogen narcosis is avoided by replacing air with helium-oxygen mixtures, enabling descent to 700 m.

At these great depths direct effect of pressure on neurones can cause tremor, hemiparesis and cognitive impairment.

Table 17.2 Pressure in relation to sea depth

Sea depth (m)	Atmospheric pressure (atmospheres)	mmHg
0	1	760
10	2	1520
50	6	4560
90	10	7600

Oxygen narcosis

Pure oxygen is not used for diving because oxygen is toxic. Lung damage (atelectasis, endothelial cell damage and pulmonary oedema) occurs when the alveolar oxygen pressure exceeds 1.5 atmospheres (5 m of water). At around 10 m of water the nervous system is affected. Apprehension, nausea and sweating is followed by muscle twitching and generalized convulsions with possible underwater fatalities.

Decompression problems (i.e. ascent)

Breath-hold (shallow-water) diving

Shallow-water swimmers and free divers deliberately hyperventilate prior to a dive to drive off CO_2 - reducing the stimulus to breathe. The subsequent breath-hold causes a rise in P_aco_2 and a fall of P_ao_2. However, on surfacing, decompression further lowers P_ao_2. This may cause syncope.

Decompression sickness

Decompression sickness ('the bends') occurs in divers on returning to the surface and is caused by the release of bubbles of inert gases (nitrogen or helium). Bubbles develop only if ascent is too rapid. Decompression tables indicate the time needed for safe return from given depths.

The bends can be mild (type 1 non-neurological bends), with skin irritation, mottling or joint pain only. Type 2 (neurological) bends are more serious - cortical blindness, hemiparesis, sensory disturbances or cord lesions develop. If nitrogen bubbles form in pulmonary vessels, divers experience retrosternal discomfort, dyspnoea and cough ('the chokes'). These develop within minutes or hours of a dive.

Treatment is with oxygen. All but the mildest forms of decompression sickness (i.e. skin mottling alone) require recompression in a pressure chamber.

A long-term problem is aseptic necrosis (e.g. of the hip) due to nitrogen bubbles causing infarction of nutrient arteries of bone. Neurological damage may also persist.

Lung rupture, pneumothorax and surgical emphysema

These emergencies occur principally when divers 'breath-hold' while making emergency ascents after losing their gas supply. There is severe dyspnoea, cough and haemoptysis. Pneumothorax and emphysema usually respond to 100% oxygen. Air embolism may occur and should be treated with recompression and hyperbaric oxygen.

IONIZING RADIATION

Ionizing radiation is either penetrating (X-rays, gamma rays or neutrons) or non-penetrating (alpha or beta particles). Penetrating radiation affects the whole body, while non-penetrating radiation affects only the skin. All radiation effects, however, depend on the type of radiation, the distribution of dose and the dose rate.

Radiation dosage is measured in joules per kilogram (J/kg); 1 J/kg is also known as 1 gray (1 Gy). This is equivalent to 100 rads. Radioactivity is measured in becquerels (Bq); 1 Bq is equal to the amount of radioactive material in which there is one disintegration per second. One curie (Ci) is equal to 3.7×10^{10} Bq.

Radiation differs in the density of ionization it causes. Therefore a dose-equivalent called a sievert (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual background radiation is approximately 2.5 mSv. A chest X-ray gives 0.02 mSv, while a CT scan of the abdomen/pelvis is 10 mSv.

Excessive exposure to ionizing radiation occurs following accidents in hospitals, industry, nuclear power plants and strategic nuclear explosions. '.

Mild acute radiation sickness

Nausea, vomiting and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2-3 weeks later by a fall in all white cells and platelets. There is a late risk of leukaemia and solid tumours.

Severe acute radiation sickness

Many systems are affected; the extent of the damage depends on the dose of radiation received. The effects of radiation are summarized in Table 17.3.

Table 17.3 The effects of radiation

Acute effects	Delayed effects
Haemopoietic syndrome	Infertility
Gastrointestinal syndrome	Teratogenesis
CNS syndrome Radiation dermatitis	Cataract Neoplasia:
	Acute myeloid leukaemia
	Thyroid
	Salivary glands
	Skin
	Others

Haemopoietic syndrome

Absorption of doses between 2 and 10 Gy is followed by early and transient vomiting in some individuals, followed by a period of relative well-being. Lymphocytes are particularly sensitive to radiation damage, and severe lymphopenia develops over several days. A decrease in granulocytes and platelets occurs 2-3 weeks later as no new cells are being formed by the damaged marrow. Thrombocytopenia with bleeding develops and frequent overwhelming infections occur, with a very high mortality.

Gastrointestinal syndrome

Absorption of doses greater than 6 Gy causes vomiting several hours after exposure. This then stops, only to recur some 4 days later accompanied by severe diarrhoea. Owing to radiation inhibition of cell division, the villous lining of the intestine becomes denuded. Intractable bloody diarrhoea follows, with dehydration, secondary infection and death.

CNS syndrome

Exposures above 30 Gy are followed rapidly by nausea, vomiting, disorientation and coma. Death due to severe cerebral oedema follows within 36 hours.

Radiation dermatitis

Skin erythema, purpura, blistering and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure of at least 5 Gy.

Late effects of radiation exposure

Survivors of the nuclear bombing of Hiroshima and Nagasaki have provided information on the long-term effects of radiation. The risk of developing acute myeloid leukaemia or cancer, particularly of the skin, thyroid and salivary glands, increases. Infertility, teratogenesis and cataract are also late sequelae of radiation exposure.

Treatment

Acute radiation sickness is a medical emergency. Hospitals should be informed immediately of the type and length of exposure so that suitable arrangements can be made to receive the patient. The initial radiation dose absorbed can be reduced by removing clothing contaminated by radioactive materials.

Treatment of radiation sickness is largely supportive and consists of prevention and treatment of infection, haemorrhage and fluid loss. Storage of the patient's white cells and platelets for future use should be considered, if feasible.

Accidental ingestion of, or exposure to, bone-seeking radioisotopes (e.g. strontium-90 and caesium-137) should be treated with chelating agents (e.g. EDTA) and massive doses of oral calcium. Radioiodine contamination should be treated immediately with potassium iodide 133 mg per day. This will block 90% of radioiodine absorption by the thyroid if given immediately before exposure.

ELECTRIC SHOCK

Electric shock may produce clinical effects in several ways:

- *Pain and psychological sequelae.* The common 'electric shock' is usually a painful, but harmless, stimulus but an unpleasant and frightening experience. It produces no lasting neurological damage or skin damage.
- *Cardiac, neurological and muscle damage.* Ventricular fibrillation, muscular contraction and spinal cord damage follow a major shock. These are seen typically following a lightning strike, which is a very high voltage and amperage current.
- *Electrical burns.* These commonly only involve the skin (lightning may cause a fern-shaped burn), but subcutaneous or deep injuries can occur.

SMOKE

Air pollution is discussed on page 894.

Smoke consists of particles of carbon in hot air and gases. These particles are coated with organic acids and aldehydes and synthetic materials. On combustion, other toxins such as carbon monoxide, sulphur dioxide, sulphuric and hydrochloric acids are released. Polyvinyl chloride is no longer used in household goods.

Respiratory symptoms may be immediate or delayed. Patients are dyspnoeic and tachypnoeic. Laryngeal stridor may require intubation. Hypoxia and pulmonary oedema can be fatal.

Patients should breathe through an aspirator or wet towel. Remove the patient from the smoke. Give O_2 and ITU support. Smoke alarms should be used in households.

NOISE

Sound intensity is expressed as the square of sound pressure. The bel is a ratio and is equivalent to a 10-fold increase in sound intensity; a decibel (dB) is one-tenth of a bel. Sound is made up of a number of frequencies ranging from 30 Hz to 20 kHz, with most being between 1 and 4 kHz. When measuring sound, these different frequencies must be taken into account. In practice a scale known as A-weighted sound is used; sound levels are then reported as dB(A). A hazardous sound source is defined as one with an overall sound pressure greater than 90dB(A).

Repeated prolonged exposure to loud noise, particularly between 2 and 6 kHz, causes first temporary and later permanent hearing loss by physically destroying hair cells in the organ of Corti and, eventually, auditory neurones. This is a common occupational problem, not only in industry and the armed forces, but also in the home (electric drills and sanders), in sport (motor racing), and in entertainment (pop stars, disc jockeys and their audiences).

Serious noise-induced hearing loss is almost wholly preventable by personal protection (ear muffs, ear plugs). Little help can be offered once deafness becomes established.

Other effects of noise

Noise is undoubtedly irritative and increases or produces anxiety. It has been suggested that excess noise affects child development and reading skills.

BIOTERRORISM/BIOWARFARE

Interest in biological warfare and bioterrorism became intense at the time of the 1991 Iraq war especially following the bombing of the Twin Towers in New York when other terrorist attacks were expected. The potential of bacteria as a weapon is illustrated by the fact that a few kilograms of anthrax spores can kill as many people as a Hiroshima size nuclear weapon.

Potential pathogens

The Centers for Disease Control in Atlanta, Georgia, in the United States have developed a classification of potential biological agents which might be used as weapons (Table 17.4). The most likely to be employed are smallpox, anthrax, botulism and plague.

Smallpox

Smallpox is an infectious disease with a mortality of at least 30% for which there is no proven therapy. There is an effective vaccine. However, universal vaccination against smallpox was stopped in the early 1970s and the vast majority of the world's population is unprotected against the virus. The potential therefore exists for a world-wide epidemic of smallpox initiated by a bioterrorist act. One simulated incident outlined an outbreak of smallpox originating in a university function in North America attended by 1000 students. It resulted in an international outbreak of the infection with exhaustion of the world's supply of smallpox vaccine.

Table 17.4 **The critical biological agents (CDC)**

Category A pathogens
Very infectious and/or readily disseminated organisms which would produce high mortality and have a major impact on public health causing public panic (smallpox, anthrax, botulinism, plague)

Category B pathogens
Moderately easy to disseminate organisms causing moderate morbidity and mortality (Q fever, brucellosis, glanders, food/water-borne pathogens, influenza)

Category C pathogens
Category includes emerging and possible genetically engineered pathogens (viral haemorrhagic fevers, encephalitis viruses, drug-resistant tuberculosis)

From Khan AS, Morse S, Lillibridge S (2000) Reprinted with permission from Elsevier. *Lancet* **356:** 1179-1182

Fig. 17.2 **Smallpox rash.**

Smallpox has an incubation period of around 12 days, allowing a bioterrorist act to go undetected until a rash (Fig. 17.2), similar to that of chicken pox, develops on the second or third day of the illness. The infection is transmitted by the airborne route and the patient becomes infectious to others 12-24 hours before the rash appears, thus allowing an infected 'volunteer' to pass the infection on to others before being recognized as suffering from the disease. If the vaccine is given within 3 days of contact, the disease may be prevented. The smallpox virus is still stored in two laboratories in the world - one in Russia and the other in the United States of America.

Anthrax

Anthrax is described on page 82. In late 2001, anthrax organisms were sent through the United States mail and infected 22 individuals; 11 had pulmonary anthrax, five of whom died, and 11 suffered from cutaneous anthrax. A major post sorting office became contaminated with anthrax spores.

A simulated anthrax bioterrorist attack postulated the release of anthrax powder from a truck passing a large football stadium containing 74 000 spectators with the infection of 16 000, of whom 4000 died. In an accidental release of anthrax from a bioweapons factory in Russia the death rate in those living in the neighbourhood, especially downwind of the factory, was 75%.

Botulism

Botulism is described on page 73. The toxin produced by the organism *Clostridium botulinwn* is the most potent poison known to man. It has been claimed that Iraq at some time had 19 000 L of botulinum toxin, sufficient to kill the entire population of the world three times over.

As a bioweapon, the toxin could be transmitted by food or by the airborne route, e.g. from a crop-spraying plane. It is inactivated by chlorine in domestic water supplies. There is no vaccine available. Following a terrorist event it is possible that many hundreds of intensive care beds with ventilators might be required.

Plague

Plague (p. 87) could be transmitted as a bioweapon either by airborne dissemination (causing pneumonia) or by infected rats. There is no effective vaccine.

Route of dissemination of biological weapons

Pathogenic microorganisms could be delivered as a weapon by a number of routes, e.g. by aerosol, by crop-spraying aeroplane, via the mail, in food or drink, by a bomb or rocket, or by a human volunteer infected with an organism.

The 'ideal' weapon

An 'ideal' biological weapon could have some, or all, of the following properties:

- Able to produce high morbidity/mortality (e.g. smallpox).
- Capable of being aerosolized or weaponized (e.g. anthrax, plague, smallpox).
- Relatively easy to produce (anthrax).
- Capable of being used against a non-immune target population (smallpox).
- Capable of being made antibiotic-resistant and/ or genetically modified to increase pathogenicity (e.g. ? plague; ? smallpox).

Clinical presentations of a bioterrorist attack

Infection associated with a bioterrorist act could present in a number of ways, e.g. with diarrhoea and vomiting (salmonella infection), a respiratory illness (anthrax, plague), a rash (smallpox, viral haemorrhagic fever), a neurological presentation (botulism) or an unexplained febrile illness (Q fever, influenza, tuberculosis). The first indication of an attack could be a cluster of individuals with similar symptoms.

Emergency planning

Most western countries have plans to deal with a bio-terrorist attack. These include the training of healthcare staff, ambulance personnel and police. Such plans stress the importance of awareness of the possibility and preparedness for an attack. Stockpiling of vaccines, anti-biotics and protective clothing is essential.

DROWNING AND NEAR-DROWNING

Drowning is the third commonest cause of accidental death in the UK; it caused over 500 000 deaths worldwide in 2000. Approximately 40% of drownings occur in children under five. People also drown after an epileptic seizure or a myocardial infarct whilst in water. Exhaustion, alcohol, drugs and hypothermia all contribute to drowning.

'Dry' drowning

Between 10% and 15% of drownings occur without water aspiration into the lungs. Laryngeal spasm occurs, apnoea, anoxia and cardiac arrest.

'Wet' drowning

Aspiration of fresh water affects pulmonary surfactant, with alveolar collapse and ventilation/perfusion mismatch and hypoxaemia. Aspiration of hypertonic seawater (5% NaCl) pulls additional fluid into the lungs with further ventilation/perfusion mismatch. In practice, however, there is little difference between saltwater and freshwater drowning. In both, severe hypoxaemia develops rapidly after water aspiration. Severe metabolic acidosis develops in the majority of survivors.

Emergency treatment of near-drowning

Patients can survive for up to 30 minutes under water without suffering brain damage - and for longer if the water temperature is near 0°C. This is probably related to the protective role of the diving reflex - submersion causes reflex slowing of the pulse and vasoconstriction. In addition, hypothermia decreases oxygen consumption. CPR should be started immediately (see p. 759).

Resuscitation should always be attempted, even in the absence of a pulse and the presence of fixed dilated pupils. Patients frequently make a dramatic recovery. All patients should be subsequently admitted to hospital for intensive monitoring. Survivors are liable to develop acute lung injury.

Prognosis

This is good if the patient regains consciousness promptly but poor if they remain in coma 30 minutes after resuscitation.

Modell JH (1993) Drowning. *New England journal of Medicine* 328: 253-256.

TRAVEL

Motion sickness

This common problem, particularly in children, is caused by repetitive stimulation of the labyrinth. It occurs frequently at sea and in cars, but may occur on horseback or on less usual forms of transport such as camels or elephants. It is a major issue in space travel. Nausea, sweating, dizziness, vertigo and profuse vomiting occur, accompanied by an irresistible desire to stop moving.

Prophylactic antihistamines or vestibular sedatives (hyoscine or cinnarizine) are of some value.

Jet-lag

Jet-lag, or circadian dyschronism, is a well-known phenomenon after changing multiple time-zones, particularly from West to East. Fatigue, intense insomnia, headache, irritability, poor concentration and loss of appetite are common. Symptoms last several days.

Mechanisms are poorly understood but relate to the hypothalamic body clock, sited within the suprachiasmatic nuclei. The clock is regulated by various zeitgebers ('time-givers'), e.g. light and melatonin.

Management of jet-lag includes its acceptance as a phenomenon causing poor performance and waiting for 3-5 days to recover. Various hypnotics can help insomnia, but their place is disputed. Oral melatonin is widely used to reduce jet-lag. This increases sleepiness and hastens resetting of the body clock. Melatonin is not available on prescription.

BUILDING-RELATED ILLNESSES

Modern office buildings have a controlled environment with automated heating, ventilation and air-conditioning systems, often without outdoor air. More than half the adult workforce in developed countries work in offices.

Non-specific building-related illness

Headache, fatigue and difficulty in concentrating, sometimes in apparent epidemics, are common complaints of office-workers. Psychological factors may have a role. Temperature, humidity, dust, volatile organic compounds (e.g. paints, solvents) have all been implicated. Maintenance of continuous outdoor air supply is recommended. However, changes in ventilation sometimes fail to improve matters.

Specific building-related illness

Legionnaires' disease (see p. 925) is frequently due to contamination of air-conditioned systems. Humidifier fever (p. 943) is also due to contaminated systems, probably by fungi, bacteria and protozoa. Many common viruses are easily transmitted in the enclosed environment (e.g. the common cold, influenza and rarely pulmonary tuberculosis). Allergic disorders (e.g. rhinitis, asthma and dermatitis) also occur owing to exposure to indoor allergens such as dust mites and plants. Office equipment (e.g. fumes from photocopiers) has also been implicated. Passive smoking (p. 894) is also a problem.

HORMONAL ACTIVITY

Hormones are chemical messengers produced by a variety of specialized secretory cells. They may be transported in the blood to a distant site of action (the classic 'endocrine' effect) or act directly upon nearby cells ('paracrine' activity). In the hypothalamus, elsewhere in the brain and in the gastrointestinal tract there are many such cells secreting hormones, some of which have true endocrine or paracrine activity, while others behave more like neurotransmitters or neuromodulators. At the molecular level there is little difference in the way cellular activity is regulated between classical neurotransmitters that act across synaptic clefts, intercellular factors acting across gap junctions, classic endocrine and paracrine activity and a variety of other chemical messengers involved in cell regulation - such as cytokines, growth factors and interleukins; progress in basic cell biology has revealed the biochemical similarities in the messengers, receptors and intracellular post-receptor mechanisms underlying all these aspects of cell function.

Synthesis, storage and release of hormones

Hormones may be of several chemical structures: polypeptide, glycoprotein, steroid or amine. Hormone release is the end-product of a long cascade of intracellular events. In the case of polypeptide hormones, neural or endocrine stimulation of the cell leads to increased transcription from DNA to a specific mRNA, which is in turn translated to the peptide product. This is often in the form of a precursor molecule that may itself be biologically inactive. This 'prohormone' may be further processed before being packaged into granules, in the Golgi apparatus. These granules are then transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca^{2+}-dependent process, or it may be 'constitutive' (immediate and continuous secretion).

Plasma transport

Most classical hormones are secreted into the systemic circulation where they travel to have effects elsewhere in the body. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that much higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases, only the free (unbound) hormone is available to the tissues and thus biologically active. This binding serves to buffer against very rapid changes in plasma levels of the hormone, and some binding protein interactions may also be involved in the active regulation of hormone action. Many tests of

Table 18.1 Plasma hormones with their proteins binding

Hormone	Binding protein(s)
Thyroxine (T_4)	Thyroxine-binding globulin (TBG)
	Thyroxine-binding prealbumin fTBPA)
	Albumin
Triiodothyronine (T_3) (less bound than T_4)	Thyroxine-binding globulin (TBG)
	Albumin
Cortisol	Cortisol-binding globulin (CBG)
Testosterone, estradiol	Sex hormone-binding globulin (SHBG)
Insulin-like growth factor-I (IGF-I)	IGF-binding proteins (mainly IGF-BP3)

endocrine function often measure total rather than free hormone, since binding proteins are frequently altered in disease states. Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG) and other less-specific low-affinity ones, such as prealbumin and albumin. The clinically relevant binding proteins are shown in Table 18.1.

Hormone action and receptors

Hormones act by binding to specific receptors in the target cell, which may be at the cell surface and/or within the cell. Most hormone receptors are proteins with complex tertiary structures, parts of which complement the tertiary structure of the hormone to allow highly specific interactions, while other parts are responsible for the effects of the activated receptor within the cell. Many hormones bind to specific cell-surface receptors where they trigger internal messengers, while others bind to nuclear receptors which interact directly with DNA. Cell-surface receptors usually contain hydrophobic sections which span the lipid-rich plasma membrane, while nuclear receptors contain characteristic amino-acid sequences to bind nuclear DNA (e.g. so-called 'zinc fingers', see p. 167) as in the glucocorticoid receptor.

In order to achieve their intracellular effects, hormone receptors interact with a variety of other regulatory factors within the cell membrane, in the cytosol or within the nucleus of the cell. In each case, binding of the hormone to its receptor results in a conformational change in the structure of the receptor, which may result in a number of possible outcomes which are illustrated in Figure 3.4 (p. 158):

- activation of, or modified binding to, other regulatory factors within the cell membrane or cytosol(e.g. binding of transmembrane receptors to the cell-membrane G-proteins, thereby activating the stimulatory or inhibitory effects of the latter on other intracellular mediators)
- activation of enzyme activity in the receptor or its regulatory factors (e.g. receptor adenylate cyclase, other protein kinases, phospholipase C) to generate a variety of intracellular 'second messengers' (e.g. cAMP, cGMP, phosphatidylinositol metabolites, calmodulin) which usually form a complex, branching and interacting intracellular cascade of enzyme activation and inhibition and/or mobilization of intra cellular stores of ions (primarily calcium)
- altered binding of the receptor to DNA or to nuclear transcription factors in order to stimulate or inhibit transcription of one or more genes
- altered activity of cell-membrane channels or trans porters (e.g. for glucose, potassium or for other ions)
- dimerization of the receptor, or internalization of some cell-surface receptors.

These immediate effects of hormone binding may then cause rapid alterations in cell-membrane ion transport or intracellular calcium concentrations, or slower responses such as DNA, RNA and protein synthesis.

In each case, binding of the hormone to its receptor is the first step in a complex cascade of interrelated intra-cellular events which eventually lead to the overall effects of that hormone on cellular function.

Common 'second messengers' involved in these cascades include *cyclic AMP* (for adrenocorticotrophic hormone (ACTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH) and parathyroid hormone (PTH)), *a calciutn-phospholipid system* (for thyrotrophin-releasing hormone (TRH), vasopressin and angiotensin II), *tyrosine kinase* and *other intracellular kinases* (for insulin and insulin-like growth factor-l (IGF-1)) and *membrane-bound phosphoinositide pathways.*

Some general characteristics of selected hormone systems are shown in Table 18.2.

Table 18.2 Characteristics of some different hormone systems

	Peptides and catecholamines	Steroids and thyroid hormones
Protein binding	Sometimes for growth hormone and insulin-like growth factor	Yes
Changes in plasma concentrations	Rapid changes	Slow fluctuations
Plasma half-life	Short (seconds to minutes)	Long (minutes to days)
Type of receptors	Cell membrane Activate	Intracellular
Mechanism	preformed enzymes Secretory	Stimulate protein synthesis
Secretion	granules Constitutive + bursts	Direct passage rapidly
	Rapid (seconds to minutes)	Related to secretion rate
Speed of effect		Slow (hours to days)

The sensitivity and/ or number of receptors for a hormone are often decreased after prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive ('downregulation', e.g. angiotensin II receptors, (3-adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity ('upregulation').

Abnormal receptors are an occasional, though rare, cause of endocrine disease (see p. 1041), but are recognized and characterized more frequently owing to advances in molecular endocrinology.

Control and feedback

Most hormone systems are controlled by some form of feedback; an example is the hypothalamic-pituitary-thyroid axis (Fig. 18.1).

- TRH (thyrotrophin-releasing hormone) is secreted in the hypothalamus and travels via the portal system to the pituitary where it stimulates the thyrotrophs to produce thyroid-stimulating hormone (TSH).
- TSH is secreted into the systemic circulation where it stimulates increased thyroidal iodine uptake and thyroxine (T_4) and triiodothyronine (T_3) synthesis and release.
- Serum levels of T_3 and T_4 are thus increased by TSH; in addition, the conversion of T_4 to T_3 (the more active hormone) in peripheral tissues is stimulated by TSH.
- T_3 and T_4 then enter cells where they bind to nuclear receptors and promote increased metabolic and cellular activity.

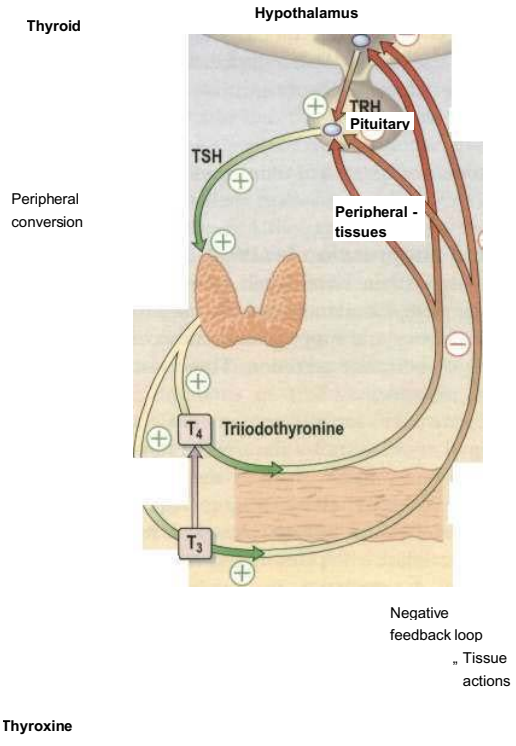

Fig. 18.1 **The hypothalamic-pituitary-thyroid** axis. The green line indicates positive feedback at the hypothal amic and pituitary level. . : , ; , . - - , .

- Levels of T_3 (from the blood and from local conversion of T_4) are sensed by receptors in the pituitary and possibly the hypothalamus. If they rise above normal, TRH and TSH production is suppressed, leading to reduced T_3 and T_4 secretion.
- Peripheral T_3 and T_4 levels thus fall to normal.
- If, however, T_3 and T_4 levels are low (e.g. after thyroidectomy), increased amounts of TRH and thus TSH are secreted, stimulating the remaining thyroid to produce more T_3 and T_4; blood levels of T_3 and T_4 may be restored to normal, although at the expense of increased TSH drive, reflected by a high TSH level ('compensated euthyroidism'). Conversely, in thyrotoxicosis when factors other than TSH itself are maintaining high T_3 and T_4 levels, the same mechanisms lead to suppression of TSH secretion.

This is known as a 'negative feedback' system, referring to the effect of T_3 and T_4 on the pituitary and hypothalamus, which represents the most common mechanism for regulation of circulating hormone levels. There are also 'positive feedback' systems, classically seen in the regulation of the normal menstrual cycle (p. 1050).

Patterns of secretion

Hormone secretion is continuous or intermittent. The former is shown by the thyroid hormones, where T_4 has a half-life of 7-10 days and T_3 of about 6-10 hours. Levels over the day, month and year show little variation.

In contrast, secretion of the gonadotrophins, LH and FSH, is normally pulsatile, with major pulses released every 1-2 hours depending on the phase of the menstrual cycle. Continuous infusion of LH to produce a steady equivalent level does not produce the same result (e.g. ovulation in the female) as the intermittent pulsatility, and may indeed produce downregulation. Thus a long-acting superactive gonadotrophin-releasing hormone (GnRH) analogue, such as buserelin, produces down-regulation of the GnRH receptors and subsequent very low androgen or oestrogen levels, which are clinically valuable both in carcinoma of the prostate in men and in ovulation-induction regimens in infertile women. In contrast, pulsatile GnRH administration can produce normal menstrual cyclicity, ovulation and fertility in women with hypothalamic amenorrhoea but intact pituitary LH and FSH stores.

Biological rhythms

Circadian means changes over the 24 hours of the day-night cycle and is best shown for the pituitary-adrenal axis. Figure 18.2 shows plasma cortisol levels measured over 24 hours - levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus 'normal' cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart (Fig. 18.2). The circadian (light-dark) rhythm is seen in reverse with the pineal hormone, melatonin, which shows high levels during dark.

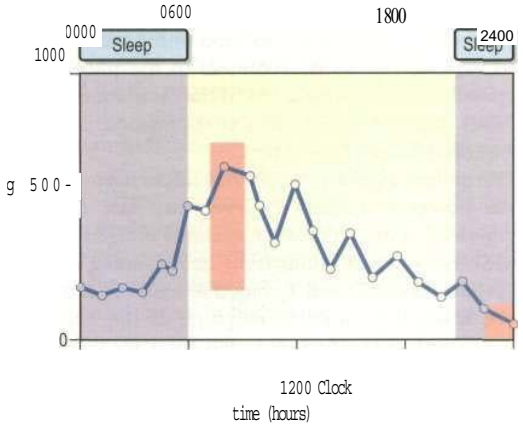

Fig. 18.2 **Plasma cortisol levels during a 24-hour period.** Note both the pulsatility and the shifting baseline. Normal ranges for 0900h (180-700 nmol/L) and 2400h (less than 100 nmol/L; must be taken when asleep) are shown in the orange boxes. Purple shading shows sleep.

Melatonin may be involved in entraining other hormonal rhythms and systems to the current light-dark cycle, but there is no known clinical syndrome related to abnormalities of this hormone, though a synthetic preparation is widely used for 'jet-lag' (p. 1033).

The *menstrual cycle* is the best example of a longer and more complex (28-day) biological rhythm (see p. 1050).

Other regulatory factors

- *Stress*. Physiological 'stress' and acute illness produce rapid increases in ACTH and cortisol, growth hormone (GH), prolactin, epinephrine (adrenaline) and norepinephrine (noradrenaline). These can occur within seconds or minutes.
- *Sleep*. Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.
- *Feeding and fasting*. Many hormones regulate the body's control of energy intake and expenditure and are therefore profoundly influenced by feeding and fasting. Thus, secretion of insulin is increased and growth hormone decreased after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

All these factors must be considered when attempting to measure hormone levels in normal individuals and in patients with disease. For example, cortisol levels will often be high and fail to suppress during standard tests in a patient who is severely stressed by serious illness, and growth hormone will usually be low in postprandial individuals during the daytime.

TESTING ENDOCRINE FUNCTION

Ideally, the *activity* of hormones would be measured at the cellular level, but this is usually impossible. Measurement of hormone *levels* in body fluids is the normal substitute but, although usually an excellent approximation, does not always reflect the current tissue action of the relevant hormone. Most commonly, hormone levels in the blood (or, more technically, levels in plasma or serum) are measured, and all references to hormone levels in this chapter refer to blood/plasma levels unless stated otherwise.

Basal blood levels

Assays for all clinically relevant hormones are available. Obviously the time, day and condition of measurement may make great differences to hormone levels, and the method and timing of samples will depend upon the characteristics of the endocrine system involved. There may also be sex, developmental and age differences.

Basal levels are especially useful for systems with long half-lives (e.g. T_4 and T_3). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for other hormones may also be satisfactory if interpreted with respect to normal ranges for the time of day/month, diet or posture concerned. Examples are FSH, oestrogen and progesterone (varying with time of cycle) and renin/aldosterone (varying with sodium intake, posture and age). For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

Stress-related hormones

Stress-related hormones (e.g. catecholamines, prolactin, GH, ACTH and cortisol) may require samples to be taken via an indwelling needle some time after initial venepuncture; otherwise, high levels may be artefactual.

Urine collections

Collections over 24 hours have the advantage of providing an 'integrated mean' of a day's secretion but in practice are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection.

Saliva

Saliva is sometimes used for steroid estimations, especially in children.

Stimulation and suppression tests

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency, and suppression tests to confirm suspected excess of hormone secretion. These tests are valuable in many instances.

For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the synacthen (SYNthetic-ACTH-en) test for adrenal reserve (Fig. 18.3(a) and Box 18.1), the healthy subject shows a normal response while the subject with primary hypoadrenalism (Addison's disease) demonstrates an impaired cortisol response to ACTH.

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with

FK ***Box 18.1*** **Short tetracosactide (synacthen)**

Indication
Diagnosis of Addison's disease
Screening test for ACTH deficiency

Procedure
Intravenous cannula for sampling
Any time of day, but best at 0900h; non-fasting
Tetracosactide 250 *[ig,* i.v. or i.m. at time 0
Measure serum cortisol at time 0 and time +30 min

Normal response
30 min cortisol > 600nmol/L*
(400-600 nmol/L borderline and may indicate deficiency

* Precise cortisol normal ranges are variable between laboratories and assays - appropriate local reference ranges must be used

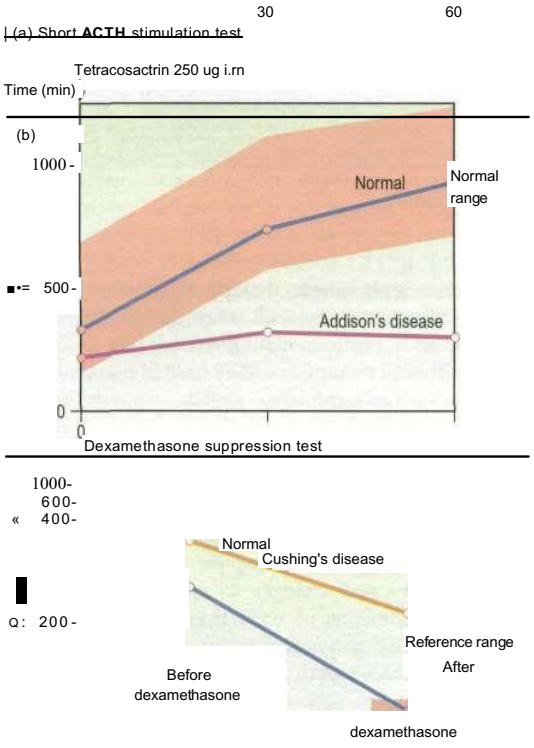

Fig. 18.3 **Synacthen and dexamethasone tests.**
(a) Short ACTH stimulation test showing a normal response in a healthy subject and a decreased response in a patient with Addison's disease.
(b) Dexamethasone suppression tests in a normal subject and in a patient with Cushing's disease showing inadequate suppression.

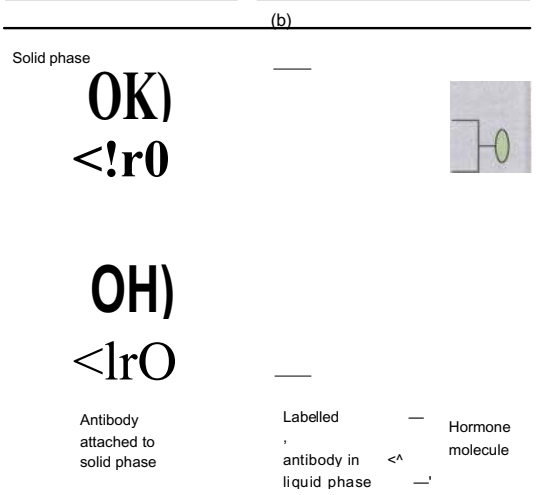

Fig. 18.4 **Principles of measurement of hormone levels in plasma by immunoassay** (precise details vary with different assays and manufacturers). Immunoassays use two antibodies specific to the hormone being measured - one typically attached to a solid phase and one labelled antibody in the liquid phase.
(a) High hormone levels in plasma: large amount of hormone binds to antibody on solid phase - large amount of labelled antibody linked to solid phase via molecules of the hormone.
(b) Low hormone levels in plasma: less hormone, and therefore less labelled antibody, is linked to the solid phase. Label (radioactive, chemiluminescent, enzymatic or fluorescent) can be measured in either solid or liquid phase after separation of phases; levels of label will be proportional to the amount of hormone in the sample.

Cushing's disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. Figure 18.3(b) shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing's disease shows inadequate suppression.

The detailed protocol for each test must be followed exactly, since even slight differences in technique will produce variations in results.

Measurement of hormone concentrations

Circulating levels of most hormones are very low (10^{-9}-10^{-12} mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays which rely on highly specific antibodies (polyclonal or more usually monoclonal) which bind specifically to the hormone being measured during the assay incubation. This hormone-antibody interaction is measured by use of labelled hormone after separation of bound and free fractions (Fig. 18.4).

Immunoassay is sensitive but has limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity. Other measurement techniques include high-pressure liquid chromatography (HPLC).

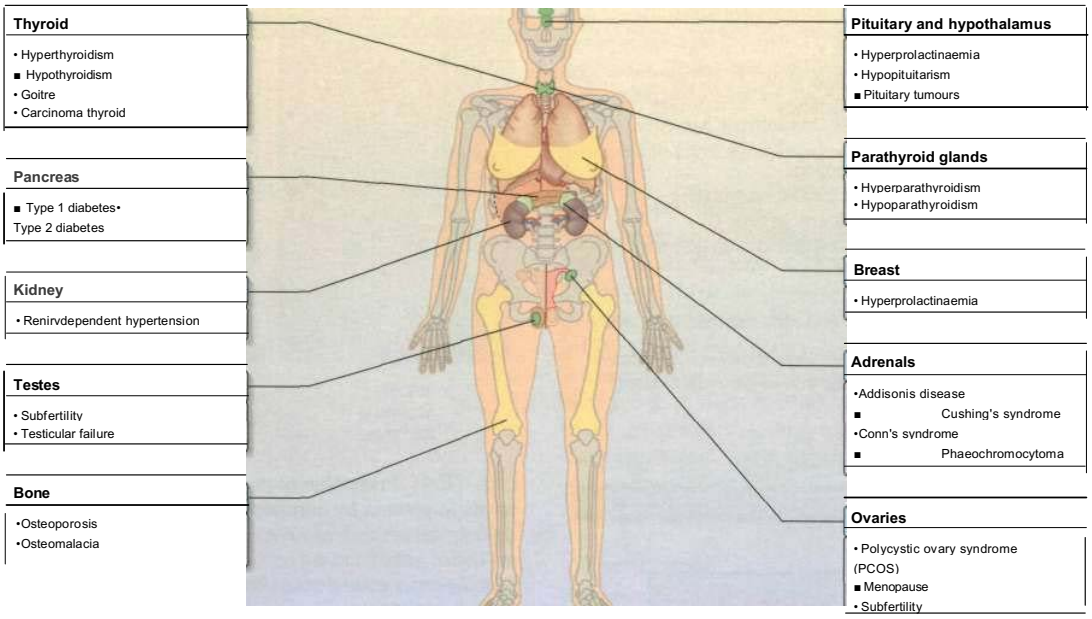

Fig. 18.5 The major endocrine organs and common endocrine problems.

ENDOCRINE DISEASE: AN INTRODUCTION _

See Figure 18.5.

Epidemiology

The most common endocrine disorders, excluding diabetes mellitus (Ch. 19), are:

- thyroid disorders, affecting 4-8 new patients per primary care physician each year (the most common problems are thyrotoxicosis, primary hypothyroidism and goitre)
- subfertility, affecting 5-10% of all couples, often with an endocrine component
- menstrual disorders and excessive hair growth in young women, most commonly polycystic ovary syndrome (PCOS)
- osteoporosis, especially in postmenopausal women largely owing to gonadal steroid deficiency
- primary hyperparathyroidism, affecting about 0.1% of the population
- disorders of growth or puberty.

While most other endocrine conditions are uncommon, they often affect young people and are usually curable or completely controllable with appropriate therapy.

Hormones as therapy

Hormones are also widely used therapeutically:

- The oral contraceptive pill is the choice of perhaps 20-30% of women aged 18-35 years using contraception.
- Hormone replacement therapy (HRT; oestrogens + progestogens) may be used for control of menopausal symptoms in postmenopausal women (see p. 1052).
- Corticosteroid therapy is widely used in non-endocrine disease such as asthma (see p. 918).

Symptoms

Hormones produce widespread effects upon the body, and states of deficiency or excess typically present with symptoms that are generalized rather than focused on the anatomical location of the gland. Many endocrine symptoms are diffuse and vague, and the differential diagnosis is often wide. Symptoms of tiredness, weakness or lack of energy or drive and changes in appetite or thirst are common presentations of endocrine disease, and other typical 'hormonal' symptoms include changes in body size and shape, problems with libido and potency, periods or sexual development, and changes in the skin (dry, greasy, acne, bruising, thinning, thickening) and hair (loss or excess). Endocrine disorders should be always considered when assessing any patient with these common complaints.

History and examination

A detailed history including the past, family and social history is essential for making the diagnosis, planning appropriate management and interpreting results of borderline hormonal blood tests. The past history should include previous surgery or radiation involving endocrine glands, menstrual history, pregnancy and growth in childhood. A full drug history is mandatory as endocrine problems are quite often iatrogenic (Table 18.3). Family history of autoimmune disease, endocrine disease

Table 18.3 **Drugs and endocrine disease**

Drug*	Effect
Drugs inducing endocrine	**> disease**
Chlorpromazine Metoclopramide (and all dopamine antagonists) Oestrogens	Increase prolactin, causing galactorrhoea
Iodine Amiodarone	Hyperthyroidism
Lithium Amiodarone	Hypothyroidism
Chlorpropamide	Inappropriate ADH secretion
Ketoconazole Metyrapone, aminoglutethimide	Hypoadrenalism
Chemotherapy	Ovarian and testicular failure
Drugs simulating endocrine disease	
Sympathomimetics Amfetamines	Mimic thyrotoxicosis or phaeochromocytoma
Liquorice Carbenoxolone	Increase mineralocorticoid activity; mimic aldosteronism
Purgatives	Hypokalaemia
Diuretics	Secondary aldosteronism
ACE inhibitors	Hypoaldosteronism
Drugs affecting hormone-binding proteins	
Anticonvulsants	Bind to TBG - decrease total T_4/cortisol
Oestrogens	Raise TBG and CBG -increase total T_4/cortisol
Exogenous hormones or stimulating agents	
Use, abuse or misuse, by patient or doctor, of the following:	
Steroids	Cushing's syndrome Diabetes
Thyroxine	Thyrotoxicosis factitia
Vitamin D preparations Milk and alkali preparations	Hypercalcaemia
Insulin Sulphonylureas	Hypoglycaemia

*Drugs causing gynaecomastia are listed in Table 18.15
Amiodarone may cause both hypo- or hyperthyroidism

including tumours, diabetes and cardiovascular disease is frequently relevant, and knowledge of family members' height, weight, body habitus, hair growth and age of sexual development may aid interpretation of the patient's own symptoms.

Physical signs are listed under the relevant systems.

Aetiology of endocrine disease

Aetiological mechanisms common to many endocrine disorders include:

Autoimmune disease

Organ-specific autoimmune diseases can affect every major endocrine organ (Table 18.4). They are characterized by the presence of specific antibodies in the serum, often present years before clinical symptoms are evident. The conditions are usually more common in women and have a strong genetic component, often with an identical-twin concordance rate of 50% and with HLA associations (see individual diseases). Several of the autoantigens have been identified.

Endocrine tumours

Hormone-secreting tumours occur in all endocrine organs, most commonly pituitary, thyroid and parathyroid. Fortunately, they are more commonly benign than malignant. While often considered to be 'autonomous' - that is, independent of the physiological control mechanisms - many do show evidence of feedback occurring at a higher 'set-point' than normal (e.g. ACTH secretion from a pituitary basophil adenoma).

The molecular basis of some of these tumours is sometimes a very specific mutation of a single gene, such as the mutations of the Ref-proto-oncogene in MEN 2 (see p. 1099), but more commonly a wide variety of different lesions in tumour suppressor genes, growth factor receptors and other intracellular mediators have been identified.

Enzymatic defects

The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH). Again the molecular basis has usually been identified as mutations or deletions of the gene encoding the relevant enzymes.

Receptor abnormalities (see p. 158)

Hormones work by activating cellular receptors. There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g. testicular feminization). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (p. 1103); other examples include nephrogenic diabetes insipidus, thyroid hormone resistance and pseudohypoparathyroidism.

CENTRAL CONTROL OF ENDOCRINE FUNCTION

Anatomy

Many peripheral hormone systems are controlled by the hypothalamus and pituitary. The hypothalamus is sited at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary

Table 18.4 **Types of autoimmune disease affecting endocrine organs**

wmmmmmmummmm if known	wmmmmmmmmmmmmmmmm	Antigen if known	Clinical syndrome
Stimulating			
Thyroid (1 in 100)	Thyroid-stimulating immunoglobulin (**TSI**, TSAb)	TSH receptor	Graves' disease, neonatal thyrotoxicosis
Destructive			
Thyroid (1 in 100)	Thyroid microsomal Thyroglobulin	Thyroid peroxidase enzyme (TPO)	Primary hypothyroidism (myxoedema)
Adrenal (1 in 20 000)	Adrenal cortex	21-Hydroxylase enzyme	Primary hypoadrenalism (Addison's disease)
Pancreas (1 in 500)	Islet cell	GAD (see p. 1105)	Type 1 (insulin-dependent) diabetes
Stomach	Gastric parietal cell Intrinsic factor	Gastric parietal cell Intrinsic factor	Pernicious anaemia
Skin	Melanocyte	Melanocyte	Vitiligo
Ovary (1 in 500)	Ovary		Primary ovarian failure
Testis	Testis		Primary testicular failure
Parathyroid	Parathyroid chief cell	Parathyroid chief cell	Primary hypoparathyroidism
Pituitary	Pituitary-specific cells		Selective hypopituitarism (e.g. GH deficiency, diabetes insipidus)

Frequencies are approximate and refer to the population in Northern Europe
GAD, glutamic acid dehydrogenase
NB: Other related diseases include myasthenia gravis and autoimmune liver diseases

itself, carrying the hypophyseal-pituitary portal blood supply.

The anatomical relationships of the hypothalamus and pituitary (Fig. 18.6) include the optic chiasm just above the pituitary fossa; any expanding lesion from the pituitary or hypothalamus can thus produce visual field defects by pressure on the chiasm. Such upward expansion of the gland through the diaphragma sellae is termed 'suprasellar extension'. Lateral extension of pituitary lesions may involve the vascular and nervous structures in the cavernous sinus and may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box; any lateral, anterior or posterior expansion must cause bony erosion.

Embryologically, the anterior pituitary is formed from Rathke's pouch (ectodermal) which meets an outpouching of the third ventricular floor which becomes the posterior pituitary.

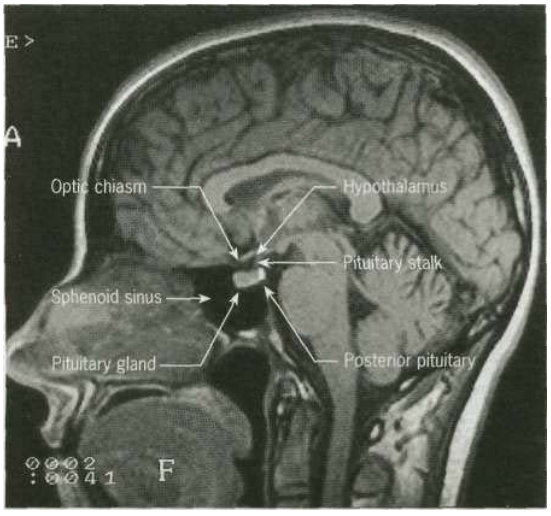

Fig. 18.6 **MR image of a sagittal section of the brain, showing the pituitary fossa and adjacent structures.** (By kind permission of Dr Martin Jeffree.)

Physiology

Hypothalamus

This contains many vital centres for such functions as appetite, thirst, thermal regulation and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in the circadian rhythm, menstrual cyclicity, and responses to stress, exercise and mood.

Hypothalamic neurones secrete pituitary hormone-releasing and -inhibiting factors and hormones into the portal system which runs down the stalk to the pituitary. As well as the classical hormones described in Table 18.5, the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP) and nitric oxide that can also alter pituitary hormone secretion but whose role is less well defined.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.

Table 18.5 Nomenclature and biochemistry of hypothalamic, pituitary and peripheral hormones

Hypothalamic hormones	Pituitary hormones	Peripheral hormones
Gonadotrophin-releasing hormone (GnRH, LHRH) *(Decapeptide)*	Luteinizing hormone (LH) Follicle-stimulating hormone (FSH) *(Two-chain a, fi peptides)*	Oestrogens/androgens *(Steroid ring)*
Dopamine (prolactin inhibiting factor, PIF) *(Amine)*	Prolactin (PRL) *(Single chain peptide)*	
Growth hormone-releasing hormone (GHRH) *(Peptide)* Somatostatin (GHRIH) *(Cyclic peptide)*	Growth hormone (GH) *(Peptide)*	Insulin-like growth factor-1 (IGF-1) *(Peptide)*
Thyrotrophin-releasing hormone (TRH) *(Tripeptide)*	Thyroid-stimulating hormone (TSH) *(Two-chain* a, p *peptide)*	Thyroxine (T_4), triiodothyronine (T_3) *(Thyronines)*
Corticotropin-releasing hormone (CRH) *(Single-chain peptide)*	Adrenocorticotrophic hormone (ACTH) *(Single-chain peptide)*	Cortisol *(Steroid ring)*
Vasopressin (antidiuretic hormone; ADH) *(Nonapeptide)*		
Oxytocin *(Nonapeptide)*		

NB: The a chains of LH, FSH and TSH are identical
GHRIH, growth hormone release inhibitory hormone

Anterior pituitary

Hormone secretion is controlled by hypothalamic releasing or inhibitory hormones (Table 18.5 and Fig. 18.7). Many hormones are under dual control by both stimulatory and inhibitory hypothalamic factors. Examples are:

- Growth hormone release is stimulated by growth hormone-releasing hormone (GHRH) but inhibited by somatostatin (growth hormone release inhibitory hormone, GHRIH).
- TSH release is stimulated by TRH but partially inhibited by somatostatin.

Some hormones have a dual stimulatory control. For example, corticotropin-releasing hormone (CRH) and vasopressin are both endogenous stimulators of ACTH

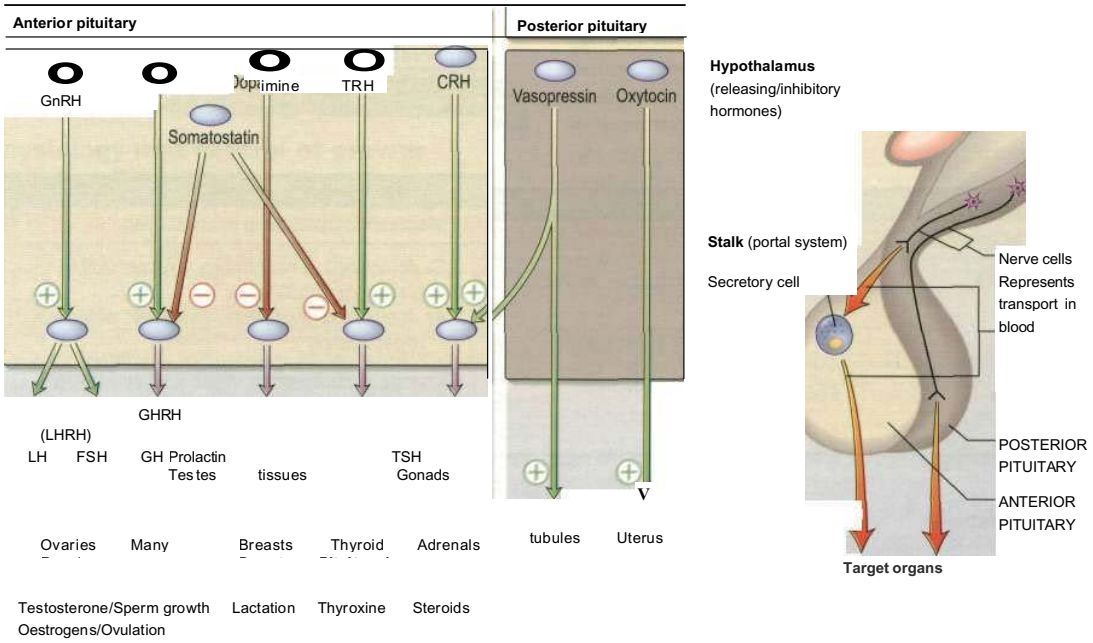

Fig. 18.7 **Hypothalamic releasing hormones and the pituitary trophic hormones.** See the text for abbreviations and an explanation.

release. Uniquely, prolactin is under predominant inhibitory dopaminergic control with some stimulatory TRH control.

Posterior pituitary

This, in contrast, acts merely as a storage organ. Antidiuretic hormone (ADH, vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraopric and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary. This means that damage to the stalk or pituitary alone does not prevent synthesis and release of ADH and oxytocin. ADH is discussed on page 1089; oxytocin produces milk ejection and uterine myometrial contraction.

PRESENTATIONS OF HYPOTHALAMIC AND PITUITARY DISEASE

Diseases of the pituitary can cause under- or overactivity of each of the hypothalamo-piruitary-end-organ axes which are under the control of this gland. The clinical features of the syndromes associated with such altered pituitary function can be the presenting symptom of pituitary disease and are discussed later in sections related to the respective hormone axis. First, however, we consider clinical features of pituitary disease which are common to all hormonal axes.

Pituitary space-occupying lesions and tumours

Pituitary tumours (Table 18.6) are the most common cause of pituitary disease, and the great majority of these are benign pituitary adenomas, usually monoclonal in origin. Problems may be caused by excess hormone secretion, by local effects of a tumour, or as the result of inadequate production of hormone by the remaining normal pituitary - hypopituitarism.

Investigations

The investigation of a possible or proven tumour follows three lines.

Is there a tumour?

If there is, how big is it and what local anatomical effects is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss, and more rarely:
- **the** cavernous sinus, with III, IV and VI cranial nerve lesions
- bony structures and the meninges surrounding the fossa, causing headache
- hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness or precocious puberty
- the ventricles, causing interruption of cerebrospinal fluid (CSF) flow leading to hydrocephalus
- the sphenoid sinus with invasion causing CSF rhinorrhoea.

Investigations:

- **Lateral skull X-ray.** This may show enlargement of the fossa. Although an X-ray is rarely requested as a definitive investigation, this remains a common incidental finding.
- **Visual fields.** These should be plotted formally by automated computer perimetry or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as target is also sensitive and valuable. Common defects are upper-temporal quadrantanopia and bitemporal hemianopia (see p. 1179). Subtle defects may also be revealed by delay or attenuation of visual evoked potentials (VEPs).

Table 18.6 **Characteristics of common pituitary and related tumours**

Tumour or condition	Usual size	Most common clinical presentation
Prolactinoma	Most < 10 mm (microprolactinoma) Some > 10 mm (macroprolactinoma)	Galactorrhoea, amenorrhoea, hypogonadism, erectile dysfunction As above plus headaches, visual field defects and hypopituitarism
Acromegaly	Few mm to several cm	Change in appearance, visual field defects and hypopituitarism
Cushing's disease	Most small - few mm (some cases are hyperplasia)	Central obesity, cushingoid appearance (local symptoms rare)
Nelson's syndrome	Often large - > 10 mm	Post-adrenalectomy, pigmentation, sometimes local symptoms
Non-functioning tumours	Usually large - > 10 mm	Visual field defects; hypopituitarism (microadenomas may be incidental finding)
Craniopharyngioma	Often very large and cystic (skull X-ray abnormal in > 50%; calcification common)	Headaches, visual field defects, growth failure (50% occur below age 20; about 15% arise from within sella)

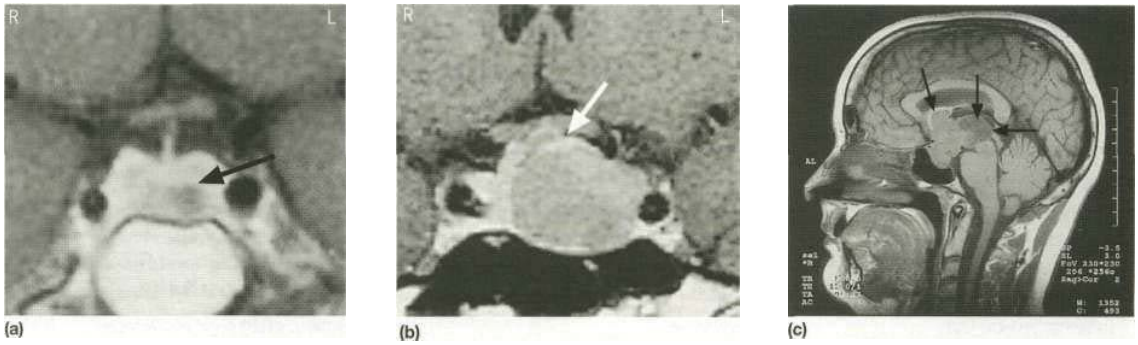

Fig. 18.8 (a) Coronal MRI of pituitary, showing a left-sided lucent intraseliar microadenoma (arrowed). The pituitary stalk is deviated slightly to the right, (b) Coronal MRI of pituitary, showing macroadenoma with moderate suprasellar extension, and lateral extension compressing left cavernous sinus. The top of the adenoma is compressing the optic chiasm (arrowed). (c) Sagittal MRI of head, showing a pituitary macroadenoma with massive suprasellar extension (arrows).

- **MRI of the pituitary.** MRI is superior to CT scanning (Fig. 18.8) and will readily show any significant pituitary mass. However, small lesions within the pituitary fossa on MRI consistent with small pituitary microadenomas are very common, reported in as many as 10% of normal individuals in some studies. Such small lesions are sometimes detected during MRI scanning of the head for other reasons - so-called 'pituitary incidentalomas'.

Is there a hormonal excess?

There are three major conditions usually caused by secretion from pituitary adenomas which will show positive immunostaining for the relevant hormone:

- prolactin excess (prolactinoma or hyperprolactinaemia) - histologically, prolactinomas are 'chromophobe' adenomas (a description of their appearance on classical histological staining)
- GH excess, leading to acromegaly or gigantism - somatotroph adenomas, usually 'acidophil', and sometimes due to specific G-protein mutations (see p. 156)
- Cushing's disease and Nelson's syndrome (excess ACTH secretion) - corticotroph adenomas, usually 'basophil'.

Many tumours are able to synthesize several pituitary hormones, and occasionally more than one hormone is secreted in clinically significant excess (e.g. both GH and prolactin).

The clinical features of acromegaly, Cushing's disease or hyperprolactinaemia are usually (but not always) obvious, and are discussed on pages 1068, 1085, and 1062. Hyperprolactinaemia may be clinically 'silent'. Tumours producing LH, FSH or TSH are well described but very rare.

Some pituitary tumours cause no clinically apparent hormone excess and are referred to as 'non-functioning' tumours, which are common and usually 'chromophobe' adenomas. Laboratory studies such as immunocytochemistry show that these tumours may often produce LH and FSH or the ce-subunit of LH, FSH and TSH (see Table 18.5), and occasionally ACTH.

Is there a deficiency of any hormone?

Clinical examination may give clues; thus, short stature in a child with a pituitary tumour is likely to be due to GH deficiency. A slow, lethargic adult with pale skin is likely to be deficient in TSH and/or ACTH. Milder deficiencies may not be obvious, and require specific testing (see Table 18.9).

Treatment

Treatment depends on the type and size of tumour (Table 18.7) and is discussed in more detail in the relevant sections (acromegaly, see p. 1069; prolactinoma, see p. 1063). In general, therapy has three aims:

Removal/control of tumour

Surgery via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transfrontal route.

Radiotherapy - by an external three-beam technique, stereotactic or rarely via implant of yttrium needles - is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The standard regimen involves a dose of about 45 Gy, given as 20-25 fractions via three fields.

Octreotide or dopamine agonists sometimes cause shrinkage of specific types of tumour (see p. 1069).

Reduction of excess hormone secretion

Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. Growth hormone antagonists are available for acromegaly (p. 1069).

Replacement of hormone deficiencies

Replacement of hormone deficiencies is detailed in Table 18.10.

Small tumours producing no significant symptoms, pressure or endocrine effects may be observed with

Table 18.7 **Comparisons of primary treatments for pituitary tumours**

Treatment method	Advantages	Disadvantages
Surgical		
Trans-sphenoidal adenomectomy or hypophysectomy	Relatively minor procedure Potentially curative for microadenomas and smaller macroadenomas	Some extrasellar extensions may not be accessible Risk of CSF leakage and meningitis
Transfrontal	Good access to suprasellar region	Major procedure; danger of frontal lobe damage High chance of subsequent hypopituitarism
Radiotherapy		
External (40-50 Gy)	Non-invasive Reduces recurrence rate after surgery	Slow action, often over many years Not always effective Possible late risk of tumour induction
Stereotactic Yttrium implantation	Precise administration of high dose to lesion High local dose	Long-term follow-up data limited Only ever used in a few centres
Medical		
Dopamine agonist therapy (e.g. bromocriptine)	Non-invasive; reversible	Usually not curative Significant side-effects in minority
Somatostatin analogue therapy (octreotide, lanreotide)	Non-invasive; reversible	Usually not curative; expensive; side-effects
Growth hormone receptor antagonist (pegvisomant)	Highly selective	Usually not curative

appropriate clinical, visual field, imaging and endocrine assessments.

Differential diagnosis of pituitary or hypothalamic masses

Although pituitary adenomas are the most common mass lesion of the pituitary, a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

Other tumours

Craniopharyngioma, a usually cystic hypothalamic tumour, which is often calcified, arising from Rathke's pouch often mimics an intrinsic pituitary lesion. It is the most common pituitary tumour in children but may present at any age.

Uncommon tumours include meningiomas, gliomas, chondromas, germinomas and pinealomas. Secondary deposits occasionally present as apparent pituitary tumours, typically presenting with headache and diabetes insipidus.

Hypophysitis and other inflammatory masses

A variety of inflammatory masses may occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g. postpartum hypophysitis, lymphocytic hypophysitis, giant cell hypophysitis), or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans' cell histiocytosis, Wegener's granulomatosis).

Other lesions

Carotid artery aneurysms may masquerade as pituitary tumours. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

Hypopituitarism

Pathophysiology

Deficiency of hypothalamic releasing hormones or of pituitary trophic hormones is either selective or multiple. There are, for example, rare isolated deficiencies of LH/FSH and ACTH, some of which may be congenital, autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function, usually in the order shown from left to right in Figure 18.7. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected. *Panhypopituitarism* refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery or radiotherapy. Multiple deficiencies can also rarely result from congenital defects, e.g. mutation of the gene for the pituitary-specific transcription factor 'Pit-1' causes deficiency in GH, prolactin and TSH.

Vasopressin and oxytocin secretion will be significantly affected only if the hypothalamus is involved, either by a hypothalamic tumour or by major suprasellar extension of a pituitary lesion. Posterior pituitary deficiency is rare in an uncomplicated pituitary adenoma.

Causes

Disorders causing hypopituitarism are listed in Table 18.8. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

Table 18.8 Causes of hypopituitarism

Congenital
Isolated deficiency of pituitary hormones (e.g. Kallmann's syndrome)
Pit-1 deficiency

Infective
Basal meningitis (e.g. tuberculosis)
Encephalitis Syphilis

Vascular
Pituitary apoplexy Sheehan's syndrome (postpartum necrosis)
Carotid artery aneurysms

Immune-logical
Pituitary antibodies

Neoplastic
Pituitary or hypothalamic tumours
Craniopharyngioma
Meningiomas Gliomas
Pinealoma
Secondary deposits, especially breast
Lymphoma

Traumatic
Skull fracture through base
Surgery, especially transfrontal
Perinatal trauma

Infiltrations
Sarcoidosis
Langerhans' cell histiocytosis
Hereditary haemochromatosis
Hypophysitis
Postpartum
Lymphocytic
Giant cell

Others
Radiation damage
Fibrosis Chemotherapy
Empty sella syndrome

'Functional'
Anorexia nervosa
Starvation Emotional deprivation

Clinical features

Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint by the patient. In general, symptoms of deficiency of a pituitary-stimulating hormone are the same as primary deficiency of the peripheral endocrine gland (e.g. TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion). Thus, secondary hypothyroidism and adrenal failure both lead to tiredness and general malaise; hypothyroidism may cause slowness of thought and action, dry skin and cold intolerance, while hypoadrenalism may cause mild hypotension, hyponatraemia and ultimately cardiovascular collapse during severe intercurrent stressful illness. Loss of libido, loss of secondary sexual hair, amenorrhoea and impotence are symptoms of gonadotrophin and thus gonadal deficiencies, while hyperprolactinaemia may cause galactorrhoea and hypogonadism. GH deficiency may be relatively clinically 'silent' except in children, but may cause markedly impaired well-being in some adults. Weight may increase (due to hypothyroidism) or decrease in severe combined deficiency (pituitary cachexia). Long-standing panhypopituitarism gives the classic picture of pallor with hairlessness ('alabaster skin').

Particular syndromes related to hypopituitarism are:

Kallmann's syndrome

This syndrome is isolated gonadotrophin (GnRH) deficiency (p. 1055).

Sheehan's syndrome

This situation, now rare, is pituitary infarction following postpartum haemorrhage.

Pituitary apoplexy

A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache and sudden severe visual loss sometimes followed by acute life-threatening hypopituitarism.

The 'empty sella' syndrome

An 'empty sella' is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation) or may follow spontaneous infarction of a tumour. All or most of the sella turcica is devoid of apparent pituitary tissue, but, despite this, pituitary function is usually normal, the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

Investigations

Each axis of the hypothalamic-pituitary system requires separate investigation. However, the presence of normal gonadal function (ovulatory/menstruation or normal libido/erections) suggests that multiple defects of anterior pituitary function are unlikely.

Tests range from the simple basal levels (e.g. free T_4 for the thyroid axis), to stimulatory tests for the pituitary, and tests of feedback for the hypothalamus (Table 18.9). Assessment of the hypothalamo-pituitary-adrenal axis remains critical but controversial: basal 0900h cortisol levels above 400nmol/L usually indicate an adequate reserve, while levels below lOOnmol/L predict an inadequate stress response. In many cases basal levels are equivocal and a dynamic test is essential: the insulin tolerance test (Box 18.2) is widely regarded as the 'gold standard' but the synacthen test (see Box 18.1), though an indirect measure, is used by many as a routine test of hypothalamic-pituitary-adrenal status. Overall, the assessment of adrenal reserve is best left to an endocrinologist.

Treatment

Steroid and thyroid hormones are essential for life. Both are given as oral replacement drugs, as in primary thyroid and adrenal deficiency, aiming to restore the patient to clinical and biochemical normality (Table 18.10) and levels may be monitored by routine hormone assays. Sex hormone production is replaced with androgens and oestrogens, both for symptomatic control and to prevent long-term problems related to deficiency (e.g. osteoporosis). When fertility is desired, gonadal function may be stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH), purified or biosynthetic gonadotrophins, or indirectly by pulsatile gonadotrophin-releasing hormone (GnRH - also known as luteinizing hormone-releasing hormone, LHRH); all are expensive and time-consuming and should be restricted to specialist units.

Table 18.9 Tests for hypothalamic-pituitary (HP) function

All hormone levels are measured in plasma unless otherwise stated.
Tests **shown in bold** are those normally measured on a single basal 0900h sample in the initial assessment of pituitary function.

Axis	Basal investigations: Pituitary hormone product/function	Basal investigations: End-organ	Common dynamic tests	Other tests
Anterior pituitary HP-ovarian	**LH** **FSH**	**Estradiol** Progesterone (day 21 of cycle)		Ovarian ultrasound LHRH test*
HP-testicular	**LH** **FSH**	**Testosterone**		Sperm count LHRH test*
Growth	GH	IGF-1 IGF-BP3	Insulin tolerance test	GH response to sleep, exercise or arginine infusion GHRH test*
Prolactin	**Prolactin**	**Prolactin**	-	-
HP-thyroid	**TSH**	**Free T_4, T_3**		TRH test*
HP-adrenal	ACTH	**Cortisol**	Insulin tolerance test Short synacthen (tetracosactide) test	Glucagon test CRH test* Metyrapone test

"Releasing hormone tests were a traditional part of pituitary function testing, but have been largely replaced by the advent of more reliable assays for basal hormones. They test only the 'readily releasable pool' of pituitary hormones and normal responses may be seen in hypopituitarism

1

Box 18.2 Insulin tolerance test

Indication

Diagnosis or exclusion of ACTH and growth hormone deficiency

Procedure

Should only be performed in experienced, specialist units Exclude cardiovascular disease (ECG), epilepsy or unexplained blackouts; exclude severe untreated hypopituitarism (basal cortisol must be > 100 nmol/L; normal free T_4) Intravenous hydrocortisone and glucose available for emergency

Overnight fast, begin at 0800-0900h Soluble insulin, 0.15 Units/kg, i.v. at time 0 Glucose, cortisol and GH at 0, 30, 45, 60, 90, 120 min

Normal response

Cortisol rises above 550 nmol/L*

GH rises above 20 mU/L (severe deficiency = < 9 mU/L (3 ng/L)) Glucose must be < 2.2 mmol/L to achieve adequate stress response

"Precise cortisol normal ranges are variable between laboratories and assays - appropriate local reference ranges must be used

Table 18.10 Replacement therapy for hypopituitarism

Axis	Usual replacement therapies
Adrenal	Hydrocortisone 15-40 mg daily (starting dose 10 mg on rising/5 mg lunchtime/ 5 mg evening) (Normally no need for mineralocorticoid replacement)
Thyroid	Thyroxine 100-150 ug daily
Gonadal	
Male	Testosterone intramuscularly, orally, transdermally or implant
Female	Cyclical oestrogen/progestogen orally or as patch
Fertility	HCG plus FSH (purified or recombinant) or pulsatile GnRH to produce testicular development, spermatogenesis or ovulation
Growth	Recombinant human GH used routinely to achieve normal growth in children Also advocated for replacement therapy in adults where GH has effects on muscle mass and well-being Desmopressin 10-20 ug
Thirst	one to three times daily by nasal spray or orally 100-200 ug three times daily Carbamazepine and thiazides are rarely used in mild diabetes insipidus
Breast (Prolactin inhibition)	Dopamine agonist (e.g. cabergoline, 500 ug weekly)

GH therapy is given in the growing child, under the care of a paediatric endocrinologist. In adult GH deficiency, GH therapy also produces improvements in body composition, work capacity and psychological well-being, together with reversal of lipid abnormalities associated with a high cardiovascular risk, and this may result in significant symptomatic benefit in some cases. Although symptomatically helpful in many patients and now licensed for such use in most countries, the long-term safety and efficacy of GH therapy in adults is not yet fully established, and its cost is £2500-6000 per annum.

Two points should be noted:

- Thyroid replacement should not commence until normal glucocorticoid function has been demonstrated or replacement steroid therapy initiated, as an adrenal 'crisis' may otherwise be precipitated.
- Glucocorticoid deficiency may mask impaired urine concentrating ability, diabetes insipidus only becoming apparent after steroid replacement.

***r* Sox *18.3* Definitions in reproductive medicine**

Menarche	Age at first period
Primary amenorrhoea	Failure to begin spontaneous menstruation by age 16
Secondary amenorrhoea	Absence of menstruation for 3 months in a woman who has previously had cycles
Oligomenorrhoea	Irregular long cycles; often used for any length of cycle above 32 days
Dyspareunia	Pain or discomfort in the female during intercourse
Libido	Sexual interest or desire; often difficult to assess and is greatly affected by stress, tiredness and psychological factors
Menstruation	Onset of spontaneous (usually regular) uterine bleeding in the female
Impotence (erectile dysfunction)	Inability of the male to achieve or sustain an erection adequate for satisfactory intercourse
Azoospermia	Absence of sperm in the ejaculate
Oligospermia	Reduced numbers of sperm in the ejaculate; normal values are disputed
Virilization	Occurrence of male secondary sexual characteristics in the female

REPRODUCTION AND SEX

The normal physiology of the female and male reproductive systems will be considered first, followed by their common disorders. Some relevant terminology is set out in Box 18.3.

Embryology

Up to 8 weeks of **gestation the sexes share a** common development, with a primitive genital tract including the Wolffian and Mullerian ducts. There are additionally a primitive perineum and primitive gonads.

In the presence of a Y chromosome the potential testis develops while the ovary regresses.

In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Mullerian inhibitory factor from the early 'testis' produces atrophy of the Mullerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra and scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5-1 mL.

PHYSIOLOGY

The male

An outline of the hypothalamic-pituitary-testicular axis is shown in Figure 18.9.

1. Pulses of GnRH (LHRH) are released from the hypothalamus and stimulate LH and FSH release from the pituitary.
2. LH stimulates testosterone production from Leydig cells of the testis.
3. Testosterone acts systemically to produce male secondary sexual characteristics, anabolism and the maintenance of libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex hormone-binding globulin (SHBG) (see p. 1036). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.
4. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.

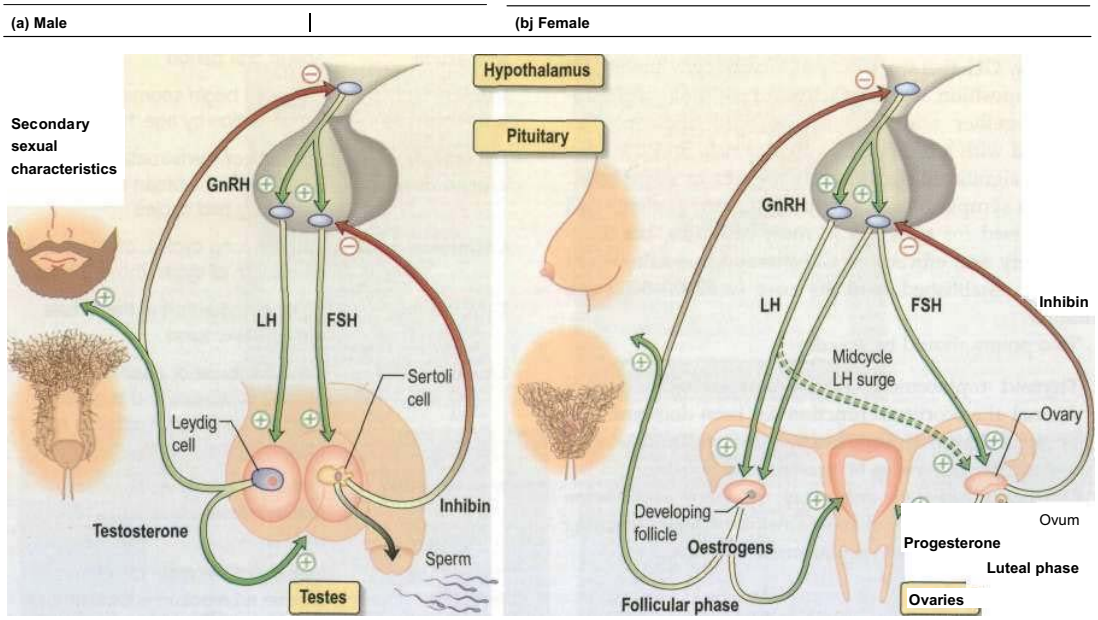

Fig. 18.9 **Male and female hypothalamic-pituitary-gonadal axes.** Note the close parallels. The positive and negative signs indicate feedback.

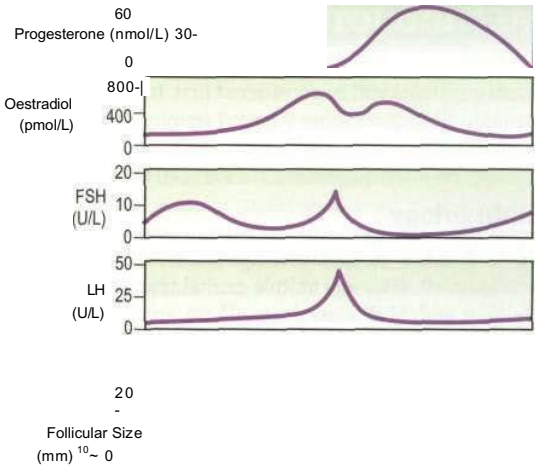
5. Inhibin causes feedback on the pituitary to decrease FSH secretion.

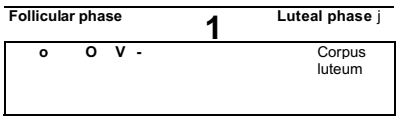
The secondary sexual characteristics of the male for which testosterone is necessary are the growth of pubic, axillary and facial hair, enlargement of the external genitalia, deepening of the voice, sebum secretion, muscle growth and frontal balding.

The female

The female situation is more complex (Figs 18.9 and 18.10).

1. In the adult female, higher brain centres impose a menstrual cycle of 28 days upon the activity of hypothalamic GnRH.
2. Pulses of GnRH, at about 2-hour intervals, stimulate release of pituitary LH and FSH.
3. LH stimulates ovarian androgen production by the ovarian theca cells.
4. FSH stimulates follicular development and aromatase activity (an enzyme required to convert ovarian androgens to oestrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release.
5. Although many follicles are 'recruited' for development in early folliculogenesis, by day 8-10 a 'leading' (or 'dominant') follicle is selected for development into a mature Graafian follicle.
6. Oestrogens show a double feedback action on the pituitary (Fig. 18.9), initially inhibiting gonadotrophin secretion (negative feedback), but later high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge inducing ovulation from the leading follicle (Fig. 18.10).
7. The follicle then differentiates into a corpus luteum, which secretes both progesterone and estradiol during the second half of the cycle (luteal phase).
8. Oestrogen initially and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation) allowing increased GnRH and FSH secretion.





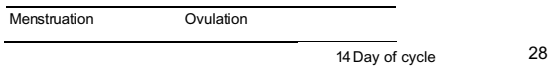


Fig. 18.10 **Hormonal and follicular changes during the normal menstrual cycle.**

9. If implantation and pregnancy follow, human chorionic gonadotrophin (HCG) production from the trophoblast maintains corpus luteum function until 10-12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.

Oestrogens also induce secondary sexual characteristics, especially development of the breast and nipples, vaginal and vulval growth and pubic hair development. They also induce growth and maturation of the uterus and Fallopian tubes. They circulate largely bound to SHBG.

Physiology of prolactin secretion

The hypothalamic-pituitary control of prolactin secretion is illustrated in Figure 18.11.

Prolactin is under tonic dopamine inhibition, while other factors known to increase prolactin secretion (e.g. TRH) are probably of less importance. Prolactin stimulates milk secretion but also reduces gonadal activity. It decreases GnRH pulsatility at the hypothalamic level and, to a lesser extent, blocks the action of LH on the ovary or testis, producing hypogonadism even when the pituitary gonadal axis itself is intact.

Puberty

The mechanisms initiating puberty are poorly understood but are thought to result from withdrawal of central inhibition of GnRH release. Environmental and physical factors are involved in the timing of puberty (including body fat changes, physical exercise) as well as genetic factors (e.g. a G protein-coupled receptor gene, *GPR 54)* required for pubertal maturation.

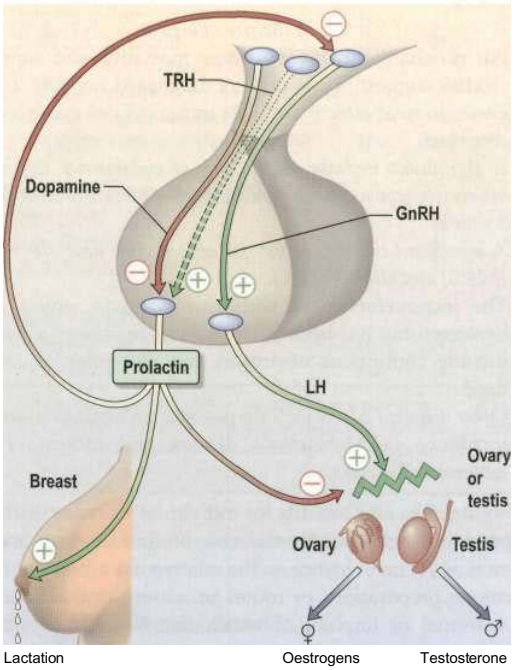

Fig. 18.11 The control of prolactin secretion.

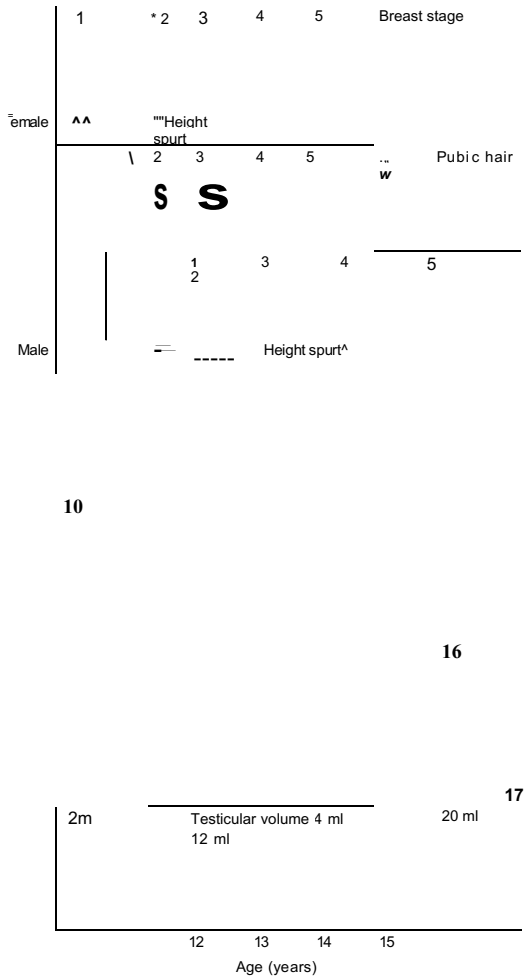

Fig. 18.12 **The age of development of features of puberty.** Stages and testicular size show mean ages, and all vary considerably between individuals. The same is true of height spurt, shown here in relation to other data. Numbers 2 to 5 indicate stages of development (see the text).

LH and FSH are both low in the prepubertal child. In early puberty, FSH begins to rise first, initially in nocturnal pulses; this is followed by a rise in LH with a subsequent increase in testosterone/oestrogen levels. The milestones of puberty in the two sexes are shown in Figure 18.12.

In boys, pubertal changes begin at between 10 and 14 years and are complete at between 15 and 17 years. The genitalia develop, testes enlarge and the area of pubic hair increases. Peak height velocity is reached between ages 12 and 17 years during stage 4 of testicular development. Full spermatogenesis occurs comparatively late.

In girls, events start a year earlier. Breast bud enlargement begins at ages 9-13 years and continues to 12-18 years. Pubic hair growth commences at ages 9-14 years and is completed at 12-16 years. Menarche occurs relatively late (age 11-15 years) but peak height velocity is reached earlier (at age 10-13 years), and growth is completed much earlier than in boys.

Precocious puberty

Development of secondary sexual characteristics, or menarche in girls, at or before the age of 9 years is premature. All cases require specialist assessment by a paediatric endocrinologist.

Idiopathic (true) precocity is most common in girls and very rare in boys. This is a diagnosis of exclusion. With no apparent cause for premature breast or pubic hair development, and an early growth spurt, it may be normal and may run in families. Treatment with long-acting GnRH analogues (given by nasal spray, by

subcutaneous injection or by implant) causes suppression of gonadotrophin release via downregulation of the receptor - and therefore reduced sex hormone production - and is moderately effective; cyproterone acetate, an anti-androgen with progestational activity, may also be used. The following are other forms of precocity:

- *Cerebral precocity.* Many causes of hypothalamic disease, especially tumours, may present in this way. In boys this must be rigorously excluded. MRI scan is almost always indicated to exclude this diagnosis.
- *McCune-Albright syndrome.* This is usually in girls, with precocity, polyostotic fibrous dysplasia and skin pigmentation (cafe-au-lait). An activating mutation of the *GNAS1* gene encoding the a-subunit of Gs protein has been found.
- *Premature thelarche.* This is early breast development alone, usually transient, at age 2-4 years. It may regress or persist until puberty. There is no evidence of follicular development.
- *Premature adrenarche.* This is early development of pubic hair without significant other changes, usually after age 5 years and more commonly in girls.

Delayed puberty

Over 95% of children show signs of pubertal development by age 14 years. In its absence, investigation should begin by age 15 years. Causes of hypogonadism (see below) are clearly relevant but most cases represent constitutional delay.

In constitutional delay, pubertal development, bone age and stature are in parallel. A family history may confirm that other family members experienced the same delayed development, which is common in boys but very rare in girls.

In boys, a testicular volume > 5 mL indicates the onset of puberty. A rising serum testosterone is an earlier clue.

In girls, the breast bud is the first sign. Ultrasound allows accurate assessment of ovarian and uterine development.

Basal LH/FSH levels may identify the site of a defect, and GnRH (LHRH) tests can indicate the stage of early puberty.

If any progression into puberty is evident clinically, investigations are not required. When delay is great and problems are serious (e.g. severe teasing at school), low-dose short-term sex hormone therapy is used. Specialist assessment is advisable.

The menopause

The menopause, or cessation of periods, naturally occurs about the age of 45-55 years. During the late forties, FSH initially, and then LH concentrations begin to rise, probably as follicle supply diminishes. Oestrogen levels fall and the cycle becomes disrupted. Most women notice irregular scanty periods coming on over a variable period, though in some sudden amenorrhoea or menorrhagia occur. Eventually the menopausal pattern of low estradiol levels with grossly elevated LH and FSH levels (usually > 50 and > 25 U/L, respectively) is established. Menopause may also occur surgically, with radiotherapy to the ovaries and with ovarian disease (e.g. premature menopause).

Clinical features and treatment

Features of oestrogen deficiency are hot flushes (which occur in most women and can be disabling), vaginal dryness and atrophy of the breasts. There may also be vague symptoms of loss of libido, loss of self-esteem, non-specific aches and pains, irritability, depression, loss of concentration and weight gain.

Women show a rapid loss of bone density in the 10 years following the menopause (osteoporosis, see p. 594) and the premenopausal protection from ischaemic heart disease disappears.

Symptomatic patients should usually be treated but the previous widespread use of hormone replacement therapy (HRT) has been thrown into doubt by a number of large prospective studies which have reported in recent years. Although there is no universal agreement, the overall benefits and risks may be summarized as follows (percentages are from the Women's Health Initiative (WHI) study of 16 600 women):

- *Symptomatic improvement in most menopausal symptoms* for the majority of women. Oestrogen-deficient symptoms respond well to oestrogen replacement, the vaguer symptoms generally, but not always, less well. Vaginal symptoms respond to local oestrogen preparations.
- *Protection against fractures of wrist, spine and hip, secondary to osteoporosis (-24-33%)* (see Ch. 10), owing to protection of predominantly trabecular bone (p. 595).
- *A significant reduction in the risk of large bowel cancer (-33%).*
- *A significant increase in the risk of breast cancer (+26%)* -but no change in breast cancer mortality, and some studies suggest breast cancers diagnosed on HRT are easier to treat effectively. This increased risk has been disputed.
- *A significant increase in the risk of endometrial cancer* when unopposed oestrogens are given to women with a uterus.
- *A significant increase in the risk of ischaemic heart disease (+29%) and stroke (+41%).*
- The inconvenience of withdrawal bleeds, unless a hysterectomy has been performed or regimens which include continuous oestrogen and progesterone are used.
- *Other disputed effects* include possible reductions in the incidence of Alzheimer's disease and increase in general well-being.

Absolute risks and benefits for individual women clearly depend on their background risk of that disease, and there is as yet no evidence on the relative risks of different hormone preparations or routes of administration (oral, transdermal or implant). Overall, the WHI study estimated that, over 5 years of treatment, an extra 1 woman in every 100 would develop an illness that would not have occurred had she not been taking HRT. However,

the decision about whether or not a woman takes HRT is now very much an individual decision based on the severity of that woman's menopausal symptoms, her personal risk of conditions which may be prevented or made more likely by HRT, and ultimately individual patient choice. For example, the decision is likely to be very different for a non-smoking 50-year-old with severe menopausal symptoms and a family history of osteoporosis, compared to a 60-year-old hypertensive smoker with mild symptoms and a family history of breast cancer. HRT is no longer recommended purely for prevention of postmenopausal osteoporosis in the absence of menopausal symptoms. Where symptomatic treatment is given, use of the lowest effective dose is now advocated, usually for short-term rather than long-term treatment. However, its exact place in therapy is still unclear.

Selective oestrogen receptor modulators, SERMs (e.g. raloxifene), offer a potentially attractive combination of positive oestrogen effects on bone and cardiovascular system with no effects on oestrogen receptors of uterus and breast and possible reduction in breast cancer incidence; long-term outcome studies, however, are still awaited.

Premature menopause

The most common cause of premature menopause in women (before age 40) is ovarian failure, which may be autoimmune or of unknown aetiology. Bilateral oophorectomy causes the same oestrogen-deficiency state. HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweigh the risks at this younger age. HRT may still also be actively recommended when normal menopause occurs relatively early (e.g. before age 50).

The ageing male

In the male there is no sudden 'change of life'. However, there is a progressive loss in sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely, but overall testicular volume diminishes and sex hormone-binding globulin (SHBG) and gonadotrophin levels gradually rise. If premature hypogonadism is present for any reason, replacement testosterone therapy should be given to prevent osteoporosis (see p. 598). More widespread androgen replacement of the ageing male is under evaluation, primarily in the USA, with promising early results, but no long-term follow-up data are available.

Conversely, lowering of androgens forms part of the therapy of prostate hypertrophy and prostate cancer. Finasteride, an inhibitor of 5a-reductase, is used in benign prostatic hypertrophy. It prevents the conversion of testosterone to dihydrotestosterone, which causes prostatic hypertrophy, and is effective, though somewhat delayed in action (see p. 685). GnRH analogues are used to lower testosterone levels and induce disease remission in patients with prostate cancer.

CLINICAL FEATURES OF DISORDERS SEX AND REPRODUCTION

A detailed history and examination of all systems is required (Box 18.4). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate (check with the partner!).

Tests of gonadal function

Basal measurements of the gonadotrophins, oestrogens/testosterone and prolactin:

- *Low testosterone or estradiol with high gonadotrophins* indicates primary gonadal disease.
- *Low levels of LH/FSH and of testosterone/estradiol* imply hypothalamic-pituitary disease.
- Demonstration of *ovulation* (by measurement of luteal phase serum progesterone and/ or by serial ovarian ultrasound in the follicular phase) or a healthy *sperm count* (20-200 x 10^6/mL, > 60% grade I motility and < 20% abnormal forms), provide absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.
- Pregnancy provides complete demonstration of normal male and female function.
- *Hyperprolactinaemia* can be confirmed or excluded by direct measurement. Levels may increase with stress; ideally, a cannula should be inserted and samples taken through it 30 minutes later.

Sox *18.4* Sexual and menstrual disorders

Galactorrhoea

Table 18.11 Tests of gonadal function

Test	Uses/comments
Male	
Basal testosterone	Normal levels exclude hypogonadism
Sperm count	Normal count excludes deficiency Motility and abnormal sperm forms should be noted
Female	
Basal estradiol	Normal levels exclude hypogonadism If > 30 nmol/L, suggests ovulation To confirm ovulation
Luteal phase progesterone (days 18-24 of cycle)	
Ultrasound of ovaries	
Both sexes	
Basal LH/FSH	Demonstrates state of feedback system for hormone production (LH) and germ cell production (FSH)
HCG test (testosterone or estradiol measured)	Response shows potential of ovary or testis; failure demonstrates primary gonadal problem
Clomifene test (LH and FSH measured)	Tests hypothalamic negative feedback system; clomifene is oestrogen antagonist and causes LH/FSH to rise
LHRH test (rarely used)	Shows adequacy (or otherwise) of LH and FSH stores in pituitary

More detailed tests are indicated in Table 18.11.

DISORDERS IN THE MALE

Hypogonadism

Clinical features

Male hypogonadism may be a presenting complaint or an incidental finding, such as during investigation for subfertility. The testes may be small and soft. Except with subfertility, the symptoms are usually of androgen deficiency, primarily poor libido, impotence and loss of secondary sexual hair (Table 18.12) rather than deficiency of semen production. Sperm makes up only a very small proportion of seminal fluid volume.

Causes of male hypogonadism are shown in Table 18.13.

Investigations

Testicular disease may be immediately apparent but basal levels of testosterone, LH and FSH should be measured. These will allow the distinction between primary gonadal (testicular) failure and hypothalamic-pituitary disease to be made. Depending on the causes, semen analysis, chromosomal analysis (e.g. to exclude Klinefelter's syndrome) and bone age estimation are required.

Table 18.12 Effects of androgens and consequences of androgen deficiency in the male

Physiological effect	Consequences of deficiency
General	
Maintenance of libido	Loss of libido
Deepening of voice	High-pitched voice (if prepubertal) No temporal recession
Frontotemporal balding	
Facial, axillary and limb hair	Decreased hair
Maintenance of erectile and ejaculatory function	Loss of erections/ejaculation
Pubic hair	
Maintenance of male pattern	Thinning and loss of pubic hair
Testes and scrotum	
Maintenance of testicular size/consistency (needs gonadotrophins as well)	Small soft testes
Rugosity of scrotum	Poorly developed penis/scrotum
Stimulation of spermatogenesis	Subfertility
Musculoskeletal	
Epiphyseal fusion	Eunuchoidism (if prepubertal)
Maintenance of muscle bulk and power	Decreased muscle bulk
Maintenance of bone mass	Osteoporosis

Table 18.13 Causes of male hypogonadism

Reduced gonadotrophins (hypothalamic-pituitary disease)
Hypopituitarism
Selective gonadotrophic deficiency (Kallmann's syndrome)
Severe systemic illness
Severe underweight

Hyperprolactinaemia

Primary gonadal disease (congenital)
Anorchia/Leydig cell agenesis Cryptorchism (testicular maldescent) Chromosome abnormality (e.g. Klinefelter's syndrome) Enzyme defects: 5a-reductase deficiency

Primary gonadal disease (acquired)
Testicular torsion
Orchidectomy
Local testicular disease
Chemotherapy/radiation toxicity
Orchitis (e.g. mumps)
Renal failure
Cirrhosis/alcohol
Sickle cell disease

Androgen receptor deficiency/abnormality

In clear-cut gonadotrophin deficiency, pituitary MRI scan, prolactin levels and other pituitary function tests are needed. However, equivocal lowering of serum testosterone (7-10 nmol/L) without elevation of gonadotrophins is a relatively common biochemical finding, and

Table 18.14 **Androgen replacement therapy**

Preparation	Dose	Route	Remarks
Testosterone mixed esters			Usual first-line maintenance therapy
Testosterone enanthate	250 mg x every 3 weeks	IM	Injection can be painful
Testosterone propionate	50-100 mg 2-3 x weekly	IM	Frequent injections needed as half-life is short Good initial therapy
Testosterone undecanoate	80-240 mg daily, in divided doses	Oral	Variable dose, irregular absorption
Testosterone implant	600 mg every 4-5 months	Implant	Requires implant procedure
Testosterone transdermal	2.5-7.5 mg/24 h	Dermal	Patch or gel preparations

is a frequent cause of referral in men with poor libido or erectile dysfunction. Such tests are compatible with mild gonadotrophin deficiency, but may also be seen in acute illness of any cause and often simply represent the lower end of the normal range or the normal circadian rhythm of testosterone when bloods are checked in afternoon or evening surgeries. A therapeutic trial of testosterone replacement is often justified and forms part of the investigation in many patients; full pituitary evaluation may be required in such cases to exclude other pituitary disease. 'Anabolic' steroid (i.e. androgen) abuse causes similar biochemical findings, and an index of suspicion is required if the patient appears well virilized.

Treatment

The cause can rarely be reversed. Replacement therapy should be commenced (Table 18.14). Primary gonadal failure should be treated with androgens. Patients with hypothalamic-pituitary disease are routinely replaced with androgens, but may be given LH and FSH (purified or synthetic) or pulsatile GnRH when fertility is required.

Special instances of hypogonadism

Cryptorchidism

By the age of 5 years both testes should be in the scrotum. After that age the germinal epithelium is increasingly at risk, and lack of descent by puberty is associated with subfertility. Surgical exploration and orchidopexy are usually undertaken but a short trial of HCG occasionally induces descent: an HCG test with a testosterone response 72 hours later excludes anorchia. Intra-abdominal testes have an increased risk of developing malignancy; if presentation is after puberty, orchidectomy is advised.

Klinefelter's syndrome

Klinefelter's syndrome (seminiferous tubule dysgenesis), a chromosomal disorder (47XXY) affecting 1 in 1000 males, involves both loss of Leydig cells and seminiferous tubular dysgenesis. Patients usually present with poor sexual development, small or undescended testes, gynaecomastia or infertility. They are occasionally mentally retarded. Clinical examination shows small pea-sized but firm testes, usually gynaecomastia and often signs of androgen deficiency. Confirmation is by chromosomal analysis. Treatment is androgen replacement therapy unless testosterone levels are normal. No treatment is possible for the abnormal seminiferous tubules and infertility.

Kallmann's syndrome

This is isolated GnRH deficiency. It is often associated with decreased or absent sense of smell (anosmia), and sometimes with other bony (cleft palate), renal and cerebral abnormalities (e.g. colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the *KALI* gene which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism (see p. 1056). Fertility is possible.

Oligospermia or azoospermia

These may be secondary to androgen deficiency and can be corrected by androgen replacement. More often they result from primary testicular diseases, in which case they are rarely treatable.

Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

Lack of libido and erectile dysfunction ('impotence')

Lack of libido is a loss of sexual desire leading to erectile dysfunction. Erectile dysfunction (ED) may be psychological, neurogenic, vascular, endocrine or related to drugs and often includes contributions from several causes. ED is a common symptom in hypogonadism, but most patients with ED have normal hormones and many have no definable organic cause. The *endocrine* causes are those of hypogonadism (see above) and can be excluded by normal testosterone, gonadotrophin and prolactin levels, and the presence of nocturnal emissions and frequent satisfactory morning erections makes endocrine disease unlikely. *Vascular disease* is a common aetiology, especially in smokers, and is often associated with vascular problems elsewhere. *Autonomic neuropathy,* most commonly from diabetes mellitus, is a common partial, if not total, identifiable cause (see p. 1129). Many drugs produce ED (see Table 22.8). A careful history of physical disease, related symptoms, stress and psychological factors, together with drug and alcohol abuse, must be taken.

Psychogenic impotence is frequently a diagnosis of exclusion, though complex tests of penile vasculature and function are available in some centres.

Offending drugs should be stopped. Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil) which increase penile blood flow (see p. 1129) are usually first

Table 18.15 Causes of gynaecomastia

Physiological	Drugs
Neonatal	Oestrogenic
Pubertal	oestrogens
Old age	digoxin
	cannabis
Hyperthyroidism	diamorphine
Liver disease	Anti-androgens
	spironolactone
Oestrogen-producing	cimetidine
tumours (testis, adrenal)	cyproterone
HCG-producing tumours	Others
(testis, lung)	gonaadotropnin:
Starvation/refeeding	
Carcinoma of breast	

choice for therapy. Other treatments include apomorphine, intracavernosal injections of alprostadil, papaverine or phentolamine, vacuum expanders and penile implants.

If no organic disease is found, or if there is clear evidence of psychological problems, the couple should receive psychosexual counselling.

Gynaecomastia

Gynaecomastia is development of breast tissue in the male. Causes are shown in Table 18.15.

Pubertal gynaecomastia occurs in perhaps 50% of normal boys, often asymmetrically. It usually resolves spontaneously within 6-18 months, but after this duration may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

In the older male, gynaecomastia requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g. Ley dig cell tumour). Drug effects are common (especially digoxin and spironolactone), and once these and significant liver disease are excluded most cases have no definable cause. Surgical removal is occasionally necessary.

DISORDERS IN THE FEMALE

Hypogonadism

Impaired ovarian function, whether primary or secondary, will lead both to oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which the failure develops. Thus, before puberty, primary amenorrhoea will occur, possibly with delayed puberty; if after puberty, secondary amenorrhoea and hypogonadism will result.

Oestrogen deficiency

The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Table 18.16.

Table 18.16 Effects of oestrogens and consequences of oestrogen deficiency

Physiological effect	Consequence of deficiency
Breast	
Development of connective and duct tissue Nipple enlargement and areolar pigmentation	Small, atrophic breast
Pubic hair	
Maintenance of female pattern	Thinning and loss of pubic hair
Vulva and vagina	
Vulval growth Vaginal glandular and epithelial proliferation	Atrophic vulva Atrophic vagina
Vaginal lubrication	Dry vagina and dyspareunia
Uterus and tubes	
Myometrial and tubal hypertrophy Endometrial proliferation	Small, atrophic uterus and tubes Amenorrhoea
Skeletal	
Epiphyseal fusion	Eunuchoidism (if prepubertal)
Maintenance of bone mass	Osteoporosis

Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) are the commonest presentation of female gonadal disease. The clinical assessment of such patients is shown in Box 18.5, and common causes listed in Table 18.17.

Polycystic ovary syndrome

Polycystic ovary syndrome is the most common cause of oligomenorrhoea and amenorrhoea in clinical practice

Box 18.5 Clinical assessment of amenorrhoea

History
- Date of onset
- Age of menarche, if any
- Sudden or gradual onset
- General health
- Weight, absolute and changes in recent past
- Stress (job, lifestyle, exams, relationships)
- Excessive exercise Drugs
- Hirsutism, acne, virilization
- Headaches/visual symptoms
- Sense of smell
- Past history of pregnancies
- Past history of gynaecological surgery
- ? Pregnant

Examination
- General health
- Body shape and skeletal abnormalities Weight and height Hirsutism and acne Evidence of virilization
- Maturity of secondary sexual characteristics
- Galactorrhoea Normality of vagina, cervix and uterus

Table 18.17 **Amenorrhoea - differential diagnosis and investigation**

"These conditions may present as primary amenorrhoea
LH, Luteinizing hormone; FSH, follicle-stimulating hormone; E2, Estradiol; PRL, Prolactin; T, Testosterone; DHEAS, dehydroepiandrosterone sulphate; SHBG, sex hormone-binding globulin; HCG, human chorionic gonadotropin; LHRH, luteinizing hormone-releasing hormone N = Normal; i = Low; T = High; T t = Very high; N t = Normal or high; Ni = Normal or low

and should always be considered in the context of menstrual dysfunction.

Weight-related amenorrhoea

A minimum body weight is necessary for regular menstruation. While anorexia nervosa is the extreme form (see p. 1310), this condition is common and may be seen at weights with the 'normal' range. The biochemistry is indistinguishable from gonadotrophin deficiency and some patients have additional mild endocrine disease (e.g. polycystic ovarian disease). Restoration of bodyweight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved then

oestrogen replacement is necessary. Similar problems occur with intensive physical training in athletes and dancers.

Hypothalamic amenorrhoea

Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease, weight loss or excessive exercise is described as hypothalamic amenorrhoea. This may be related to 'stress', to previous weight loss or stopping the contraceptive pill, but some patients appear to have defective cycling mechanisms without apparent explanation. Leptin (p. 253) administration for the relative leptin deficiency found in these women has recently been shown to be of benefit.

Hypothyroidism

Oligomenorrhoea and amenorrhoea are frequent findings in severe hypothyroidism in young women.

Other

Pregnancy must always be considered as a possible cause. The possibility of genital tract abnormalities, such as an imperforate hymen, should also be remembered, especially in primary amenorrhoea. Severe illness, even in the absence of weight loss, can lead to amenorrhoea.

Investigations

Basal levels of FSH, LH, oestrogen and prolactin allow initial distinction between primary gonadal and hypothalamic-pituitary causes (Table 18.17). Ovarian biopsy may occasionally be necessary to confirm the diagnosis of primary ovarian failure, although elevation of LH and FSH to menopausal levels is usually adequate. Subsequent investigations are shown in Table 18.17.

Treatment

Treatment is that of the cause wherever possible (e.g. hypothyroidism, low weight, stress, excessive exercise).

Primary ovarian disease is rarely treatable except in the rare condition of 'resistant' ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis. Hyperprolactinaemia should be corrected (see below). Poly cystic ovary syndrome is discussed in detail below. In all other cases oestrogen replacement is usually indicated to prevent the long-term consequences of deficiency.

Hirsutism and polycystic ovary syndrome

Pathophysiology

The extent of normal hair growth varies between individuals, families and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick dark hair. It is therefore impossible to draw an absolute dividing line between 'normal' and 'abnormal' degrees of facial and body hair in the female. Soft vellous hair is normally present all over the body and this type of hair on the face and elsewhere is 'normal' and is not sex-hormone dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, pubic and thigh areas is sex-hormone dependent. Any excess in the latter regions is thus usually a marker of increased ovarian or adrenal androgen production, most commonly polycystic ovary syndrome (PCOS) but occasionally other rarer causes.

Patients with hirsutism, no elevation of serum androgen levels and no other clinical features are sometimes labelled 'idiopathic hirsutism'. However, studies suggest that most patients with 'idiopathic hirsutism' have some radiological or biochemical evidence of PCOS on more detailed investigation, and indeed several studies have demonstrated evidence of mild PCOS in up to 20% of the normal female population. Therefore, in routine clinical practice, the majority of patients with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

PCOS, originally known in its severe form as the *Stein-Leventhal syndrome,* is characterized by multiple small cysts within the ovary and by excess androgen production from the ovaries and to a lesser extent from the adrenals, although whether the basic defect is in the ovary, adrenal, pituitary or a more generalized metabolic defect remains unknown. The precise levels of androgens in blood vary widely from patient to patient. In addition, androgens are normally converted to oestrogens in adipose tissue, but aromatase levels are low (partly due to decreased FSH levels) so that, instead of androgen (mainly androstenedione) being converted to oestrogen, androstenedione is secreted and converted to testosterone in peripheral tissue. Furthermore, SHBG levels are often low (due to high insulin levels), and therefore free androgen levels are high. The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

The ovarian 'cysts' represent arrested follicular development. Studies have shown an association of polycystic ovary syndrome with anovulation, hyperinsulinaemia and insulin resistance, which may also be associated with hypertension, hyperlipidaemia and increased cardiovascular disease (the metabolic syndrome). The precise mechanisms which link the aetiology of polycystic ovaries, hyperandrogenism, anovulation and insulin resistance remain to be elucidated.

Familial or idiopathic hirsutism does occur, but usually involves a distribution of hair growth which is not typically androgenic. Iatrogenic hirsutism also occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol. Non-androgen-dependent hair growth (hypertrichosis) occurs with drugs such as phenytoin, diazoxide, minoxidil and ciclosporin.

Rarer, and more serious, endocrine causes of hirsutism and virilization include congenital adrenal hyperplasia (CAH,

see p. 1087), Cushing's syndrome (p. 1085) and virilizing tumours of the ovary and adrenal. All these conditions should be considered in any patient with hirsutism - as this may be the only presenting complaint.

Clinical features

PCOS usually presents with amenorrhoea/oligomenorrhoea, hirsutism and acne (alone or in combination), usually beginning shortly after menarche. Clinical, biochemical and radiological features of PCOS merge imperceptibly into those of the normal populations. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities.

The extent and severity of hirsutism

This should be recorded objectively, ideally using a scoring system, to document the problem and to monitor treatment. The method and frequency of physical removal (e.g. shaving, plucking) should also be recorded. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).

Age and speed of onset

Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.

Accompanying virilization

Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset frontal balding, male phenotype) implies substantial androgen excess, and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern — androgenic alopecia — occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.

Menstruation

Most patients with hirsutism will have some disturbance of menstruation - typically oligo-/amenorrhoea although more frequent erratic bleeding can also occur.

Weight

Many patients with hirsutism are also overweight or obese. This worsens the underlying androgen excess and insulin resistance and inhibits the response to treatment, and is an indication for appropriate advice on diet and exercise. In severe cases the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the axillae (see Fig. 23.24).

Investigations

A variety of investigations may aid the diagnosis of patients with hirsutism:

- **Serum testosterone** may be elevated in PCOS and is invariably substantially raised in virilizing tumours (usually > 5 nmol/L). Patients with hirsutism and normal testosterone level frequently have low levels of sex hormone-binding globulin (SHBG), leading to high free androgen levels.
- **Other androgens.** Androstenedione and dehydroepiandrosterone sulphate are frequently elevated in PCOS, and even more elevated in congenital adrenal hyperplasia and virilizing tumours.
- **17a-Hydroxyprogesterone** is elevated in classical CAH (congenital adrenal hyperplasia), but may be apparent in late-onset CAH only after stimulation tests.
- **Gonadotrophin levels.** LH hypersecretion is a consistent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a 'classic' increased LH/FSH ratio is not always observed on a random sample.
- **Oestrogen levels.** Estradiol is usually normal in PCOS, but esrrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.
- **Ovarian ultrasound** is a useful investigation (Fig. 18.13), although a skilled observer is necessary. The typical ultrasonic features are those of a thickened capsule, multiple 3-5 mm cysts and a hyperechogenic stroma. It should also be noted that prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.
- **Serum prolactin.** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

If a virilizing tumour is suspected clinically or after investigation, then more complex tests may include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

Differential diagnosis

Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have polycystic ovary syndrome, but the rarer alternative diagnoses should be excluded, e.g. late-onset congenital adrenal hyperplasia (early-onset, raised serum 17a-OH-progesterone), Cushing's syndrome (look for other clinical features) and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

Treatments

The underlying cause should be removed in the rare instances where this is possible (e.g. drugs, adrenal or ovarian tumours). Treatment of CAH and Cushing's are discussed on page 1087 and page 1086, respectively. Other therapy depends upon whether the aim is to reduce hirsutism, regularize periods or produce fertility.

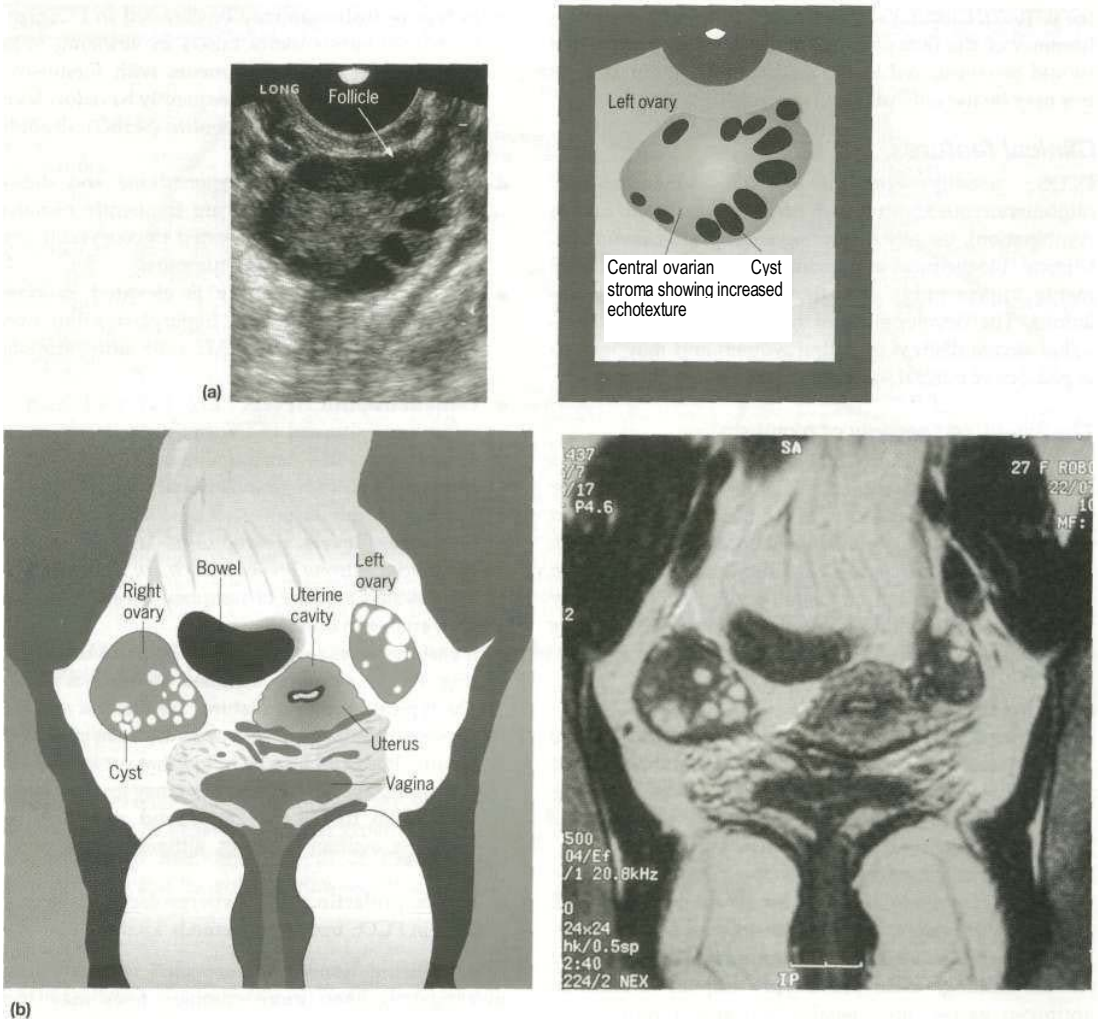

Fig. 18.13 **Polycystic ovary syndrome, (a) Longitudinal transvaginal ultrasound of ovary,** revealing multiple cysts with central ovarian stroma showing increased echo texture, **(b) MR image (coronal) of polycystic ovaries,** also showing pelvic anatomy. (Reproduced by kind permission of Barbara Hochstein and Geoffrey Cox, Auckland Radiology Group.)

Local therapy for hirsutism

Cosmetic appearance may be controlled by regular plucking, bleaching, depilatory cream, waxing or shaving. Such removal neither worsens nor improves the underlying severity of hirsutism. More 'permanent' solutions include electrolysis and a variety of 'laser' hair removal systems - all appear effective but have not been evaluated in long-term studies, are expensive, and still often require repeated long-term treatment.

Systemic therapy for hirsutism

This always requires a year or more of treatment for maximal benefit, and long-term treatment is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits.

Oestrogens (e.g. oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined pills, which contain a non-androgenic progestogen (e.g. co-cyprindiol), have an advantage over older combined pills, will result in a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication. Long-term follow-up studies of the use of the 'pill' for contraception give firm reassurance about the safety of the long-term treatment which is very often required. After the menopause, HRT preparations which contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.

Cyproterone acetate (50-100 mg daily) is an antiandrogen but is also a progestogen, teratogenic and a weak glucocorticoid. Given continuously it produces amenorrhoea, and so is normally given for days 1-14

of each cycle. In women of childbearing age, contraception is essential.

- *Spironolactone* (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism in selected cases.
- *Tinasteride* (5 mg daily), a 5oe-reductase inhibitor which prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is awaited.

It should be noted that none of these drugs is actually licensed in the UK for the treatment of hirsutism; while spironolactone and cyproterone are widely used, both are subject to Committee of Safety of Medicine (CSM) warnings. Flutamide, another antiandrogen, is not used owing to the high incidence of hepatic side-effects.

Treatment of menstrual disturbance

Cyclical oestrogen/progestogen will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism, but may also be used when menstrual disturbance is the only symptom.

Drugs to improve the hyperinsulinaemia associated with PCOS and obesity are increasingly used (and requested by patients). Metformin (500 mg three times daily) improves menstrual cyclicity and ovulation in short-term studies, and some patients also report improvement in hirsutism and ease of weight loss - but gastrointestinal upset may limit use. Glitazones are also effective, but there are few studies of currently-available preparations.

Treatment for fertility

- Metformin alone may improve ovulation and achieve conception.
- Clomifene 50-100 mg can be given daily on days 2-6 of the cycle. This can occasionally cause the *ovarian hyperstimulation syndrome,* an iatrogenic complication of ovulation-induction therapy, causing ovarian en largement, oedema, hypovolaemia, renal failure, and can lead to shock; specialist supervision is essential. It is recommended that clomifene should not normally be used for longer than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).
- *Reverse arcadian rhythm.* Prednisolone (2.5 mg in the morning, 5 mg on retiring) suppresses pituitary production of ACTH, upon which adrenal androgens partly depend. Regular ovulatory cycles often ensue. A steroid instruction leaflet and a card must be supplied.

More intensive techniques to stimulate ovulation may also be indicated in specialist hands, including low-dose *gonadotrophin therapy,* and ovarian hyperstimulation techniques associated with in vitro fertilization.

Wedge resection of the ovary was a traditional therapy which is rarely required, although laparoscopic ovarian electrodiathermy may be helpful.

Oral contraception

Malignancy

The combined oestrogen-progestogen pill is widely used for contraception and has a low failure rate (< 1 per 100 woman-years). 'Pills' contain 20-40 (xg of oestrogen, usually ethinylestradiol, together with a variable amount of one of several progestogens. The mechanism of action is twofold:

- suppression by oestrogen of gonadotrophins, thus preventing follicular development, ovulation and luteinization
- progestogen effects on cervical mucus, making it hostile to sperm, and on tubal motility and the endometrium.

Side-effects of these preparations are shown in Box 18.6. Most of the serious ones are rare and are less common on typical modern 20-30 u.g oestrogen pills, although evidence suggests that thromboembolism may be slightly more common on 'third-generation pills' containing desogestrel and gestodene (approx. 30/100 000 woman-years compared with 15/100 000 on older pills and 5/100 000 on no treatment) and on co-cyprindiol. While some problems require immediate cessation of the pill, other milder side-effects must be judged against the hazards of pregnancy occurring with inadequate contraception, especially if other effective methods are not practicable or acceptable.

Increase in cancer of the

Box 18.6 **Adverse effects and drug interactions of oral contraceptives (mixed oestrogen-progesterone combinations)**

Drug interactions (reduced contraceptive effect owing to enzyme induction)
Antibiotics
Barbiturates
Phenytoin
Carbamazepine
Rifampicin
St John's Wort

•Common reasons for stopping oral contraceptives

Hazards of the combined pill are increased in smokers, in obesity, in those with other risk factors for cardiovascular disease (e.g. hypertension, hyperlipidaemia, diabetes) especially in women aged over 35 years (avoid if over 50 years). The 'mini-pill' (progestogen only, usually norethisterone) is less effective but is often suitable where oestrogens are contraindicated (Box 18.6). A progesterone antagonist, mifepristone, in combination with a prostaglandin analogue, induces abortion of pregnancy at up to 9 weeks' gestation. It prevents progesterone-induced inhibition of uterine contraction.

Hyperprolactinaemia

Hyperprolactinaemia has many causes. Common pathological causes include prolactinoma, co-secretion of prolactin in acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovary syndrome, hypothyroidism and 'idiopathic' hyperprolactinaemia; rarer causes are oestrogen therapy (e.g. the 'pill'), renal failure, liver failure, post-ictal and chest wall injury. Dopamine antagonist drugs (metoclopramide, domperidone, phenothiazines) are a common iatrogenic cause, as well as most other antiemetics (except cyclizine) and opiates. Physiological hyperprolactinaemia occurs in pregnancy, lactation and severe stress, as well as during sleep and coitus. The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in Figure 18.14. Mildly increased prolactin levels (400-600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

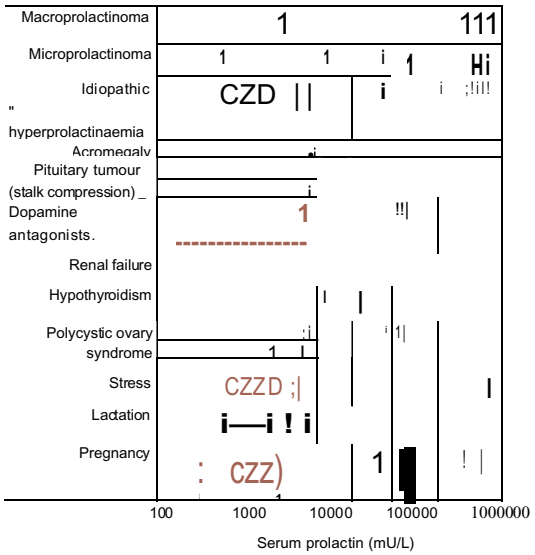

Fig. 18.14 Range of serum prolactin seen in common causes of hyperprolactinaemia.

Clinical features

Hyperprolactinaemia stimulates milk production in the breast and inhibits GnRH and gonadotrophin secretion per se. It usually presents with:

- galactorrhoea, spontaneous or expressible (60% of cases)
  oligomenorrhoea or amenorrhoea
  decreased libido in both sexes
  decreased potency in men
  subfertility
  symptoms or signs of oestrogen or androgen deficiency - in the long term osteoporosis may result, especially in women
- delayed or arrested puberty in the peripubertal patient.

Additionally, headaches and/or visual field defects may be present if there is a pituitary tumour (more common in men). Not all patients with galactorrhoea have hyperprolactinaemia, but the other causes are poorly understood - 'normoprolactinaemic galactorrhoea' and duct ectasia.

Investigations

Hyperprolactinaemia should be confirmed by repeat measurement. Further tests are appropriate after physiological and drug causes have been excluded:

- **Visual fields** should be checked.
- **Hypothyroidism** must be excluded since this is a cause of hyperprolactinaemia.
- **Anterior pituitary function** should be assessed if there is any clinical evidence of hypopituitarism or radiological evidence of a pituitary tumour (Table 18.9; Box 18.1 and Box 18.2).
- **MRI of the pituitary** is necessary if there are any clinical features suggestive of a pituitary tumour, and desirable in all cases when prolactin is significantly elevated (above 1000 mU/L).

In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary rumour causing stalk-disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or of no radiological abnormality), strongly suggest a prolactinoma (see p. 1044). Macroprolactinoma refers to tumours above 10 mm diameter, microprolactinoma to smaller ones.

Treatment

Hyperprolactinaemia should usually be treated to avoid **the** long-term effects of oestrogen deficiency (even if the patient would otherwise welcome the lack of periods!) or testosterone deficiency in the male. Exceptions include minor elevations (400-1000 mU/L) with preservation of normal regular menstruation (or normal male testosterone levels) and postmenopausal patients with microprolactinomas who are not taking oestrogen replacement. Hyperprolactinaemia is controlled with a dopamine agonist. Cabergoline (500 ug once or twice a week judged

on clinical response and prolactin levels) is the best tolerated and longest-acting drug. Bromocriptine is the longest-established therapy and therefore preferred if pregnancy is planned: initial doses should be small (e.g. 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation and cold peripheries. Quinagolide (75-150 ig once daily) is another alternative. These dopamine receptor agonists have been associated with pulmonary, retroperitoneal and pericardial fibrotic reactions and patients need careful monitoring.

Definitive therapy will depend upon the size of the tumour, the patient's wishes, including desire for fertility, and local expertise and facilities. In most cases a dopamine agonist will be the first and only therapy. Prolactinomas usually shrink in size on a dopamine agonist; in macroadenomas any pituitary mass effects commonly resolve and in most cases it is simply sufficient to continue successful dopamine agonist therapy in the long term. Prolactin should therefore always be measured before surgery on any mass in the pituitary region. Microprolactinomas may not recur after several years of dopamine agonist therapy in a substantial minority of cases, but in the majority hyperprolactinaemia will recur if treatment is stopped.

Trans-sphenoidal surgery may restore normoprolactinaemia in patients with microadenoma, but is rarely completely successful with macroadenomas and risks damage to normal pituitary function. Therefore most patients and physicians elect to continue medical therapy rather than proceed to surgery. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult - but others dissent from this view.

Radiotherapy usually controls adenoma growth and is slowly effective in lowering prolactin but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially where families are complete, but many workers simply advocate continuation of dopamine agonist therapy in responsive cases.

Rarely, tumours enlarge during pregnancy to produce headaches and visual defects. Dopamine agonists, which are traditionally stopped during pregnancy, should be restarted.

SUBFERTILITY

mtr

Subfertility, or 'infertility', is defined as the inability of a couple to conceive after 1 year of unprotected intercourse. Investigation requires the combined skills of gynaecologist, endocrinologist and, ideally, andrologist. Both partners must be involved and every aspect of the physiology critically examined.

Causes (Fig. 18.15)

A significant proportion of couples have both male and female contributing factors.

Inadequate intercourse, hostile cervical mucus and vaginal factors are uncommon (5%). Fifteen per cent of cases appear to be idiopathic, and natural fertility decreases with increasing age.

Male factors

About 30-40% of couples have a major identifiable male factor. There is some evidence that male sperm counts are declining in many populations. Untreated male hypogonadism of any cause (see Table 18.13) is likely to be associated with subfertility.

Female factors

Female tubal problems account for perhaps 20%; a similar proportion have ovulatory disorders. Any cause of oligomenorrhoea or amenorrhoea (see Table 18.17) is likely to be associated with suboptimal ovulation or anovulation.

Clinical assessment

Both partners should be seen and the following factors checked:

- *The man.* Look for previous testicular damage (orchitis, trauma), undescended testes, urethral symptoms and venereal problems, local surgery, and use of alcohol and drugs. A semen analysis early in the investigations is essential.
- *The woman.* Look for previous pelvic infection, regularity of periods, previous surgery, alcohol intake and smoking, and adequacy of bodyweight (see p. 1057).
- *Together.* Check the frequency and adequacy of inter course, and the use of lubricants.

Investigations

Appropriate tests for particular defects are shown in Figure 18.15.

Treatment

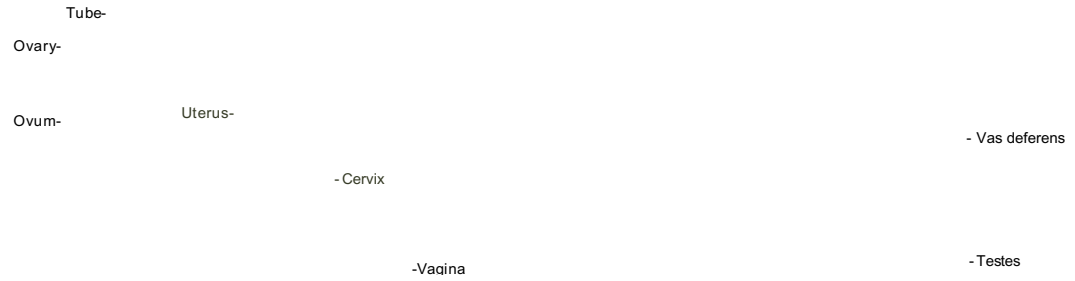
Counselling of both partners is essential. Any defect(s) found should be treated if possible. Ovulation can usually be induced by exogenous hormones if simpler measures fail, while in vitro fertilization (IVF) and similar techniques are widely used, especially where there is tubal blockage, oligospermia or 'idiopathic subfertility'. Intracytoplasmic sperm injection (ICSI) appears particularly effective for severe oligospermia and poor sperm function.

DISORDERS OF SEXUAL DIFFERENTIATION

Disorders of sexual differentiation are rare but may affect chromosomal, gonadal, endocrine and phenotypic development (Table 18.18). Such cases always require extensive, multidisciplinary clinical management. An individual's sex can be defined in several ways:

- *Chromosomal sex.* The normal female is 46XX, the normal male 46XY. The Y chromosome confers male sex; if it is not present, development follows female lines.

Female factors				Joint factors	Male factors		
? Ovulation	? Tubal problems	? Uterine problems	? Cervix Vaginal problems	? Adequate intercourse	? Normal sperm count		
	Patency Function	Anatomy Implantation	Infection Cervical hostility	Frequency Timing Technique	Potency blockage	Vas	Testicular disease



Investigation:

	Hysteroscopy				Testosterone	
Serum progesterone					Testicular biopsy	
Laparoscopy / Egg collection						

Fig. 18.15 **Major factors involved in subfertility and their investigation.** LH, luteinizing hormone; FSH, follicle-stimulating hormone.

Table 18.18 **Disorders of sexual differentiation**

Condition	Chromosomes	Gonads	Phenotype	Remarks
Turner's syndrome	45X (50%) 46,X,i(Xq)(5-10%) 45,X, mosaicism (remainder)	Streak	Female	Often morphological features (e.g. short stature, web neck, coarctation of aorta)
Gonadal dysgenesis	46XY	Streak or minimal testes*	Immature female	
Congenital adrenal hyperplasia	46XX	Ovary	Female with variable virilization	Obvious androgen excess
Virilizing tumour	46XX	Ovary	Female with variable virilization	Obvious androgen excess
True hermaphroditism	46XX/XY or mosaic	Testis and ovary	Male or ambiguous	
Klinefelter's syndrome	47XXY	Small testes	Male, often with gynaecomastia	Many are hypogonadal
Testicular feminization	46XY	Testes*	Ambiguous or infantile female	Androgen receptor defective
Testicular synthetic defects	46XY	Testes*	Cryptorchid, ambiguous	
5a-Reductase deficiency	46XY	Testes	Cryptorchid, ambiguous	Impaired conversion of testosterone to dihydrotestosterone
Anorchia	46XY	Absent	Immature female	

'Gonadectomy advised because of high risk of malignancy, i = isochromosome

Gonadal sex. This is obviously determined predominantly by chromosomal sex, but requires normal embryological development.
Phenotypic sex. This describes the normal physical appearance and characteristics of male and female body shape. This in turn is a manifestation of gonadal sex and subsequent sex hormone production. *Social sex (gender).* This is heavily dependent on phenotypic sex and normally assigned on appearance of the external genitalia at birth. *Sexual orientation* - heterosexual, homosexual or bisexual.

THE GROWTH AXIS

Physiology and control of growth hormone (GH) (Fig. 18.16)

GH is the pituitary factor responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control by somatostatin. A separate GH stimulating system involves a distinct receptor (GH secretogogue receptor), which interacts with ghrelin (see p. 254). It is not known how these two systems interact. GH acts through a single transmembrane receptor, followed by saturation of Janus kinases (see p. 157). GH acts by binding to a specific (single transmembrane) receptor located mainly in the liver. This induces an intracellular phosphorylation cascade involving the JAK/STAT (signal transducing activators of transcription) pathway (p. 157). This leads to hepatic synthesis and secretion of IGF (insulin-like growth factor-1) which stimulates growth. Plasma levels of IGF-1, however, reflect local growth activity poorly, partly as there are multiple IGF-binding proteins (IGF-BP) - mainly IGF-BP3. The metabolic actions of the system are:

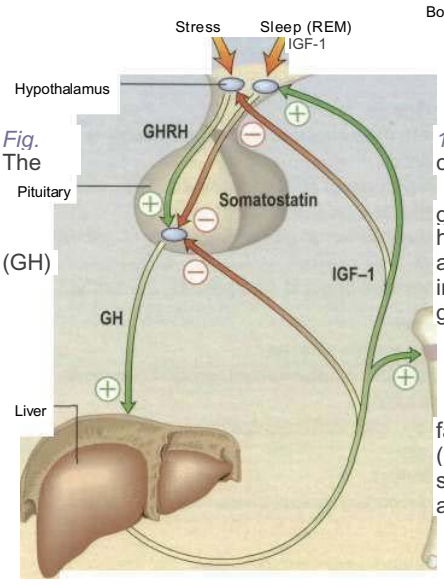

Fig. 18.16 The control of growth hormone and insulin-like growth factor-1 (IGF-1) secretion and action.

Ghrelin is a growth hormone-releasing peptide and is produced in the stomach.

- increasing collagen and protein synthesis
- promoting retention of calcium, phosphorus and nitrogen, necessary substrates for anabolism
- opposing the action of insulin.

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release while, in the normal subject, hyperglycaemia suppresses it.

IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

Normal growth

There are factors other than GH involved in linear growth in the human.

- *Genetic factors.* Children of two short parents will probably be short and vice versa.
- *Nutritional factors.* Adequate nutrients must be available. Impaired growth can result from inadequate dietary intake or small-bowel disease (e.g. coeliac disease).
- *General health.* Any serious systemic disease in childhood is likely to reduce growth (e.g. renal failure).
- *Intrauterine growth retardation.* These infants often grow poorly in the long term, while infants with

Box 18.7 **Assessment of problems of growth and development**

History

Pregnancy records

Rate of growth (home/school records, e.g. heights on kitchen door)

Comparison with peers at school and siblings Change in appearance (old photographs) Change in shoe/glove/hat size or frequency of 'growing out' Age of appearance of pubic hair, breasts, menarche

Physical signs

Evidence of systemic disease

Body habitus, size, relative weight, proportions (span versus height)

Skin thickness, interdental separation Facial features Spade hands/feet Grading of secondary sexual characteristics

simple prematurity usually catch up. There is some evidence that low birthweight may predispose to hypertension, diabetes and other health problems in later adult life (p. 229).

- *Emotional deprivation and psychological factors.* These can impair growth by complex, poorly understood mechanisms, probably involving temporarily decreased GH secretion.

The relevant aspects of history and examination in the assessment of problems are shown in Box 18.7.

Assessment of growth

Charts showing ranges of height and weight for normal British children are available (Fig. 18.17), and other national data are available. Height must be measured very carefully, ideally at the same time of day on the same instrument by the same observer.

In general, there are three overlapping phases of growth: infantile (0-2 years), which appears largely substrate (food) dependent; childhood (age 2 years to puberty), which is largely GH dependent; and the adolescent 'growth spurt', dependent on GH and sex hormones.

Height velocity is more helpful than current height. It requires at least two measurements some months apart and, ideally, multiple serial measurements. Height velocity is the rate of current growth (cm per year), while already attained height is largely dependent upon previous growth.

Standard deviation scores (SDS) based on the degree of deviation from age-sex norms are widely used by experts - these and growth velocities are far more sensitive than simple charts in assessing growth. Computer programs also allow calculation of many of these indices.

The approximate future height of a child ('mid-parental height') can be simply predicted from the parental heights. For a boy, this is:

[(Maternal height + 14 cm (5.5 inches) + Paternal height)/2]

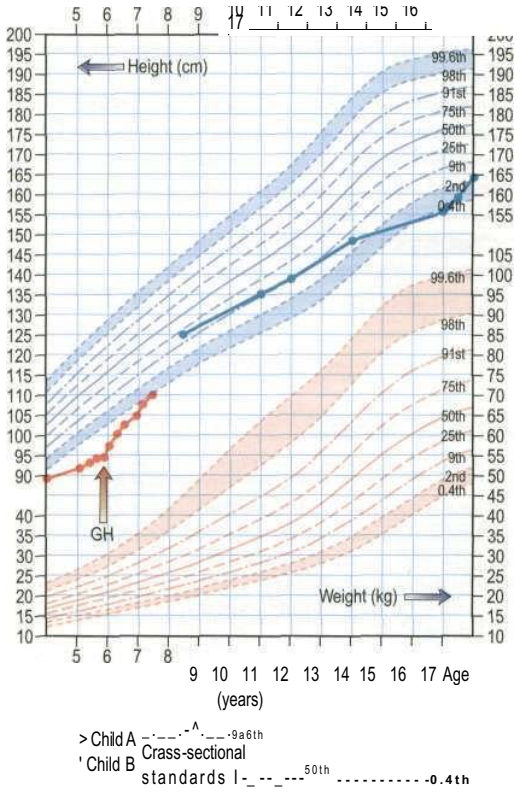

Fig. 18.17 **A height chart for boys. Child A illustrates the course of a child with hypopituitarism,** initially treated with cortisol and thyroxine, but showing growth only after growth hormone treatment. **Child B shows the course of a child with constitutional growth delay without treatment.** (Chart © the Child Growth Foundation.)

and for a girl:

[(Paternal height - 14 cm (5.5 inches) + Maternal height)/2].

Thus, with a father of 180 cm and mother of 154 cm, the predicted heights are 174 cm for a son and 160 cm for a daughter.

GROWTH FAILURE: SHORT STATURE

When children or their parents complain of short stature, particular attention should focus on:

- intrauterine growth retardation, weight and gestation at birth
- possible systemic disorders - any system, but especially small-bowel disease
- evidence of skeletal, chromosomal or other congenital abnormalities
- endocrine status - particularly thyroid
- dietary intake and use of drugs, especially steroids for asthma
- emotional, psychological, family and school problems.

Table 18.19 **Clinical features of common causes of short stature**

Cause	Family history	Growth pattern, clinical features and puberty	Bone age	Remarks
Constitutional delay	Often present	Slow from birth, immature but appropriate with late but spontaneous puberty	Moderate delay	Often difficult to differentiate from GH deficiency Growth velocity measurement vital
Familial short stature	Positive	Slow from birth, clinically normal with normal puberty	Normal	Need heights of family members Growth velocity normal
GH insufficiency	Rare	Slow growth, immature, often overweight, delayed puberty	Moderate delay, increasing with time	Early investigation and treatment vital Increased suspicion if child is plump Measure TSH, T_4
Primary hypothyroidism	Rare	Slow growth, immature and delayed puberty	Marked delay	in all cases of short stature Clear clinical signs not obvious
Small bowel disease	Sometimes	Slow, immature, usually thin for height, delayed puberty	Delayed	Diarrhoea and/or macrocytosis/anaemia Occasionally no GI symptoms

School, general practitioner, clinic and home records of height and weight should be obtained if possible to allow growth-velocity calculation. If unavailable, such data must be obtained prospectively.

A child with normal growth velocity is unlikely to have significant endocrine disease. However, low growth velocity without apparent systemic cause requires further investigation. Sudden cessation of growth suggests major physical disease; if no gastrointestinal, respiratory, renal or skeletal abnormality is apparent, then a cerebral tumour or hypothyroidism is likeliest.

Consistently slow-growing children require full endocrine assessment. Features of the more common causes of growth failure are given in Table 18.19.

Around the time of puberty, where constitutional delay is clearly shown and symptoms require intervention, then very-low-dose sex steroids in 3- to 6-month courses will usually induce acceleration of growth.

Investigations

Systemic disease having been excluded, the following should be undertaken:

- **Thyroid function tests** - serum TSH and free T_4 to exclude hypothyroidism.
- **GH status.** Basal levels are of little value, though urinary GH measurements may prove to be of some value in screening. Dynamic tests include the GH response to insulin (the 'gold standard'; Box 18.4), arginine, exercise, clonidine and Bovril. Tests should only be performed in centres experienced in their use and interpretation. Normal responses depend on test and GH assay used.
- **Assessment of bone age.** Non-dominant hand and wrist X-rays allow assessment of bone age by comparison with standard charts.

Treatment

Systemic illness should be treated and primary hypothyroidism replaced with thyroxine.

For GH insufficiency, recombinant GH (somatropin) is given as nightly injections in doses of 0.17-0.35 mg/kg per week. Treatment is expensive and should be supervised in expert centres. Human GH (collected from pituitaries) was previously used but was withdrawn as cases of Creutzfeldt-Jakob disease were reported.

GH treatment in so-called 'short normal' children has not been shown to produce any worthwhile increase in final height. In Turner's syndrome (see p. 1064) large doses of GH are effective in increasing final height, especially in combination with appropriate very-low-dose oestrogen replacement. Familial cases of resistance to GH owing to an abnormal GH receptor (Laron-type dwarfism) are well described. They are very rare but may respond to therapy with synthetic IGF-1.

TALL STATURE

The most common causes are hereditary (two tall parents!), idiopathic (constitutional) or early development. It can occasionally be due to hyperthyroidism. Other causes include chromosomal abnormalities (e.g. Klinefelter's syndrome, Marfan's syndrome) or metabolic abnormalities. GH excess is a very rare cause and is usually clinically apparent.

GROWTH HORMONE EXCESS: GIGANTISM AND ACROMEGALY

GH stimulates skeletal and soft-tissue growth. GH excess therefore produces gigantism in children (if acquired before epiphyseal fusion) and acromegaly in adults.

Acromegaly

This is due to a pituitary tumour in almost all cases. Hyperplasia due to GHRH excess is very rare. Overall incidence is approximately 3-4/ million per year and prevalence 50-80/million.

Clinical features

Symptoms and signs of acromegaly are shown in Figure 18.18. One-third of patients present with changes in appearance, one-quarter with visual field defects or headaches; in the remainder the diagnosis is made by an alert observer in another clinic, e.g. GP, diabetic, hypertension, dental, dermatology.

Investigations

- **GH levels** may exclude acromegaly if undetectable but a detectable value is non-diagnostic. Normal adult levels are < 1 mU/L for most of the day except during stress or a 'GH pulse'.
- **The glucose tolerance test** is diagnostic. Acromegalics fail to suppress GH below 1 mU/L and some show a paradoxical rise; about 25% of acromegalics have a diabetic glucose tolerance test.
- **IGF-1 levels** are almost always raised in acromegaly - a single plasma level of IGF-1 reflects mean 24-hour GH levels and is useful in diagnosis.
- **Visual field defects** are common.
- **MRI scan of pituitary** - will almost always reveal the pituitary adenoma.
- **Pituitary function** - partial or complete anterior hypopituitarism is common.
- **Prolactin** - mild to moderate hyperprolactinaemia occurs in 30% of patients (Fig. 18.14). In some, the adenoma secretes both GH and prolactin.

Management and treatment

Untreated acromegaly results in markedly reduced survival with most deaths from heart failure, coronary artery disease and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large-bowel tumours. Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. There is now consensus agreement that the aim of therapy should be to achieve a mean growth hormone level below 5 mU/L, which has been shown to reduce mortality to normal levels.

Complete cure is often slow, if possible at all. The choice lies between trans-sphenoidal surgery, pituitary radiotherapy, somatostatin analogues, and growth hormone agonists dopamine agonists. Progress can be assessed by monitoring GH and IGF-1 levels. The general pros and cons of surgery, radiotherapy and medical treatment are discussed on page 1045.

When present, hypopituitarism should be corrected (see p. 1048) and concurrent diabetes and/or hypertension should be treated conventionally; both usually improve with treatment of the acromegaly.

Surgery

Trans-sphenoidal surgery is generally agreed as the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60-90%) with pituitary microadenoma, but in only 50% of those with macroadenoma. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas.

Pituitary radiotherapy

External radiotherapy is normally used after pituitary

Symptoms

Change in appearance
Increased size of hands/feet
Headaches Excessive sweating
Visual deterioration Tiredness
Weight gain Amenorrhoea
oligomenorrhoea
in women Galactorrhoea
Impotence or poor libido Deep voice Goitre
Breathlessness Pain/tingling in hands Polyuria/polydipsia
Muscular weakness Joint pains

Old photographs are frequently useful Symptoms of hypopituitarism may also be present

Signs

Prominent supraorbital ridge
Prognathism Interdental separation Large tongue
Hirsutism Thick greasy skin
Spade-like hands and feet
Tight rings
Carpal tunnel syndrome
Visual field defects
Galactorrhoea
Hypertension
Oedema
Heart failure
Arthropathy
Proximal myopathy
Glycosuria
(plus possible signs of hypopituitarism)

Fig. 18.18 **Acromegaly - symptoms and signs.** Bold type indicates signs of greater discriminant value.

surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment with a somatostatin analogue or a dopamine agonist because of the slow biochemical response to radiotherapy, which may take 10 years or more. Stereotactic radiotherapy is used in some centres.

Somatostatin analogues

Octreotide and lanreotide are synthetic analogues of somatostatin (p. 1065) which are the treatment of choice in resistant cases, and employed as a short-term treatment while other modalities become effective. They reduce GH and IGF levels in most patients. Both drugs are typically administered as monthly depot injections and are generally well tolerated but are associated with an increased incidence of gallstones and are expensive.

Dopamine agonists

Dopamine agonists were the original medical therapy for acromegaly, and remain useful in some cases. They can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed growth-hormone-producing (somatotroph) and prolactin-producing (mammotroph) tumours. The doses are bromocriptine 10-60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas) but should be started slowly (see p. 1063). Given alone they reduce GH to 'safe' levels in only a minority of cases - but may be useful for mild residual disease or in combination with somatostatin analogues.

Growth hormone antagonists

Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist which has its effect by binding to and preventing dimerization of the GH receptor. It has been shown to normalize IGF-1 levels in 90% of patients. Its main role at the present time is treatment of patients in whom GH and IGF levels cannot be reduced to safe levels with somatostatin analogues alone, surgery or radiotheraphy.

THE THYROID AXIS

The metabolic rate of many tissues is controlled by the thyroid hormones, and overactivity and underactivity of the gland are the most common of all endocrine problems.

Anatomy

The thyroid gland consists of two lateral lobes connected by an isthmus. It is closely attached to the thyroid cartilage and to the upper end of the trachea, and thus moves on swallowing. It is often palpable in normal women.

Embryologically it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of descent. The gland has a rich blood supply from superior and inferior thyroid arteries.

The thyroid consists of follicles lined by cuboidal epithelioid cells. Inside is the colloid, which is an iodinated glycoprotein, thyroglobulin, synthesized by the follicular cells. Each follicle is surrounded by basement membrane, between which are parafollicular cells containing calcitonin-secreting C cells.

Biochemistry

The thyroid hormones, T_4 and T_3, are synthesized within the gland (Fig. 18.19).

More T_4 than T_3 is produced, but T_4 is converted in some peripheral tissues (liver, kidney and muscle) to the more active T_3 by 5'-monodeiodination; an alternative 3'-monodeiodination yields the inactive reverse T_3 (rT_3). The latter step occurs particularly in severe non-thyroidal illness (see below).

In plasma, more than 99% of all T_4 and T_3 is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for tissue action, where T_3 binds to specific nuclear receptors within the cell. Factors affecting TBG are shown in Table 18.20; all may result in

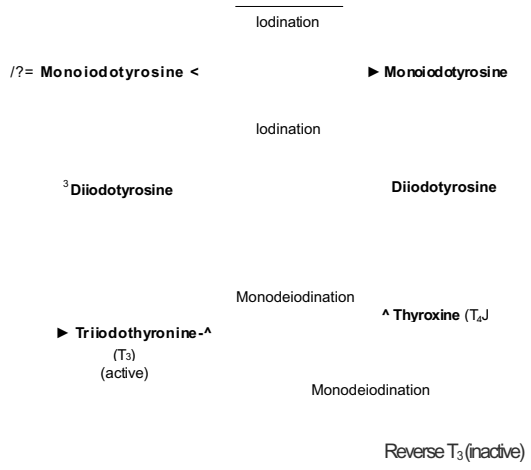

Fig. 18.19 Synthesis and metabolism of the thyroid hormones.

Table 18.20 **Factors affecting thyroxine-binding globulin (TBG) levels**

Increased TBG
Hereditary Pregnancy
Oestrogen therapy Oral contraceptive use
Hypothyroidism
Phenothiazines Acute viral hepatitis

Decreased TBG
Hereditary Androgens
Corticosteroid excess
Thyrotoxicosis Nephrotic syndrome Major illness
Malnutrition Chronic liver disease

Drug causing altered binding
Non-steroidal anti-inflammatory drugs
Phenytoin

confusing total T_4 levels in blood, and most laboratories therefore now measure free T_4 levels.

Iodine deficiency

Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 jig, and dietary supplementation of salt and bread has reduced the number of areas where 'endemic goitre' still occurs (see below).

Physiology of the hypothalamic-pituitary-thyroid axis (see Fig. 18.1)

1. TRH is released in the hypothalamus and stimulates release of TSH from the pituitary.
2. TSH stimulates the TSH receptor in the thyroid to increase synthesis of both T_4 and T_3 and also to release stored hormone, producing increased plasma levels of T_4 and T_3.
3. T_3 feeds back on the pituitary and perhaps hypo thalamus to reduce TRH and TSH secretion.

Thyroid function tests

Immunoassays for free T_4, free T_3 and TSH are widely available. There are only minor circadian rhythms, and measurements may be made at any time. Particular uses of the tests are summarized in Table 18.21, with typical findings in common disorders.

TSH measurement

TSH levels can discriminate between hyperthyroidism, hypothyroidism and euthyroidism. There are pitfalls, however. These are mainly with hypopituitarism, with the 'sick euthyroid' syndrome and with dysthyroid eye disease, all of which may give 'false' (i.e. misleading, not incorrect) low results implying hyperthyroidism. As a single test of thyroid function it is the most sensitive in most circumstances, but accurate diagnosis requires at least two tests - for example, TSH plus free T_4 or free T_3 where hyperthyroidism is suspected, TSH plus serum free T_4 where hypothyroidism is likely.

'Free' T_4 tests

These attempt to measure only the unbound active hormone. Although not perfect, they are in routine clinical use in most laboratories. TBG can also be measured directly.

TRH test

This has been rendered almost obsolete by modern sensitive TSH assays except for investigation of hypothalamic-pituitary dysfunction.

Problems in interpretation of thyroid function tests

There are three major areas of difficulty.

Serious acute or chronic illness

Thyroid function is affected in several ways: (a) reduced concentration and affinity of binding proteins, (b) decreased peripheral conversion of T_4 to T_3 with more rT_3 and (c) reduced hypothalamic-pituitary TSH production. Systemically ill patients can therefore have an apparently low total and free T_4 and T_3 with a normal or low basal TSH (the 'sick euthyroid' syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

Table 18.21 **Characteristics of thyroid function tests in common thyroid disorders (the clinically most informative tests in each situation are shown in bold)**

	TSH (0.3-3.5 mU/L)	Free T_4 (10-25 pmol/L)	Free T_3 (3.5-7.5 pmol/L)
Thyrotoxicosis	**Suppressed (< 0.05 mU/L)**	**Increased**	**Increased**
Primary hypothyroidism	**Increased (> 10 mU/L)**	Low/low-normal	Normal or low
TSH deficiency	Low-normal or subnormal	**Low/low-normal**	Normal or low
T_3 toxicosis	Suppressed (< 0.05 mU/L)	Normal **Normal**	**Increased**
Compensated euthyroidism	**Slightly increased (5-10 mU/L)**		**Normal**

Pregnancy and oral contraceptives
These lead to greatly increased TBG levels and thus to high or high-normal total T_4. Free T_4 is usually normal. Normal ranges for free T_4 and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely cause clinical problems.

Drugs
Many drugs affect thyroid function tests by interfering with protein binding. The most common are listed in Table 18.20. Basal TSH should be measured.

Antithyroid antibodies

Serum antibodies to the thyroid are common and may be either destructive or stimulating; both occasionally coexist in the same patient.

Destructive antibodies may be directed against the microsomes or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10-20% of these develop overt hypothyroidism.

TSH receptor IgG antibodies (TRAb) typically stimulate, but occasionally block, the receptor; they can be measured in two ways:

- by the inhibition of binding of TSH to its receptors (TSH-binding inhibitory immunoglobulin, TBII)
- by demonstrating that they stimulate the release of cyclic AMP (thyroid-stimulating immunoglobulin/ antibody TSI, TSAb).

HYPOTHYROIDISM

Pathophysiology

Underactivity of the thyroid is usually primary, from disease of the thyroid, but may be secondary to hypothalamic-pituitary disease (reduced TSH drive) (Table 18.22). It is one of the most common endocrine conditions with an overall UK prevalence of over 1% in women, but under 0.1% in men; lifetime prevalence for an individual is higher - perhaps as high as 9% for women and 1% for men with mean age at diagnosis around 60 years.

Causes of primary hypothyroidism

Atrophic (autoimmune) hypothyroidism
This is the most common cause of hypothyroidism and is associated with antithyroid autoantibodies leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune disease such as pernicious anaemia, vitiligo and other endocrine deficiencies (p. 1041). In some instances intermittent hypothyroidism occurs with recovery; antibodies which block the TSH receptor may sometimes be involved in the aetiology.

Table 18.22 **Causes of hypothyroidism** **1**

PRIMARY	**POST-SURGERY**
Congenital	*Post-irradiation*
Agenesis	Radioactive iodine therapy
Ectopic thyroid remnants	External neck irradiation
Defects of hormone synthesis	*Infiltration*
Iodine deficiency	Tumour
Dyshormonogenesis	**SECONDARY**
Antithyroid drugs Other drugs (e.g. lithium, amiodarone, interferon)	*Hypopituitarism*
	Isolated TSH deficiency
Autoimmune	*Peripheral resistance to thyroid hormone*
Atrophic thyroiditis	
Hashimoto's thyroiditis	
Postpartum thyroiditis	
Infective	
Post-subacute thyroiditis	

Hashimoto's thyroiditis
This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (> 1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, 'Hashi-toxicity'. Thyroxine therapy may shrink the goitre even when the patient is not hypothyroid.

Postpartum thyroiditis
This is usually a transient phenomenon observed following pregnancy and may involve hyperthyroidism, hypothyroidism or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism.

Iodine deficiency
In mountainous areas (the Alps, Himalayas, South America, Central Africa) dietary iodine deficiency still exists, in some areas as 'endemic goitre' where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency.

Dyshormonogenesis
This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with a goitre. One particular familial form is associated with sensorineural deafness (Pendred's syndrome).

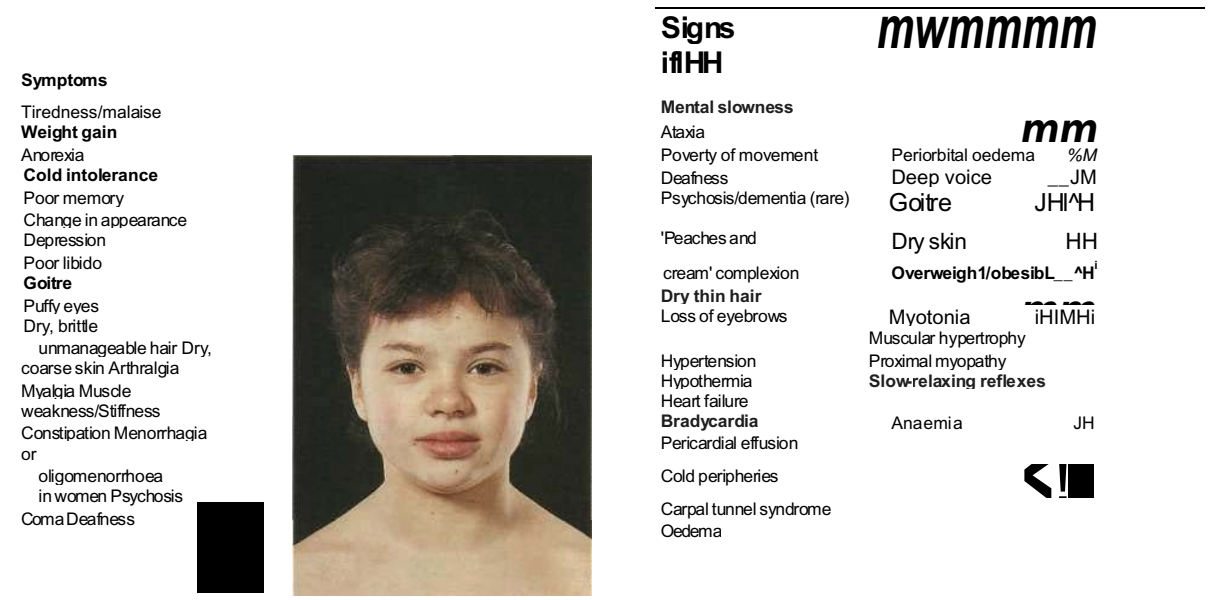

Fig. 18.20 **Hypothyroidism - symptoms and signs.** Bold type indicates signs of greater discriminant value. A history from a relative is often revealing. Symptoms of other autoimmune disease may be present.

Clinical features (Fig. 18.20)

Hypothyroidism may produce many symptoms. The alternative term 'myxoedema' refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain, cold intolerance, bradycardia and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of non-specific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:

- *Children with hypothyroidism* may not show classic features but often have a slow growth velocity, poor school performance and sometimes arrest of pubertal development.
- *Young women with hypothyroidism* may not show obvious signs. Hypothyroidism should be excluded in all patients with oligomenorrhoea/amenorrhoea, menorrhagia, infertility or hyperprolactinaemia.
- *The elderly* show many clinical features that are difficult to differentiate from normal ageing.

Investigation of primary hypothyroidism

Serum TSH is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free T_4 level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

anaemia, which is usually normochromic and normocytic in type but may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia)

- *increased serum aspartate transferase levels,* from muscle and/or liver
- *increased serum creatine kinase levels,* with associated myopathy
- *hypercholesterolaemia*
- *hyponatraemia* due to an increase in ADH and impaired free water clearance.

Treatment

Replacement therapy with levothyroxine (thyroxine, i.e. T_4) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially cardiac performance. In the young and fit, 100 fig daily is suitable, while *50* ug daily (increased to 100 iig after 2-4 weeks) is more appropriate for the small, old or frail. Patients with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and long-standing. Most physicians would then begin with 25 |Xg daily and perform serial ECGs, increasing the dose at 3- to 4-week intervals if angina does not occur or worsen and the ECG does not deteriorate.

Adequacy of replacement should be assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose; the aim is to restore T_4 and TSH to well within the normal range. If serum TSH remains high, the dose of T_4 should be increased in increments of 25-50 |ig and the tests repeated 6 weeks later. This stepwise progression should be continued until TSH becomes normal, though some physicians believe that complete well-being is only restored in some patients when the T_4 is high-normal and the TSH is slightly suppressed. The usual maintenance dose is 100-150 fig given as a single

daily dose; over-replacement may increase the risk of atrial fibrillation in those aged over 60. An annual thyroid function test is recommended - this is usually performed in the primary care setting, often assisted and prompted by district 'thyroid registers'.

Clinical improvement on T_4 may not begin for 2 weeks or more and full resolution of symptoms may take 6 months. The importance of lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison's disease or pernicious anaemia, should be considered. During pregnancy, an increase in T_4 dosage of about 25-50 |lg is often needed to maintain normal TSH levels, and the necessity of optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

Borderline hypothyroidism or 'compensated euthyroidism'

Patients are frequently seen with low-normal serum T_4 levels and slightly raised TSH levels. Sometimes this follows surgery or radioactive iodine therapy when it can reasonably be seen as 'compensatory'. Treatment with thyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3-6 months later. Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in patients with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a 'therapeutic trial' of replacement may be needed to confirm that symptoms are unrelated to the thyroid.

Myxoedema coma

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare: hypothermia is often present and the patient may have severe cardiac failure, hypoventilation, hypoglycaemia and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data lacking; most physicians would advise T_3 orally or intravenously in doses of 2.5-5 u,g every 8 hours, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

oxygen (by ventilation if necessary) monitoring of cardiac output and pressures gradual rewarming hydrocortisone 100 mg i.v. 8-hourly glucose infusion to prevent hypoglycaemia.

'Myxoedema madness'

Depression is common in hypothyroidism but rarely with severe hypothyroidism in the elderly the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting T_4 replacement.

Screening for hypothyroidism

The incidence of congenital hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage ('cretinism'). Routine screening of the newborn using a blood-spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if T_4 is started within the first few months of life.

Screening of elderly patients for thyroid dysfunction has a low pick-up rate, is controversial and not currently recommended. However, patients who have undergone thyroid surgery or received radioiodine should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

HYPERTHYROIDISM

Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2-5% of all females at some time and with a sex ratio of 5 :1, most often between ages 20 and 40 years. Nearly all cases (> 99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (Table 18.23).

Graves' disease

This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to the thyroid TSH receptor stimulating thyroid hormone production, behaving like TSH. These TSH receptor antibodies can be measured in serum. There is an

Table 18.23 **Causes of hyperthyroidism**

Common
Graves' disease (autoimmune)
Toxic multinodular goitre
Solitary toxic nodule/adenoma

Uncommon
Acute thyroiditis
- viral (e.g. de Quervain's)
- autoimmune
- post-irradiation
- postpartum

Gestational thyrotoxicosis (HCG stimulated) Neonatal thyrotoxicosis (maternal thyroid antibodies) Exogenous iodine Drugs - amiodarone Thyrotoxicosis factitia (secret T_4 consumption)

Rare
TSH-secreting pituitary tumours
Metastatic differentiated thyroid carcinoma
HCG-producing tumours
Hyperfunctioning ovarian teratoma (struma ovarii)

association with HLA-B8, DR3 and DR2 and 50% concordance is seen amongst monozygotic twins with a 5% concordance rate in dizygotic twins.

Yersinia enterocolitica as well as *Escherichia coli* and other Gram-negative organisms contain TSH binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible 'molecular mimicry' in a genetically susceptible individual, but the precise initiating mechanisms remain unproven in most cases.

Thyroid eye disease accompanies the hyperthyroidism in many cases (see below) but other components of Graves' disease, e.g. Graves' dermopathy, are very rare. Rarely lymphadenopathy and splenomegaly may occur. Graves' disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo and myasthenia gravis.

The natural history is one of fluctuation, many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.

Other causes of hyperthyroidism/ thyrotoxicosis

Toxic solitary adenoma/nodule (Plummer's disease)

This is the cause of about 5% of cases of hyperthyroidism. It does not usually remit after a course of antithyroid drugs.

Toxic multinodular goitre

This commonly occurs in older women. Again, antithyroid drugs are rarely successful in inducing a remission - although they can control the hyperthyroidism.

de Quervain's thyroiditis

This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase. Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis

This is described on page 1071.

Clinical features of hyperthyroidism

The symptoms and signs of hyperthyroidism affect many systems (Fig. 18.21).

Symptomatology and signs vary with age and with the underlying aetiology.

- *The eye signs, pretibial myxoedema and thyroid acropachy* occur only in Graves' disease. Pretibial myxoedema is an infiltration on the shin, essentially occurring only with eye disease (see below). Thyroid acropachy is very rare and consists of clubbing, swollen fingers and periosteal new bone formation.
- *In the elderly,* a frequent presentation is with atrial fibrillation, other tachycardias and/or heart failure, often with few other signs. Thyroid function tests are mandatory in any patient with atrial fibrillation.
- *Children* frequently present with excessive height or excessive growth rate, or with behavioural problems

Symptoms

Weight loss
Increased appetite
Irritability/behaviour change
Restlessness
Malaise
Stiffness
Muscle weakness
Tremor
Choreoathetosis
Breathlessness
Palpitation
Heat intolerance
Itching
Thirst
Vomiting
Diarrhoea
Eye complaints*
Goitre
Oligomenorrhoea
Loss of libido
Gynaecomastia
Onycholysis
Tall stature (in children)
Sweating

*Only in Graves' disease

Signs

Tremor
Hyperkinesis
Irritability
Psychosis

Tachycardia or atrial fibrillation Full pulse
Warm vasodilated peripheries Systolic hypertension Cardiac failure

Exophthalmos* Lid lag and 'stare'
Conjunctival oedema
Ophthalmoplegia*
Periorbital oedema
Goitre, bruit
Weight loss

*Only in Graves' disease

Proximal myopathy
Proximal muscle wasting
Onycholysis Palmar erythema

Graves' dermopathy*
Thyroid acropachy
Pretibial myxoedema

Fig. 18.21 Hyperthyroidism - symptoms and signs. Bold type indicates signs of greater discriminant value.

Table 18.24 **Drugs used in the treatment of hyperthyroidism**

Drug	Usual starting dose	Side-effects	Remarks
Antithyroid drugs			
Carbimazole	20-40 mg daily, 8-hourly, or in single dose	Rash, nausea, vomiting, arthralgia, agranulocytosis (0.1%), jaundice	Active metabolite is thiamazole (methimazole) Mild immunosuppressive activity
Propylthiouracil	100-200 mg 8-hourly	Rash, nausea, vomiting, agranulocytosis	Additionally blocks conversion of T_4 to T_3
Beta-blocker for symptomatic control			
May need higher doses than normal in hyperthyroidism as metabolism is increased			
Propranolol	40-80 mg every 6-8 hours	Avoid in asthma Use with care in heart failure	Use agents without intrinsic sympathomimetic activity as receptors highly sensitive

such as hyperactivity. They may also show weight gain rather than loss.

- *So-called 'apathetic thyrotoxicosis'* in some elderly patients presents with a clinical picture more like hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

Differential diagnosis

Hyperthyroidism is often clinically obvious but treatment should never be instituted without biochemical confirmation.

Differentiation of the mild case from anxiety states may be difficult; useful positive clinical markers are eye signs, a diffuse goitre, proximal myopathy and wasting. The hyperdynamic circulation with warm peripheries seen with hyperthyroidism can be contrasted with the clammy hands of anxiety.

Investigations

Serum TSH is suppressed in hyperthyroidism (< 0.05 mU/L), except for the very rare instances of TSH hypersecretion. Diagnosis is confirmed with a raised free T_4 or T_3; T_4 is almost always raised but T_3 is more sensitive as there are occasional cases of isolated 'T_3 toxicosis'. TPO and thyroglobulin antibodies are present in most cases of Graves' disease.

TSH receptor antibodies are not measured routinely, but are commonly present: thyroid-stimulating immunoglobin (TSI) 80% positive, TSH-binding inhibitory immunoglobin (TBII) 60-90% in Graves' disease (see p. 1073).

Treatment

Three possibilities are available: antithyroid drugs, radioiodine and surgery. Practices and beliefs differ widely within and between countries.

Antithyroid drugs

Carbimazole is most often used in the UK, and propylthiouracil is also used. Thiamazole (methimazole), the active metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiamazole is also an immunosuppressive agent. Initial doses and side-effects are detailed in Table 18.24.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T_4 (7 days) means that clinical benefit is not apparent for 10-20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers may be used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T_4 to T_3. Drugs preferred are those without intrinsic sympathomimetic activity, e.g. propranolol (Table 18.24). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or a 'block and replace' regimen. Neither regimen has been shown to be unequivocally superior.

Gradual dose titration

1. Review after 4-6 weeks and reduce dose of carbimazole depending on clinical state and T_4/T_3 levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
2. When clinically and biochemically euthyroid, stop beta-blockers.
3. Review after 2-3 months and, if controlled, reduce carbimazole.
4. Gradually reduce dose to 5 mg daily over 6-24 months if hyperthyroidism remains controlled.
5. When the patient is euthyroid on 5 mg daily carbimazole, discontinue.

Propylthiouracil is used in similar fashion (Table 18.24).

'Block and replace' regimen

With this policy, full doses of antithyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 ug of thyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of over- or undertreatment and the better use of the immunosuppressive action of carbimazole. This regimen is

contraindicated in pregnancy as T_4 crosses the placenta less well than carbimazole.

Relapse

About 50% of patients will relapse after a course of carbimazole or propylthiouracil, mostly within the following 2 years but occasionally much later. Long-term antithyroid therapy is then used or surgery or radio therapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre but those with large single or multinodular goitres are unlikely to remit after a course of antithyroid drugs. Severe bio chemical hyperthyroidism is also less likely to remain in remission.

Toxicity

The major side-effect is agranulocytosis that occurs in approximately 1 in 1000 patients usually within 3 months of treatment. All patients must be warned to seek immediate medical attention if they develop unexplained fever or sore throat - written information is essential. Rashes are more frequent and usually require a change of drug. If toxicity occurs on carbimazole, propylthiouracil may be used and vice versa; side-effects are only occasionally repeated on the other drug.

Radioactive iodine

Radioactive iodine (RAI) may be given to patients of all ages, although it is contraindicated in pregnancy and while breast-feeding. RAI is the most common treatment modality in the USA whereas antithyroid drugs tend to be favoured in Europe. Iodine-131 in an empirical dose (usually 200-500 MBq), accumulates in the thyroid and destroys the gland by local radiation - though it takes several months to be fully effective. Strict radiation safety rules apply in the UK and may be inconvenient or disconcerting for some patients. Patients must be rendered euthyroid before treatment though they have to stop antithyroid drugs at least 4 days before radioiodine, and not recommence until 3 days after radioiodine. (Many patients who are well controlled before RAI do not need to restart at all.)

Early discomfort in the neck and immediate worsening of hyperthyroidism are sometimes seen; if worsening occurs, the patient should receive propranolol (Table 18.24); if necessary carbimazole can be restarted. Euthyroidism normally returns in 2-3 months. Patients with dysthyroid eye disease are more likely to show worsening of eye problems after radioiodine than after antithyroid drugs; this represents a partial contraindication to RAI, although worsening can usually be prevented by steroid administration.

Apart from the immediate problems above, a major complication is the progressive incidence of subsequent hypothyroidism affecting the majority of subjects over the following 20 years. Though 75% of patients are rendered euthyroid in the short term, a small proportion remain hyperthyroid; increasing the radioiodine dose improves the speed and rate of response but increases the rate of hypothyroidism. Long-term surveillance of thyroid function is necessary with frequent tests in the first year after therapy, and at least annually thereafter.

Risk of carcinogenesis has been long debated, but it is now clear that overall cancer incidence and mortality are not increased after radioactive iodine (and indeed are significantly reduced in some studies) but the risk of thyroid cancer is significantly increased, although the risk remains very low in absolute terms.

Surgery: subtotal thyroidectomy

Thyroidectomy should be performed only in patients who have previously been rendered euthyroid. Conventional practice is to stop the antithyroid drug 10-14 days before operation and to give potassium iodide (60 mg three times daily), which reduces the vascularity of the gland.

The operation should be performed only by experienced surgeons to reduce the chance of complications:

- Early postoperative bleeding causing tracheal com pression and asphyxia is a rare emergency requiring immediate removal of all clips/sutures to allow escape of the blood/haematoma.
- Laryngeal nerve palsy occurs in 1%. Vocal chord movement should be checked preoperatively. Mild hoarseness is more common and thyroidectomy is best avoided in professional singers!
- Transient hypocalcaemia occurs in up to 10% but with permanent hypoparathyroidism in fewer than 1%.
- Recurrent hyperthyroidism occurs in 1-3% within 1 year, then 1% per year.
- Hypothyroidism occurs in about 10% of patients with in 1 year, and this percentage increases with time. It is likeliest if TPO antibodies are positive. Automated computer thyroid registers with annual TSH screening are used in some regions, and have demonstrated that a high proportion of patients become hypothyroid in the long term.

Choice of therapy

Indications for either surgery or radioiodine are:

- patient choice
- persistent drug side-effects
- poor compliance with drug therapy
- recurrent hyperthyroidism after drugs.

Particular indications for surgery include:

- a large goitre, which is unlikely to remit after anti thyroid medication.

Special situations in hyperthyroidism

Thyroid crisis or 'thyroid storm'

This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia and extreme restlessness. It is usually precipitated by stress, infection, surgery in an unprepared patient, or radioiodine therapy. With careful management it should no longer occur and most cases referred as 'crisis' are simply severe but uncomplicated thyrotoxicosis.

Treatment is urgent. Propranolol in full doses is started immediately together with potassium iodide, antithyroid drugs, corticosteroids (which suppress many of the manifestations of hyperthyroidism) and full supportive measures.

Hyperthyroidism in pregnancy and neonatal life

Maternal hyperthyroidism during pregnancy is uncommon and usually mild. Diagnosis can be difficult because of misleading thyroid function tests, although TSH is largely reliable. The pathogenesis is almost always Graves' disease. Thyroid-stimulating immunoglobulin (TSI) crosses the placenta to stimulate the fetal thyroid. Carbimazole also crosses the placenta, but T_4 does so poorly so a 'block-and-replace' regimen is contra-indicated. The smallest dose of carbimazole necessary is used and the fetus must be monitored (see below). The paediatrician should be informed and the infant checked immediately after birth - overtreatment with carbimazole can cause fetal goitre. Breast-feeding while on usual doses of carbimazole or propylthiouracil appears to be safe.

If necessary (high doses needed, poor patient compliance or drug side-effects), surgery can be performed, preferably in the second trimester. Radioactive iodine is absolutely contraindicated.

The fetus and maternal Graves' disease

Any mother with a history of Graves' disease may have circulating TSI. Even if she has been treated (e.g. by surgery), the immunoglobulin may still be present to stimulate the fetal thyroid, and the fetus can thus become hyperthyroid, while the mother remains euthyroid.

Any such patient should therefore be monitored during pregnancy. Fetal heart rate provides a direct biological assay of fetal thyroid status, and monitoring should be performed at least monthly. Rates above 160 per minute are strongly suggestive of fetal hyperthyroidism, and maternal treatment with carbimazole and/or propranolol may be used. To prevent the mother becoming hypothyroid, T_4 may be given as this does not easily cross the placenta. Sympathomimetics, used to prevent premature labour, are contraindicated as they may provoke fatal tachycardia in the fetus.

Hyperthyroidism may also develop in the neonatal period as TSI has a half-life of approximately 3 weeks. Manifestations in the newborn include irritability, failure to thrive and persisting weight loss, diarrhoea and eye signs. Thyroid function tests are difficult to interpret as neonatal normal ranges vary with age.

Untreated neonatal hyperthyroidism is probably associated with hyperactivity in later childhood.

Thyroid hormone resistance

Thyroid hormone resistance is an inherited condition caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback control mechanisms (see Fig. 18.1, p. 1037) result in high blood levels of thyroxine with a normal TSH in order to maintain a euthyroid state. This has two consequences:

- First, thyroid function tests appear abnormal even when the patient is euthyroid and requires no treatment; this is not a particular problem as free T_4 and TSH levels are measured.
- Second, different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so that these tissues may exhibit 'thyrotoxic' effects in spite of a normal serum TSH. This 'partial thyroid hormone resistance' can be very difficult to manage effectively.

Long-term consequences of hyperthyroidism

Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis.

THYROID EYE DISEASE

This is also known as dysthyroid eye disease or ophthalmic Graves' disease.

Pathophysiology

The ophthalmopathy of Graves' disease is due to a specific immune response that causes retro-orbital inflammation. Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis which is usually bilateral but can sometimes be unilateral. Ultimately increased pressure on the optic nerve may cause optic atrophy. Histology shows focal oedema and glycosaminoglycan deposition followed by fibrosis. The precise autoantigen which leads to the immune response remains to be identified, but it appears to be an antigen in retro-orbital tissue with similar immunoreactivity to the TSHreceptor.

Eye disease is a manifestation of Graves' disease and can occur in patients who may be hyperthyroid, euthyroid or hypothyroid. TSH receptor antibodies are almost invariably found in the serum but their role in the pathogenesis is unclear. Ophthalmopathy is more common in smokers.

Clinical features

The clinical appearances are characteristic (Fig. 18.21) but thyroid eye disease demonstrates a wide range of severity. A high proportion of patients with Graves' disease notice some soreness, painful watering or prominence of the eyes and the 'stare' of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement and visual impairment due to optic nerve compression are

relatively uncommon. Proptosis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is periorbital oedema and conjunctival oedema and inflammation.

Eye manifestations do not parallel the degree of biochemical thyrotoxicosis, nor the need for antithyroid therapy, but exacerbation of eye disease is more common after radioiodine treatment (15% vs 3% on antithyroid drugs). Only 5-10% of cases threaten sight, but the discomfort and cosmetic problems cause great patient anxiety.

Investigations

Few investigations are necessary if the appearances are characteristic and bilateral. TSH, T_3 and free T_4 are measured.

There are a variety of grading systems but none is universally accepted. It is essential to clearly document eye movements and the degree of oedema and inflammation. The exophthalmos should be measured to allow progress to be monitored. If appearances or measurements are markedly discrepant in the two eyes, other retro-orbital space-occupying lesions should be considered: MRI of the orbits will exclude other causes and show enlarged muscles and oedema.

Treatment

If the patient is thyrotoxic this should be treated, but this will not directly result in an improvement of the ophthalmopathy, and hypothyroidism must be avoided as this may exacerbate the eye problem. Smokers should be advised to stop. Treatment of the eyes may be either local or systemic, and always requires close liaison between specialist endocrinologist and ophthalmologist:

- *Methylcellulose or hypromellose eyedrops* are given to aid lubrication and improve comfort.
- *Some patients gain relief by sleeping upright.* The eyelids can be taped to ensure closure at night.
- *Systemic steroids* (prednisolone 30-120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be more rapidly effective in severe cases.
- *Irradiation of the orbits* (20 Gy in divided doses) is used in severe instances. This improves inflammation and occular motility but has little effect on proptosis.
- *Lid surgery* will protect the cornea if lids cannot be closed.
- *Surgical decompression of the orbit(s)* is occasionally needed.
- *Corrective eye muscle surgery* may improve diplopia due to muscle changes, but should be deferred until the situation has been stable for 6 months. Plastic surgery around the eyes may also be of value.

GOITRE (THYROID ENLARGEMENT)

Goitre is more common in women than in men and may be either physiological or pathological.

Clinical features

Goitres are present on examination in up to 9% of the population. Most commonly a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency and mobility of the gland as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient's clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are:

- Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
- Pain in a goitre may be caused by thyroiditis, bleeding into a cyst or (rarely) a thyroid tumour.
- Excessive doses of carbimazole or propylthiouracil will induce goitre.
- Iodine deficiency and dyshormonogenesis (see above) can also cause goitre.

Assessment

There are two major aspects of any goitre: its pathological nature and the patient's thyroid status.

The nature can often be judged clinically. Goitres (Table 18.25) are usually separable into diffuse and nodular types, the causes of which differ.

Diffuse goitre

Simple goitre

In this instance no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

Table 18.25 **Goitre - causes and types**

Diffuse	**Nodular**
Simple	Multinodular goitre Solitary nodular Fibrotic (Reidel's thyroiditis) **Cysts**
Physiological (puberty, pregnancy) Autoimmune	**Tumours**
Graves' disease	Adenomas
Hashimoto's disease	Carcinoma
Thyroiditis	Lymphomas
Acute (de Quervain's thyroiditis) Iodine deficiency (endemic goitre)	**Miscellaneous**
Dyshormonogenesis Goitrogens (e.g. sulphonylureas)	Sarcoidosis Tuberculosis

Autoimmune thyroid disease v f
Hashimoto's thyroiditis and thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

Thyroiditis :-
Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de Quervain's). This is usually associated with a systemic viral illness and may produce transient clinical hyperthyroidism with an increase in serum T_4 (see p. 1074).

Nodular goitres

Multinodular goitre

Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may be hyperthyroid or borderline with suppressed TSH levels but normal T_4 and T_3. Multinodular goitre is the most common cause of tracheal and/ or oesophageal compression and can cause laryngeal nerve palsy. It may also extend retrosternally. The classical 'multinodular goitre' is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

Solitary nodular goitre

Such a goitre presents a difficult problem of diagnosis. Malignancy should be considered in any solitary nodule - however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multinodular goitre. The diagnostic challenge is to identify the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. A history of pain, rapid enlargement or associated lymph nodes in such a situation suggests the possibility of thyroid carcinoma, but investigations are paramount. Risk factors for malignancy include previous irradiation, long-standing iodine deficiency and occasional familial cases.

Solitary toxic nodules (Plummer's syndrome) are quite uncommon and may be associated with T_3 toxicosis.

Fibrotic goitre

Fibrotic goitre (Riedel's thyroiditis) is a rare condition, usually producing a 'woody' gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard.

Malignancy

In addition to thyroid carcinomas (see below), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.

Investigations

Clinical findings will dictate appropriate initial tests:

Thyroid function tests - TSH plus free T_4 or T_3 (see Table 18.21).

Ultrasound. Ultrasound with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and performed under ultrasound control at the same time as the scan.

Chest and thoracic inlet X-rays to detect tracheal compression and large retrosternal extensions in patients with very large goitre or clinical symptoms.

Fine-needle aspiration (FNA). In patients with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy; in view of this, FNA should be performed. This can be done in the outpatient clinic. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodule.

FNA has reduced the need for isotope scans and reduces the necessity for surgery, but there is a 5% false-negative rate which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.

Thyroid scan. FNA has largely replaced isotope scans in the diagnosis of thyroid nodules. Thyroid scan (^{125}I or ^{131}I) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is rarely malignant; however, a cold nodule is malignant in 10% of cases.

Treatment

Many goitres are small, cause no symptoms and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. When thyroid function is abnormal the patient should be rendered euthyroid. Indications for surgical intervention are:

- *The possibility of malignancy. A* history of rapid growth, pain, cervical lymphadenopathy, change in voice or previous irradiation to the neck are worrying features. A positive or suspicious FNA makes surgery mandatory and surgery may be necessary if doubt persists even in the presence of a negative FNA (especially if the patient is concerned by the false negative rate).
- *Pressure symptoms on the trachea or, more rarely, oesophagus.* The possibility of retrosternal extension should be excluded.
- *Cosmetic reasons. A* large goitre is often a considerable anxiety to the patient even though functionally and anatomically benign.

Table 18.26 **Types of thyroid malignancy**

Cell type	Frequency	Behaviour	Spread	Prognosis
Papillary	70%	Occurs in young people	Local, sometimes lung/bone secondaries	Good, especially in young
Follicular	20%	More common in females	Metastases to lung/bone	Good if resectable
Anaplastic	<5%	Aggressive	Locally invasive	Very poor
Lymphoma	2%	Variable		Sometimes responsive to radiotherapy
Medullary cell	5%	Often familial	Local and metastases	Poor, but indolent course

THYROID CARCINOMA

Types of thyroid carcinoma, their characteristics and treatment are listed in Table 18.26. While not common, these tumours are responsible for 400 deaths annually in the UK. In 90% of cases they present as thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic or bone metastases.

Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated) or anaplastic (undifferentiated), while medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. Lymphomas also arise within the thyroid. The pathogenesis of thyroid epithelial carcinomas is not understood except for occasional familial papillary carcinoma and those cases related to previous head-and-neck irradiation or ingestion of radioactive iodine (e.g. post-Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker.

Papillary and follicular carcinomas

The primary treatment is surgical, normally total or near-total thyroidectomy for local disease. Regional, or more extensive, neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine. If initial disease is extensive (or 'high risk') or if thyroglobulin levels rise during follow-up, patients may be given a therapeutic radioiodine dose (high dose: 5.5-7.5 GBq), which will be taken up by remaining thyroid tissue or metastatic lesions. After ablation of normal thyroid in this way, radioiodine scanning may be used to localize residual disease (using low doses) or to treat it (using high doses). Local invasion and lymph node involvement is most common and lungs and bone are the most common sites of distant metastases.

Where surgical excision is histologically complete and/or radioiodine therapy and scanning completed, patients are placed on suppressive doses of thyroxine (sufficient to suppress TSH levels below the normal range). Patient progress is monitored both clinically and biochemically using serum thyroglobulin levels as a tumour marker; levels are low on thyroxine unless there is residual tumour. The measurement of thyroglobulin is either by following the withdrawal of thyroxine therapy (for periods sufficient to significantly raise the TH), or more easily, by using recombinant TSH (thyrotropin alfa, rhTSH).

The prognosis is extremely good when these types of tumour are excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Age below 40 years and papillary tumours do better than those over 40 and with a follicular histology.

Anaplastic carcinomas and lymphoma

These do not respond to radioactive iodine, and external radiotherapy produces only a brief respite.

Medullary carcinoma

Medullary carcinoma, often associated with multiple endocrine neoplasia (MEN 2, see p. 1099), is usually treated by total thyroidectomy. Local invasion or metastasis is frequent, and the tumour responds poorly to treatment, although progression is often slow. The patient's family should be screened for this and other endocrine neoplastic conditions.

THE GLUCOCORTICOID AXIS

Adrenal anatomy and function

The human adrenals weigh 8-10 g together and comprise an outer cortex with three zones (reticularis, fasciculata and glomerulosa) producing steroids, and an inner medulla that synthesizes, stores and secretes catecholamines (see adrenal medulla, p. 1098).

The adrenal steroids are grouped into three classes based on their predominant physiological effects.

Table 18.27 The major actions of glucocorticoids

Increased or stimulated	Decreased or inhibited
Gluconeogenesis Glycogen deposition Protein catabolism Fat deposition Sodium retention Potassium loss Free water clearance Uric acid production Circulating neutrophils	Protein synthesis Host response to infection Lymphocyte transformation Delayed hypersensitivity Circulating lymphocytes Circulating eosinophils

Glucocorticoids >

These are so named after their effects on carbohydrate metabolism. Major actions are listed in Table 18.27.

The relative potency of common steroids is shown in Table 18.28.

Mineralocorticoids

Their predominant effect is on the extracellular balance of **sodium and** potassium in **the distal tubule** of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution. The mineralocorticoid activity of cortisol is weak but it is present in considerable excess. However, the mineralocorticoid receptor in the kidney is largely protected from this excess by the intrarenal conversion ('shuttle') of cortisol to the inactive cortisone by the enzyme 11 p-hydroxysteroid dehydrogenase.

Table 18.28 The relative glucocorticoid and mineralocorticoid potency of equal amounts of common natural and synthetic steroids

Steroid	Glucoccorticol effect	Mineralocorticoid effect
Cortisol (hydrocortisone)*	**1**	1
Prednisolone	4	**0.7**
Dexamethasone	40	2
Aldosterone	0.1	400
Fludrocortisone	10	400

•Cortisol is arbitrarily defined as 1

Androgens

Although secreted in considerable quantities, most have only relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone.

Biochemistry

All steroids have the same basic skeleton (Fig. 18.22(b)) and the chemical differences between them are slight. The major biosynthetic pathways are shown in Figure 18.22(a).

Physiology

Glucocorticoid production by the adrenal is under hypothalamic-pituitary control (Fig. 18.23).

Corticotropin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress and

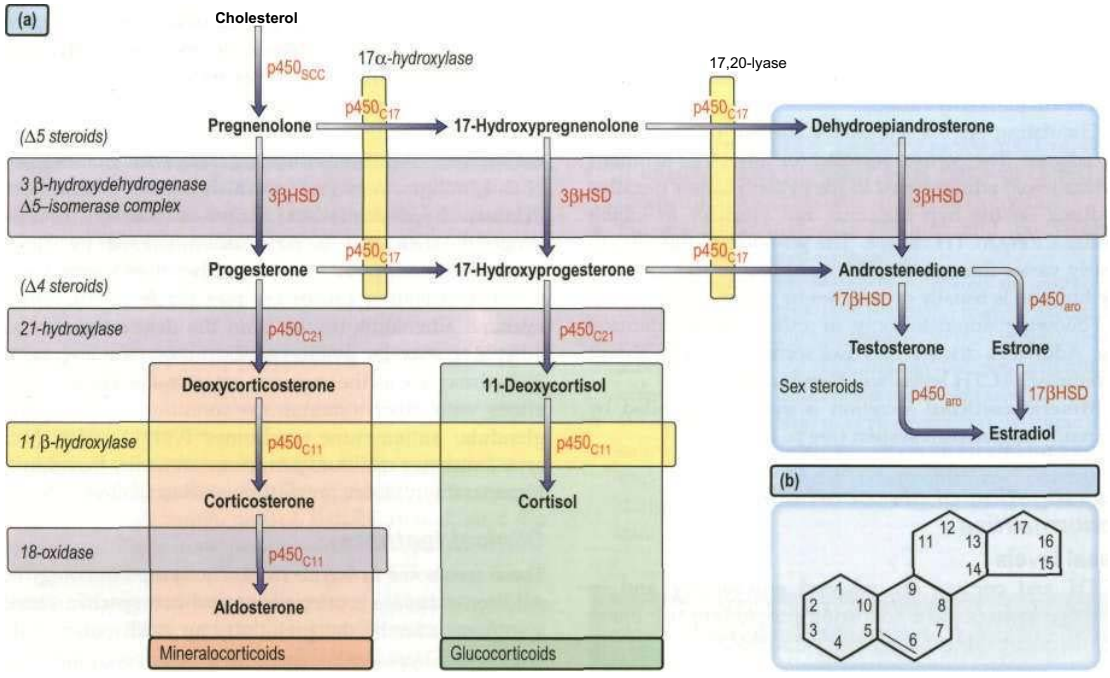

Fig. 18.22 **(a) The major steroid biosynthetic pathways.** Enzymes catalysing reactions are in red: p450 enzymes are in mitochondria and each catalyses several reaction steps; 3pHSD (hydroxysteroid dehydrogenase) is in cytoplasm, bound to endoplasmic reticulum; 17pHSD and $p450_{aro}$ are found mainly in gonads. (b) **The steroid molecule.**

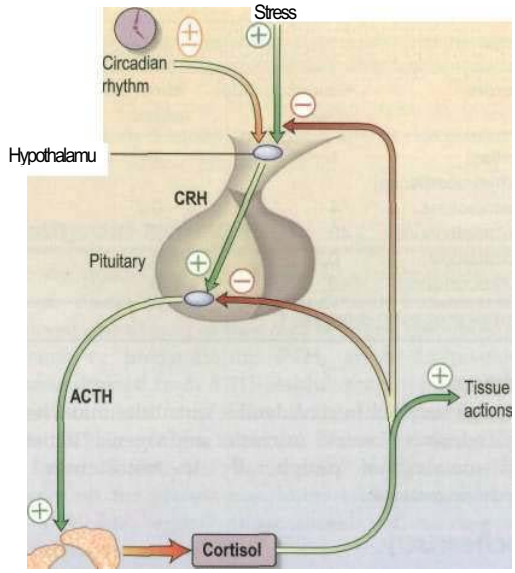

Fig. 18.23 Control of the hypothalamic-pituitary-adrenal axis. CRH, corticotropin-releasing hormone.

other stimuli. CRH travels down the portal system to stimulate ACTH release from the anterior pituitary. ACTH is derived from the prohormone pro-opiomelanocortin, which undergoes complex processing within the pituitary to produce ACTH and a number of other peptides including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)-like sequences which cause pigmentation when levels of ACTH are markedly raised.

Circulating ACTH stimulates cortisol production in the adrenal. The cortisol secreted (or any other synthetic corticosteroid administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system clearly varies through the day according to the circadian rhythm, and is usually overridden by severe stress.

Following adrenalectomy or other adrenal damage (e.g. Addison's disease), cortisol secretion will be absent or reduced; ACTH levels will therefore rise.

Mineralocorticoid secretion is mainly controlled by the renin-angiotensin system (see p. 1096).

Investigation of glucocorticoid abnormalities

Basal levels

ACTH and cortisol are released episodically and in response to stress. The following precautions are therefore necessary when taking a blood sample:

- Sampling time should be recorded accurately. Conventionally, basal levels are obtained at between 0800h and 0900h near the peak of the circadian variation.
- Stress should be minimized.
- Appropriate reference ranges (for time and assay method) should be used.

Suppression and stimulation tests are used in suspected excess and deficient cortisol production, respectively.

Dexamethasone suppression tests

Administration of a synthetic glucocorticoid to a normal subject produces prompt feedback suppression of CRH and ACTH levels and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays). Three forms of the test, used in the diagnosis and differential diagnosis of Cushing's syndrome, are available (Table 18.29).

ACTH stimulation tests

Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production. Details are given in Table 18.29 and Box 18.1 on page 1039.

Addison's disease: primary hypoadrenalism

Pathophysiology and causes

In this condition there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid and sex steroid production are therefore all reduced. (This differs from hypothalamic-pituitary disease, in which mineralocorticoid secretion remains largely intact, being predominantly stimulated by angiotensin II. Adrenal sex steroid production is also largely independent of pituitary action.) In Addison's disease reduced cortisol levels lead, through feedback, to increased CRH and ACTH production, the latter being directly responsible for the hyperpigmentation.

Incidence. Addison's disease is rare, with an incidence of 3-4/million/year and prevalence of 40-60/million. Primary hypoadrenalism shows a marked female preponderance and is most often caused by autoimmune disease (> 90% in UK) rather than tuberculosis (< 10%). All other causes are rare (Table 18.30). Autoimmune adrenalitis results from the destruction of the adrenal cortex by organ-specific autoantibodies, with 21-hydroxylase as the common antigen. There are associations with other autoimmune conditions in the polyglandular autoimmune syndromes Types I and II (e.g. type I diabetes mellitus, pernicious anaemia, thyroiditis, hypoparathyroidism, premature ovarian failure).

Clinical features

These are shown in Figure 18.24. The symptomatology of Addison's disease is often vague and non-specific. These symptoms may be the prelude to an Addisonian crisis with severe hypotension and dehydration precipitated by intercurrent illness, accident or operation.

Pigmentation (dull, slaty, grey-brown) is the predominant sign in over 90% of cases.

Table 18.29 Details of dexamethasone suppression and ACTH (synacthen) tests in the diagnosis of Cushing's syndrome and Addison's disease

Test and protocol	Measure	Normal test result or positive suppression	Use and explanation
Dexamethasone (for Cushing's)			
Overnight			
Take 1 mg on going to bed at 2300h	Plasma cortisol at 0900h next morning	Plasma cortisol < 100 nmol/L	Outpatient screening test Some 'false positives'
'Low-dose'			
0.5 mg 6-hourly Eight closes from 0900h on day 0	Plasma cortisol at 0900h on days 0 and +2	Plasma cortisol < 50 nmol/L on second sample	For diagnosis of Cushing's syndrome
'High-dose' used in differential diagnosis			
2 mg 6-hourly Eight doses from 0900h on day 0	Plasma cortisol at 0900h on days 0 and +2	Plasma cortisol on day +2 less than 50% of that on day 0 suggests pituitary-dependent disease	Differential diagnosis of Cushing's syndrome Pituitary-dependent disease suppresses in about 90% of cases
ACTH (synacthen) (for Addison's)			
Short			
Tetracosactide 250 |jg i.v. or i.m. at time 0	Plasma cortisol at times 0, +30 min	Cortisol at +30 min > 600 nmol/L	To exclude primary adrenal failure
Long			
Depot tetracosactide 1 mg i.m. at time 0	Plasma cortisol at times 0, +1, +2, +3, +4, +5, +8 and +24 h	Maximum > 1000 nmol/L Rise > 550 nmol/L	To demonstrate or exclude adrenal suppression (rather than primary adrenal failure)

Plasma cortisol values are very dependent upon the assay used - local reference ranges must be consulted

Table 18.30 Causes of primary hypoadrenalism

Autoimmune disease (approx. 90% in UK)	Infiltration Malignant destruction Amyloid Schilder's disease (adrenal leucodystrophy)
Tuberculosis (< 10% in UK)	
Surgical removal	
Haemorrhage/infarction)	
Meningococcal septicaemia	
Venography	

Postural systolic hypotension, due to hypovolaemia and sodium loss, is present in 80-90% of cases, even if supine blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

Investigations

Once Addison's disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone 100 mg should be given intramuscularly together with intravenous saline. Ideally this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Alternatively, an ACTH stimulation test can be performed immediately. Full investigation should be delayed until emergency treatment (see below) has improved the patient's condition. Otherwise, tests are as follows:

Single cortisol measurements are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol > 550 nmol/L makes the diagnosis unlikely (but not impossible).

The short ACTH stimulation test should be performed (see Table 18.29). An absent or impaired cortisol response is seen, confirmed if necessary by a long ACTH stimulation test to exclude adrenal suppression by steroids or ACTH deficiency. **A 0900h plasma ACTH level** - a high level (> 80 ng/L) with low or low-normal cortisol confirms primary hypoadrenalism.

Electrolytes and urea classically show hyponatraemia, hyperkalaemia and a high urea, but they can be normal.

Blood glucose may be low, with symptomatic hypoglycaemia.

Adrenal antibodies are present in many cases of autoimmune adrenalitis.

Chest and abdominal X-rays may show evidence of tuberculosis and/or calcified adrenals. **Serum aldosterone** is reduced with high plasma renin activity.

Hypercalcaemia and anaemia (after rehydration) are sometimes seen. They resolve on treatment, but are occasionally the first clue to the diagnosis.

Fig. 18.24 **Primary hypoadrenalism (Addison's disease) - symptoms and signs.** Bold type indicates signs of greater discriminant value.

Treatment

Acute hypoadrenalism needs urgent treatment (Emergency box 18.1).

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Table 1831. Dehydroepiandrosterone (DHEA) replacement has also been advocated, and studies suggest that this may cause symptomatic improvements, although long-term results are awaited.

Adequacy of glucocorticoid dose is judged by:

- clinical well-being and restoration of normal, but not excessive, weight
- normal cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids).

Fludrocortisone replacement is assessed by:

- restoration of serum electrolytes to normal
- blood pressure response to posture (it should not fall > 10 mmHg systolic after 2 minutes' standing)
- suppression of plasma renin activity to normal.

Patient advice

All patients requiring replacement steroids should:

- know how to increase steroid replacement dose for intercurrent illness
- carry a 'Steroid Card'
- wear a Medic-Alert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
- keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family or GP.

Emergency Box 18.1
Management of acute hypoadrenalism

Clinical context: hypotension, hyponatraemia, hyperkalaemia, hypoglycaemia, dehydration, pigmentation often with precipitating infection, infarction, trauma or operation. The major deficiencies are of salt, steroid and glucose.

Assuming normal cardiovascular function, the following are required:

One litre of 0.9% saline should be given over 30-60 minutes with 100 mg of intravenous bolus hydrocortisone.

Subsequent requirements are several litres of saline within 24 hours (assessing with central venous pressure line if necessary) plus hydrocortisone, 100 mg i.m., 6-hourly, until the patient is clinically stable.

Glucose should be infused if there is hypoglycaemia.

Oral replacement medication is then started, unless unable to take oral medication, initially hydrocortisone 20 mg, 8-hourly, reducing to 20-30 mg in divided doses over a few days (Table 18.31).

Fludrocortisone is unnecessary acutely as the high cortisol doses provide sufficient mineralocorticoid activity - it should be introduced later.

Table 18.31 **Average replacement steroid dosages for adults with primary hypoadrenalism**

Drug	Dose
Glucocorticoid	
Hydrocortisone	20-30 mg daily e.g. 10 mg on waking, 5 mg at 1200h, 5mgat 1800h
or	
Prednisolone	7.5 mg daily 5 mg on waking, 2.5 mg at 1800h
rarely	
Dexamethasone	0.75 mg daily 0.5 mg on waking, 0.25 mg at 1800h
Mineralocorticoid	
Fludrocortisone	50-300 |jg daily

Secondary hypoadrenalism

This may arise from hypothalamic-pituitary disease (inadequate ACTH production) or from long-term steroid therapy leading to hypothalamic-pituitary-adrenal suppression.

Most patients with the former have panhypopituitarism (see p. 1046) and need T_4 replacement as well as cortisol; in this case hydrocortisone must be started before T_4.

The most common cause of secondary hypoadrenalism is long-term corticosteroid medication for non-endocrine disease. The hypothalamic-pituitary axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. The long ACTH stimulation test should demonstrate a delayed cortisol response. Weaning off steroids is often a long and difficult process.

Cushing's syndrome

Cushing's syndrome is the term used to describe the clinical state of increased free circulating glucocorticoid. It occurs most often following the therapeutic administration of synthetic steroids or ACTH (see below). All the spontaneous forms of the syndrome are rare.

Pathophysiology and causes

Spontaneous Cushing's syndrome is rare, with an incidence of < 5/million/year.

Causes of Cushing's syndrome are usually subdivided into two groups (Table 18.32):

- increased circulating ACTH from the pituitary (65% of cases), known as Cushing's disease, or from an 'ectopic', non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequential glucocorticoid excess
- a primary excess of endogenous cortisol secretion (25% of spontaneous cases) by an adrenal tumour or nodular hyperplasia, with subsequent (physiological) suppression of ACTH. Rare cases are due to aberrant expression of receptors for other hormones (e.g. glucose-dependant insulinotrophic peptide [GIP], LH or catecholamines) in adrenal cortical cells.

***Table 18.32* Causes of Cushing's syndrome**

ACTH-dependent disease
Pituitary-dependent (Cushing's disease)
Ectopic ACTH-producing tumours ACTH administration
Non-ACTH-dependent causes
Adrenal adenomas Adrenal carcinomas Glucocorticoid administration
Others
Alcohol-induced pseudo-Cushing's syndrome

Clinical features

The predominant clinical features of Cushing's syndrome are those of glucocorticoid excess and are illustrated in Figure 18.25.

- *Pigmentation* occurs only with ACTH-dependent causes.

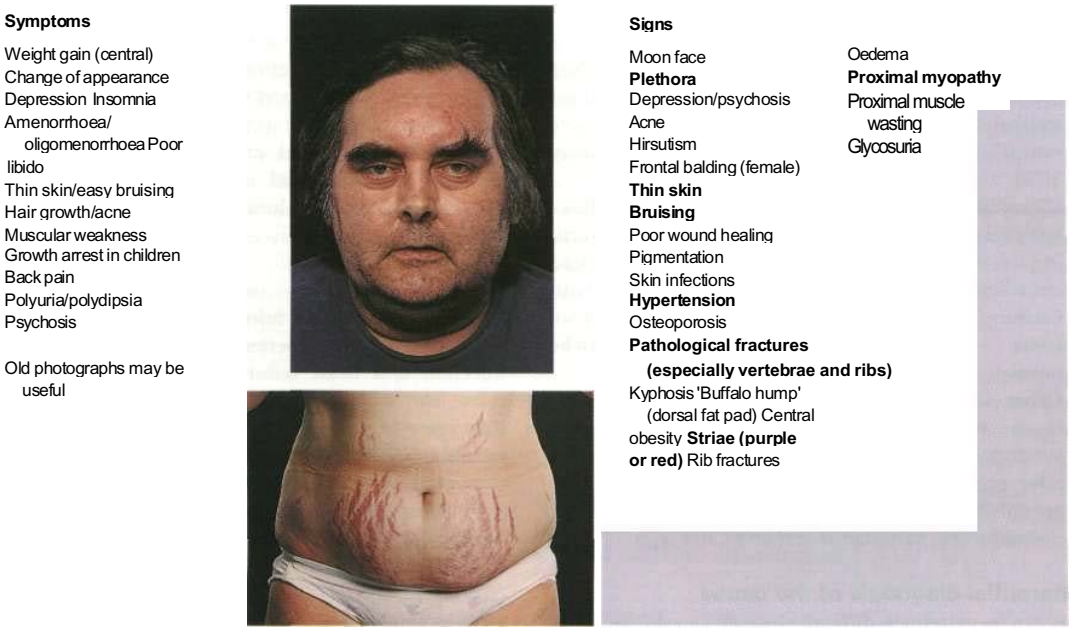

***Fig. 18.25* Cushing's syndrome - symptoms and signs.** Bold type indicates signs of most value in discriminating Cushing's syndrome from simple obesity and hirsutism.

A cushingoid appearance can be caused by excess alcohol consumption (pseudo-Cushing's syndrome) — the pathophysiology is poorly understood.

- *Impaired glucose tolerance* or frank diabetes are common, especially in the ectopic ACTH syndrome.
- *Hypokalaemia* due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.

Diagnosis

There are two phases to the investigation:

1. confirmation of the presence or absence of Cushing's syndrome
2. differential diagnosis of its cause (e.g. pituitary, adrenal or ectopic).

Confirmation

Most obese, hirsute, hypertensive patients do not have Cushing's syndrome, and some cases of genuine Cushing's have relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion, not suppressed by exogenous glucocorticoids: difficulties occur with obesity and depression where cortisol dynamics are often abnormal. Random cortisol measurements are of no value. Occasional patients are seen with so-called 'cyclical Cushing's' where the abnormalities come and go.

Investigations to confirm the diagnosis include:

- **48-hour low-dose dexamethasone test** (see Table 18.29). Normal individuals suppress plasma cortisol to < 50 nmol/L. Patients with Cushing's syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (> 97%). The overnight dexamethasone test is slightly simpler, but has a higher false-positive rate.
- **24-hour urinary free cortisol measurements.** This is simple, but less reliable - repeatedly normal values (corrected for body mass) render the diagnosis most unlikely, but some patients with Cushing's have normal values on some collections (approximately 10%).
- **Circadian rhythm.** After 48 hours in hospital, cortisol samples are taken at 0900h and 2400h (without warning the patient). Normal subjects show a pronounced circadian variation (see Fig. 18.2, p. 1038); those with Cushing's syndrome have high midnight cortisol levels (> 100 nmol/L), though the 0900h value may be normal.
- **Other tests.** There are frequent exceptions to the classic responses to diagnostic tests in Cushing's syndrome. If any clinical suspicion of Cushing's remains after preliminary tests then specialist investigations are still indicated, these may include insulin stress test, desmopressin stimulation test and CRH tests.

Differential diagnosis of the cause

This can be extremely difficult since all causes can result in clinically identical Cushing's syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmentation and weight loss, unprovoked hypokalaemia, clinical or chemical diabetes and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

- **Adrenal CT or MRI scan.** Adrenal adenomas and carcinomas causing Cushing's syndrome are relatively large and always detectable by CT scan. Carcinomas are distinguished by large size, irregular outline and signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.
- **Pituitary MRI.** A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.
- **Plasma potassium levels.** Hypokalaemia is common with ectopic ACTH secretion. (All diuretics must be stopped.)
- **High-dose dexamethasone test** (Table 18.29). Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH or an adrenal tumour.
- **Plasma ACTH levels.** Low or undetectable ACTH levels (< 10 ng/L) on two or more occasions are a reliable indicator of non-ACTH-dependent disease.
- **CRH test.** An exaggerated ACTH and cortisol response to exogenous CRH suggests pituitary-dependent Cushing's disease, as ectopic sources rarely respond.
- **Chest X-ray** is mandatory to look for a carcinoma of the bronchus or a bronchial carcinoid. Carcinoid lesions may be very small; if ectopic ACTH is suspected, whole-lung and mediastinal CT scanning should be performed.

Further investigations may involve selective catheterization of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body in a search for ectopic sources. Bronchoscopy, cytology and regional arteriograms are occasionally necessary. Radiolabelled octreotide (^{111}In octreotide) is occasionally helpful in locating ectopic ACTH sites.

Treatment

Untreated Cushing's syndrome has a very bad prognosis, with death from hypertension, myocardial infarction, infection and heart failure. Whatever the underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality is otherwise associated with operating on unprepared patients, especially when abdominal surgery is required. The usual drug is metyrapone, an 11(3-hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in three to four divided doses. Ketoconazole (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day to 150-300 nmol/L, equivalent to normal production rates.

Aminoglutethimide and trilostane (which reversibly inhibits 3(3-hydroxysteroid dehydrogenase/8-5,4 isomers) are occasionally used.

Choice of further treatment depends upon the cause.

Cushing's disease (pituitary-dependent hyperadrenalism)

m Trans-sphenoidal removal of the tumour is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH-deficient immediately post-operatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75-80% of cases - but results vary considerably and an experienced surgeon is essential.

- *External pituitary irradiation* alone is slow acting, only effective in 50-60% even after prolonged follow-up and mainly used after failed pituitary surgery. Children, however, respond much better to radiotherapy, 80% being cured.
- *Medical therapy* to reduce ACTH (e.g. bromocriptine, cyproheptadine) is rarely effective.
- *Bilateral adrenalectomy* is an effective last resort if other measures fail to control the disease. This can be performed laparoscopically.

Other causes

Adrenal adenomas should be resected after achievement of clinical remission with metyrapone or ketoconazole. Contralateral adrenal suppression may last for years.

Adrenal carcinomas are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug op'DDD (Mitotane) may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Some would also give radiotherapy to the tumour bed after surgery.

Tumours secreting ACTH ectopically should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour. Control of the Cushing's syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral adrenalectomy may be appropriate to give complete control of the Cushing's syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

Nelson's syndrome

Nelson's syndrome is increased pigmentation (because of high levels of ACTH) associated with an enlarging pituitary tumour, which occurs in about 20% of cases after bilateral adrenalectomy for Cushing's disease. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson's adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

Incidental adrenal tumours ('incidentalomas')

With the advent of abdominal CT, MRI and high-resolution ultrasound scanning, unsuspected adrenal masses have been discovered in 1% of scans. These obviously include the adrenal tumours described above, but cysts, myelolipomas and metastases are also seen. Functional tests to exclude secretory activity should be performed (adenomas often secrete cortisol at a low level); if none is found then most authorities recommend removal of large (> 4-5 cm) and functional tumours but observation of smaller hormonally inactive lesions.

Congenital adrenal hyperplasia (CAH)

Pathophysiology

This condition results from an autosomal recessive deficiency of an enzyme in the cortisol synthetic pathways. There are six major types, but most common is 21-hydroxylase deficiency which occurs in about 1 in 15 000 births and which has been shown to be due to defects on chromosome 6 near the HLA-region affecting one of the cytochrome p450 enzymes ($p450_{C2i}$).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion to maintain adequate cortisol - leading to adrenal hypoplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see Fig. 18.22(a)). Thus, 17-hydroxyprogesterone, androstenedione and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect llfi-hydroxylase, 17a-hydroxylase, 3fS-hydroxysteroid dehydrogenase and a cholesterol side-chain cleavage enzyme ($p450_{scc}$) (see Fig. 18.22(a)).

Clinical features

If severe, this presents at birth with sexual ambiguity or adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). In the female, clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common, but the syndrome may be unrecognized in the male.

Precocious puberty with hirsutism is a later presentation, whereas rare, milder cases only present in adult life, usually accompanied by primary amenorrhoea. Hirsutism developing before puberty is suggestive of CAH.

Investigations

Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency, and with ambiguous genitalia such advice must be sought urgently before any assignment of gender is made.

- 17-Hydroxyprogesterone levels are increased.
- Urinary pregnanetriol excretion is increased.
- Basal ACTH levels are raised.

Treatment

Replacement of glucocorticoid activity, and mineralocorticoid activity if deficient, is as for primary hypo-

adrenalism (see above). Correct dosage is often difficult to establish in the child but should ensure normal 17-hydroxyprogesterone levels while allowing normal growth; excessive replacement leads to stunting of growth.

Uses and problems of therapeutic steroid therapy

Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions (Box 18.8). Short-term use (e.g. for acute asthma) carries only small risks of significant side-effects except for the simultaneous suppression of immune responses. The danger lies in their continuance, often through medical oversight or patient default. In general, therapy for 3 weeks or less, or a dose of prednisolone less than 10 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic endogenous Cushing's syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity.

Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used, but inhaled steroids rarely cause Cushing's syndrome, although they commonly cause adrenal suppression.

The major hazards are detailed in Box 18.9. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents (e.g. azathioprine) should always be considered and screening and prophylactic therapy for osteoporosis introduced (see p. 596).

Supervision of steroid therapy

All patients receiving steroids should carry a 'Steroid Card'. They should be made aware of the following points:

- Long-term steroid therapy must never be stopped suddenly.
- Doses should be reduced very gradually, with most being given in the morning at the time of withdrawal — this minimizes adrenal suppression. Many authorities believe that 'alternate-day therapy' produces less suppression.
- Doses need to be increased in times of serious intercurrent illness (defined as presence of a fever), accident and stress. Double doses should be taken during these times.
- Other physicians, anaesthetists and dentists must be told about steroid therapy.
- Patients should also be informed of potential side-effects and all this information should be documented in the clinical record.
- Regular supervision including, e.g. DXA scan.

Steroids and surgery

Any patient receiving steroids or who has recently received them (within the last 12 months) and may still have adrenal suppression requires careful control of steroid medication around the time of surgery. Details are shown in Table 18.33.

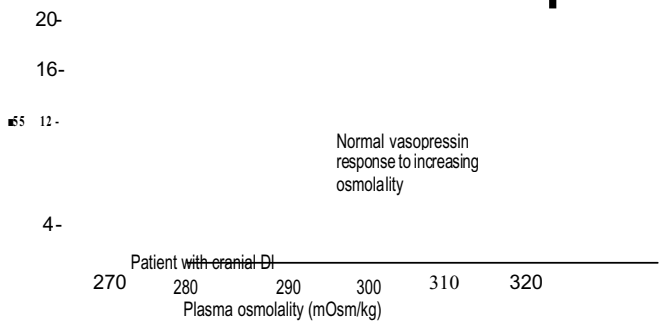

Fig. 18.26 **Plasma vasopressin response to increasing osmolality in normal subjects and in a patient with DI.**

THE THIRST AXIS

Thirst and water regulation are largely controlled by vasopressin, also known as antidiuretic hormone (ADH), which is synthesized in the hypothalamus, and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to ADH deficiency as the hormone can still 'leak' from the damaged end of the intact axon.

At normal concentrations the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the V2 receptors allows the collecting tubule to become permeable to water, thus permitting reabsorption of hypotonic luminal fluid (p. 694). Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations vasopressin also causes vasoconstriction via the VI receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg) maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (Fig. 18.26).

Other factors affecting vasopressin release are shown in Table 18.34.

Disorders of vasopressin secretion or activity include:

- deficiency as a result of hypothalamic disease ('cranial' diabetes insipidus)
- inappropriate excess of the hormone
- 'nephrogenic' diabetes insipidus - a rare condition in which the renal tubules are insensitive to vasopressin, an example of a receptor abnormality.

While all these are uncommon, they need to be distinguished from the occasional patient with 'primary polydipsia' and those whose renal tubular function has been impaired by electrolyte abnormalities, such as hypokalaemia or hypercalcaemia.

Table 18.33 **Steroid cover for operative procedures**

Procedure	Premedication	Intra- and postoperative	Resumption of normal maintenance
Simple procedures (e.g. gastroscopy, simple dental extractions)	Hydrocortisone 100 mg i.m		Immediately if no complications and eating normally
Minor surgery (e.g. laparoscopic surgery, veins, hernias)	Hydrocortisone 100 mg i.m.	Hydrocortisone 20 mg orally 6-hourly or 50 mg i.m. every 6 hours for 24 h if not eating	After 24 h if no complications
Major surgery (e.g. hip replacement, vascular surgery)	Hydrocortisone 100 mg i.m.	Hydrocortisone 50-100 mg i.m every 6 hours for 72 h	After 72 h if normal progress and no complications Perhaps double normal dose for next 2-3 days
GI tract surgery or major thoracic surgery (not eating or ventilated)	Hydrocortisone 100 mg i.m.	Hydrocortisone 100 mg i.m. every 6 hours for 72 h or longer if still unwell	When patient eating normally again Until then, higher doses (to 50 mg 6-hourly) may be needed

Diabetes insipidus (DI)

Clinical features

Deficiency of vasopressin or insensitivity to its action leads to polyuria, nocturia and compensatory polydipsia. Daily urine output may reach as much as 10-15 L, leading to dehydration that may be very severe if the thirst mechanisms or consciousness are impaired or the patient is denied fluid.

Causes of DI are listed in Table 18.35. The most common is hypothalamic-pituitary surgery, following which transient DI is common, frequently remitting after a few days or weeks. Primary overdrinking (polydipsia) is a common differential diagnosis.

DI may be masked by simultaneous cortisol deficiency - cortisol replacement allows a water diuresis and DI then becomes apparent.

DIDMOAD (Wolfram) syndrome is a rare autosomal recessive disorder comprising Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy and Deafness. MR scanning may show an absent or poorly developed posterior pituitary.

Table 18.35 Causes of diabetes insipidus

Cranial diabetes insipidus	Nephrogenic diabetes insipidus

Post-surgical	
Transfrontal	
Trans-sphenoidal Post-radiotherapy (cranial) Vascular	
Haemorrhage/thrombosis	
Sheehan's syndrome	
Aneurysm Trauma (e.g. head injury)	

Mild temporary nephrogenic DI can occur after prolonged polyuria due to any cause, including cranial DI and primary polydipsia

Biochemistry

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia plasma osmolality tends to be low)
- Resultant high or high-normal plasma sodium
- High 24-h urine volumes (less than 2 L excludes need for further investigation)
- Failure of urinary concentration with fluid deprivation
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points may be studied with a formal water-deprivation test (Box 18.10). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in 'cranial' DI) or not concentrating after vasopressin if nephrogenic DI is present. This test can give equivocal results and measurement of vasopressin during the test is helpful.

***Box 18.10* Water deprivation test**

Indication

Diagnosis or exclusion of diabetes insipidus

Procedure

Fasting and no fluids from 7.30 a.m. (or overnight if only mild DI is expected and polyuria is only modest)

Monitor serum and urine osmolality, urine volume and weight hourly for up to 8 hours

Abandon fluid deprivation if weight loss > 3% occurs

If serum osmolality > 300 mOsm/kg and/or urine osmolality > 600 mOsm/k give desmopressin, 2 ug i.m. at end of test. Allow free fluid but measure urine osmolality for 2-4 hours

Normal response

Serum osmolality remains within normal range (275-295 mOsm/kg) Urine osmolality rises to > 600 mOsm/kg

Diabetes insipidus

Serum osmolality rises above normal without adequate concentration of urine osmolality Response to desmopressin indicates cranial (pituitary) DI rather than nephrogenic DI

Treatment

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200-400 mg daily) or chlorpropamide (200-350 mg daily).

Nephrogenic diabetes insipidus

In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin. It may be inherited as a rare sex-linked recessive, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an ADH-sensitive water channel, aquaporin-2. More commonly it can be acquired as a result of renal disease, sickle cell disease, drug ingestion (e.g. lithium), hypercalcaemia or hypokalaemia. Wherever possible the cause should be reversed.

Other causes of polyuria and polydipsia

Diabetes mellitus, hypokalaemia and hypercalcaemia should be excluded. In the case of diabetes mellitus the cause is an osmotic diuresis secondary to glycosuria which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

Primary or hysterical polydipsia

This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of 'renal medullary washout', with a fall in the concentrating ability of the kidney.

Characteristically the diagnosis is made by a water-deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient's urine becomes concentrated (albeit 'maximum' concentrating ability may be impaired); the initially low urine osmolality gradually increases with the duration of the water deprivation.

Syndrome of inappropriate antidiuretic hormone (SIADH)

Clinical features

Inappropriate secretion of ADH leads to retention of water and hyponatraemia. The presentation is usually vague, with confusion, nausea, irritability and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities. The syndrome must be distinguished from those causing similar dilutional hyponatraemia from excess infusion of dextrose/water solutions or diuretic administration (thiazides or amiloride, see p. (

Table 18.36 **Common causes of the syndrome of inappropriate ADH secretion (SIADH)**

Head injury Subdural haematoma Cerebral abscess SUE
vasculitis

Metabolic causes
Alcohol withdrawal
Porphyria

Drugs
Chlorpropamide
Carbamazepine
Cyclophosphamide
Vincristine
Phenothiazines

Diagnosis

The usual features are:

- dilutional hyponatraemia due to excessive water retention
- low plasma osmolality with 'inappropriate' urine osmolality which is higher than plasma osmolality
- continued urinary sodium excretion > 30 mmol/L
- absence of hypokalaemia (or hypotension)
- normal renal and adrenal and thyroid function.

The causes are listed in Table 18.36.

Treatment

The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:

- Fluid intake should be restricted to 500-1000 mL daily. If tolerated, and complied with, this will correct the biochemical abnormalities in almost every case.
- Plasma osmolality and sodium and bodyweight should be measured frequently.
- If water restriction is poorly tolerated or ineffective, demeclocycline (600-1200 mg daily) may be given; this inhibits the action of vasopressin on the kidney, causing a reversible form of nephrogenic diabetes insipidus. It often, however, causes photosensitive rashes.
- When the syndrome is very severe, rarely hypertonic saline (300 mmol/L slowly i.v.) is given and furosemide may be used. These treatments are potentially dangerous and should only be used with extreme caution.

DISORDERS OF CALCIUM METABOLISM

Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia

is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia occurs in about 1 in 1000 of the population, with an incidence of 25-30 per 100 000 population. It occurs mainly in elderly females, and is usually due to primary hyperparathyroidism (primary HPT).

Parathyroid hormone

There are normally four parathyroid glands which are situated posterior to the thyroid, but occasionally additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from a 115-residue preprohormone, is secreted from the chief cells of the four parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:

- increasing osteoclastic resorption of bone (occurring rapidly)
- increasing intestinal absorption of calcium (a slow response)
- increasing synthesis of $1,25\text{-}(OH)_2D_3$
- increasing renal tubular reabsorption of calcium
- increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenyl cyclase messenger activity.

PTH measurements

PTH measurements use two-site immunometric assays that measure only the intact PTH molecule; interpretation requires a simultaneous calcium measurement in order to differentiate most causes of hyper- and hypocalcaemia. Urinary cyclic adenosine monophosphate (cyclic AMP) concentration is an index of the bioactivity of PTH. Vitamin D metabolism is discussed on page 592.

Hypercalcaemia

Pathophysiology and causes

The major causes of hypercalcaemia are listed in Table 18.37; primary hyperparathyroidism and malignancies are by far the most common (> 90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (> 80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15-20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g. multiple endocrine neoplasia (MEN) syndrome type 1 or 2a). Parathyroid carcinoma is rare (< 1%), though it usually produces severe and intractable hypercalcaemia.

Primary hyperparathyroidism is of unknown cause, though it appears that adenomas are monoclonal. Hyperplasia may also be monoclonal. Chromosomal rearrangements in the 5' regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

Table 18.37 **Causes of hypercalcaemia**

Excessive parathormone (PTH) secretion
Primary hyperparathyroidism (commonest by far), adenoma (common), hyperplasia or carcinoma (rare)
Tertiary hyperparathyroidism
Ectopic PTH secretion (very rare indeed)

Malignant disease (second commonest cause)
Myeloma
Secondary deposits in bone
Production of osteoclastic factors by tumours PTH-related protein secretion

Excess action of vitamin D
Iatrogenic or self-administered excess
Granulomatous diseases, e.g. sarcoidosis, TB
Lymphoma

Excessive calcium intake
'Milk-alkali' syndrome

Other endocrine disease (mild hypercalcaemia only)
Thyrotoxicosis
Addison's disease

Drugs
Thiazide diuretics
Vitamin D analogues
Lithium administration (chronic)
Vitamin A

Miscellaneous
Long-term immobility
Familial hypocalciuric hypercalcaemia

Secondary hyperparathyroidism (see p. 668) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in renal failure or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to normal after correction of the cause of hypocalcaemia where this is possible.

Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after long-standing secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Parathyroidectomy is necessary at this stage.

Symptoms and signs

Mild hypercalcaemia (e.g. adjusted calcium < 3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:

- *General features.* There may be tiredness, malaise, dehydration and depression.
- *Renal features.* Renal colic from stones, polyuria or nocturia, haematuria and hypertension occurs. The polyuria results from the effect of hypercalcaemia on renal tubules, reducing their concentrating ability - a

form of mild nephrogenic diabetes insipidus. Primary hyperparathyroidism is present in about 5% of patients who present with renal calculi.

- *Bones.* There may be bone pain. Hyperparathyroidism mainly affects cortical bone, and bone cysts and locally destructive 'brown tumours' occur but only in advanced disease. Only 5-10% of all cases have definite bony lesions even when sought.
- *Abdominal.* There may be abdominal pain.
- *Chondrocalcinosis and ectopic calcification.* These are occasional features.
- *Corneal calcification.* This is a marker of long-standing hypercalcaemia but causes no symptoms.

There may also be symptoms from the underlying cause. Malignant disease is usually advanced by the time hypercalcaemia occurs, typically with bony metastases. The common primary tumours are bronchus, breast, myeloma, oesophagus, thyroid, prostate, lymphoma and renal cell carcinoma. True 'ectopic PTH secretion' by the tumour is very rare, and most cases are associated with raised levels of PTH-related protein. This is a 144-amino-acid polypeptide, the initial sequence of which shows an approximate homology with the biologically active part of PTH, which is necessary in fetal development but does not have a clearly defined role in the adult. Local bone resorbing cytokines and prostaglandins may be involved locally where there are metastatic skeletal lesions, leading to local mobilization of calcium by osteolysis with subsequent hypercalcaemia.

Severe hypercalcaemia (> 3 mmol/L) is usually associated with malignant disease, hyperparathyroidism, renal failure or vitamin D therapy.

Investigations and differential diagnosis

Biochemistry

- *Several* fasting serum calcium and phosphate samples should be performed.
- *Serum PTH.* The hallmark of primary hyperparathyroidism is hypercalcaemia and hypophosphataemia with detectable or elevated intact PTH levels during hypercalcaemia. When this combination is present in an asymptomatic patient then further investigation is usually unnecessary.
- There is often a mild *hyperchloraemic acidosis.*
- *Renal function* is usually normal but should be measured as a baseline.

Where PTH is undetectable or equivocal, a number of other tests may lead to the diagnosis

- *Protein electrophoresis:* to exclude myeloma
- *Serum TSH:* to exclude hyperthyroidism
- *0900h cortisol and/or synacthen test:* to exclude Addison's disease
- *Serum ACE:* helpful in the diagnosis of sarcoidosis
- *Hydrocortisone suppression test:* hydrocortisone 40 mg three times daily for 10 days leads to suppression of plasma calcium in sarcoidosis, vitamin D-mediated hypercalcaemia and some malignancies.

Imaging

Abdominal X-rays may show renal calculi or nephrocalcinosis. High-definition hand X-rays can show subperiosteal erosions in the middle or terminal phalanges. DXA bone density scan is useful to detect bone effects in asymptomatic patients with HPT in whom conservative management is planned.

Parathyroid imaging is generally indicated only for patients who have undergone previous parathyroid surgery, as techniques have an overall sensitivity of just 60-70% and a substantial false-positive rate, which is far less accurate than the expert surgical success rate of at least 90%. Methods include:

- ultrasound which, though insensitive for small tumours, is simple and safe
- high-resolution CT scan or MRI (the most sensitive technique)
- radioisotope subtraction scanning - a picture of the parathyroid tissue derived from the difference in up take between ^{201}Th (taken up by thyroid and para thyroid) and ^{99m}Tc (by thyroid only).

Treatment of hypercalcaemia

Details of emergency treatment for severe hypercalcaemia are given in Emergency box 18.2. Thereafter, treatment is management of the underlying disease.

Treatment of primary hyperparathyroidism

Medical management

There are no effective medical therapies at present for primary hyperparathyroidism, but a high fluid intake

Emergency Box 18.2
Treatment of acute hypercalcaemia

Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness and altered consciousness. The serum Ca^{2+} is over 3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca^{2+} is above 3.5 mmol/L. Specialist help is advised.

- Adequate rehydration is essential - usually at least 4-6 L of 0.9% saline on day 1, and 3-4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.
- Intravenous bisphosphonates are the treatment of choice for hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (15-60 mg as an intravenous infusion in 0.9% saline or dextrose over 2-8 hours or, if less urgent, over 2-4 days).
- Calcitonin (200 units i.v. 6-hourly) has a short-lived action and is little used.
- Prednisolone (30-60 mg daily) is effective in some instances (e.g. in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.
- Oral phosphate (sodium cellulose phosphate 5 g three times daily) produces diarrhoea. Intravenous phosphate rapidly lowers plasma Ca^{2+} but is dangerous and should not be used.

should be maintained, a high calcium or vitamin D intake avoided, and exercise encouraged. New therapeutic agents that target the calcium-sensing receptors in the kidney may be of value in the future.

Surgery

Indications for surgery in primary hyperparathyroidism remain controversial. There is agreement that surgery is indicated for:

- patients with renal stones or impaired renal function
- bone involvement or marked reduction in cortical bone density
- unequivocal marked hypercalcaemia (> 3.0 mmol/L)
- the uncommon younger patient, below age 50 years
- a previous episode of severe acute hypercalcaemia.

The situation where plasma calcium is mildly raised (2.65-3.00 mmol/L) is more controversial. Most authorities feel that young patients should be operated on, as should those who have reduced cortical bone density or significant hypercalciuria, as this is associated with stone formation.

In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be estimated every 3-5 years.

Surgical technique and complications

Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres over 90% of operations are successful, involving removal of the adenoma, or removal of all four hyperplastic parathyroids.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery - bleeding and recurrent laryngeal nerve palsies (< 1%). Vocal cord function should be checked preoperatively.

If initial exploration is unsuccessful, a full work-up including venous catheterization and scanning is essential, remembering that parathyroid tissue can be ectopic.

Postoperative care

The major danger after operation is hypocalcaemia, which is more common in patients with significant bone disease - the 'hungry bone' syndrome. Some authorities pretreat such patients with alfacalcidol 2 u.g daily from 2 days preoperatively for 10-14 days. Chvostek's and Trousseau's signs (see p. 1095) should be checked regularly in all these patients. Plasma calcium measurements are performed daily for at least 2—5 days (more often if low) — a mild transient hypoparathyroidism often continues for 1—2 weeks. Depending on its severity, oral or intravenous calcium (for details see p. 1095) should be given temporarily, as only a few patients (< 1%) will develop long-standing surgical hypoparathyroidism.

Familial hypocalciuric hypercalcaemia

This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. It is caused by mutations in the gene on the long arm of chromosome 3 encoding for the calcium-ion-sensing G-protein-coupled receptor in the kidney and parathyroid gland. Family members are often affected, detected by genetic analysis. Parathyroid surgery is not indicated as the course appears benign.

Hypocalcaemia and hypoparathyroidism

Pathophysiology

Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, secondary to high phosphate levels or other causes of hypocalcaemia (Table 18.38). All forms of hypoparathyroidism, except transient surgical effects, are uncommon. ■

Causes

- *Renal failure* is the most common cause of hypocalcaemia.
- *Hypocalcaemia after thyroid or parathyroid surgery* is common but usually transient - fewer than 1% of thyroidectomies leave permanent damage (see above).
- *Idiopathic hypoparathyroidism* is one of the rarer autoimmune disorders, often accompanied by vitiligo, cutaneous moniliasis and other autoimmune disease.

The *DiGeorge syndrome* (p. 218) is a familial condition where the hypoparathyroidism is associated with intellectual impairment, cataracts and calcified basal ganglia, and occasionally with specific autoimmune disease.

Pseudohypoparathyroidism is a syndrome of end-organ resistance to PTH owing to a mutation in the G_{Sa}-protein which is coupled to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcifi-

cation and sometimes by intellectual impairment. Variable degrees of resistance involving other G-protein-linked hormone receptors may also be seen (TSH, LH, FSH).

Pseudo-pseudohypoparathyroidism describes the phenotypic defects but without any abnormalities of calcium metabolism. These individuals may share the same gene defect as pseudohypoparathyroidism and occur in the same families.

Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesiae, circumoral numbness, cramps, anxiety and tetany (Box 18.11) are followed by convulsions, laryngeal stridor, dystonia and psychosis. Two signs of hypocalcaemia are Chvostek's sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau's sign, where inflation of the sphygmomanometer cuff above systolic pressure for 3 minutes induces tetanic spasm of the fingers and wrist. Severe hypocalcaemia may cause papilloedema and frequently a prolonged QT interval on the ECG.

Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:

- **serum and urine creatinine** for renal disease
- **PTH levels** in the serum: absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia
- **parathyroid antibodies** (present in idiopathic hypo parathyroidism)
- **25-hydroxy vitamin D serum level** (low in vitamin D deficiency)
- **X-rays** of metacarpals, showing short fourth metacarpals which occur in pseudohypoparathyroidism.

Treatment

Alpha-hydroxylated derivatives of vitamin D are preferred for their shorter half-life, and especially in renal disease as the others require renal hydroxylation. Usual daily maintenance doses are 0.25-2 ug for alfacalcidol (la-OH-D_3). During treatment, plasma calcium must be monitored frequently to detect hypercalcaemia.

ENDOCRINOLOGY OF BLOOD PRESSURE CONTROL

The control of blood pressure (BP) is complex, involving neural, cardiac, hormonal and many other mechanisms.

BP is dependent upon cardiac output and peripheral resistance. Although cardiac output can be increased in endocrine disease (e.g. hyperthyroidism), the main role of hormonal mechanisms is control of peripheral resistance and of circulating blood volume. The oral contraceptive pill is a common endocrine cause of mild hypertension.

When to investigate for secondary hypertension

Endocrine causes account for less than 5% of all hypertension (Table 18.39). It is impracticable and unnecessary to screen all hypertensive patients for secondary causes. The highest chances of detecting such causes are in:

- subjects under 35 years, especially those without a family history of hypertension
- those with accelerated (malignant) hypertension

Table 18.39 **Endocrine causes of hypertension**

Excessive renin, and thus angiotensin II, production
Renal artery stenosis Other local renal disease Renin-secreting tumours

Excessive production of catecholamines
Phaeochromocytoma

Excessive GH production
Acromegaly

Excessive aldosterone production

Dexamethasone-suppressible hyperaldosteronism

Excessive production of other mineralocorticoids
Cushing's syndrome (massive excess of cortisol, a weak mineralocorticoid)
Congenital adrenal hyperplasia (in some cases) Tumours producing other mineralocorticoids, e.g. corticosterone

Exogenous 'mineralocorticoids' or enzyme inhibitors
Liquorice ingestion (inhibits 11 p-hydroxylase)
Abuse of mineralocorticoid preparations

- those with indications of renal disease (e.g. proteinuria, unequal renal sizes)
- those with hypokalaemia before diuretic therapy
- those resistant to conventional antihypertensive therapy (e.g. more than three drugs)
- those with unusual symptoms (e.g. sweating attacks or weakness).

The renin-angiotensin-aldosterone axis: biochemistry and actions

The renin-angiotensin-aldosterone system is illustrated in Figure 18.27.

Angiotensinogen, an alpha$_2$-globulin of hepatic origin, circulates in plasma. The enzyme, renin, is secreted by the kidney in response to decreased renal perfusion pressure or flow; it cleaves the decapeptide *angiotensin I* from angiotensinogen. Angiotensin I is inactive but is further cleaved by angiotensin-converting enzyme (ACE; present in lung and vascular endothelium) into the active peptide, *angiotensin II,* which has two major actions (mediated by two types of receptor, AI^ and AT$_2$). The AT, subtype which is found in the heart, blood vessels, kidney, adrenal cortex, lung and brain mediates the vasoconstrictor effect. AT$_2$ is probably involved in vascular growth. Angiotension II:

- causes rapid, powerful vasoconstriction
- stimulates the adrenal zona glomerulosa to increase aldosterone production (over hours or days).

As BP increases and sodium is retained, the stimuli to renin secretion are reduced. Dietary sodium excess also suppresses renin secretion, whereas sodium deprivation or urinary sodium loss will increase it.

The renin-angiotensin system can be blocked at several points with renin inhibitors, angiotensin-converting enzyme inhibitors (ACEI) and angiotensin II receptor antagonists (A-IIRA). The latter two are useful agents in treatment of hypertension and heart failure (see pp. 862 and 792) but have differences in action: ACEIs also block kinin production while A-IIRAs are specific for the AT-II receptors.

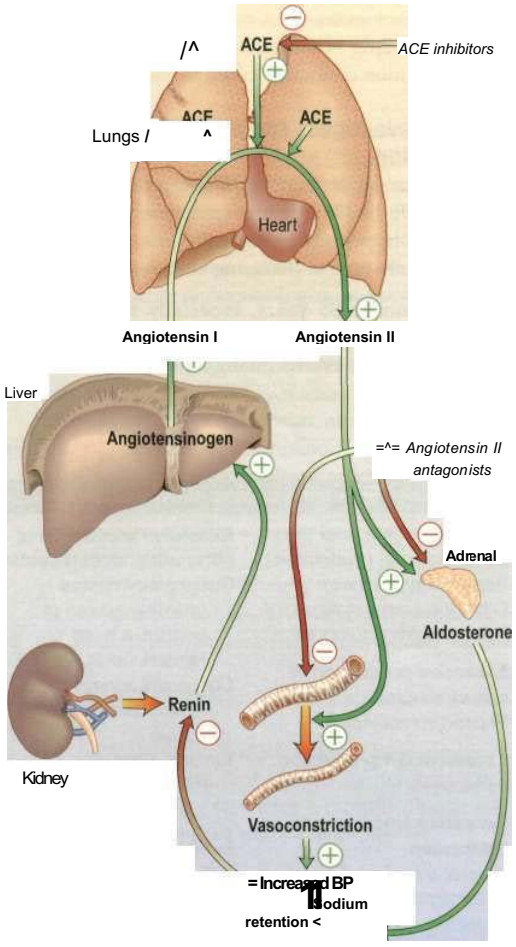

Fig. 18.27 The renin-angiotensin-aldosterone system. ACE, angiotensin-converting enzyme.

Atrial and brain natriuretic factors/peptides (ANP and BNP)

Atrial natriuretic peptides, a family of varying length forms, are secreted from atrial granules in response to atrial stretch. They produce marked effects on the kidney, increasing sodium and water excretion and glomerular filtration rate and lowering BP, plasma renin activity and plasma aldosterone (p. 612).

Brain natriuretic peptide is found in the ventricle as well as the brain and has moderate sequence homology with ANP; normally its circulating level is much less than for ANP but may exceed it in congestive cardiac failure.

ANP and BNP appear to play a significant role in cardiovascular and fluid homeostasis, but there is no evidence of primary defects in their secretion causing disease. BNP may accurately reflect the presence and severity of heart failure and appears to be useful in defining prognosis and the need for adjustment of treatment.

Agents that both inhibit the endopeptidases that break down ANP and inhibit ACE (the receptors concerned are similar) are available but long-term clinical studies are awaited.

RENIN (AND ANGIOTENSIN) DEPENDENT HYPERTENSION

Many forms of unilateral and bilateral renal diseases are associated with hypertension. The classic example is renal artery stenosis: the major hypertensive effects of this and other situations such as renin-secreting tumours are directly or indirectly due to angiotensin II.

Angiotensin II receptor antagonists (e.g. losartan, valsartan, candesartan and irbesartan) are effective in hypertension and congestive cardiac failure, similar to angiotensin-converting enzyme inhibitors (ACEI). They produce much the same clinical effects, though with fewer side-effects (e.g. no cough and less hyperkalaemia).

Renal artery stenosis

This is discussed on page 646.

DISORDERS OF ALDOSTERONE SECRETION

Primary hyperaldosteronism

Pathophysiology

This rare condition (< 1% of all hypertension) is caused by excess aldosterone production leading to sodium retention, potassium loss and the combination of hypokalaemia and hypertension.

Causes (see Table 18.39)

Adrenal adenomas (Conn's syndrome) account for 60% of cases; 30% are due to bilateral adrenal hyperplasia of uncertain aetiology.

Clinical features

The usual presentation is with hypertension and hypokalaemia (< 3.5 mmol/L), although 20-40% of patients have initial potassium levels of 3.5^12 mmol/L. The few symptoms are non-specific; rarely muscle weakness, nocturia and tetany are seen. The hypertension may be severe and associated with renal, cardiac and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before age 40 years and is more common in males.

Investigations

The characteristic features are as follows:

- **Hypokalaemia.** A high-salt diet should be given for several days before testing and diuretics must be stopped 3 weeks before investigation; plasma samples must be separated quickly.
- **Urinary potassium loss.** Levels > 30 mmol daily during hypokalaemia are inappropriate.
- **An elevated plasma aldosterone: renin ratio** is a valuable screening test.
- **Elevated plasma aldosterone levels** that are not suppressed with 0.9% saline infusion (300 mmol over 4 hours) or fludrocortisone administration.
- **Suppressed plasma renin activity.** Beta-blockers and other drugs may interfere with renin activity.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI (not infallible as tumours may be very small), complex biochemical testing including diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 0900h supine and 1300h erect samples; in contrast they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma), adrenal scintillation scanning, and venous catheterization for aldosterone levels.

A rare cause is glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual cross-over at meiosis between the genes encoding aldosterone synthase and adrenal ll(3-hydroxylase produces aldosterone which is under ACTH control. Treatment with glucocorticoid resolves the problem.

Treatment

An adenoma should be removed surgically - usually laparoscopically; BP falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist spironolactone (100^100 mg daily); frequent side-effects include nausea, rashes and gynaecomastia (p. 1056). Spironolactone in long-term use has been linked with tumour development in animals. Amiloride and calcium-channel blockers are moderately effective in controlling the hypertension but do not correct the hyperaldosteronism.

Secondary hyperaldosteronism

This situation arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes are accelerated hypertension and renal artery stenosis, when the patient will be hypertensive. Causes associated with normotension include congestive cardiac failure and cirrhosis, where excess aldosterone production contributes to sodium retention.

Angiotensin-converting enzyme inhibitors (e.g. captopril, enalapril or lisinopril), and angiotensin II antagonists (e.g. losartan, candesartan) are effective in heart failure, both symptomatically and in increasing life expectancy (see p. 792). Spironolactone is of value in both situations, and 25 mg/day has been shown to improve survival in heart failure (see p. 792).

Syndrome of apparent mineralocorticoid excess

This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme llp-hydroxysteroid dehydrogenase type 2 (11P-HSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not) and therefore 'exposes' the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excess ingestion of liquorice - which inhibits the UfS-HSD2 enzyme.

Hypoaldosteronism

Except as part of primary hypoadrenalism (Addison's disease, see p. 1082), this is very uncommon. Causes include hyporeninaemic hypoaldosteronism, aldosterone biosynthetic defects, and drugs (e.g. ACE inhibitors, heparin).

Table 18.40 Symptoms and signs of phaeochromocytoma

THE ADRENAL MEDULLA

The major catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine) are produced in the adrenal medulla (Fig. 18.28), although most noradrenaline is derived from sympathetic neuronal release. While noradrenaline and adrenaline undoubtedly produce hypertension when infused, they probably play little part in BP regulation in normal humans.

Phaeochromocytoma

Phaeochromocytomas, tumours of the sympathetic nervous system, are very rare (less than 1 in 1000 cases of hypertension). Ninety per cent arise in the adrenal, while 10% occur elsewhere in the sympathetic chain. Some are associated with MEN 2 syndromes (see below) and the von Hippel-Lindau syndrome (p. 683). Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine) but large tumours and extra-adrenal tumours produce almost entirely norepinephrine.

Pathology

Oval groups of cells occur in clusters and stain for chromogranin A. Twenty-five percent are multiple and 10% malignant, the latter being more frequent in the extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

Clinical features

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Table 18.40). The diagnosis should particularly be considered

Symptoms	hythmias Bradycardia Orthostatic hypotension
Anxiety or panic attacks	Pallor or flushing Glycosuria Fever (Signs of
Palpitations	hypertensive damage)
Tremor	
Sweating	
Headache	
Flushing	
Nausea and/or vomiting	
Weight loss	
Constipation or diarrhoea	
Raynaud's phenomenon	
Chest pain	
Polyuria/nocturia	

when cardiovascular instability has been demonstrated, and in severe hypertension in pregnancy.

Diagnosis

Specific tests are:

- **Measurement of urinary catecholamines and metabolites** (preferably metanephrines rather than vanillylmandelic acid (VMA) - Fig. 18.28) is a useful screening test; normal levels on three 24-hour collections of metanephrines virtually exclude the diagnosis. Many drugs and dietary vanilla interfere with these tests.
- **Resting plasma catecholamines** are raised.
- **Plasma chromogranin A** (a storage vesicle protein) is raised.
- **Clonidine suppression and glucagon stimulation** tests may be appropriate, but should only be performed in specialist centres.
- CT **scans,** initially of the abdomen, are helpful to localize the tumours which are often large.
- **MRI** usually shows the lesion clearly.
- **Scanning with [^{131}I]metaiodobenzylguanidine** (mIBG) produces specific uptake in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours.

e

...

Treatment

Tumours should be removed if this is possible; 5-year survival is about 95% when not malignant. Medical preoperative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20-80 mg daily initially in divided doses), then propranolol (120-240 mg daily), plus transfusion of whole blood to re-expand the contracted plasma volume. The alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labetolol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are both vital and sodium nitroprusside should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long term. Radionucleotide treatment with mlBG has been attempted with limited success.

Patients should be kept under clinical and biochemical review after tumour resection as over 10% recur or develop a further tumour. Catecholamine excretion measurements should be performed at least annually.

OTHER ENDOCRINE DISORDERS

DISEASES OF MANY GLANDS

Multiple gland failure (polyglandular autoimmune syndromes)

These are caused by autoimmune disease as detailed in Table 18.4 on page 1042. Most common are the associations of primary hypothyroidism and type 1 diabetes, and either of these with Addison's disease or pernicious anaemia.

Multiple endocrine neoplasia

This is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (Table 18.41). They are inherited in an autosomal dominant manner and arise from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome. The defect in MEN 1 is in a novel gene *(meniri)* on the long arm of chromosome 11 which encodes for a 610-amino-acid protein. MEN 2a and 2b are caused by mutations of the J?ef-proto-oncogene on chromosome 10. This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a the mutation is in the extracellular domain; for 2b in the intracellular domain.

Management

Treatment is surgical.

For type 1, all four parathyroid glands are removed (as all may be involved), followed by vitamin D (1,25-dihydrocalciferol) replacement therapy. Pancreatic tumours are often multiple and recurrence after partial pancreatectomy is invariable. Other tumours are treated surgically if necessary.

Table 18.41 **Multiple endocrine neoplasia (MEN) syndromes**

Organ	Frequency	Tumours/manifestations
Typei		
Parathyroid	95%	Adenomas/hyperplasia
Pituitary	70%	Adenomas - prolactinoma, ACTH or growth hormone secreting (acromegaly)
Pancreas	50%	Islet cell tumours (secreting insulin, glucagon, somatostatin, VIP, pancreatic polypeptide, growth hormone-releasing factor) Zollinger—Ellison syndrome (gastrinoma). Non-functional tumour
Adrenal	40%	Non-functional adenoma
Thyroid	20%	Adenomas - multiple or single
Type 2a	Most	
Adrenal		Phaeochromocytoma (70% bilateral)
Thyroid	Most	Cushing's syndrome Medullary carcinoma (calcitonin producing)
Parathyroid	60%	Hyperplasia
Type 2b		
Type 2a with marfanoid phenotype and intestinal and visceral ganglioneuromas but not hyperparathyroidism Neuromas also present around lips and tongue		

Type 2 tumours may also be recurrent or bilateral and a careful follow-up is necessary.

Screening

A careful family history should first be taken. If the precise gene mutation has been identified in a particular family, then family members at risk can be screened directly for the presence of the mutation. In affected individuals, biochemical screening is then required. If initial biochemical screening is negative, this does not exclude later involvement and needs repeating at regular intervals, typically annually, with more intensive investigation when symptoms arise.

Screening for type 1

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene positive family member) other typical screening bloods include prolactin, GH/IGF1 and 'gut hormones'. Repeated imaging is rarely practical.

Screening for type 2

Serum calcium levels will easily detect hyperparathyroidism

Medullary carcinoma of thyroid (MCT) - with the known presence of the gene defect, total thyroidectomy in childhood is recommended. Calcitonin is a useful tumour marker but stimulation (with pentagastrin or calcium infusion test) is needed to pick up 'C' cell hyperplasia which precedes tumour development. Total thyroidectomy is then indicated. *Phaeochromocytoma* — metanephrine or catecholamine estimations.

ECTOPIC HORMONE SECRETION

This terminology refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:

- *Hypercalcaemia of malignant disease,* often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved, but very rarely PTH itself (see p. 1093). Treatment is also discussed on page 1093. *SIADH* (see p. 695). Again, this is most common from a primary lung tumour.

  Ectopic ACTH syndrome (see p. 1085). Small-cell carcinoma of the lung, carcinoid tumours and medullary thyroid carcinomas are the most common causes, though many other tumours rarely cause it. *Production of insulin-like activity* may result in hypoglycaemia (see p. 1133).

ENDOCRINE TREATMENT OF OTHER MALIGNANCIES

Endocrine forms of treatment for malignancy have been used for many years; for example oophorectomy for breast cancer and orchidectomy for prostatic malignancy. More acceptable therapies include the anti-oestrogen tamoxifen for breast carcinoma and the GnRH analogues, buserelin and goserelin, for prostatic cancer.

19

HYPERGLYCAEMIA, INSULIN AND INSULIN ACTION

Introduction

Diabetes mellitus (DM) is a syndrome of chronic hyperglycaemia due to relative insulin deficiency, resistance, or both. It affects more than 120 million people world-wide, and it is estimated that it will affect 220 million by the year 2020. Diabetes is usually irreversible and, although patients can have a reasonably normal lifestyle, its late complications result in reduced life expectancy and major health costs. These include macrovascular disease, leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke, and microvascular damage causing diabetic retinopathy and nephropathy. Neuropathy is another major complication.

Insulin structure and secretion

Insulin is the key hormone involved in the storage and controlled release within the body of the chemical energy available from food. It is coded for on chromosome 11 and synthesized in the beta-cells of the pancreatic islets. The synthesis, intracellular processing and secretion of insulin by the beta-cell is typical of the way that the body produces and manipulates many peptide hormones. The manufacture and release of insulin from the beta-cell is illustrated in Figure 19.1. Figure 19.2 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the residue is broken down by the kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion), but is mainly degraded by the kidneys.

An outline of glucose metabolism

Blood glucose levels are closely regulated in health and rarely stray outside the range of 3.5-8.0 mmol/L (63-144 mg/dL), despite the varying demands of food, fasting and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines 3-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the 6-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

About 200 g of glucose is produced and utilized each day. More than 90% is derived from liver glycogen and hepatic gluconeogenesis, and the remainder from renal gluconeogenesis.

Glucose utilization

The brain is the major consumer of glucose. Its requirement is 1 mg/kg bodyweight per minute, or 100 g daily in

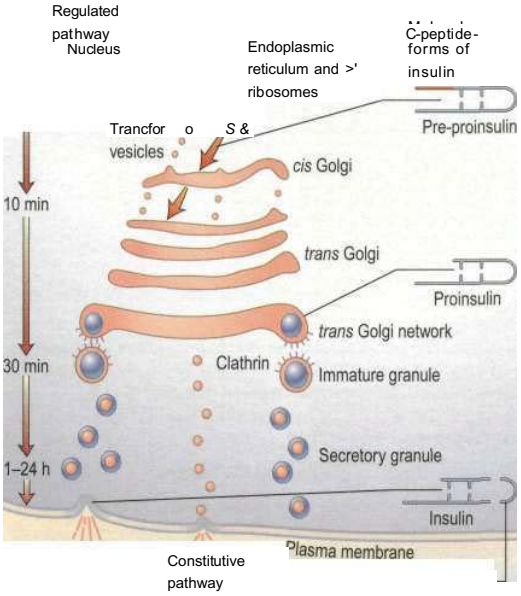

Fig. 19.1 **Part of a beta-cell.** The ribosomes manufacture pre-proinsulin from insulin mRNA. The hydrophobic 'pre' portion of pre-proinsulin allows it to transfer to the Golgi apparatus, and is subsequently enzymatically cleaved off. Proinsulin is parcelled into secretory granules in the Golgi apparatus. These mature and pass towards the cell membrane where they are stored before release. The proinsulin molecule folds back on itself and is stabilized by disulphide bonds. The biochemically inert peptide fragment known as connecting (C) peptide splits off from proinsulin in the secretory process, leaving insulin as a complex of two linked peptide chains. Equimolar quantities of insulin and C-peptide are released into the circulation. A small amount of insulin is secreted by the beta-cell directly via the 'constitutive pathway', which bypasses the secretory granules.

a 70 kg man. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Other tissues, such as muscle and fat, are facultative glucose consumers. The effect of insulin peaks associated with meals is to lower the threshold for glucose entry into cells; at other times, energy requirements are largely met by fatty-acid oxidation. Glucose taken up by muscle is stored as glycogen or broken down to lactate, which re-enters the circulation and becomes a major substrate for hepatic gluconeogenesis. Glucose is used by fat tissue as a source of energy and as a substrate for triglyceride synthesis; lipolysis releases fatty acids from triglyceride together with glycerol, another substrate for hepatic gluconeogenesis.

Hormonal regulation

Insulin is the major regulator of intermediary metabolism, although its actions are modified in many respects by other hormones. Its actions in the fasting and postprandial states differ (Fig. 19.3). In the fasting state its main action is to regulate glucose release by the liver, and in the postprandial state it additionally facilitates glucose uptake by fat and muscle. The effect of counter-regulatory hormones (glucagon, epinephrine (adrenaline), cortisol and growth hormone) is to cause greater production of glucose from the liver and less utilization of glucose in fat and muscle for a given level of insulin.

Glucose transport

Cell membranes are not inherently permeable to glucose. A family of specialized glucose-transporter (GLUT) proteins carry glucose through the membrane into cells.

- GLUT-1 - enables basal non-insulin-stimulated glucose uptake into many cells (see Fig. 6.21).
- GLUT-2 - transports glucose into the beta-cell: a prerequisite for glucose sensing.

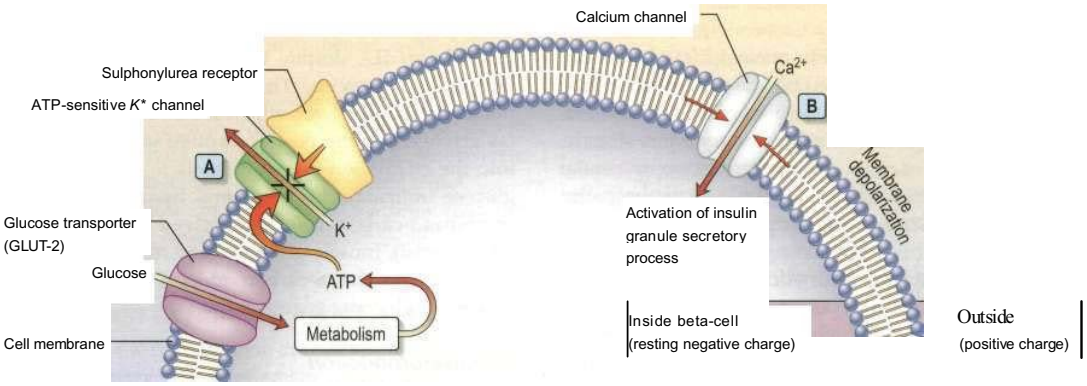

Fig. 19.2 **Local forces regulating insulin secretion from beta-cells.** Glucose enters the beta-cell via the GLUT-2 transporter protein, which is closely associated with the glycolytic enzyme glucokinase. Metabolism of glucose within the beta-cell generates ATP. ATP closes potassium channels in the cell membrane (A). If a sulphonylurea binds to its receptor, this also closes potassium channels. Closure of potassium channels predisposes to cell membrane depolarization, allowing calcium ions to enter the cell via calcium channels in the cell membrane (B). The rise in intracellular calcium triggers activation of calcium-dependent phospholipid protein kinase which, via intermediary phosphorylation steps, leads to fusion of the insulin-containing granules with the cell membrane and exocytosis of the insulin-rich granule contents. Similar mechanisms produce hormone-granule secretion in many other endocrine cells.

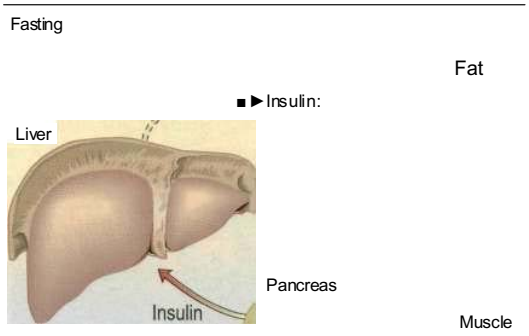

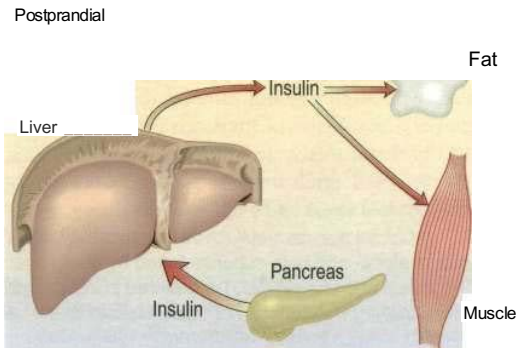

Fig. 19.3 **Fasting and postprandial effects of insulin.** In the *fasting state* insulin concentrations are low and it acts mainly as a hepatic hormone, modulating glucose production (via glycogenolysis and gluconeogenesis) from the liver. Hepatic glucose production rises as insulin levels fall. In the *postprandial state* insulin concentrations are high and it then suppresses glucose production from the liver and promotes the entry of glucose into peripheral tissues (increased glucose utilization).

- GLUT-3 - enables non-insulin-mediated glucose uptake into brain neurones and placenta.
- GLUT-4 - enables much of the peripheral action of insulin. It is the channel through which glucose is taken up into muscle and adipose tissue cells following stimulation of the insulin receptor (Fig. 19.4).

The insulin receptor

This is a glycoprotein (400 kDa), coded for on the short arm of chromosome 19, which straddles the cell membrane of many cells (Fig. 19.4). It consists of a dimer with two alpha-subunits, which include the binding sites for insulin, and two beta-subunits, which traverse the cell membrane. When insulin binds to the alpha-subunits it induces a conformational change in the beta-subunits, resulting in activation of tyrosine kinase and initiation of a cascade response involving a host of other intracellular substrates. One consequence of this is migration of the GLUT-4 glucose transporter to the cell surface and increased transport of glucose into the cell. The insulin-receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

TYPES OF DIABETES

Diabetes may be primary or secondary (Table 19.1). Although secondary diabetes accounts for barely 1-2% of all new cases at presentation, it should not be missed because the cause can often be treated. Type 1 diabetes (insulin-dependent diabetes mellitus) and type 2 diabetes (non-insulin-dependent diabetes mellitus) represent two distinct diseases from the epidemiological point of view, but clinical distinction can sometimes be difficult. The two diseases should, in clinical terms, be seen as a spectrum, distinct at the two ends but overlapping to some extent in the middle (Table 19.2). Varying degrees of insulin secretory failure may be present in both forms of diabetes. For example, some patients with immune-mediated diabetes may not at first require insulin, whereas many with type 2 diabetes will eventually do so.

Type 1 diabetes mellitus

Epidemiology

Type 1 diabetes is a disease resulting in insulin deficiency. In western countries almost all patients have the immune-mediated form of the disease (type 1A). Type 1 diabetes is prominent as a disease of childhood, reaching a peak incidence around the time of puberty, but can present at any age. A 'slow-burning' variant with slower progression to insulin deficiency occurs in later life and is sometimes called latent autoimmune diabetes of adults (LADA). This may be difficult to distinguish from type 2 diabetes. Clinical clues are: considerable weight loss, hyperglycaemia which fails to correct with diet and tablet treatment, the presence of strong or persistent ketonuria at diagnosis, and autoantibody tests indicating autoimmune disease. The highest rates of type 1 diabetes in the world are seen in Finland and other Northern

Table 19.1 **Causes of secondary diabetes**

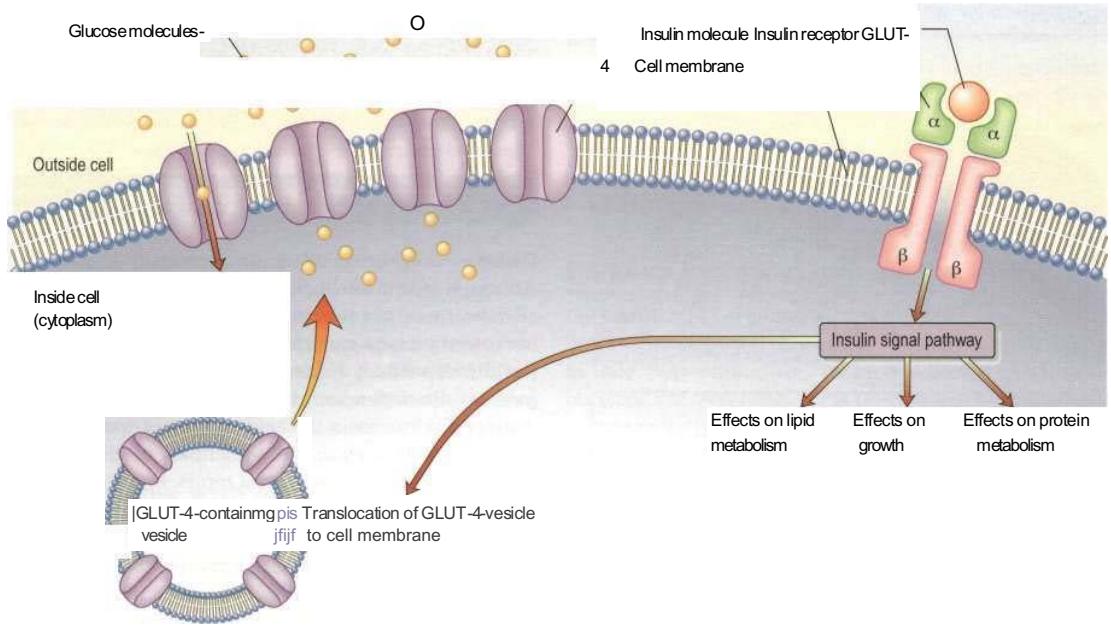

Fig. 19.4 **Insulin signalling in peripheral cells.** The insulin receptor consists of alpha- and beta-subunits linked by disulphide bridges (top right of figure). The beta-subunits straddle the cell membrane. The transporter protein GLUT-4 is stored in intracellular vesicles. The binding of insulin to its receptor initiates many intracellular actions including translocation of these vesicles to the cell membrane, carrying GLUT-4 with them.

Table 19.2 **The spectrum of diabetes: a comparison of type 1 and type 2 diabetes mellitus**

	Type 1 (insulin dependent)	Type 2 (non-insulin dependent)
Epidemiology	Younger (usually < 30 years of age) Usually lean Increased in those of Northern European ancestry Seasonal incidence	Older (usually > 30 years of age) Often overweight All racial groups. Increased in peoples of Asian, African, Polynesian and American-Indian ancestry
Heredity	HLA-DR3 or DR4 in > 90% 30-50% concordance in identical twins	No HLA links ~ 50% concordance in identical twins
Pathogenesis	Autoimmune disease: Islet cell autoantibodies Insulitis Association with other autoimmune diseases Immunosuppression after diagnosis delays beta-cell destruction	No immune disturbance Insulin resistance
Clinical	Insulin deficiency May develop ketoacidosis Always need insulin	Partial insulin deficiency May develop hyperosmolar state Many come to need insulin when beta-cells fail over time
Biochemical	Eventual disappearance of C-peptide	C-peptide persists

European countries, with the exception of the island of Sardinia, which for unknown reasons has the second highest rate in the world (Fig. 19.5). The incidence of type 1 diabetes appears to be increasing in most populations. In Europe the annual increase is of the order of 3-4%, and is most marked in children under the age of 5 years. A subtype of type 1 diabetes (type IB) has recently been described in Japanese patients with an abrupt onset, no autoimmune disease and high serum pancreatic enzyme concentrations at diagnosis. This has not been described in other populations. WHO (1995) estimated that there are 19.4 million people with type 1 diabetes and that the number will rise to 57.2 million by 2025.

Causes

Type 1 diabetes belongs to a family of HLA-associated immune-mediated organ-specific diseases. Genetic susceptibility is polygenic, with the greatest contribution

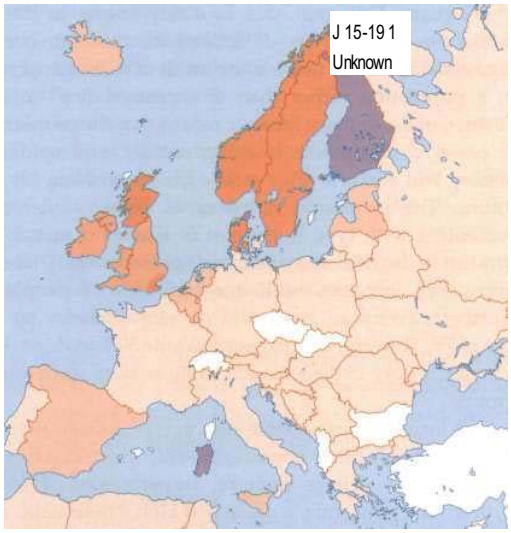

***Fig. 19.5* Age-standardized incidence rates of type 1 diabetes (onset 0-14 years) in Europe, per 100 000 per year.** From Green A, Gale EAM et al. (1992) *Lancet* **339:** 905-909.

from the HLA region. Autoantibodies directed against pancreatic islet constituents appear in the circulation within the first few years of life, and predate clinical onset by many years. Autoantibodies are also found in older patients with LADA and predict progression to insulin therapy in this group.

Genetic susceptibility

Type 1 diabetes is not genetically predetermined, but increased susceptibility to the disease may be inherited.

Inheritance

The identical twin of a patient with type 1 diabetes has a 30-50% chance of developing the disease. Since twins with identical genes may never develop the disease, non-genetic factors must also be involved. Children of people with type 1 diabetes have an increased chance of developing type 1 diabetes. The risk of developing diabetes by age 20, curiously, is greater with a diabetic father (3-7%) than with a diabetic mother (2-3%). If one child in a family has type 1 diabetes, each sibling has a ~ 6% risk of developing diabetes by age 20. If siblings are HLA-identical (share the san.- HLA type as the affected child), the risk rises to about 20%. Longer-term follow-up has, however, shown that the lifetime risk of diabetes in first-degree relatives is considerably greater than this.

HLA system. The HLA genes on chromosome 6 are highly polymorphic and modulate the immune defence system of the body. More than 90% of patients with type 1 diabetes carry HLA-DR3-DQ2, HLA-DR4-DQ8, or both, as compared with some 35% of the background population. All DQBl alleles with an aspartic acid at residue 57 confer neutral to protective effects with the strongest effect from DQBl*0602 (DQ6), while DQBl alleles with an alanine at the same position (i.e. DQ2 and DQ8) confer strong susceptibility. Genotypic combinations have a major influence upon risk of disease. For example HLA DR3-DQ2/HLA DR4-DQ8 heterozygotes have a considerably increased risk of disease. The presence or absence of certain HLA class I alleles substantially modifies the risk conferred by class II susceptibility genes.

Other gene regions. Genome-wide searches for regions conferring susceptibility to, or protection against, type 1 diabetes have been carried out, and 10-20 regions of interest have been identified. These are designated *1DDM1* (HLA locus), *IDDM2* and so on. It is already clear that individually these make a much smaller contribution to genetic susceptibility than the HLA region. An intensive search to identify these genes and their products continues.

A DNA region close to the insulin gene on chromosome 11 is designated *IDDM2,* and short, intermediate and long insertions (see p. 177) have been reported. Homozygosity of the short (class I) allele is found in some 80% of patients with type 1 diabetes as against 40% of controls.

The *CTLA-4* gene has also been implicated in type 1 diabetes and might be a common factor in a variety of HLA-associated autoimmune conditions.

Autoimmunity and insulin-dependent diabetes mellitus

Several pieces of evidence suggest that type 1 diabetes is an immune-mediated disease. These include the HLA associations described above, and associations with other organ-specific autoimmune diseases including autoimmune thyroid disease, Addison's disease and pernicious anaemia. Autopsies of patients who died soon after diagnosis show infiltration of the pancreatic islets by mononuclear cells. This appearance, known as insulitis, resembles that in other autoimmune diseases such as thyroiditis. Autoantibodies directed against islet constituents are also present in some 90% of newly presenting patients. A number of islet antigens have been characterized, and include insulin itself, the enzyme glutamic acid decarboxylase (GAD), and the intracellular portion of two islet peptides from the tyrosine phosphatase family (Fig. 19.6). Confirmation of the autoimmune nature of the disease came from the observation that treatment with immunosuppressive agents such as ciclosporin following diagnosis prolongs beta-cell survival.

Environmental factors

The incidence of childhood type 1 diabetes is rising steadily, suggesting that environmental factor(s) are involved in its pathogenesis. Early exposure to enteroviruses such as Coxsackie B4 has often been suspected, but the role of viruses in the causation of the disease has yet to be confirmed. It has also been suggested that a cleaner environment with less early stimulation of the immune system in childhood may increase susceptibility

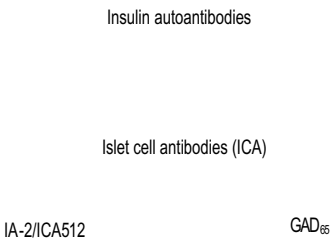

Fig. 19.6 **Islet autoantibodies.** Islet cell antibodies are detected by a fluorescent antibody technique which detects binding of autoantibodies to islet cells. Much of this staining reaction is due to antibodies specific for glutamic acid decarboxylase (GAD) and protein tyrosine phosphatase - IA-2 (also known as ICA512). Not all the staining seen with ICA is due to these two autoantibodies, so it is assumed that other islet autoantibodies are also involved. Insulin autoantibodies also appear in the circulation but do not contribute to the ICA reaction.

for type 1 diabetes, as for atopic/allergic conditions (the hygiene hypothesis).

Pre-type 1 diabetes and prevention of type 1 diabetes

Prospective studies of first-degree relatives of children with diabetes have shown that islet autoantibodies appear in the circulation in the first few years of life - demonstrating that the process culminating in diabetes is initiated very early - and many years before diagnosis. Further, they can predict development of the disease, especially when present in combination. The ability to predict the disease has opened the way to possible disease prevention, but trials using injected or oral insulin or nicotinamide have all proved unsuccessful.

Type 2 diabetes mellitus

Epidemiology

This is relatively common in all populations enjoying an affluent lifestyle. The four major determinants are increasing age, obesity, ethnicity and family history. Large differences in prevalence exist based on these characteristics. In poor countries diabetes is a disease of the rich, but in rich countries it is a disease of the poor. The disease may be present in a subclinical form for years before diagnosis. The onset may be accelerated by the stress of pregnancy, drug treatment or intercurrent illness. Estimates of prevalence using the WHO criteria (p. 1109) would suggest an overall prevalence of around 2% within the UK. Within the UK, type 2 diabetes is three to four times as prevalent in people of South Asian, African and Caribbean ancestry. High rates have also been found in people of middle Eastern or Hispanic American origin living western lifestyles. Unfortunately, people in westernized countries gain on average nearly 1 gram in weight every day of their adult life between the ages of 25-55 years. This gain, due to a tiny excess in energy intake over expenditure - 90 kcal or one chocolate-coated digestive biscuit per day - is the result of reduced exercise in a population rather than of increased food intake. Further, our sedentary lifestyle means that the proportion of obese young adults is rising rapidly, and epidemic obesity will create a huge public health problem for the future. The increasing numbers of obese adolescents presenting with type 2 diabetes is already a matter for concern in the USA and other parts of the world. Diabetes prevalence increases with age and 10% of people of Northern European stock will develop diabetes by the age of 70. This proportion rises towards 30% in those with a family history of diabetes and in those from some ethnic groups.

The insulin resistant state seen in type 2 diabetes tends to cluster with other conditions which increase cardiovascular risk. These include: hypertension, obesity, hypertriglyceridaemia, a decreased HDL-cholesterol, and the skin condition acanthosis nigricans. High insulin levels are characteristic. This has been called the insulin resistance syndrome, syndrome X or the metabolic syndrome. It seems likely that this is not a distinct entity but one end of a continuum in the relationship between exercise, lifestyle and bodyweight on the one hand, and individuals' genetic make-up on the other - resulting in a state associated with adverse clinical consequences. About a third of the adult population have features of the syndrome, not necessarily associated with diabetes.

Causes of type 2 diabetes

Genetics

Population-based studies show identical twins of patients with type 2 diabetes have a greater than 50% chance of developing diabetes; the risk to non-identical twins or siblings is of the order of 25%. These observations confirm a genetic component to the disease. Type 2 diabetes is a polygenic disorder, but the genes responsible for the great majority of cases have yet to be identified. This situation seems set to change, and as genetic causes are discovered the phenotypic differences between people currently lumped together as having 'type 2 diabetes' will probably be explained.

The genetic causes of some rare forms of type 2 diabetes are shown in Table 19.3.

A rare variant of type 2 diabetes is referred to as 'maturity-onset diabetes of the young' (MODY). This is dominantly inherited. Five variants have been described. The different MODY genotypes are associated with different clinical phenotypes (Table 19.4). MODY should be considered in young people presenting with a typical family history (diabetes affecting a parent and 50% expression of the disease in the family) plus a form of early-onset diabetes which appears easy to control.

Environmental factors: early and late

An association has been noted between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excess weight as adults. The concept is that poor nutrition early in life

Table 19.3 Rare genetic causes of type 2 diabetes

Disorder	Features
Insulin receptor mutations	Obesity, marked insulin resistance, hyperandrogenism in women, acanthosis nigricans (areas of hyperpigmented skin)
Maternally inherited diabetes and deafness (MIDD)	Mutation in mitochondrial DNA. Diabetes onset before age 40. Variable deafness, neuromuscular and cardiac problems, pigmented retinopathy
Wolfram syndrome (DIDMOAD - diabetes insipidus, diabetes mellitus, optic atrophy and deafness)	Recessively inherited. Mutation in the transmembrane gene, *WFS1*. Insulin-requiring diabetes and optic atrophy in the first decade. Diabetes insipidus and sensorineural deafness in the second decade progressing to multiple neurological problems. Few live beyond middle age
Severe obesity and diabetes	Alstrom, Bardet-Biedl and Prader-Willi syndromes. Retinitis pigmentosa, mental insufficiency and neurological disorders
Disorders of intracellular insulin signalling. All with severe insulin resistance	Leprechaunism Rabson-Mendenhall syndrome Pseudoacromegaly Partial lipodystrophy: lamin A/C gene mutation

impairs beta-cell development and function, predisposing to diabetes in later life. Low birthweight has also been shown to predispose to heart disease and hypertension in later life.

Immunology and inflammation

There is no evidence of immune involvement in the pathogenesis of type *2* diabetes, but as noted earlier, a proportion of late-onset patients carry islet autoantibodies directed against GAD at diagnosis, and these are more likely to progress to insulin therapy. Such cases are probably type 1 diabetes masquerading as type 2 diabetes.

A recent development is the recognition that subclinical inflammatory changes are characteristic of both type 2 diabetes and obesity. In diabetes, high-sensitivity C-reactive protein (CRP) levels are elevated in association with raised fibrinogen and increased plasminogen activator inhibitor-1 (PAI-1), and contribute to cardiovascular risk. Circulating levels of the proinflammatory cytokines TNF-a and IL-6 are elevated in both diabetes and obesity. Use of anti-inflammatory agents might potentially reduce the vascular risk associated with both conditions.

Abnormalities of insulin secretion and action

There has been considerable controversy as to the relative role of secretory failure versus insulin resistance in the pathogenesis of type 2 diabetes, but both factors are involved. Although insulin can bind normally to its receptor on the surface of cells in type 2 diabetes, unknown abnormalities attenuate insulin signalling within the cell, producing 'insulin resistance'. An excess accumulation of intracellular triglyceride in muscle and liver in type 2 diabetes may contribute to this resistance. Type 2 diabetes develops when a person cannot secrete enough insulin to overcome this burden of insulin resistance. Depleted numbers of beta-cells are thus in a state of high output failure. This leads to increased glucose production from the liver (owing to inadequate suppression by insulin) and inadequate uptake of glucose peripherally.

Patients with type 2 diabetes retain up to 50% of their beta-cell mass at the time of diagnosis. In addition, almost all show islet amyloid deposition at autopsy, derived from a peptide known as amylin or islet amyloid polypeptide (IAPP) which is co-secreted with insulin. It is not known if this is a cause or consequence of beta-cell secretory failure. Abnormalities of insulin secretion manifest early in the course of type 2 diabetes. Normal subjects have a biphasic insulin response to intravenous glucose, but the first-phase insulin response is lost as

Table 19.4 Maturity-onset diabetes of the young **(MODY)**

	HNF-4a (MODY 1)	Glucokinase (MODY 2)	HNF-1a (MODY 3)	IPF-1 (MODY 4)	HNF-1b (MODY 5)
Chromosomal location	20q	7p	12q	13q	17q
Proportion of all MODY cases	5%	15%	70%	< 1 % (MODY)	2%
Onset	Teens to thirties	Present from birth	Teens/twenties	Teens to thirties	Teens/twenties
Progression	Progressive hyperglycaemia	Little deterioration with age	Progressive hyperglycaemia	Progression unclear	Progression unclear
Microvascular complications	Frequent	Rare	Frequent	Few data	Frequent
Other features	None	Reduced birthweight	Sensitivity to sulphonylureas	Pancreatic agenesis in homozygotes	Renal cysts Proteinuria Renal failure

The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic beta-cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the beta-cell where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage

hyperglycaemia develops, and insulin secretion in response to oral glucose is delayed and exaggerated. The majority of patients manifest reduced insulin secretion relative to the prevailing glucose concentration, and progressive beta-cell loss occurs in many patients, although not to the extent seen in type 1 diabetes. It is not known whether this is due to 'exhaustion' of surviving beta-cells or to some independent process of damage.

Overview and prevention

Whether an individual develops type 2 diabetes or not is largely due to genetic factors. *When* a person develops diabetes depends on lifestyle and is more relevant. Diabetes diagnosed in a man between the ages of 40-59 can cause a reduction in life expectancy by 5-10 years. In contrast, type 2 diabetes diagnosed after the age of 70 has little appreciable effect on life expectancy in men. Clinical trials have shown that diet, exercise or agents such as metformin have a marked effect in deferring the onset of type 2 diabetes.

CLINICAL PRESENTATION OF DIABETES

Acute and subacute presentations often overlap.

Acute presentation

Young people often present with a 2- to 6-week history and report the classic triad of symptoms:

- polyuria - due to the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- thirst — due to the resulting loss of fluid and electrolytes
- weight loss - due to fluid depletion and the accelerated breakdown of fat and muscle secondary to insulin deficiency.

Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute presentation

The clinical onset may be over several months or years, particularly in older patients. Thirst, polyuria and weight loss are typically present but patients may complain of such symptoms as lack of energy, visual blurring (owing to glucose-induced changes in refraction), or pruritus vulvae or balanitis that is due to *Candida* infection.

Complications as the presenting feature

These include:

- staphylococcal skin infections
- retinopathy noted during a visit to the optician
- a polyneuropathy causing tingling and numbness in the feet
- erectile dysfunction
- arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic diabetes

Glycosuria or a raised blood glucose may be detected on routine examination (e.g. for insurance purposes) in individuals who have no symptoms of ill-health. Glycosuria is not diagnostic of diabetes but indicates the need for further investigations. About 1% of the population have renal glycosuria. This is an inherited low renal threshold for glucose, transmitted either as a Mendelian dominant or recessive trait.

Physical examination at diagnosis

Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older patients may present with established complications, and the presence of the characteristic retinopathy is diagnostic of diabetes. In occasional patients there will be physical signs of an illness causing secondary diabetes (Table 19.1).

DIAGNOSIS AND INVESTIGATION OF DIABETES

Diabetes is easy to diagnose when overt symptoms are present, and a glucose tolerance test is not necessary for most clinical purposes. The oral glucose tolerance test has, however, allowed more detailed epidemiological characterization based on the existence of separate glucose thresholds for macrovascular and microvascular disease. These correspond with the levels for the diagnosis of impaired glucose tolerance (IGT) and diabetes as specified by the WHO criteria set out in Box 19.1.

Epidemiological studies have shown that for every person with known diabetes, there is another undiagnosed

O

Box 19.1 **WHO diagnostic criteria - 1999**

WHO criteria are:

- Fasting plasma glucose > 7.0 mmol/L (126 mg/dL)
- Random plasma glucose >11.1 mmol/L (200 mg/dL)

H One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people.

The glucose tolerance test is only required for borderline cases and for diagnosis of gestational diabetes.

The glucose tolerance test - WHO criteria

	Normal	**Impaired glucose tolerance**	**Diabetes mellitus**
Fasting	Less than 7.0 mmol/L	Less than 7.0 mmol/L	More than 7.0 mmol/L
2 h after glucose	Less than 7.8 mmol/L	Between 7.8 and 11.0 mmol/L	11.1 mmol/L or more

- Adult: 75 g glucose in 300 mL water.
- Child: 1.75 g glucose/kg bodyweight.
- Only a fasting and a 120-min sample are needed.

m Results are for venous plasma - whole blood values are lower.

Note: There is no such thing as mild diabetes. All patients who meet the criteria for diabetes are liable to disabling long-term complications.

in the population. A much larger proportion fall into the intermediate category of impaired glucose tolerance.

Impaired glucose tolerance

This is not a clinical entity but a risk factor for future diabetes and cardiovascular disease. Obesity and lack of regular physical exercise make progression to frank diabetes more likely. The classification is complicated by the poor reproducibility of the oral glucose tolerance test. The group is heterogeneous; some patients are obese, some have liver disease, and others are on medication that impairs glucose tolerance. Individuals with IGT have the same risk of cardiovascular disease as in frank diabetes but do not develop the specific microvascular complications.

Impaired fasting glucose

L — m — m

This diagnostic category (fasting plasma glucose between 6.1 and 6.9 mmol/L) was introduced by the American Diabetes Association, with the practical advantage that it avoids the need for a glucose tolerance test. This is not a clinical entity, but does predict future risk of frank diabetes and cardiovascular disease. This category only overlaps with IGT to a limited extent, and therefore the associated risks of cardiovascular disease and future diabetes are not directly comparable. More recently, the lower cut-off of 5.6mmol/l has been recommended by the same association, which will of course greatly increase the number of those affected. This has yet to be considered by the WHO.

Other investigations

No further tests are needed to diagnose diabetes. Other routine investigations include screening the urine for protein, a full blood count, urea and electrolytes, liver biochemistry and random lipids. The latter test is useful to exclude an associated hyperlipidaemia and, if elevated, should be repeated fasting after diabetes has been brought under control. Diabetes may be secondary to other conditions (see Table 19.1), may be precipitated by underlying illness and be associated with autoimmune disease or hyperlipidaemia. Hypertension is present in 50% of patients with type 2 diabetes and even more in African and Caribbean patients.

TREATMENT OF DIABETES

The role of patient education and community care

The care of diabetes is based on self-management by the patient, who is helped and advised by those with specialized knowledge. The quest for improved glycaemic control has made it clear that whatever the technical expertise applied, the outcome depends on willing cooperation by the patient. This in turn depends on an understanding of the risks of diabetes and the potential benefits of glycaemic control and other measures such as maintaining a lean weight, stopping smoking and taking care of the feet. If accurate information is not supplied, misinformation from friends and other patients will take its place. For this reason the best time to educate the patient is soon after diagnosis. Organized education programmes will involve all health-care workers, including nurse specialists, dietitians and podiatrist.

Diet

The diet for people with diabetes is no different from that considered healthy for everyone. Table 19.5 lists current recommendations on the ideal composition of this diet. To achieve this, food for people with diabetes should be:

- low in sugar (though not sugar free)
- high in starchy carbohydrate (especially foods with a low glycaemic index)

high in fibre
low in fat (especially saturated **fat).**

Table 19.5 **Recommended composition of the diet for people with diabetes, with comments on how this may be achieved**

Component of diet	Comment
Protein	1 g per kg ideal bodyweight (approx.)
Total fat	< 35% of energy intake. Limit: fat/oil in cooking, fried foods, processed meats (burgers, salami, sausages), high-fat snacks (crisps, cake, nuts, chocolate, biscuits, pastry). Encourage: lower-fat dairy products (skimmed milk, reduced-fat cheese, low-fat yoghurt), lean meat
Saturated and *trans*-unsaturated fat	< 10% of total energy intake
n-6 polyunsaturated fat	< 10% of total energy intake
n-3 polyunsaturated fat	No absolute quantity recommended. Eat fish, especially oily fish, once or twice weekly. Fish oil supplements not recommended
C/s-monounsaturated fat	10-20% of total energy intake (olive oil, avocado)
Total carbohydrate	40-60% of total energy intake. Encourage: artificial (intense) sweeteners instead of sugar (sugar-free fizzy drinks, squashes and cordials). Limit: fruit juices, confectionery, cake, biscuits
Sucrose	Up to 10% of total energy intake, provided this is eaten in the context of a healthy diet (examples: fibre-rich breakfast cereals, baked beans) No absolute quantity recommended. Soluble
Fibre	fibre has beneficial effects on glycaemic and lipid metabolism. Insoluble fibre has no direct effects on glycaemic metabolism, but benefits satiety and gastrointestinal health
Vitamins and	Best taken as fruit and vegetables (five portions per day) in a mixed diet. There is no evidence for the use of supplements
Alcohol	Not forbidden. Its energy content should be taken into account, as should its tendency to cause delayed hypoglycaemia in those treated with insulin
Salt	< 6 g per day (lower in hypertension)

The overweight or obese should be encouraged to lose weight by a combination of changes in food intake and physical activity.

Carbohydrates

Slowly absorbed carbohydrates (those with a low glycaemic index) prevent rapid swings in circulating glucose. For example, the glucose peak seen in the blood after eating pasta is much flatter than that seen after eating the same amount of carbohydrate as white potato.

Prescribing a diet

Most people find it extremely difficult to modify their eating habits, and repeated advice and encouragement are needed if this is to be achieved. A diet history is taken, and the diet prescribed should involve the least possible interference with the person's lifestyle. Advice from dietitians is more likely to affect medium-term outcome than is advice from doctors. People taking insulin or oral agents have traditionally been advised to eat roughly the same amount of food (particularly carbohydrate) at roughly the same time each day, so that treatment can be balanced against food intake and exercise. Knowledgeable and motivated patients with type 1 diabetes, who get feedback from regular blood glucose monitoring, can vary the amount of carbohydrate consumed, or meal times, by learning to adjust their exercise pattern and treatment. This is the basis of the DAFNE (Dose Adjustment For Normal Eating) regimen.

Tablet treatment for type 2 diabetes

Diet and lifestyle changes are the key to successful treatment of type 2 diabetes. If satisfactory metabolic control (see 'Measuring control' below) of diabetes is not established by these measures after several weeks, tablets may be needed in addition. Tablets should only be introduced after the patient has witnessed the improvement obtained by changes in diet and lifestyle - this will establish the concept that controlling diabetes is not just a matter of swallowing tablets (but see p. 1123).

Sulphonylureas (Table 19.6)

Their principal action is to promote insulin secretion in response to glucose and other secretagogues.

Sulphonylureas close ATP-sensitive potassium channels on the beta-cell membrane, and the resulting depolarization promotes calcium influx, a signal for insulin release (see Fig. 19.2). Sulphonylureas are ineffective in patients without a functional beta-cell mass and should be avoided in young ketotic patients, who require early insulin therapy, and they are usually avoided in pregnancy (p. 1132).

Sulphonylureas should be used with care in patients with liver disease, and only those primarily excreted by the liver should be given to patients with renal impairment. All encourage weight gain and are therefore not drugs of first choice in obese patients. Tolbutamide is the safest drug in the very elderly because of its short duration of action.

Table 19.6 **Properties of the most commonly used sulphonylureas**

Drug	Features
Tolbutamide	Lower maximal efficacy than other sulphonylureas Short half-life - preferable in elderly
Largely metabolized by liver - can use in renal impairment	
Glibenclamide, glipizide and glimepiride	Long biological half-life Active metabolites Renal excretion - avoid in renal impairment
Gliclazide	Fairly long biological half-life
Largely metabolized by liver - can use in renal impairment More costly	
Chlorpropamide	Very long biological half-life Renal excretion - avoid in renal impairment 1-2% develop inappropriate ADH-like syndrome Facial flush with alcohol Very inexpensive - major issue for developing countries

Drug interactions and side-effects. All sulphonylureas bind to circulating albumin and may be displaced by other drugs, such as sulphonamides, that compete for their binding sites. They interact with warfarin.

Hypoglycaemia is the most common and dangerous side-effect. Because the action of many sulphonylureas persists for more than 24 hours, recurrent or prolonged hypoglycaemia is likely, and hospital admission is advisable. Skin rashes and other sensitivity reactions do rarely occur.

Meglitinides

Repaglinide and nateglinide are insulin secretagogues known as the meglitinides. Meglitinides are the non-sulphonylurea moiety of glibenclamide. As with the sulphonylureas, they act via closure of the K^+-ATP channel in the beta-cells (Fig. 19.2), although their receptor-binding characteristics are different. They are short-acting agents that promote insulin secretion in response to meals, and which might thus reduce between-meal hypoglycaemia. They are more expensive than standard sulphonylureas. Whether they have advantages over established short-acting sulphonylureas such as tolbutamide has not been addressed by clinical trials.

Biguanides

Metformin is currently the best validated primary treatment for type 2 diabetes. Its mechanism of action remains unclear but it reduces gluconeogenesis, thus suppressing hepatic glucose output, and it increases insulin sensitivity. Unlike the sulphonylureas it does not induce hypoglycaemia in normal volunteers. It is particularly helpful in the overweight since it does not promote weight gain. It may be given in combination with sulphonylureas or thiazolidinediones.

Its side-effects include anorexia, epigastric discomfort and diarrhoea. A colonoscopy should never be ordered without testing the effect of stopping metformin! Lactic acidosis has occurred in patients with severe hepatic or renal disease, and metformin is contraindicated when these are present.

A Cochrane review showed little risk of lactic acidosis with standard clinical use. Most diabetologists withdraw the drug when serum creatinine exceeds 150 u.mol/L.

Thiazolidinediones

The thiazolidinediones (more conveniently known as the 'glitazones') reduce insulin resistance by interaction with peroxisome proliferator-activated receptor-gamma (PPAR-gamma), a nuclear receptor which regulates genes involved in lipid metabolism and insulin action. The paradox that glucose metabolism should respond to a drug that binds to nuclear receptors mainly found in fat cells is still not fully understood. One suggestion is that they act indirectly via the glucose-fatty acid cycle, lowering free fatty acid levels and thus promoting glucose consumption by muscle.

The glitazones lower circulating insulin relative to plasma glucose, but do not return glucose levels to normal. They can be used alone or in combination with other agents. The glitazones reduce hepatic glucose production, an effect that is synergistic with that of metformin, and also enhance peripheral glucose uptake. They thus potentiate the effect of endogenous insulin.

Troglitazone, the first agent in this class, was withdrawn because of problems with hepatic toxicity. Rosiglitazone and pioglitazone are currently licensed in the UK and USA. Liver biochemistry should be monitored. They are useful in patients who cannot tolerate metformin or sulphonylureas (NICE guidelines). They cause weight gain and a degree of salt and water retention. Anaemia is an occasional side-effect. The place of this group of agents is not yet clear, whilst the outcome of comparative controlled clinical trials is awaited.

Intestinal enzyme inhibitors

Alpha-glucosidase inhibitors. These offer an alternative approach to the treatment of overweight patients with type 2 diabetes. They inhibit the enzymes involved in carbohydrate digestion in the intestine. Acarbose is a sham sugar that competitively inhibits alpha-glucosidase enzymes situated in the brush border of the intestine. As a result, dietary carbohydrate is poorly absorbed, and the postprandial rise in blood glucose is reduced. Undigested starch may then enter the large intestine where it will be broken down by fermentation. Abdominal discomfort, flatulence and diarrhoea can result, and dosage needs careful adjustment to avoid these side effects. Very little enters the circulation, since it is mainly inactivated in the gut, but liver dysfunction may rarely occur at high doses

Lipase inhibitors. Orlistat causes fat malabsorption by rendering intestinal lipase enzymes less effective, and

therefore reducing the absorption of fat from the diet. It can contribute to weight loss in patients who are already under careful dietary supervision possibly because it has the effect of inducing unpleasant steatorrhoea, and patients therefore reduce their fat intake and lose weight. Its place in diabetes management remains unclear.

Insulin treatment

Insulin is found in every creature with a backbone, and the key parts of the molecule show few species differences. Small differences in the amino acid sequence may alter the antigenicity of the molecule. The glucose and insulin profiles in normal subjects are shown in Figure 19.7.

Short-acting insulins

Animal insulins are still used widely in developing countries but have now largely been replaced in most of the West by biosynthetic human insulin. This is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells. The proinsulin is subsequently enzymatically cleaved to insulin.

Short-acting insulins are the standard insulins for use in multiple dose regimens and for continuous intravenous infusion in labour and during medical emergencies. Soluble human or animal insulin formulations have a number of limitations. The short-acting preparations enter the circulation too slowly, reaching a peak 60-90 minutes after injection, and their effect persists too long after meals, predisposing to hypoglycaemia. This delay in absorption is due mainly to the fact that soluble insulin forms hexamers, in which six insulin molecules form around a zinc core. These hexamers are too big to be easily absorbed from subcutaneous tissues and dissociate relatively slowly following injection.

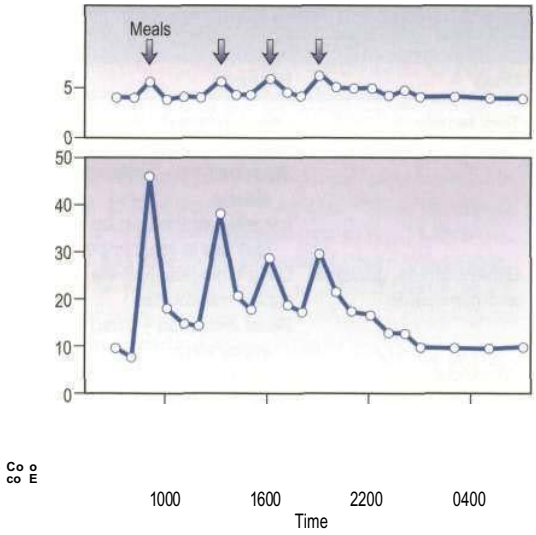

Fig. 19.7 **Glucose and insulin profiles in normal subjects.**

Short-acting insulin analogues have the structure of the insulin molecule modified in such a way as to change its pharmacokinetics without altering the biological effect. Insulin analogues such as insulin lispro and insulin aspart have a modification of small numbers of the amino acids on the B chain producing insulins which dissociate much more rapidly from hexamers, and thus enter the circulation more rapidly, and equally disappear from the circulation more rapidly, than soluble insulin (Fig. 19.8).

Fig. 19.8 **Amino acid structure of human insulin.** Lispro is a genetically engineered rapidly acting insulin analogue created by reversing the order of the amino acids proline and lysine in positions 28 and 29 of the B chain. Insulin aspart is a similar analogue created by replacing proline at position 28 of the B chain with an aspartic acid residue. Insulin glargine is a genetically engineered long-acting insulin created by replacing asparagine in position 21 of the A chain with a glycine residue and adding two arginines to the end of the B chain. Insulin detemir discards threonine in position 30 of the B chain and adds a fatty acyl chain to lysine in position B29.

Longer-acting insulins

Protamine or zinc can be added to human and animal insulins to aid the formation of insulin crystals. Crystals dissolve slowly; insulin prepared in this way is cloudy in appearance.

- *Protamine* or NPH (neutral protamine Hagedorn) insulin, also known as isophane insulin, can be premixed with soluble insulin to form stable mixtures. A range of these mixtures is available, but the combination of 30% soluble with 70% NPH is the most widely used.
- *Zinc* insulins are prepared by precipitation of insulin crystals in the presence of excess zinc. The duration of action of the insulin is proportional to the size of the crystals. Since an excess of zinc is present in the vial, these insulins cannot be premixed with soluble insulin, but zinc insulins can be mixed in the syringe with soluble insulin immediately prior to injection.
- *Long-acting analogues* have their structure modified (Fig. 19.8). Insulin glargine has reduced solubility at physiological pH, thus prolonging its duration of action. It is injected as a slightly acidic (pH 4) solution and then precipitates in the tissues. The precipitates then dissolve slowly from the injection site, giving the preparation a longer duration of action and a less peaked concentration profile in the blood than conventional long-acting insulins. Insulin detemir binds to serum albumin, and its slow dissociation from the bound state prolongs its duration of action.

Inhaled insulin will shortly become available, and clinical trials suggest that this may become a feasible means of maintenance therapy. Only short-acting insulin can be administered by this route, so longer-acting insulins still need to be given by injection. The principle is to disperse the insulin into particles sufficiently fine to reach the alveoli. The main limitation is that only about 10% of the inhaled dose reaches the circulation, and this has cost implications. Variability of absorption remains a concern, and it seems unlikely that this form of delivery will ever match the precision of injected insulin.

Practical management of diabetes

All patients with diabetes require diet therapy. Good glycaemic control is unlikely to be achieved with insulin or oral therapy when diet is neglected, especially when the patient is also overweight.

Regular exercise helps to control weight and reduces cardiovascular risk. Walking instead of using transport, gardening regularly, renting an allotment or getting a dog are all to be encouraged. Blood pressure control is vital using an ACE inhibitor or AIIR antagonist (p. 863); virtually all patients require a statin (p. 1123).

Type 2 diabetes

The great majority of patients presenting over the age of 40 will have type 2 diabetes but do not miss the occasional type 1 patient presenting late. An approach to their management is illustrated in Figure 19.9. Diet alone should be tried in the first instance, and dietary knowledge and compliance should always be reassessed with care before proceeding to the next step. This is of particular importance in the obese patient who fails to lose weight. Metformin is being used in all patients by some diabetologists as it reduces cardiovascular risk. Goals of treatment are described on page 1117.

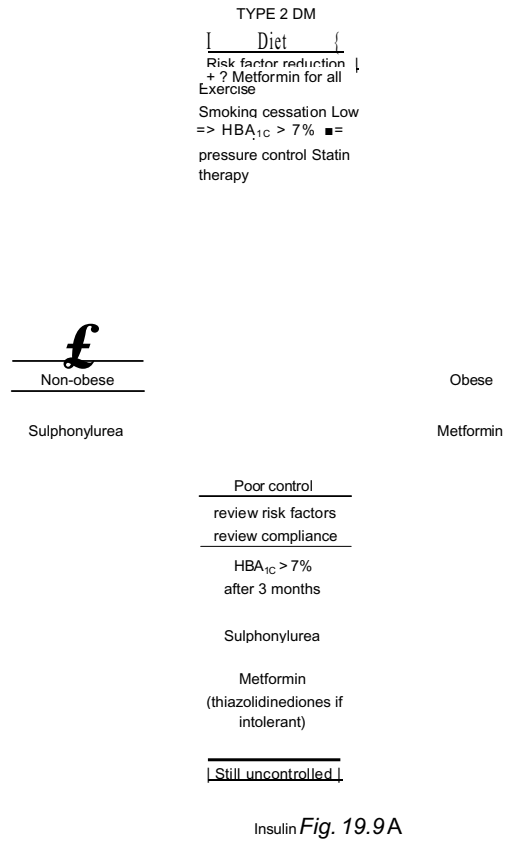

Fig. 19.9 A treatment pathway for type 2 DM.

In type 2 diabetes there is a progressive secretory failure of the beta-cells. The diabetes slowly worsens over years and those patients who are initially adequately controlled with diet, or diet and a tablet, will need gradual increases of their treatment over time, even when adhering well to their diet. An annual review is a convenient way of ensuring that a regular review, and increment, of treatment occurs. For most patients, tablets will eventually fail to achieve adequate metabolic control and a change to insulin treatment will become necessary. The most widespread error in management at this stage is procrastination; the patient whose control is inadequate on oral therapy should start insulin without undue delay. (Consider insulin in all type 2 patients if HbA_{1c} > 9% and in most cases when HbA_{1c} > 7.5%.)

There is little consensus regarding insulin therapy in type 2 diabetes, but an intermediate insulin given at night with metformin during the day is initially as effective as multidose insulin regimens in controlling glucose levels, and is less likely to promote weight gain. Metformin is a useful adjunct to insulin in those able to tolerate it. A second morning dose of insulin may become necessary to control postprandial hyperglycaemia. Twice-daily injections of premixed soluble and isophane insulins (e.g. Mixtard or Humulin M insulins) are widely used and reasonably effective (Fig. 19.10a). More aggressive treatment, such as with multiple injections or pumps, is increasingly used in younger patients with type 2 diabetes.

Type 1 diabetes

Insulin is always indicated in a patient who has been in ketoacidosis, and is usually indicated in all patients who present under the age of 40 years.

Principles of insulin treatment

Injections

The needles used to inject insulin are very fine and sharp. Even though most injections are virtually painless, patients are understandably apprehensive and treatment begins with a lesson in injection technique. Insulin is usually administered by a pen injection device but can be drawn up from a vial into special plastic insulin syringes marked in units (100 U in 1 mL). Injections are given into the fat below the skin on the abdomen, thighs or upper arm, and the needle is usually inserted to its full length. Slim adults and children usually use a 31 gauge 6 mm needle and fatter adults a 30 gauge 8 mm needle. Both reusable and disposable pen devices are available.

The injection site used should be changed regularly to prevent areas of lipohypertrophy. The rate of insulin absorption depends on local subcutaneous blood flow, and is accelerated by exercise, local massage or a warm environment. Absorption is more rapid from the abdomen than from the arm, and is slowest from the thigh. All these factors can influence the shape of the insulin profile.

Insulin administration

In normal subjects a sharp increase in insulin occurs after meals; this is superimposed on a constant background of secretion (Fig. 19.7). Insulin therapy attempts to reproduce this pattern, but ideal control is usually impossible to achieve for four reasons:

- In normal subjects, insulin is secreted directly into the portal circulation and reaches the liver in high concentration; about 50% of the insulin produced by the pancreas is cleared by the liver. In contrast, insulin injected subcutaneously passes into the systemic circulation before passage to the liver. Insulin-treated patients therefore have lower portal levels of insulin and higher systemic levels relative to the physiological situation.
- Subcutaneous soluble insulin takes 60-90 minutes to achieve peak plasma levels, so the onset and offset of action are too slow.
- The absorption of subcutaneous insulin into the circulation is variable.
- Basal insulin levels are constant in normal people, but injected insulin invariably peaks and declines in people with diabetes, with resulting swings in metabolic control.

A multiple injection regimen with short-acting insulin and a longer-acting insulin at night is appropriate for most younger patients (Fig. 19.10b). The advantages of multiple injection regimens are that the insulin and the food go in at roughly the same time so that meal times and sizes can vary, without greatly disturbing metabolic control. The flexibility of multiple injection regimens is of great value to patients with busy jobs, shift workers and those who travel regularly. Some recovery of endogenous insulin secretion may occur over the first few months (the 'honeymoon period') in type 1 patients and the insulin dose may need to be reduced or even stopped for a period. Requirements rise thereafter. Strict glucose control from diagnosis in type 1 diabetes prolongs beta-cell function, resulting in better glucose levels and less hypoglycaemia. Some type 1 diabetes patients will opt for twice-daily mixed insulin injections (Fig. 19.10a) and put up with the

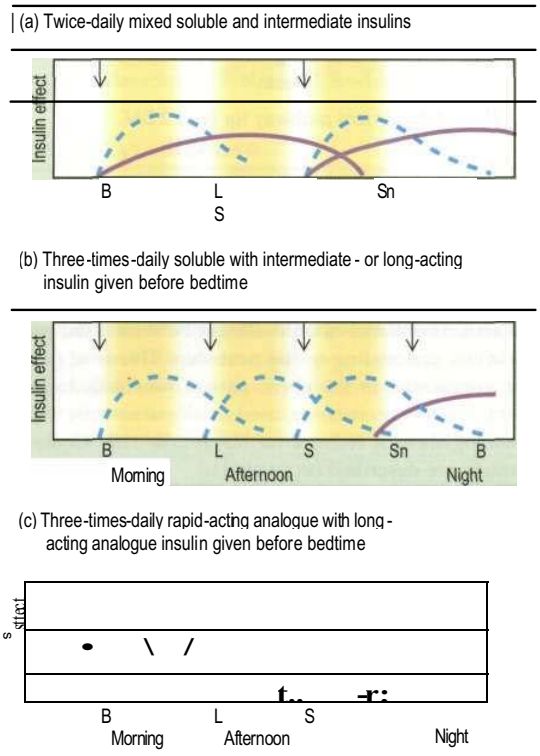

Fig. 19.10 **Insulin** regimens. Profiles of soluble insulins are shown as dashed lines, intermediate- or long-acting insulin as solid lines (purple) and rapid-acting insulin as dotted lines (blue). The arrows indicate when the injections are given. B, breakfast; L, lunch; S, supper; Sn, snack (bedtime).

Table 19.7 **Guide to adjusting insulin dosage according to blood glucose test results**

	Blood glucose persistently too high	Blood glucose persistently too low
Before breakfast	Increase evening long-acting insulin	Reduce evening long-acting insulin
Before lunch	Increase morning short-acting insulin	Reduce morning short-acting insulin or increase mid-morning snack
Before evening meal	Increase morning long-acting insulin or lunch short-acting insulin Increase	Reduce morning long-acting insulin or lunch short-acting insulin or increase mid-afternoon snack
Before bed	evening short-acting insulin	Reduce evening short-acting insulin

lifestyle restrictions that this imposes (with twice-daily regimens, the size and timing of meals are fixed more rigidly). Target blood glucose values should normally be 4-7 mmol/L before meals, 4—10 mmol/L after meals.

All patients need careful training for a life with insulin. This is best achieved outside hospital, provided that adequate facilities exist for outpatient diabetes education. A scheme for adjusting insulin regimens is given in Table 19.7.

When to use insulin analogues

Hypoglycaemia between meals and particularly at night is the limiting factor for many patients on multiple injection regimens. The more expensive rapid-acting insulin analogues (Fig. 19.10c) are a useful substitute for soluble insulin in some patients. Curiously, they offer particular benefit in reducing the frequency of nocturnal hypoglycaemia owing to reduced carry-over effect from the day-time. They are often used on grounds of convenience, since patients can inject shortly before meals. This is illogical since standard insulins injected at the same time give equivalent overall control. High or erratic morning blood sugar readings can prove a problem for about a quarter of all patients on conventional multiple injection regimens, because of waning of the bedtime intermediate-acting insulin and variable absorption. The long-acting insulin analogues insulin glargine and insulin detemir help to overcome these problems and reduce the risk of nocturnal hypoglycaemia

Infusion devices

CSII (continuous subcutaneous insulin infusion) is delivered by a small pump strapped around the waist that infuses a constant trickle of insulin via a needle in the subcutaneous tissues. Meal-time doses are delivered when the patient touches a button on the side of the pump.

This approach is particularly useful in the overnight period, since the basal overnight infusion rate can be programmed to fit each patient's needs. Disadvantages include the nuisance of being attached to a gadget, skin infections, and the risk of ketoacidosis if the flow of insulin is broken (since these patients have no protective reservoir of depot insulin) and cost. Infusion pumps should only be used by specialized centres able to offer a round-the-clock service to their patients. This form of treatment has revolutionized the lives of some patients.

Complications of insulin therapy

At the injection site

Shallow injections result in intradermal insulin delivery and painful, reddened lesions or even scarring. Injection site abscesses occur but are extremely rare.

Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. Generalized allergic responses are exceptionally rare. Fatty lumps, known as lipohypertrophy, may occur as the result of overuse of a single injection site with any type of insulin.

Insulin resistance

The most common cause of mild insulin resistance is obesity. Occasional unstable patients require massive insulin doses, often with a fluctuating requirement. There are often associated behavioural problems. Insulin resistance associated with antibodies directed against the insulin receptor has been reported in patients with acanthosis nigricans (see Table 19.3).

Weight gain

Many patients show weight gain on insulin treatment, especially if the insulin dose is increased inappropriately - insulin makes you feel hungry! Sticking to a careful dietary regimen is vital when on insulin. Patients who are in poor control when insulin is started tend to gain most weight.

Whole pancreas and pancreatic islet transplantation

Whole pancreas transplantation has been performed for some 20 years, usually in diabetic patients who require immunosuppression for a kidney transplant. In experienced hands lasting graft function can be achieved, but the procedure adds to the risks of renal transplantation, and long-term prognosis has not improved.

Islet transplantation is performed by harvesting pancreatic islets from cadavers (two or three pancreata are usually needed); these are then injected into the portal vein and seed themselves into the liver. This form of treatment was attempted for many years with poor results, but recent success has been achieved by an improved protocol developed in Edmonton, Canada. It remains an experimental therapy but experience is slowly accumulating. The main disadvantage is the need for powerful immunosuppressive therapy, with associated costs and complications.

Hypoglycaemia during insulin treatment

This is the most common complication of insulin therapy, and limits what can be achieved with insulin treatment. It is a major cause of anxiety for patients and relatives. Symptoms develop when the blood glucose level falls below 3 mmol/L and typically develop over a few minutes, with most patients experiencing 'adrenergic' features of sweating, tremor and a pounding heartbeat. Physical signs include pallor and a cold sweat. Many patients with long-standing diabetes report loss of these warning symptoms and are at a greater risk of progressing to more severe hypoglycaemia. Such patients appear pale, drowsy or detached, signs that their relatives quickly learn to recognize. Behaviour is clumsy or inappropriate, and some become irritable or even aggressive. Others slip rapidly into hypoglycaemic coma. Occasionally, patients develop convulsions during hypoglycaemic coma, especially at night. This must not be confused with idiopathic epilepsy, particularly as patients with frequent hypoglycaemia often have abnormalities on the electroencephalogram. Another presentation is with a hemiparesis that resolves within a few minutes when glucose is administered.

Hypoglycaemia is a common problem. Virtually all patients experience intermittent symptoms and one in three will go into a coma at some stage in their lives. A small minority suffer attacks that are so frequent and severe as to be virtually disabling. Hypoglycaemia results from an imbalance between injected insulin and a patient's normal diet, activity and basal insulin requirement. The times of greatest risk are before meals and during the night. Irregular eating habits, unusual exertion and alcohol excess may precipitate episodes; other cases appear to be due simply to variation in insulin absorption.

Hypoglycaemic unawareness. People with diabetes have an impaired ability to counter-regulate glucose levels after hypoglycaemia. The glucagon response is invariably deficient, even though the alpha-cells are preserved and respond normally to other stimuli. The epinephrine (adrenaline) response may also fail in patients with a long duration of diabetes, and this is associated with loss of warning symptoms. Recurrent hypoglycaemia may itself induce a state of hypoglycaemia unawareness, and the ability to recognize the condition may sometimes be restored by relaxing control for a few weeks.

Nocturnal hypoglycaemia. Basal insulin requirements fall during the night but increase again from about 4 a.m. onwards, at a time when levels of injected insulin are falling. As a result many patients wake with high blood glucose levels, but find that injecting more insulin at night increases the risk of hypoglycaemia in the early hours of the morning. The problem may be helped by the following:

- checking that a bedtime snack is taken regularly
- for patients taking twice-daily mixed insulin to separate their evening dose and take the intermediate insulin at bedtime rather than before supper
- reducing the dose of soluble insulin before supper, since the effects of this persist well into the night
- changing patients on a multiple injection regimen with soluble insulin to a rapid-acting insulin analogue
- changing to a long-lasting insulin analogue at night.

Urgent treatment of hypoglycaemia

Patients and their families quickly learn to recognize and treat the symptoms of hypoglycaemia.

Mild hypoglycaemia

Any form of rapidly absorbed carbohydrate will relieve the early symptoms, and sufferers should always carry glucose or sweets. Drowsy individuals will be able to take carbohydrate in liquid form (e.g. Lucozade). All patients and their close relatives need careful training about the risks of hypoglycaemia. They should be warned not to take more carbohydrate than necessary, since this causes a rebound to hyperglycaemia. The dangers of alcohol excess and hypoglycaemia while driving need to be emphasized.

Severe hypoglycaemia

The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and can usually be made on clinical grounds, backed by a bedside blood test. If real doubt exists, blood should be taken for glucose estimation before treatment is given. Patients should carry a card or wear a bracelet or necklace identifying themselves as diabetic, and these should be looked for in unconscious patients.

Unconscious patients should be given either intramuscular glucagon (1 mg) or intravenous glucose (25-50 mL of 50% dextrose solution) followed by a flush of normal saline to preserve the vein (since 50% dextrose scleroses veins). Glucagon acts by mobilizing hepatic glycogen, and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work after a prolonged fast. Oral glucose is given to replenish glycogen reserves once the patient

Measuring the metabolic control of diabetes

Urine tests

Some patients will not perform capillary blood glucose monitoring at home. Urine tests give such patients some feedback on whether their diet and treatment are achieving reasonable metabolic control. They are simple to perform using dipsticks, and it can usually be assumed that a patient with consistently negative tests and no symptoms of hypoglycaemia is fairly well controlled. Even so, the correlation between urine tests and simultaneous blood glucose is poor for three reasons:

- Changes in urine glucose lag behind changes in blood glucose.
- The mean renal threshold is around 10 mmol/L but the range is wide (7—13 mmol/L). The threshold also rises with age.

- Urine tests can give no guidance concerning blood glucose levels below the renal threshold.

Home blood glucose testing

The home provides the best place for assessment of day-to-day control. The fasting blood glucose concentration is a useful guide to therapy in tablet-treated type 2 diabetes, but random blood glucose testing (e.g. in the clinic) is of limited value. Patients may easily be taught to provide their own profiles by testing finger-prick blood samples with reagent strips and reading these with the aid of a meter. Most patients are willing and able to provide reasonably accurate results provided they have been properly taught. Blood is taken from the side of a finger tip (not from the tip, which is densely innervated) using a special lancet usually fitted to a spring-loaded device. There is a huge variety of finger-pricking devices and of blood glucose test meters. Patients will normally be able to talk through the use of various devices with a diabetes nurse specialist to select the most appropriate devices for their own purposes. Patients are asked to take regular profiles (e.g. four daily samples on two days each week) and to note these in a diary or record book. Home blood glucose monitoring is an essential aid to good glycaemic control. Patients on insulin are encouraged to adjust their insulin dose as appropriate (Table 19.7) and should ideally be able to obtain advice over the telephone when needed.

Glycosylated haemoglobin (HbA_1 or HbA_{1c}) and fructosamine

Glycosylation of haemoglobin occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the |3 chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. Glycosylated haemoglobin is expressed as a percentage of the normal haemoglobin (standardized range 4-6.5%). This test provides an index of the average blood glucose concentration over the life of the haemoglobin molecule (approximately 6 weeks). The figure will be misleading if the life-span of the red cell is reduced or if an abnormal haemoglobin or thalassaemia is present. There is considerable inter-individual variations in HbA_{1c} levels, even in normal people. Although the glycosylated haemoglobin test provides a rapid assessment of the level of glycaemic control in a given patient, blood glucose testing is needed before the clinician can know what to do about it. *Glycosylated plasma proteins ('fructosamine')* may also be measured as an index of control. Glycosylated albumin is the major component, and fructosamine measurement relates to glycaemic control over the preceding 2-3 weeks. It is useful in patients with anaemia or haemoglobinopathy and in pregnancy (when haemoglobin turnover is changeable) and other situations where changes of treatment need a swift means of assessing progress.

Targets

Data from the UK Prospective Diabetic Study (UKPDS) and the Diabetes Control and Complications Trial (DCCT) suggest that under ideal circumstances patients with both type 1 diabetes and type 2 diabetes would be aiming to run their glycosylated haemoglobin readings in the region of 7.5%, or corrected fructosamine readings of 350 mg/100 g protein, in order to reduce the risk of long-term microvascular complications (Table 19.8). Hypoglycaemia, patterns of eating and lifestyle, weight problems and problems accepting and coping with diabetes limit what can be achieved (see p. 1119). Some will, but most will not, be able to reach these target values, particularly as their duration of diabetes increases. Realistic goals should be set for each patient, taking into account what is likely to be achievable.

Table 19.8 **Target goals of risk factors for diabetic patients**

Parameter	Ideal	Reasonable but not ideal
HbA_{1c}	<7%	< 8.5%
Blood pressure (mmHg)	< 130/80	< 140/90
Total cholesterol (mmol/L)	<4.5	<6
LDL	<2.6	
HDL*	**>1.1**	
Triglycerides	**<1.7**	<2.0

Standards from American Diabetes Association (2003)
* In women > 1.3 mmol/L.

Does good metabolic control of diabetes matter?

Blood glucose is just one measure of the diverse metabolic consequence of diabetes which not only affects carbohydrate metabolism but also the metabolism of lipids and proteins. The DCCT in the USA compared standard and intensive insulin therapy in a large prospective controlled trial of young patients with type 1 diabetes. Despite intensive therapy, mean blood glucose levels were still 40% above the non-diabetic range, but even at this level of control, the risk of progression to retinopathy was reduced by 60%, nephropathy by 30% and neuropathy by 20% over the 7 years of the study. Near-normoglycaemia should, therefore, be the goal for all young patients with type 1 diabetes. The unwanted effects of this policy include weight gain and a two- to threefold increase in the risk of severe hypoglycaemia. Control should be less strict in those with a history of recurrent severe hypoglycaemia.

The UKPDS compared standard and intensive treatment in a large prospective controlled trial of type 2 diabetes patients. There was a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated patients. There appeared to be little difference in outcome between the tools used to achieve good metabolic control (metformin, sulphonylurea or insulin). A proportion of the total patients in the UKPDS were further randomized into standard and intensive blood pressure control groups. Cardiovascular risk was very considerably reduced in the intensive treatment arm.

Can established complications be halted or reversed by intensive insulin therapy? Insulin infusion devices have made near-normal blood glucose control possible for closely supervised groups of patients. Studies in patients with established retinopathy have shown that patients with early retinopathy benefit from intensive therapy, but that patients with more advanced retinal changes generally do not. These observations suggest that microvascular lesions are self-perpetuating once a threshold level of damage has been reached.

Regular checks for patients with diabetes

Box 19.2 is modified from the guidelines set out in *The European Patients' Charter* published by the St Vincent Declaration Steering Committee of the WHO. The charter sets out goals for both the healthcare team and the patient.

Box 19.2 **Regular checks for patients with diabetes**

Checked each visit

Review of self-monitoring results and current treatment.
Talk about targets and change where necessary. -
Talk about any general or specific problems.
Continued education.

Checked at least once a year

Biochemical assessment of metabolic control (e.g. glycosylated Hb test).
* Measure bodyweight.
Measure blood pressure.
r. Measure plasma lipids (except in extreme old age).
* Measure visual acuity.
* Examine state of retina (ophthalmoscope or retinal photo).
B Test urine for proteinuria/microalbuminuria.
» Test blood for renal function (creatinine).
K Check condition of feet, pulses and neurology.
* Review cardiovascular risk factors.
* Review self-monitoring and injection techniques.
B Review eating habits.

PSYCHOSOCIAL IMPLICATIONS OF DIABETES

Patients starting tablet or insulin treatment should be encouraged to live as normal a life as possible, but this is not easy. Tact, empathy, encouragement and practical support are needed from all members of the clinical team. Diabetes, like any chronic disease, has psychological sequelae. Most patients will experience periods of not coping, of helplessness, of denial and of acceptance often fluctuating over time. Other problems include:

- *It is impossible to take a holiday from diabetes* - yet the human psyche is poorly developed to cope with unremitting adversity.
- *Concessions or sympathy are often denied* to the person with diabetes, since its presence is invisible.
- *The treatment is complex and demanding,* and the person with diabetes is expected to make trade-offs between short-term and long-term well-being.
- *Embarrassing loss of control over personal behaviour* or consciousness can occur in insulin-treated patients after only a slight miscalculation.
- *Risk-taking behaviour* is indulged in by all human beings when emotion is in conflict with logical thought, but its effects can be much greater for the person with diabetes (particularly the risks of unplanned pregnancy, alcohol and tobacco).
- *Poor self-image* is a very common problem.
- *Eating disorders* are more common in people with diabetes - 30-40% of young women with diabetes will exhibit a clinically significant eating disorder.
- *Insulin omission* is common since non-adherence to treatment regimens is universal in all illness. Insulin omission is also very common in young women where the pressure to lose weight overcomes concerns about long-term complications.

Adolescence

Adolescence magnifies the internal conflicts that all human beings cope, or intermittently fail to cope, with during life. A period of poor metabolic control, or dropping out of medical care for a time and re-emerging with complications, is very common. Diabetic Holiday Camps (for example run by Diabetes UK) help prevent a feeling of isolation and not knowing anyone else with the same problem. Separate adolescent clinics allow:

- *Treatment without marginalization* in a larger group of older people
- *Meeting peers with similar problems* in the waiting room
- *Gradual separation from parents* and assumption of personal responsibility for the illness
- *Age-appropriate literature* to be available.

Practical aspects

On a practical level patients need to inform the driving and vehicle licensing authority and their insurance companies after diagnosis. They would also be wise to inform their family, friends and employers in case unexpected hypoglycaemia occurs. Insulin treatment can be undertaken by people in most walks of life; a few jobs are unsuitable. These include driving Heavy Goods or Public Service vehicles, working at heights, piloting aircraft or working close to dangerous machinery in motion. Certain professions such as the police and the armed forces are barred to all diabetic patients. There are few other limitations, although a considerable amount of ill-informed prejudice exists. Doctors can sometimes help support patients in the face of misinformed work practices.

DIABETIC METABOLIC EMERGENCIES

The main terms used are defined in Table 19.9.

Table 19.9 **Terms used in uncontrolled diabetes**

Ketonuria	Detectable ketone levels in the urine; it should be appreciated that ketonuria occurs in fasted non-diabetics and may be found in relatively well-controlled patients with insulin-dependent diabetes mellitus
Ketosis	Elevated plasma ketone levels in the absence of acidosis
Diabetic ketoacidosis	A metabolic emergency in which hyperglycaemia is associated with a metabolic acidosis due to greatly raised (> 5 mmol/L) ketone levels
Non-ketotic hyperosmolar state	A metabolic emergency in which uncontrolled hyperglycaemia induces a hyperosmolar state in the absence of significant ketosis
Lactic acidosis	A metabolic emergency in which elevated lactic acid levels induce a metabolic acidosis In diabetic patients it is rare and associated with biguanide therapy

Diabetic ketoacidosis

Diabetic ketoacidosis is the hallmark of type 1 diabetes. It is usually seen in the following circumstances:

- previously undiagnosed diabetes
- interruption of insulin therapy
- the stress of intercurrent illness.

The majority of cases reaching hospital could have been prevented by earlier diagnosis, better communication between patient and doctor, and better patient education. The most common error of management is for patients to reduce or omit insulin because they feel unable to eat owing to nausea or vomiting. This is a factor in at least 25% of all hospital admissions. Insulin should never be stopped.

Pathogenesis

Ketoacidosis is a state of uncontrolled catabolism associated with insulin deficiency. Insulin deficiency is a necessary precondition since only a modest elevation in insulin levels is sufficient to inhibit hepatic ketogenesis, and stable patients do not readily develop ketoacidosis when insulin is withdrawn. Other factors include counter-regulatory hormone excess and fluid depletion. The combination of insulin deficiency with excess of its hormonal antagonists leads to the parallel processes shown in Figure 19.11. In the absence of insulin, hepatic glucose production accelerates, and peripheral uptake by

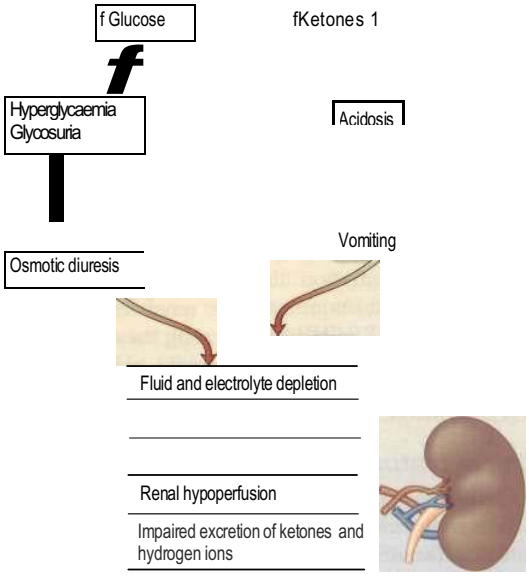

Fig. 19.11 **Dehydration occurs during ketoacidosis as a consequence of two parallel processes.** Hyperglycaemia results in osmotic diuresis, and hyperketonaemia results in acidosis and vomiting. Renal hypoperfusion then occurs and a vicious circle is established as the kidney becomes less able to compensate for the acidosis.

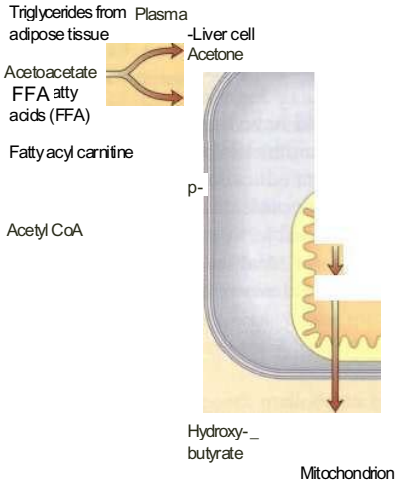

***Fig. 19.12* Ketogenesis.** During insulin deficiency, lipolysis accelerates and free fatty acids taken up by liver cells form the substrate for ketone formation (acetoacetate, acetone and p-hydroxybutyrate) within the mitochondrion. These ketones pass into the blood, producing acidosis.

tissues such as muscle is reduced. Rising glucose levels lead to an osmotic diuresis, loss of fluid and electrolytes, and dehydration. Plasma osmolality rises and renal perfusion falls. In parallel, rapid lipolysis occurs, leading to elevated circulating free fatty-acid levels. The free fatty acids are broken down to fatty acyl-CoA within the liver cells, and this in turn is converted to ketone bodies within the mitochondria (Fig. 19.12). Accumulation of ketone bodies produces a metabolic acidosis. Vomiting leads to further loss of fluid and electrolytes. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell similar to that of acetone. Respiratory compensation for the acidosis leads to hyperventilation, graphically described as 'air hunger'. Progressive dehydration impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. As the pH falls below 7.0 ($[H^+] > 100$ nmol/L), pH-dependent enzyme systems in many cells function less effectively. Untreated, severe ketoacidosis is invariably fatal.

Clinical features

The features of ketoacidosis are those of uncontrolled diabetes with acidosis, and include prostration, hyperventilation (Kussmaul respiration), nausea, vomiting and, occasionally, abdominal pain. The latter is sometimes so severe as to cause confusion with a surgical acute abdomen.

Some patients are mentally alert at presentation, but confusion and stupor are common. Up to 5% present in coma. Evidence of marked dehydration is present and the eyeball is lax to pressure in severe cases. Hyperventilation is present but becomes less marked in very severe acidosis owing to respiratory depression. The smell of ketones on the breath allows an instant diagnosis to be made by those able to detect the odour. The skin is dry and the body temperature is often subnormal, even in the presence of infection; in such cases, pyrexia may develop later.

Diagnosis

This is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis. No time should be lost, and treatment is started as soon as the first blood sample has been taken. Hyperglycaemia is demonstrated by dipstick, while a blood sample is sent to the laboratory for confirmation. Ketonaemia is confirmed by centrifuging a blood sample and testing the plasma with a dipstick that measures ketones. Hand-held sensors measuring f5-hydroxybutyrate in 30 sec are becoming available. An arterial blood sample is taken for blood gas analysis.

Management

The principles of management are as follows (Emergency box 19.1).

- Replace the *fluid losses* with physiological saline (0.9%).
- Replace the *electrolyte losses.* Potassium levels need to be monitored with great care. Patients have a total body potassium deficit although initial plasma levels may not be low. Insulin therapy leads to uptake of potassium by the cells with a consequent fall in plasma K^+ levels. Potassium is therefore given as soon as insulin is started.
- *Restore the acid-base balance.* A patient with healthy kidneys will rapidly compensate for the metabolic acidosis once the circulating volume is restored. Bicarbonate is seldom necessary and is only considered if the pH is below 7.0 ($[H^+] > 100$ nmol/L), and is best given as an isotonic (1.26%) solution.
- *Replace the deficient insulin.* Modern treatment is with relatively modest doses of insulin, which lower blood glucose by suppressing hepatic glucose output rather than by stimulating peripheral uptake, and are therefore much less likely to produce hypoglycaemia. Soluble insulin is given as an intravenous infusion where facilities for adequate supervision exist, or as hourly intramuscular injections. The subcutaneous route is avoided because subcutaneous blood flow is reduced in shocked patients.
- *Monitor blood glucose closely.* Hourly measurement is needed in the initial phases of treatment.
- *Replace the energy losses.* When plasma glucose falls to near-normal values (12 mmol/L), saline infusion should be replaced with 5% dextrose containing 20 mmol/L of potassium chloride. The insulin infusion rate is reduced and adjusted according to blood glucose.
- *Seek the underlying cause.* Physical examination may reveal a source of infection (e.g. a perianal abscess). Two common markers of infection are misleading: fever is unusual even when infection is present, and polymorpholeucocytosis is present even in the absence

Emergency Box 19.1
Guidelines for the diagnosis and management of diabetic ketoacidosis

Diagnosis
- Hyperglycaemia: measure blood glucose.
- Ketonaemia: test plasma with ketostix. Finger prick sample for p-hydroxybutyrate
- Acidosis: measure pH and blood gases.

Investigations
- Blood glucose
- Urea and electrolytes
- Full blood count
- Blood gases
- Blood and urine culture
- Chest X-ray
- ECG
- Cardiac enzymes.

Phase 1 Management
- Admit to HDU
- Insulin: soluble insulin i.v. 6 units/hour by infusion, or 20 units i.m. stat. followed by 6 units i.m. hourly.
- Fluid replacement: 0.9% sodium chloride with 20 mmol KCl per litre. An average regimen would be 1 L in 30 minutes, then 1 L in 1 hour, then 1 L in 2 hours, then 1 L in 4 hours, then 1 L in 6 hours.
- Adjust KCl concentration depending on results of 2 hours' blood K measurement.

IF:

Blood pressure below 80 mmHg, give plasma expander.
pH below 7.0 give 500 mL of sodium bicarbonate 1.26% plus 10 mmol KCl. Repeat if necessary to bring pH up to 7.0.

Phase 2 Management
- When blood glucose falls to 10-12 mmol/L change infusion fluid to 1 litre 5% dextrose plus 20 mmol KCl 6-hourly. Continue insulin with dose adjusted according to hourly blood glucose test results.

Phase 3 Management
- Once stable and able to eat and drink normally, transfer patient to four times daily subcutaneous insulin regimen (based on previous 24 hours' insulin consumption, and trend in consumption).

Special measures
- Broad-spectrum antibiotic if infection likely.
- Bladder catheter if no urine passed in 2 hours.
- Nasogastric tube if drowsy.
- Consider CVP pressure monitoring if shocked or if previous cardiac or renal impairment.
- Give s.c. prophylactic LMW heparin in comatose, elderly or obese patients.

Subsequent management
- Monitor glucose hourly for 8 hours.
- Monitor electrolytes 2-hourly for 8 hours.
- Adjust K replacement according to results.

Note: The regimen of fluid replacement set out above is a guide for patients with severe ketoacidosis. Excessive fluid can precipitate pulmonary and cerebral oedema; inadequate replacement may cause renal failure. Fluid replacement must therefore be tailored to the individual and monitored carefully throughout treatment.

of infection. Relevant investigations include a chest X-ray, urine and blood cultures, and an ECG (to exclude myocardial infarction). If infection is suspected, broad-spectrum antibiotics are started once the appropriate cultures have been taken.

Problems of management

- *Hypotension.* This may lead to renal shutdown. Plasma expanders (or whole blood) are therefore given if the systolic blood pressure is below 80 mmHg. A central venous pressure line is useful in this situation. A bladder catheter is inserted if no urine is produced within 2 hours, but routine catheterization is not necessary.
- *Coma.* The usual principles apply (see p. 1209). It is essential to pass a nasogastric tube to prevent aspiration, since gastric stasis is common and carries the risk of aspiration pneumonia if a drowsy patient vomits.
- *Cerebral oedema.* This rare, but feared, complication has mostly been reported in children or young adults. Excessive rehydration and use of hypertonic fluids such as 8.4% bicarbonate may sometimes be responsible. The mortality is high.
- *Hypothermia.* Severe hypothermia with a core temperature below 33°C may occur and may be overlooked unless a rectal temperature is taken with a low-reading thermometer.

Late complications. These include stasis pneumonia and deep-vein thrombosis, and occur especially in the comatose or elderly patient.

Complications of therapy. These include hypoglycaemia and hypokalaemia, due to loss of K^+ in the urine from osmotic diuresis. Overenthusiastic fluid replacement may precipitate pulmonary oedema in the very young or the very old. Hyperchloraemic acidosis may develop in the course of treatment since patients have lost a large variety of negatively charged electrolytes, which are replaced with chloride. The kidneys usually correct this spontaneously within a few days.

Subsequent management

Intravenous dextrose and insulin are continued until the patient feels able to eat and keep food down. The drip is then taken down and a similar amount of insulin is given as three injections of soluble insulin subcutaneously at meal times and a dose of intermediate-acting insulin at night.

Sliding-scale regimens are unnecessary and may even delay the establishment of stable blood glucose levels. The treatment of diabetic ketoacidosis is incomplete with-

out a careful enquiry into the causes of the episode and advice as to how to avoid its recurrence.

Non-ketotic hyperosmolar state

This condition, in which severe hyperglycaemia develops without significant ketosis, is the metabolic emergency characteristic of uncontrolled type 2 diabetes. Patients present in middle or later life, often with previously undiagnosed diabetes. Common precipitating factors include consumption of glucose-rich fluids (e.g. Lucozade), concurrent medication such as thiazide diuretics or steroids, and intercurrent illness. Non-ketotic coma and ketoacidosis represent two ends of a spectrum rather than two distinct disorders (Box 19.3). The biochemical differences may partly be explained as follows:

- *Age.* The extreme dehydration characteristic of non-ketotic coma may be related to age. Old people experience thirst less acutely, and more readily become dehydrated. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes.
- *The degree of insulin deficiency.* This is less severe in non-ketotic coma. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis, whereas glucose production is unrestrained.

Clinical features

The characteristic clinical features on presentation are dehydration and stupor or coma. Impairment of consciousness is directly related to the degree of hyperosmolality. Evidence of underlying illness such as pneumonia or pyelonephritis may be present, and the hyperosmolar state may predispose to stroke, myocardial infarction or arterial insufficiency in the lower limbs.

Investigations and treatment

These are, with some exceptions, according to the guidelines for ketoacidosis. The plasma osmolality is usually extremely high. It can be measured directly or calculated as $(2(Na^+ + K^+) + \text{glucose} + \text{urea})$ all in mmol/L. Many patients are extremely sensitive to insulin, and the glucose concentration may plummet. The resultant change in osmolality may cause cerebral damage. It is sometimes useful to infuse insulin at a rate of 3 U per hour for the first 2-3 h, increasing to 6 U/h if glucose is falling too slowly. The standard fluid for replacement is 0.9% physiological saline. Avoid 0.45% saline, since rapid dilution of the blood may cause more cerebral damage than a few hours of exposure to hypernatraemia.

Prognosis

The reported mortality ranges as high as 20-30%, mainly because of the advanced age of the patients and the frequency of intercurrent illness. Unlike ketoacidosis, non-ketotic hyperglycaemia is not an absolute indication for subsequent insulin therapy, and survivors may do well on diet and oral agents.

Lactic acidosis

Lactic acidosis may occur in diabetic patients on biguanide therapy. The risk in patients taking metformin is extremely low provided that the therapeutic dose is not exceeded and the drug is withheld in patients with advanced hepatic or renal dysfunction.

O

***Box 19.3* Electrolyte changes in diabetic ketoacidosis and non-ketotic hyperosmolar state Examples of blood values**

	Severe ketoacidosis	Non-ketotic hyperosmolar state
Na^+ (mmol/L)	140	155
K^+ (mmol/L)	**5**	5
Cl" (mmol/L)	100	110
HCO_3" (mmol/L)	**5**	30
Urea (mmol/L)	**8**	**15**
Glucose (mmol/L)	**30**	**50**
Arterial pH	**7.0**	**7.35**

The normal range of **osmolality** is 285-300 mOsm/kg. It can be measured directly, or can be calculated approximately from the formula:

Osmolality = $2(Na^+ + K^+)$ + glucose + urea.

For example, in the example of severe ketoacidosis given above:

Osmolality = 2(140 + 5) + 30 + 8 = 328 mOsm/kg

and in the example of non-ketotic hyperosmolar coma:

Osmolality = 2(155 + 5) + 50 + 15 = 385 mOsm/kg.

The normal **anion gap** is less than 17. It is calculated as $(Na^+ + K^+) - (Cl" + HCO_3")$. In the example of ketoacidosis the anion gap is 40, and in the example of non-ketotic hyperosmolar coma the anion gap is 20. Mild hyperchloraemic acidosis may develop in the course of therapy. This will be shown by a rising plasma chloride and persistence of a low bicarbonate even though the anion gap has returned to normal.

Patients present in severe metabolic acidosis with a large anion gap normally less than 17mmol/L), usually without significant hyperglycaemia or ketosis. Treatment is by rehydration and infusion of isotonic 1.26% bicarbonate. The mortality is in excess of 50%.

COMPLICATIONS OF DIABETES

Insulin-treated patients still have a considerably reduced life expectancy. The major cause of death in treated patients is due to cardiovascular problems (70%) followed by renal failure (10%) and infections (6%). There is no doubt that the duration and degree of hyperglycaemia play a major role in the production of complications. Better diabetic control can reduce the rate of progression of both nephropathy and retinopathy and the DCCT showed a 60% reduction in developing complications over 9 years when the HbA_{1c} was kept at around 7% in type 1 diabetes.

Pathophysiology

The mechanisms leading to damage are ill defined. The following are consequences of hyperglycaemia and may play a role:

- *Non-enzymatic glycosylation* of a wide variety of proteins, e.g. haemoglobin, collagen, LDL and tubulin in peripheral nerves. This leads to an accumulation of advanced glycosylated end-products causing injury and inflammation via stimulation of factors, e.g. com plement, cytokines.
- *Polyol pathway.* The metabolism of glucose by increased intracellular aldose reductase leads to accumulation of sorbitol and fructose. This causes changes in vascular permeability, cell proliferation and capillary structure via stimulation of protein kinase C and TGF-p\
- *Abnormal microvascular blood flow* impairs supply of nutrients and oxygen. Microvascular occlusion is due to vasoconstrictors, e.g. endothelins and thrombo-genesis, and leads to endothelial damage.
- *Other factors* include the formation of reactive oxygen species and growth factors stimulation (TGF-J3) and vascular endothelial growth factor (VEGF). These growth factors are released by ischaemic tissues and cause endothelial cells to proliferate. VEGF is currently the favoured angiogenic factor.
- *Haemodynamic changes,* e.g. in kidney (see p. 1126).

It has been proposed that all of the above mechanisms stem from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain. This exciting new paradigm offers an integrated explanation of how complications of diabetes develop.

Macrovascular complications (Table 19.10)

Diabetes is a risk factor in the development of *atherosclerosis.* This risk is related to that of the background population. For example, Japanese diabetics are much less likely than patients in Europe to develop atherosclerosis, but are much more likely to develop it than are non-diabetic Japanese. The excess risk to diabetics compared **with the** general population increases as one moves down the body:

Table 19.10 **Diabetic risk factors for macrovascular complications**

Duration
Increasing age
Systolic hypertension
Hyperinsulinaemia due to insulin resistance associated with obesity and syndrome X (metabolic syndrome)
Hyperlipidaemia, particularly hypertriglyceridaemia/low HDL
Proteinuria (including microalbuminuria)
Other factors are the same as for the general population

- Stroke is twice as likely.
- Myocardial infarction is three to five times as likely, and women with diabetes lose their premenopausal protection from coronary artery disease.
- Amputation of a foot for gangrene is 50 times as likely.

The UKPDS and DCCT studies have shown that intensive treatment of diabetes has only a small effect upon the cardiovascular risk of type 2 or type 1 diabetes patients.

Cardiovascular risk factors occurring together tend to have a multiplicative effect on the overall level of cardio-vascular risk. It is vital to tackle all cardiovascular risk factors together in diabetes, and not just to focus on glucose levels.

- *Hypertension.* The UKPDS demonstrated that aggressive treatment of hypertension produces a marked reduc tion in adverse cardiovascular outcomes, both micro vascular and macrovascular. To achieve the target for blood pressure (Table 19.8), the UKPDS found that one-third of patients needed three or more antihyper - tensive drugs in combination, and two-thirds of treated patients needed two or more.
- *Smoking:* the avoidable risk factor (see p. 893). Never give up efforts to help diabetic patients stop smoking.
- *Lipid abnormalities.* Clinical trials suggest that there is no 'safe' cut-off for serum cholesterol. The lowest achievable level seems best to aim for, and in practice this means that almost all people with type 2 diabetes will be treated with a statin.
- *Low-dose aspirin* can reduce macrovascular risk, but is associated with a morbidity and mortality from bleed ing. The benefits of aspirin outweigh the bleeding risk when the risk of a cardiovascular end-point is > 30% in the next 10 years. This risk is reached in patients aged under 45 with three strong additional cardiovascular risk factors, aged 45-54 with three additional risk factors, aged 54-65 with two additional risk factors or aged over 65 with just one additional risk factor.
- *ACE inhibitors/Angiotensin II receptor antagonists.* Treating people with diabetes and at least one other major cardiovascular risk factor with an ACE-inhibitor produces a 25-35% lowering of the risk of heart attack, stroke, overt nephropathy or cardiovascular death. ACE receptor antagonists are sometimes preferred

initially and are also used for those intolerant to ACE inhibitors.

A polypill? From the foregoing, it can be seen that people with diabetes will typically require treatment with several antihypertensives, a statin, an ACE inhibitor and low-dose aspirin.

Microvascular complications

In contrast to macrovascular disease, which is prevalent in the West as a whole, microvascular disease is specific to diabetes. Small blood vessels throughout the body are affected but the disease process is of particular danger in three sites:

- retina
- renal glomerulus
- nerve sheaths.

Diabetic retinopathy, nephropathy and neuropathy tend to manifest 10-20 years after diagnosis in young patients. They present earlier in older patients, probably because these have had unrecognized diabetes for months or even years prior to diagnosis. Genetic factors appear to contribute to the susceptibility to microvascular disease. Diabetic siblings of diabetic patients with renal and eye disease have a three- to fivefold increased risk of the same complication in both type 1 and type 2 patients. There are racial differences in the overall prevalence of nephropathy. In the USA prevalence is thus: Pima American Indians > Hispanic/Mexican > US black > US white patients.

Diabetic eye disease

Diabetes can affect the eyes in a number of ways. The most common and characteristic form of involvement is *diabetic retinopathy*. About one in three young people in this patient population is likely to develop visual problems, and in the UK 5% have in the past become blind after 30 years of diabetes. Indeed, diabetes has been the most common cause of blindness in the population as a whole up to the age of 65 years, but its contribution is falling. Other forms of eye disease may also occur:

- *The lens* may be affected by reversible osmotic changes in patients with acute hyperglycaemia, causing blurred vision, or by cataracts.
- *New vessel formation* in the iris (rubeosis iridis) may develop as a late complication of diabetic retinopathy and can cause glaucoma.
- *External ocular palsies*, especially of the sixth nerve, can occur (a mononeuritis).

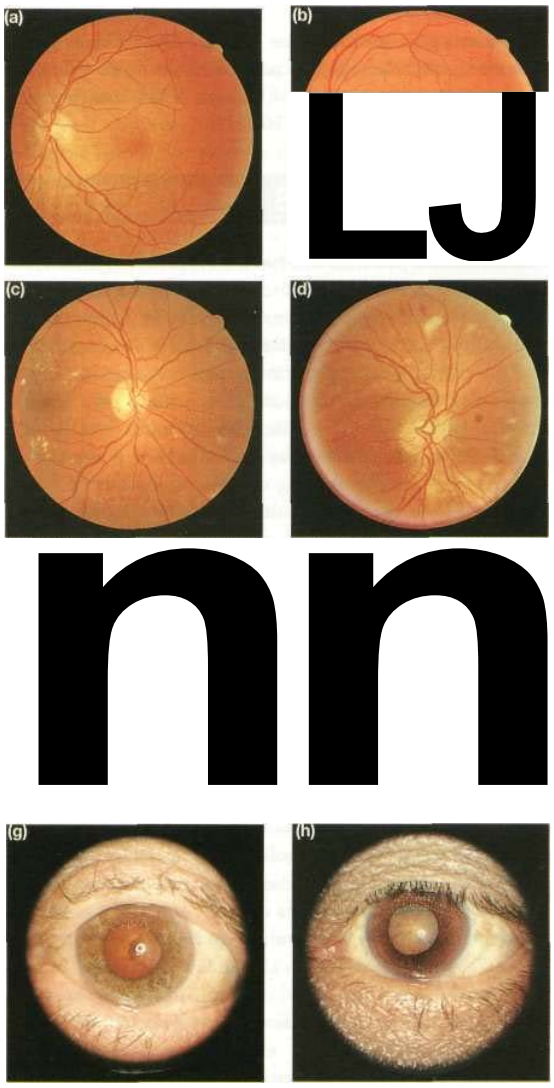

Fig. 19.13 **Features of diabetic eye disease, (a)** The normal macula (centre) and optic disc, (b) Dot and blot haemorrhages (early background retinopathy). (c) Hard exudates are present in addition in background retinopathy. (d) Multiple cotton-wool spots indicate pre-proliferative retinopathy requiring routine ophthalmic referral, (e) Multiple frond-like new vessels, the hallmark of proliferative retinopathy. White fibrous tissue is forming near the new vessels, a feature of advanced retinopathy (this eye also illustrates multiple xenon arc laser burns superiorly), (f) Exudates appearing within a disc-width of the macula are a feature of an exudative maculopathy. (g) Central and (h) cortical cataracts can be seen against the red reflex with the ophthalmoscope.

The natural history of retinopathy (Fig. 19.13)

Diabetes causes increased thickness of the capillary basement membrane and increased permeability of the retinal capillaries. Aneurysmal dilatation may occur in some vessels, while others become occluded. These changes are first detectable by fluorescein angiography: a fluorescent dye is injected into an arm vein and photographed in transit through the retinal vessels. This technique is not necessary to screen effectively for retinal disease. After 20 years of type 1 diabetes, almost all patients have some retinopathy, and 60% progress to sight-threatening proliferative retinopathy (Fig. 19.14). Fifty to eighty per cent of patients with type 2 diabetes will have retinopathy

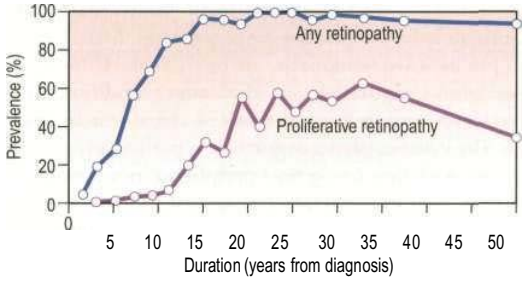

Fig. 19.14 **Prevalence of retinopathy in relation to duration of the disease in patients with insulin-dependent diabetes mellitus diagnosed under the age of 33 years.** Almost all eventually develop background change and 60% progress to proliferative retinopathy. From *Ophthalmology* **(1984)102:520.**

after 20 years. Without treatment, 50% of proliferative patients become blind within 5 years.

Non-proliferative/background retinopathy

(Fig. 19.13b,c)

The first abnormality visible through the ophthalmoscope is the appearance of dot 'haemorrhages', which are actually due to capillary microaneurysms. Leakage of blood into the deeper layers of the retina produces the characteristic 'blot' haemorrhage, while exudation of fluid rich in lipids and protein gives rise to hard exudates. These have a bright yellowish white colour and are often irregular in outline with a sharply defined margin. These changes rarely develop in young patients with a duration of diabetes under 10 years, but by 20 years virtually all eyes will manifest at least the occasional microaneurysm on careful ophthalmoscopy. In contrast, retinopathy may be present at diagnosis or shortly thereafter in older patients. Background retinopathy does not in itself constitute a threat to vision but may progress to two other distinct forms of retinopathy: maculopathy or proliferative retinopathy. Both are the consequence of damage to retinal blood vessels and resultant retinal ischaemia.

Diabetic maculopathy

This may lead to blindness in the absence of proliferation and particularly affects the older patient with type 2 diabetes. Macular oedema is the first feature of maculopathy and may in itself result in permanent macular damage if not treated early. The first, and only, sign of this is deteriorating visual acuity and this early condition cannot be diagnosed with standard photography or ophthalmoscopy. This is why it is essential to screen patients with diabetes regularly for changes in visual acuity. In most cases, however, maculopathy does not generate sufficient oedema to cause early loss of acuity. The process may then be detected in its later stages as encroachment of hard exudates on the macular area. These changes are easily visible on standard photography or ophthalmoscopy, through fully dilated pupils.

Pre-proliferative retinopathy

Progressive retinal ischaemia will, in some patients, cause background retinopathy to progress to pre-proliferative, sight-threatening retinopathy. The earliest sign is the appearance of 'cotton-wool spots', representing oedema resulting from retinal infarcts (Fig. 19.13d). They may also occur in severe hypertensive retinopathy. The term 'soft exudate' is often used synonymously but is best avoided. Cotton-wool spots are greyish white, have indistinct margins and a dull matt surface, unlike the glossy appearance of hard exudates. Other features of pre-proliferative retinopathy are described in Table 19.11.

Proliferative retinopathy

Hypoxia is thought to be the signal for formation of new vessels. These lie superficially or grow forward into the vitreous, resembling fronds of seaweed. They branch repeatedly, are fragile, bleed easily (because they lack the normal supportive tissue) and may give rise to a fibrous-tissue reaction (Fig. 19.13e). With advanced retinopathy, haemorrhages can be preretinal or into the vitreous. A vitreous haemorrhage presents as a loss of vision in one eye, sometimes noticed on waking, or as a floating shadow affecting the field of vision. Ophthalmoscopy gives the

Table 19.11 **Pathological changes in the retina in diabetic retinopathy: the action needed**

	Fundoscopy/photography findings	Action needed
Peripheral retina		
Non proliferative/background	Microaneurysms (dot haemorrhages) Blot haemorrhages Hard exudates	Annual screening only
Pre-proliferative	Multiple cotton wool spots (nerve fibre layer infarcts) Venous beading Venous loops	Non-urgent referral to an ophthalmologist
Proliferative	Intraretinal microvascular abnormalities New blood vessel formation (neovascularization) Preretinal (subhyaloid) haemorrhage Vitreous haemorrhage Retinal fibrosis Traction retinal detachment	Urgent referral to an ophthalmologist
Advanced retinopathy		Urgent referral to an ophthalmologist - but much vision already lost
Central retina	Hard exudates within one disc width of macula	
Maculopathy	Unexplained loss of acuity	Urgent referral to an ophthalmologist

appearance of a featureless, grey haze. Partial recovery of vision is the rule, as the blood is reabsorbed, but repeated bleeds may occur.

Loss of vision may also result from fibrous proliferation associated with new vessel formation. This may give rise to traction bands that contract with the course of time, producing retinal detachment.

Cataracts

Senile cataracts develop some 10-15 years earlier in diabetic patients than in the remainder of the population. The risk of cataracts was lower in the UKPDS intensively controlled group.

Juvenile or 'snowflake' cataracts are much less common. These are diffuse, rapidly progressive cataracts associated with very poorly controlled diabetes. They should be distinguished from temporary lens changes that occasionally appear during hyperosmolar states and resolve when the hyperglycaemia is brought under control.

Examination

Careful systematic examination of the eye is essential. Visual acuity and eye movements are tested, and 15-30 minutes before the eye is examined the pupils are dilated with a mydriatic such as tropicamide 0.5%. Dilating drugs should not be used, however, in patients with a history of glaucoma, except with the advice of an ophthalmologist. The ophthalmologic examination begins at arm's length. At this distance, cataracts are silhouetted against the red reflex of the retina. The ophthalmoscope is advanced until the retina is in focus. The examination begins at the optic disc, moves through each quadrant in turn, and ends with the macula (since this is least comfortable for the patient). The ophthalmoscope is then adjusted to the +10 dioptre lens for examination of the cornea, anterior chamber and lens. The location of abnormalities should always be sketched in the notes for future reference.

Management of diabetic eye disease

(Table19.11)

The DCCT and UKPDS show that the risk of developing diabetic eye disease can be reduced by striving for aggressive metabolic control of the diabetes. There is no specific medical treatment for background retinopathy. Smoking and hypertension worsen the rate of progression and need treatment. Development or progression of retinopathy may be accelerated by rapid improvement in glycaemic control, pregnancy and in those with nephropathy, and these groups need frequent monitoring. All patients with retinopathy should be examined regularly by a diabetologist or ophthalmologist. Early referral to an ophthalmologist is essential in the following circumstances:

- deteriorating visual acuity
- hard exudates encroaching on the macula
- pre-proliferative changes (cotton-wool spots or venous beading)
- new vessel formation.

The ophthalmologist may perform fluorescein angiography to define the extent of the problem. Maculopathy and proliferative retinopathy are often treatable by retinal laser photocoagulation; in the latter condition early effective therapy reduces the risk of visual loss by about 50%. The value of photocoagulation is particularly marked in those with disc (as against peripheral) new vessels. In one trial, only 15% of treated, as against 50% of untreated, eyes with disc new vessels progressed to legal blindness. Treatment in this case is by panretinal photocoagulation. Surgery can be performed to try to salvage some vision after vitreous haemorrhage and to treat traction retinal detachment in advanced retinopathy.

The diabetic kidney

The kidney may be damaged by diabetes in three main ways:

- glomerular damage
- ischaemia resulting from hypertrophy of afferent and efferent arterioles
- ascending infection.

Diabetic nephropathy

Epidemiology

Clinical nephropathy secondary to glomerular disease usually manifests 15-25 years after diagnosis and affects 25-35% of patients diagnosed under the age of 30 years. It is the leading cause of premature death in young diabetic patients. Older patients also develop nephropathy, but the proportion affected is smaller. Some centres have reported a falling incidence rate of diabetic nephropathy in type 1 diabetes. This may reflect good-quality local care for diabetes rather than a change in the natural history of the disease itself. As people with type 2 diabetes develop diabetes progressively younger, a rising incidence rate of nephropathy is seen.

Pathophysiology

The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised glomerular filtration rate. This appears soon after diagnosis and is related to poor glycaemic control. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. This increased intraglomerular pressure also leads to increased shearing forces locally which are thought to contribute to mesangial cell hypertrophy and increased secretion of extracellular mesangial matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages which normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the

Albuminuria

The earliest evidence of this is 'microalbuminuria' - amounts of urinary albumin so small as to be undetectable by standard dipsticks (see p. 614). Microalbuminuria may be tested for by radioimmunoassay or by using special dipsticks. It is a predictive marker of progression to nephropathy in type 1 diabetes, and of increased cardiovascular risk in type 2 diabetes. Microalbuminuria may, after some years, progress to intermittent albuminuria followed by persistent proteinuria. Light-microscopic changes of glomerulosclerosis become manifest; both diffuse and nodular glomerulosclerosis can occur. The latter is sometimes known as the *Kimmelstiel-Wilson lesion.* At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

At the stage of persistent proteinuria, the plasma creatinine is normal but the average patient is only some 5-10 years from end-stage renal failure. The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia.

Patients with nephropathy typically show a normochromic normocytic anaemia and a raised erythrocyte sedimentation rate (ESR). Hypertension is a common development and may itself damage the kidney still further. A rise in plasma creatinine is a late feature that progresses inevitably to renal failure, although the rate of progression may vary widely between individuals.

The natural history of this process is shown in Figure 19.15.

Ischaemic lesions

Arteriolar lesions, with hypertrophy and hyalinization of the vessels, can occur in patients with diabetes. The appearances are similar to those of hypertensive disease and lead to ischaemic damage to the kidneys.

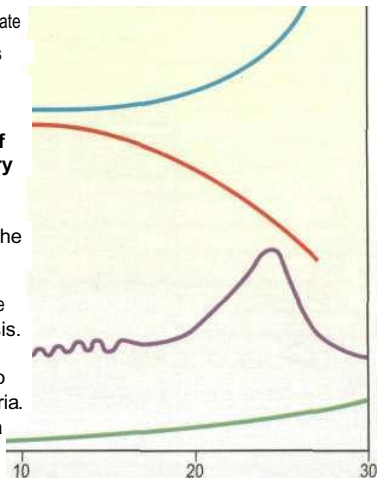

***Fig. 19.15* Schematic representation of the natural history of nephropathy.** The typical onset is 15 years after diagnosis. Intermittent proteinuria leads to persistent proteinuria. In time, the plasma creatinine rises as the glomerular filtration rate falls.

Infective lesions

Urinary tract infections are relatively more common in women with diabetes, but this does not apply to men. Ascending infection may occur because of bladder stasis resulting from autonomic neuropathy, and infections more easily become established in damaged renal tissue. Autopsy material frequently reveals interstitial changes suggestive of infection, but ischaemia may produce similar changes and the true frequency of pyelonephritis in diabetes is uncertain. Untreated infections in diabetics can result in renal papillary necrosis, in which renal papillae are shed in the urine, but this complication is rare.

Diagnosis

The urine of all diabetic patients should be checked regularly for the presence of protein. Many centres also screen younger patients for microalbuminuria since there is evidence that meticulous glycaemic control or early antihypertensive treatment at this stage may delay the onset of frank proteinuria. Once proteinuria is present, other possible causes for this should be considered (see below), but once these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. For practical purposes this implies inevitable progression to end-stage renal failure, although the time course can be markedly slowed by early aggressive antihypertensive therapy. Clinical suspicion of a non-diabetic cause of nephropathy may be provoked by an atypical history, the absence of diabetic retinopathy (usually but not invariably present with diabetic nephropathy) and the presence of red-cell casts in the urine. Renal biopsy should be considered in such cases, but in practice is rarely necessary or helpful. The risk of intravenous urography is increased in diabetes, especially if patients are allowed to become dehydrated prior to the procedure, and a renal ultrasound is preferable but not so informative. A 24-hour urine collection is performed to quantify protein loss and to measure creatinine clearance, and regular measurement is made of the plasma creatinine level.

Investigations to detect other treatable causes of nephropathy include urine microscopy and culture, serum protein electrophoresis, serum calcium, serum urate, ESR and antinuclear factor.

Management

The management of diabetic nephropathy is similar to that of other causes of renal failure, with the following provisos:

- Aggressive treatment of blood pressure with a target below 130/80 mmHg has been shown to slow the rate of deterioration of renal failure considerably. Angiotensin-converting enzyme inhibitors or an angiotensin receptor II antagonist are the drugs of choice (see p. 1096). These drugs should also be used in normotensive patients with persistent micro albuminuria. Reduction in albuminuria occurs with this treatment.
- Oral hypoglycaemic agents partially excreted via the kidney (e.g. glibenclamide) must be avoided.

- Insulin sensitivity increases and drastic reductions in dosage may be needed.
- Associated diabetic retinopathy tends to progress rapidly, and frequent ophthalmic supervision is essential.

Management of end-stage disease is made more difficult by the fact that patients often have other complications of diabetes such as blindness, autonomic neuropathy or peripheral vascular disease. Vascular shunts tend to calcify rapidly and hence chronic ambulatory peritoneal dialysis may be preferable to haemodialysis. The failure rate of renal transplants is somewhat higher than in non-diabetic patients. A segmental pancreatic graft is sometimes performed at the same time as a renal graft. Although pancreatic transplants have a limited viability, owing to progressive fibrosis within the graft, they may give the patient a year or so of freedom from insulin injections.

Diabetic neuropathy

Diabetes can damage peripheral nervous tissue in a number of ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies, but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Since hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.

The earliest functional change in diabetic nerves is delayed nerve conduction velocity; the earliest histological change is segmental demyelination, caused by damage to Schwann cells. In the early stages axons are preserved, implying prospects of recovery, but at a later stage irreversible axonal degeneration develops.

The following varieties of neuropathy occur (Fig. 19.16):

- symmetrical mainly sensory polyneuropathy (distal)
- acute painful neuropathy
- mononeuropathy and mononeuritis multiplex
  (a) cranial nerve lesions
  (b) isolated peripheral nerve lesions
- diabetic amyotrophy
- autonomic neuropathy.

Symmetrical mainly sensory polyneuropathy

This is often unrecognized by the patient in its early stages. Early clinical signs are loss of vibration sense, pain sensation (deep before superficial) and temperature sensation in the feet. At later stages patients may complain of a feeling of 'walking on cotton wool' and can lose their balance when washing the face or walking in the dark owing to impaired proprioception. Involvement of the hands is much less common and results in a 'stocking and glove' sensory loss. Complications include unrecognized trauma, beginning as blistering due to an ill-fitting shoe or a hot-water bottle, and leading to ulceration.

Sequelae of neuropathy. Involvement of motor nerves to the small muscles of the feet gives rise to interosseous wasting. Unbalanced traction by the long flexor muscles leads to a characteristic shape of the foot, with a high arch and clawing of the toes, which in turn leads to abnormal distribution of pressure on walking, resulting in callus formation under the first metatarsal head or on the tips of the toes and perforating neuropathic ulceration. Neuropathic arthropathy (Charcot's joints) may sometimes develop in the ankle. The hands show small-muscle wasting as well as sensory changes, but these signs and symptoms must be differentiated from those of the carpal tunnel syndrome, which occurs with increased frequency in diabetes and may be amenable to surgery.

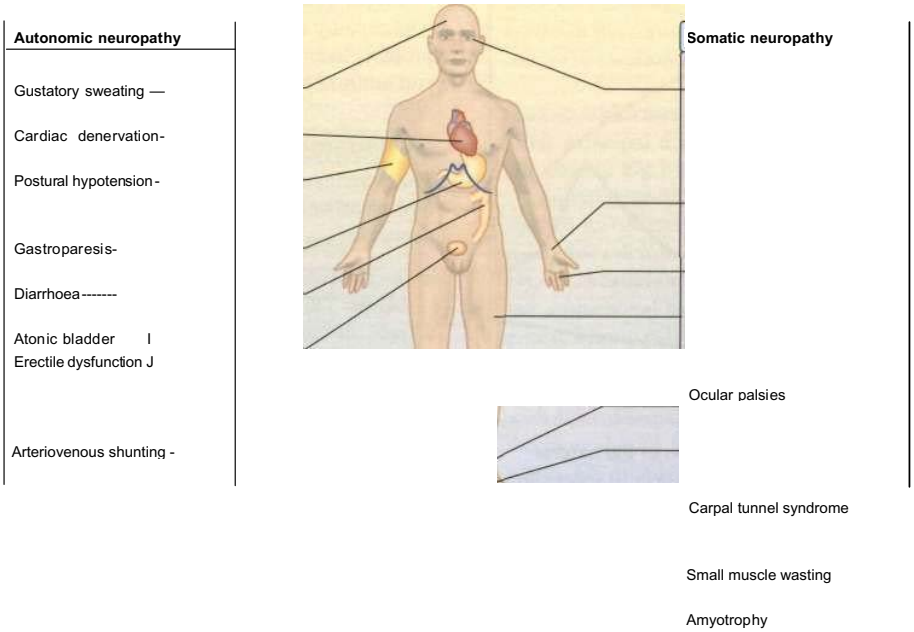

Fig. 19.16 The neuropathic man.

Acute painful neuropathy

A diffuse, painful neuropathy is less common. The patient describes burning or crawling pains in the feet, shins and anterior thighs. These symptoms are typically worse at night, and pressure from bedclothes may be intolerable. It may present at diagnosis or develop after sudden improvement in glycaemic control (e.g. when insulin is started). It usually remits spontaneously after 3-12 months if good control is maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the patient, but muscle wasting is not a feature and objective signs can be minimal.

Management is firstly to explore for non-diabetic causes (p. 1264). Explanation and reassurance about the high likelihood of remission within months may be all that is needed. Tricyclic antidepressants, gabapentin, mexiletine, valproate and carbamazepine all reduce the perception of neuritic pain somewhat, but usually not as much as patients hope for. Transepidermal nerve stimulation (TENS) benefits some patients. Topical capsaicin-containing creams help occasionally. A few report that acupuncture has helped.

Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)

Any nerve in the body can be involved in diabetic mononeuritis; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e. involvement of a spinal root) may also occur.

Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in diabetes. A characteristic feature of diabetic third nerve lesions is that pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuritis. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g. the median nerve in the carpal tunnel). The carpal tunnel syndrome (p. 1260) is a common cause for sensory symptoms in the hands in diabetes, but appears to respond less well to decompression.

Diabetic amyotrophy

This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles. The wasting may be very marked and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop and CSF protein content is elevated. Diabetic amyotrophy is usually associated with periods of poor glycaemic control and may be present at diagnosis. It often resolves in time with careful control of the blood glucose.

Autonomic neuropathy

Asymptomatic autonomic disturbances can be demonstrated on laboratory testing in many patients, but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can be disabling.

The cardiovascular system

Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes such as the Valsalva manoeuvre are impaired. Postural hypotension occurs owing to loss of sympathetic tone to peripheral arterioles. A warm foot with a bounding pulse is sometimes seen in a polyneuropathy as a result of peripheral vasodilatation.

Gastrointestinal tract

Vagal damage can lead to gastroparesis, often asymptomatic, but sometimes leading to intractable vomiting. Recently implantable devices which stimulate gastric emptying, and injections of botulinum toxin into the pylorus (to partly paralyse the sphincter) have each shown benefit in cases of this previously intractable problem. Autonomic diarrhoea often occurs at night accompanied by urgency and incontinence. Diarrhoea and steatorrhoea may occur owing to small bowel bacterial overgrowth; treatment is with antibiotics such as tetracycline.

Bladder involvement

Loss of tone, incomplete emptying, and stasis (predisposing to infection) can occur, and may ultimately result in an atonic, painless, distended bladder.

Male erectile dysfunction

This is common. The first manifestation is incomplete erection which may in time progress to total failure; retrograde ejaculation also occurs in patients with autonomic neuropathy. Erectile dysfunction in diabetes has many causes including anxiety, depression, alcohol excess, drugs, primary or secondary gonadal failure, hypothyroidism, and inadequate vascular supply owing to atheroma in pudendal arteries. The history and examination should focus on these possible causes. Blood is taken for LH, FSH, testosterone, prolactin and thyroid function. Treatment should ideally include sympathetic counselling of both partners.

Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are used in diabetic patients who do not take nitrates, e.g. for angina. If this therapy succeeds, it is worth trying without it after a few months of success, since sometimes potency will continue unaided after confidence is restored. Sixty per cent of diabetic patients can be expected to benefit from this therapy.

There are alternatives for patients who fail to improve with a phosphodiesterase, who dislike the side-effects (headache and a green tinge to vision the next day) or those in whom it is contraindicated. Apomorphine 2 or 3 mg sublingually 20 minutes before sexual activity is an alternative, but with lower efficacy. Alprostadil (prostaglandin Ej preparation) may be given after

suitable training as a small pellet inserted with a device into the urethra (125 u.g initially with a maximum of 1 mg). It has a lower success rate than intracavernosal injection treatment, but is less invasive. If the partner is pregnant, barrier contraception must be used to keep prostaglandin away from the fetus.

Other methods include intracavernosal injection of alprostadil, papaverine and phentolamine. Side-effects include priapism which needs urgent treatment should erection last more than 3 hours. Vacuum devices are also used.

The diabetic foot

Ten to fifteen per cent of diabetic patients develop foot ulcers at some stage in their lives. Diabetic foot problems are responsible for nearly 50% of all diabetes-related hospital admissions. Many diabetic limb amputations could be delayed or prevented by more effective patient education and medical supervision. Ischaemia, infection and neuropathy combine to produce tissue necrosis. Although all these factors may coexist, the ischaemic and the neuropathic foot (Table 19.12) can be distinguished. In rural India foot ulcers are common due to neuropathic and infective causes rather than vascular causes.

Management

Many diabetic foot problems are avoidable, so patients need to learn the principles of foot care (Table 19.13). Older patients should visit a chiropodist regularly and should not cut their own toe-nails. Once tissue damage has occurred in the form of ulceration or gangrene, the aim is preservation of viable tissue. The four main threats to the skin and subcutaneous tissues are:

- *Infection*. This can take hold rapidly in a diabetic foot. Early antibiotic treatment is essential, with antibiotic therapy adjusted in the light of culture results. The organisms grown from the skin surface may not be the organism causing deeper infection. Collections of pus are drained and excision of infected bone is needed if osteomyelitis develops and does not respond to appro-

Table 19.12 **Distinguishing features between ischaemia and neuropathy in the diabetic foot**

	Ischaemia	Neuropathy
Symptoms	Claudication Rest pain	Usually painless Sometimes painful neuropathy
Inspection	Dependent rubor Trophic changes	High arch Clawing of toes No trophic changes
Palpation	Cold Pulseless	Warm Bounding pulses
Ulceration	Painful Heels and toes	Painless Plantar

Table 19.13 Principles of diabetic foot care

Inspect feet daily
Seek early advice for any damage
Check shoes inside and out for sharp bodies/areas before wearing
Use lace-up shoes with plenty of room for the toes Keep feet away from sources of heat (hot sand, hot-water bottles, radiators, fires) Check the bath temperature before stepping in

priate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.

- *Ischaemia.* The blood flow to the feet is assessed clinically and with Doppler ultrasound. Femoral angiography is used to localize areas of occlusion amenable to bypass surgery or angioplasty. Relatively few patients fall into this category, and the risks (deterioration leading to amputation) and benefits of surgical intervention are finely balanced.
- *Abnormal pressure.* An ulcerated site must be kept non-weight-bearing. Resting the affected leg may need to be supplemented with special deep shoes and insoles to move pressure away from critical sites, or by removable or non-removable casts of the leg. After healing, special shoes and insoles are likely to continue to be needed to protect the feet and prevent abnormal pressure repeating damage to a healed area. In neuropathic feet particularly, sharp surgical debridement by a chiropodist is necessary to prevent callus distorting the local wound architecture and causing damage through abnormal pressure on normal skin nearby.
- *Wound environment.* Dressings are used to absorb or remove exudate, maintain moisture, and protect the wound from contaminating agents, and should be easily removable. Expensive new dressings containing growth factors and other biologically active agents may have a role to play in future, but their place is still being assessed.

Foot problems are the major cause of hospital bed occupancy by diabetic patients. Good liaison between physician, chiropodist and surgeon is essential if this period in hospital is to be used efficiently. When irreversible arterial insufficiency is present, it is often quicker and kinder to opt for an early major amputation rather than subject the patient to a debilitating sequence of conservative procedures.

Infections

There is no evidence that diabetic patients with good glycaemic control are more prone to infection than normal subjects. However, poorly controlled diabetes entails increased susceptibility to the following infections:

- *Skin*
  (a) staphylococcal infections (boils, abscesses, carbuncles)
  (b) mucocutaneous candidiasis

- *Gastrointestinal tract*
  (a) chronic periodontitis
  (b) rectal and ischiorectal abscess formation (when control very poor)
- *Urinary tract*
  (a) urinary tract infections (in women)
  (b) pyelonephritis
  (c) perinephric abscess
- *Lungs*
  (a) staphylococcal and pneumococcal pneumonia
  (b) Gram-negative bacterial pneumonia
  (c) tuberculosis.

One reason why poor control lends to infection is that chemotaxis and phagocytosis by polymorphonuclear leucocytes are impaired because at high blood glucose concentrations neutrophil superoxide generation is impaired.

Conversely, infections may lead to loss of glycaemic control, and are a common cause of ketoacidosis. Insulin-treated patients need to increase their dose by up to 25% in the face of infection, and non-insulin-treated patients may need insulin cover while the infection lasts. Patients should be told never to omit their insulin dose, even if they are nauseated and unable to eat; instead they should test their blood glucose frequently and seek urgent medical advice. Diabetic patients should receive pneumococcal vaccine (p. 41) and yearly influenza vaccine.

Skin and joints (see also p. 1345)

Joint contractures in the hands are a common consequence of childhood diabetes. The sign may be demonstrated by asking the patient to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be apposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be due to glycosylation of collagen and are not progressive. The condition is sometimes referred to as diabetic cheiroarthropathy.

Osteopenia in the extremities is also described in type 1 diabetes but rarely leads to clinical consequences.

NOTES ON SPECIAL SITUATIONS IN DIABETES

Surgery

Smooth control of diabetes minimizes the risk of infection and balances the catabolic response to anaesthesia and surgery. The procedure for insulin-treated patients is simple:

- Long-acting and/ or intermediate insulin should be stopped the day before surgery, with soluble insulin substituted.
- Whenever possible, diabetic patients should be first on the morning theatre list.
- An infusion of glucose, insulin and potassium is given during surgery. The insulin can be mixed into the glucose solution or administered separately by syringe pump. A standard combination is 16 U of soluble insulin with 10 mmol of KCl in 500 mL of 10% glucose, infused at 100 mL/h.
- Postoperatively, the infusion is maintained until the patient is able to eat. Other fluids needed in the perioperative period must be given through a separate intravenous line and must not interrupt the glucose/ insulin/ potassium infusion. Glucose levels are checked every 2-4 hours and potassium levels are monitored. The amount of insulin and potassium in each infusion bag is adjusted either upwards or downwards according to the results of regular monitoring of the blood glucose and serum potassium concentrations.

The same approach is used in the emergency situation, with the exception that a separate variable-rate insulin infusion may be needed to bring blood glucose under control before surgery.

Non-insulin-treated patients should stop medication 2 days before the operation. Patients with mild hyperglycaemia (fasting blood glucose below 8 mmol/L) can be treated as non-diabetic. Those with higher levels are treated with soluble insulin prior to surgery, and with glucose, insulin and potassium during and after the procedure, as for insulin-treated patients.

Pregnancy and diabetes

Meticulous metabolic control of the diabetes and careful medical and obstetric manag ement is required.

Metabolic control of diabetes in pregnancy

The patient should perform daily home blood glucose profiles, recording blood tests before and 2 hours after meals. The renal threshold falls in pregnancy, and urine tests are therefore of little or no value. Insulin require-ments rise progressively, and intensified insulin regimens are generally used. The aim is to maintain blood glucose and fructosamine (or HbA_{1c}) levels as close to the normal range as can be tolerated.

General management

The patient is seen at intervals of 2 weeks or less at a clinic managed jointly by physician and obstetrician. Circum-stances permitting, the aim should be outpatient manage-ment with a spontaneous vaginal delivery at term. Retinopathy and nephropathy may deteriorate during pregnancy. Expert fundoscopy and urine testing for protein should be undertaken at booking, at 28 weeks and before delivery.

Obstetric problems associated with diabetes

Poorly controlled diabetes is associated with stillbirth, mechanical problems in the birth canal owing to fetal macrosomia, hydramnios and pre-eclampsia. Ketoacidosis in pregnancy carries a 50% fetal mortality, but maternal hypoglycaemia is relatively well tolerated.

Neonatal problems

Maternal diabetes, especially when poorly controlled, is associated with fetal macrosomia. The infant of a diabetic mother is more susceptible to hyaline membrane disease than non-diabetic infants of similar maturity. In addition, neonatal hypoglycaemia may occur. The mechanism is as follows: maternal glucose crosses the placenta, but insulin does not; the fetal islets hypersecrete to combat maternal hyperglycaemia, and a rebound to hypoglycaemic levels occurs when the umbilical cord is severed.

These complications are due to hyperglycaemia in the third trimester. Poor glycaemic control around the time of conception carries an increased risk of major congenital malformations. When a pregnancy is planned, optimal metabolic control should be sought before conception.

Gestational diabetes

This term refers to glucose intolerance that develops in the course of pregnancy and usually remits following delivery. The condition is typically asymptomatic. Women who have a previous history of gestational diabetes, older or overweight women, those with a history of large for gestational age babies and women from certain ethnic groups are at particular risk, but many cases occur in women who are not in any of these categories. For this reason some advocate screening of all pregnant women on the basis of random plasma glucose testing in each trimester and by oral glucose tolerance testing if the glucose concentration is, for example, 7 mmol/L or more. There is no consensus concerning the level of blood glucose which is harmful for the baby, and therefore no consensus concerning cut-off levels for screening and intervention.

Treatment is with diet in the first instance, but most patients require insulin cover during the pregnancy. Insulin does not cross the placenta. Many oral agents cross the placenta and are usually avoided because of the potential risk to the fetus.

Gestational diabetes has been associated with all the obstetric and neonatal problems described above for pre-existing diabetes, except that there is no increase in the rate of congenital abnormalities. It is likely to recur in subsequent pregnancies. Gestational diabetes is often the harbinger of type 2 diabetes in later life.

Not all diabetes presenting in pregnancy is gestational. True type 1 diabetes may develop, and swift diagnosis is essential to prevent the development of ketoacidosis. Hospital admission is required if the patient is symp-tomatic, or has ketonuria or a markedly elevated blood glucose level.

Unstable diabetes

This is used to describe patients with recurrent ketoacidosis and/or recurrent hypoglycaemic coma. Of these, the largest group is made up of those who experience recurrent severe hypoglycaemia.

Recurrent severe hypoglycaemia

This affects 1-3% of insulin-dependent patients. Most are adults who have had diabetes for more than 10 years. By this stage, endogenous insulin secretion is negligible in the great majority of patients. Pancreatic alpha-cells are still present in undiminished numbers, but the glucagon response to hypoglycaemia is virtually absent. Long-term patients are thus subject to fluctuating hyperinsulinaemia owing to erratic absorption of insulin from injection sites, and lack a major component of the hormonal defence against hypoglycaemia. In this situation adrenaline (epinephrine) secretion becomes vital, but this too may become impaired in the course of diabetes. Loss of adrenaline (epinephrine) secretion has been attributed to autonomic neuropathy, but this is unlikely to be the sole cause; central adaptation to recurrent hypoglycaemia may also be a factor.

The following factors may also predispose to recurrent hypoglycaemia:

- *Overtreatment with insulin.* Frequent biochemical hypo glycaemia lowers the glucose level at which symptoms develop. Symptoms often reappear when overall glucose control is relaxed.
- *An unrecognized low renal threshold for glucose.* Attempts to render the urine sugar-free will inevitably produce hypoglycaemia.
- *Excessive insulin doses.* A common error is to increase the dose when a patient needs more frequent injections to overcome a problem of timing.

- *Endocrine causes.* These include pituitary insufficiency, adrenal insufficiency and premenstrual insulin sensitivity.
- *Alimentary causes.* These include exocrine pancreatic failure and diabetic gastroparesis.
- *Renal failure.* Clearance of insulin is diminished.
- *Patient causes.* Patients may be unintelligent, uncooperative or may manipulate their therapy.

Recurrent ketoacidosis

This usually occurs in adolescents or young adults, particularly girls. Metabolic decompensation may develop very rapidly. A combination of chaotic food intake and insulin omission, whether consciously or unconsciously, is now regarded as the primary cause of this problem. It almost always occurs in the context of considerable psychosocial problems, particularly eating disorders. This area needs careful and sympathetic exploration in any patient with recurrent ketoacidosis. It is perhaps not surprising that in an illness where much of one's life is spent thinking of and controlling food intake, 30% of women with diabetes have had some features of an eating disorder at some time. Other causes include:

- *Iatrogenic.* Inappropriate insulin combinations may be a cause of swinging glycaemic control. For example, a once-daily regimen may cause hypoglycaemia during the afternoon or evening and pre-breakfast hyperglycaemia due to insulin deficiency.
- *Intercurrent illness.* Unsuspected infections, including urinary tract infections and tuberculosis, may be present. Thyrotoxicosis can also manifest as unstable glycaemic control.

HYPOGLYCAEMIA IN THE NON-DIABETIC

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:

- the inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- depletion of hepatic glycogen reserves by malnutrition, fasting, exercise or advanced liver disease
- impaired gluconeogenesis (e.g. following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores, and the hypoglycaemia can be reversed by injection of glucagon. In the other two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP used to maintain the potential difference across axonal membranes.

Insulin or sulphonylurea therapy for diabetes accounts for the vast majority of cases of severe hypoglycaemia encountered in an accident and emergency department.

Insulinomas

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (multiple endocrine neoplasia). Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Table 19.14. Common misdiagnoses include psychiatric disorders, particularly pseudodementia in elderly people, epilepsy and cerebrovascular disease. Whipple's triad remains the basis of clinical diagnosis. This is satisfied when:

- symptoms are associated with fasting or exercise
- hypoglycaemia is confirmed during these episodes
- glucose relieves the symptoms.

A fourth criterion - demonstration of inappropriately high insulin levels during hypoglycaemia - may usefully be added to these.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:

- Measurement of *overnight fasting* (16 hours) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-hour *supervised fast* if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of the normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide or proinsulin during a spontaneous episode of hypoglycaemia.

Treatment of insulinoma

The most effective therapy is surgical excision of the

Table 19.14 **Presenting features of insulinoma**

Diplopia
Sweating, palpitations, weakness
Confusion or abnormal behaviour
Loss of consciousness Grand mal seizures

tumour, but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution CT scanning, scanning with radio-labelled somatostatin (some insulinomas express somatostatin receptors), and endoscopic and intraoperative ultrasound scanning. Venous sampling for the detection of 'hot spots' of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, in patients in whom a tumour cannot be located, and in elderly patients with mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

Hypoglycaemia with other tumours

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

Postprandial hypoglycaemia

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about one in four subjects will have at least one value below 3 mmol/L. The arteriovenous glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential 'organic' explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false 'hypoglycaemia' followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which 'primes' the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as 'dumping' but it is now rarely encountered (see p. 286).

Hepatic and renal causes of hypoglycaemia

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is particularly a problem with fulminant hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20 000 live births and can cause hypoglycaemia (see p. 1143).

Endocrine causes of hypoglycaemia

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotrophic hormone (ACTH) deficiency, and Addison's disease.

Drug-induced hypoglycaemia

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present:

- Sulphonylureas may be used in the treatment of diabetes or may be taken by non-diabetics in suicide attempts.
- Quinine may produce severe hypoglycaemia in the course of treatment for falciparum malaria.
- Salicylates may cause hypoglycaemia; usually accidental ingestion by children.
- Propranolol can induce hypoglycaemia in the presence of strenuous exercise or starvation.
- Pentamidine used in the treatment of resistant pneumocystis pneumonia (p. 136).

Alcohol-induced hypoglycaemia

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly nourished chronic alcoholics, binge drinkers and in children who have taken relatively small amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia.

Factitious hypoglycaemia

-aw

This is a relatively common variant of self-induced disease and is much more common than an insulinoma. Hypoglycaemia is produced by surreptitious self-administration of insulin or sulphonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulphonylurea abuse can be detected by chromatography of plasma or urine.

DISORDERS OF LIPID METABOLISM

Lipid physiology

Lipids are insoluble in water, and are transported in the bloodstream as macromolecular complexes. In these complexes, lipids (principally triglyceride, cholesterol and cholesterol esters) are surrounded by a stabilizing coat of phospholipid. Proteins (called apoproteins) embedded into the surface of these iipoprotein' particles exert a stabilizing function and allow the particles to be recognized by receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in Figure 19.17.

Five principal types of lipoprotein particles are found in the blood (Fig. 19.18). They are structurally different and can be separated in the laboratory by their density and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance. More than half of all patients aged under 60 with angiographically confirmed coronary artery disease have a lipoprotein disorder.

The genes for all the major apoproteins and that for the low-density lipoprotein (LDL) receptor have been isolated, sequenced and their chromosomal sites mapped. Production of abnormal apoproteins is known to produce, or predispose to, several types of lipid disorder, and it is likely that others will be discovered.

Chylomicrons (Fig. 19.18)

Chylomicrons are synthesized in the small intestine postprandially, passing initially into the intestinal lymphatic drainage, then along the thoracic duct into the bloodstream. They contain triglyceride and a small amount of cholesterol and its ester, and provide the main mechanism for transporting the digestion products of dietary fat to the liver and peripheral tissues. Each newly formed chylomicron contains several different apoproteins (B-48, A-I, A-II), and acquires apoproteins C-II and E by transfer from high-density lipoprotein (HDL) particles in the bloodstream. Apoprotein C-II binds to specific receptors in adipose tissue and skeletal muscle and the liver and allows the endothelial enzyme, lipoprotein lipase, to remove most of the triglyceride from the particle. The remaining chylomicron remnant particle, which contains the bulk of the original cholesterol, is taken up by the liver by mechanisms which are not fully understood, possibly mediated by apoprotein E.

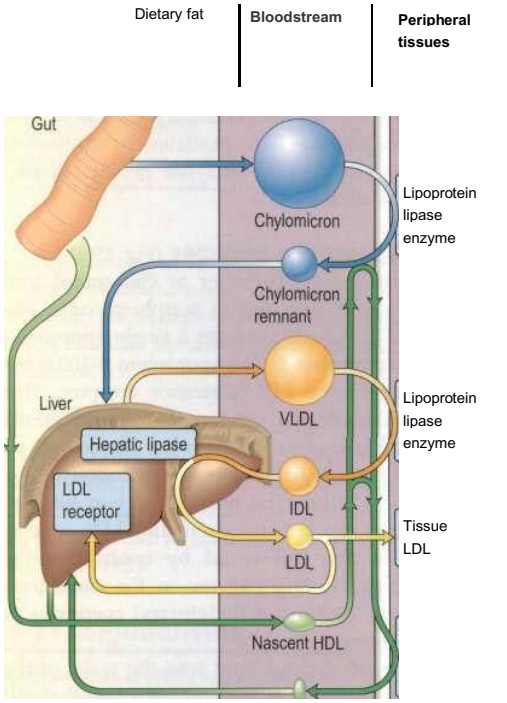

Fig. 19.18 Schematic representation of the sites of origin, interaction between, and fate of, the major lipoprotein particles.

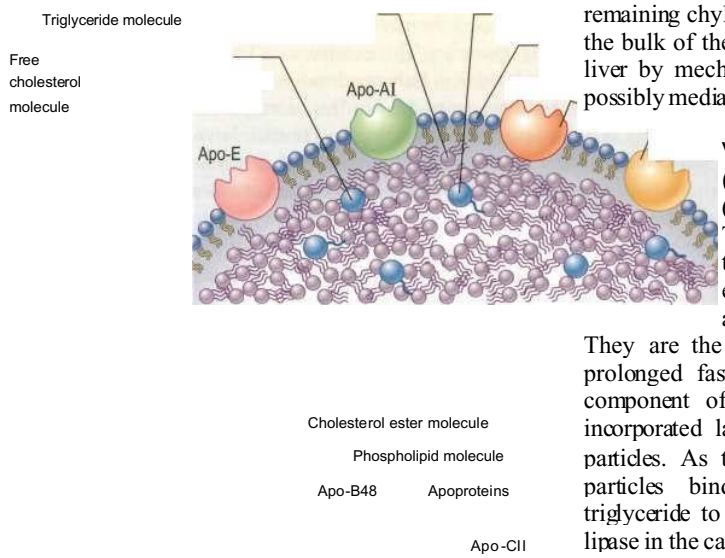

Fig. 19.17 Schematic diagram of a chylomicron particle (75-1200 nm) showing apoproteins lying in the surface membrane.

Very-low-density lipoprotein (VLDL) particles (Fig. 19.18)

These are synthesized continuously in the liver and contain most of the body's endogenously synthesized triglyceride and a smaller quantity of cholesterol. They are the body's main source of energy during prolonged fasting. Apoprotein B-100 is an essential component of VLDL. Apoproteins C-II and E are incorporated later into VLDL by transfer from HDL particles. As they pass round the circulation, VLDL particles bind through apoprotein C-II allowing triglyceride to be progressively removed by lipoprotein lipase in the capillary endothelium. This leaves a particle, now depleted of triglyceride and apoprotein C-II, called an intermediate-density lipoprotein (IDL) particle.

Intermediate-density lipoprotein particles

(Fig. 19.18)

These have apoprotein B-100 and apoprotein E molecules on the particle surface. Most IDL particles bind to liver LDL receptors through the apoprotein E molecule and are then catabolized. Some IDL particles have further triglyceride removed (by the enzyme hepatic lipase), producing LDL particles.

Low-density lipoprotein particles (Fig. 19.18) LDL particles are the main carrier of cholesterol, and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains a single apoprotein B-100, and also apoprotein E. The apoprotein B-100 is the principal ligand for the LDL clearance receptor. This receptor lies within coated pits on the surface of the hepatocyte. Once bound to the receptor, the coated pit invaginates and fuses with liposomes which destroy the LDL particle (Fig. 19.19). The number of hepatic LDL clearance receptors regulates the circulating LDL concentration, which is also influenced by controlling the activity of the rate-limiting enzyme in the cholesterol synthetic pathway, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase (Fig. 7.4).

LDL particles can deposit lipid into the walls of the peripheral vasculature. Not all the cholesterol synthesized by the liver is packaged immediately into lipoprotein particles. Some is oxidized into bile salts. Both bile salts and cholesterol are excreted in the bile: both are then reabsorbed through the terminal ileum and recirculated (enterohepatic circulation).

LDL particles become Lp(a) lipoproteins as a result of the linkage of apoprotein (a) to aproprotein B-100 with a single disulphide bond. Raised levels of Lp(a) lipoprotein are a risk factor for cardiovascular disease.

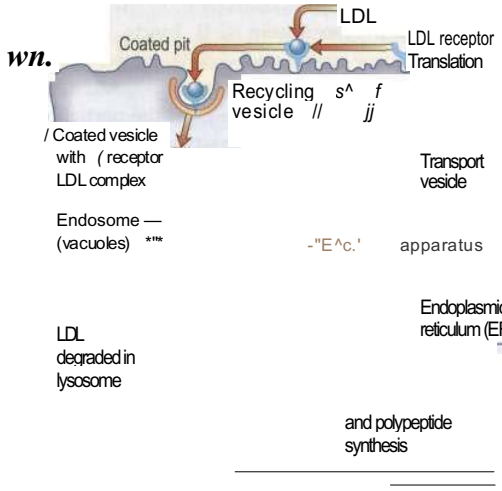

Fig. 19.19 Receptor-mediated endocytosis. LDL receptors are formed in the endoplasmic reticulum and transported via the Golgi apparatus to the surface of a hepatocyte. LDLs bind to these receptors, are internalized and taken up by the endosome. The receptor is recycled back to the surface, while the LDL is broken down by the lysosomes, freeing cholesterol needed for membrane synthesis.

High-density lipoprotein particles (Fig. 19.18)

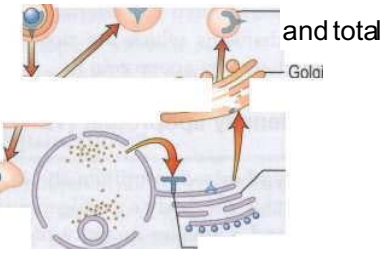
Nascent HDL particles are produced in both the liver and intestine. They are disc shaped, seemingly inert and contain apoprotein A-I. They are transmuted into mature particles by the acquisition of phospholipids, and the E and C apoproteins from chylomicrons and VLDL particles in the circulation. The more mature HDL particles take up cholesterol from cells in the peripheral tissues aided by cholesterol-efflux regulatory protein - a product of the ATP-binding cassette transporter 1 gene *(ABC1* gene). As it is taken up, the enzyme lecithin-cholesterol acyl-transferase (LCAT), activated by the apoprotein A on the particle's surface, esterifies the sequestered cholesterol. The HDL particle transports cholesterol away from the periphery and may transfer it indirectly to other particles such as VLDL in the circulation or deliver its cholesterol directly to the liver (reverse cholesterol transport) and steroid-synthetic tissues (ovaries, testes, adrenal cortex).

This direct delivery takes place through scavenger-receptor Bl. In experimental animals the absence of scavenger-receptor Bl dramatically accelerates the development of atheroma, and genetically programmed overproduction suppresses atheroma formation.

Measurement

When a laboratory measures fasting serum lipids, the majority of the total cholesterol concentration consists of LDL particles with a 20-30% contribution from HDL particles. The triglyceride concentration largely reflects the circulating number of VLDL particles, since chylomicrons are not normally present in the fasted state. If the patient is not fasted, the total triglyceride concentration will be raised owing to the additional presence of triglyceride-rich chylomicrons.

Epidemiology and lipids LDL



and total

cholesterol

Population studies have repeatedly demonstrated a strong association between both total and LDL cholesterol concentration and coronary heart risk. There is a strong link between mean fat consumption, mean serum cholesterol concentration and the prevalence of coronary heart disease between countries. The exception is France where the cardiovascular risk is only moderate - perhaps owing to high alcohol consumption. Studies of migrants, particularly of Japanese men migrating to Hawaii, have shown that as diet changes, and cholesterol concentrations rise, so does the cardiovascular risk. Such studies show the role of the environment rather than the genetic make-up of a population.

The Multiple Risk Factor Intervention Trial (MRF1T)

screened one-third of a million American men for various cardiovascular risk factors and then followed them for 6 years. Data from this study have shown that although cardiovascular risk rises progressively as total cholesterol

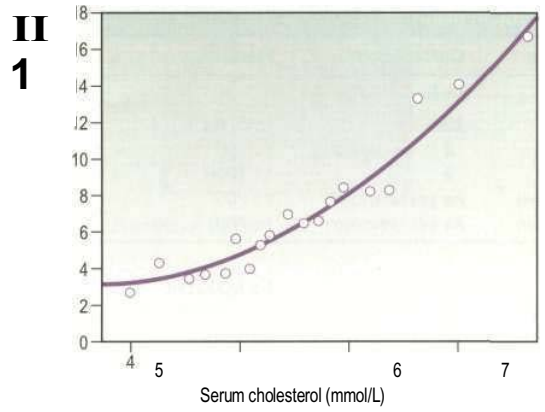


Fig. 19.20 **The Multiple Risk Factor Intervention Trial.** Relationship between levels of serum cholesterol and risks of fatal coronary artery disease in a longitudinal study of more than 361 000 men screened for entry into the trial. From Stamler J, Wentworth D, Neaton JD (1986) *Journal of the American Medical Association* **256:** 2823.

concentration increases (Fig. 19.20), the risk increase is modest for individuals with no other cardiovascular risk factors. With each additional risk factor the effect produced by the same difference in cholesterol concentration becomes greatly magnified. The Framingham Study has reproduced these findings in a separate population.

HDL cholesterol

Epidemiological studies have shown that higher HDL concentrations protect against cardiovascular disease. HDL also has effects on the function of platelets and of the haemostatic cascade. These properties may favourably influence thrombogenesis.

VLDL particles (triglycerides)

There is a relatively weak independent link between raised concentrations of (triglyceride-rich) VLDL particles and cardiovascular risk. Very raised triglyceride concentrations (> 6 mmol/L) cause a greatly increased risk of acute pancreatitis and retinal vein thrombosis. Hypertriglyceridaemia tends to occur in association with a reduced HDL concentration. Much of the cardiovascular risk associated with 'hypertriglyceridaemia' turns out on multivariate analysis to be due to the associated low HDL levels and not to the hypertriglyceridaemia itself.

Chylomicrons

Excess chylomicrons do not confer an excess cardiovascular risk, but raise the total plasma triglyceride concentration.

HYPERLIPIDAEMIA

Hyperlipidaemia results from genetic predisposition interacting with an individual's diet.

Table 19.15 **Causes of secondary hyperlipidaemia**

Hypothyroidism
Diabetes mellitus (when poorly controlled)
Obesity
Renal impairment
Nephrotic syndrome
Dysglobulinaemia
Hepatic dysfunction
Drugs:
Oral contraceptives in susceptible individuals
Retinoids, thiazide diuretics, corticosteroids, op'DDD (used in the treatment of Cushing's syndrome), sirolimus (and other immunosuppressive agents)

Secondary hyperlipidaemia

If a lipid disorder has been detected it is vital to carry out a clinical history, examination and simple special investigations to detect causes of secondary hyperlipidaemia (Table 19.15), which may need treatment in their own right. Hypothyroidism, diabetes, renal disease and abnormal liver function can all raise plasma lipid levels.

CLASSIFICATION, CLINICAL FEATURES AND INVESTIGATION OF PRIMARY HYPERLIPIDAEMIAS

As the genetic basis of lipid disorders becomes clearer, the genetic classification of Goldstein and colleagues is proving of greater clinical relevance than the Fredrickson (WHO) classification (based on the pattern of lipoproteins found in plasma). The lack of direct correspondence between these two systems of classification can be confusing. For clarity we have used the functional/genetic classification and not the Fredrickson classification. This has the advantage that the genetic disorders may be grouped by the results of simple lipid biochemistry into causes of:

- disorders of VLDL and chylomicrons - hyper triglyceridaemia alone
- disorders of LDL - hypercholesterolaemia alone
- disorders of HDL
- combined hyperlipidaemia.

Disorders of VLDL and chylomicrons - hypertriglyceridaemia alone

The majority of cases appear to be due to multiple genes acting together to produce a modest excess of circulating concentration of VLDL particles, such cases being termed polygenic hypertriglyceridaemia.

In a proportion of cases there will be a family history of a lipid disorder or its effects (e.g. pancreatitis). Such cases are often classified as familial hypertriglyceridaemia. The defect underlying the vast majority of such cases is not understood. The main clinical feature is a history of attacks of pancreatitis or retinal vein thrombosis in some individuals.

Table 19.16 **The genetic defects underlying the common lipoprotein disorders**

Disorder	Affected gene	Chromosome	Frequency
Common disorders			
Heterozygous familial hypercholesterolaemia	LDL receptor	19	1 500
Familial defective apoprotein B	Apo B-100	2	1 700
Hypobetalipoproteinaemia	Apo B-100	2	1 1000
Familial combined hyperlipidaemia	As yet unknown	As yet unknown	1 200
Familial hypertriglyceridaemia	As yet unknown	As yet unknown	200
Some rarer disorders			
Homozygous familial hypercholesterolaemia	LDL receptor	19	1 1 000 000
Lipoprotein lipase deficiency	As yet unknown	As yet unknown	1 1 000 000 (homozygous)
Apoprotein C-II deficiency	Apo C-II	19	40 cases

Lipoprotein lipase deficiency and apoprotein C-II deficiency

These are rare diseases which produce greatly elevated triglyceride concentrations owing to the persistence of chylomicrons (and not VLDL particles) in the circulation. The chylomicrons persist because the triglyceride within cannot be metabolized if the enzyme lipoprotein lipase is defective, or because the triglycerides cannot gain access to the normal enzyme owing to deficiency of the apoprotein C-II on their surface. Patients present in childhood with eruptive xanthomas, lipaemia retinalis and retinal vein thrombosis, pancreatitis and hepatosplenomegaly. If not identified in childhood, it can present in adults with gross hypertriglyceridaemia resistant to simple measures. The presence of chylomicrons floating like cream on top of fasting plasma suggests this diagnosis. It is confirmed by plasma electrophoresis or ultracentrifugation. An abnormality of apoprotein C can be deduced if the hypertriglyceridaemia improves temporarily after infusing fresh frozen plasma, and lipoprotein lipase deficiency is likely if it does not.

Disorders of LDL - hypercholesterolaemia alone

Heterozygous familial hypercholesterolaemia is an autosomal dominant monogenic disorder present in 1 in 500 of the normal population. The average primary care physician would therefore be expected to have four such patients on his or her list, but because of clustering within families the prevalence is lower in some lists and much higher in others. There is an increased prevalence in some racial groups (e.g. French Canadians, Finns, South Africans). Surprisingly, most individuals with this disorder remain undetected. Patients may have no physical signs, in which case the diagnosis is made on the presence of very high plasma cholesterol concentrations which are unresponsive to dietary modification and are associated with a typical family history of early cardiovascular disease. Diagnosis can more easily be made if typical clinical features are present. These include xanthomatous thickening of the Achilles tendons and xanthomas over the extensor tendons of the fingers. Xanthelasma may be present, but is not diagnostic of familial hypercholesterolaemia.

The genetic defect is the underproduction or malproduction of the LDL cholesterol uptake receptor in the liver (Table 19.16). Over 150 different mutations in the LDL receptor have been described to date. Fifty per cent of men with the disease will die by the age of 60, most from coronary artery disease, if untreated.

Homozygous familial hypercholesterolaemia is very rare indeed. Affected children have no LDL receptors in the liver. They have a hugely elevated LDL cholesterol concentration, and massive deposition of lipid in arterial walls, the aorta and the skin. The natural history is for death from ischaemic heart disease in late childhood or adolescence. Repeated plasmapheresis has been used to remove LDL cholesterol with some success in these patients. Liver transplantation offers the possibility of cure, but the numbers of patients having undergone this procedure is small. The possibility of gene therapy offers a glimmer of hope on the horizon for affected individuals.

Mutations in the apoprotein B-100 gene cause another relatively common single gene disorder. Since LDL particles bind to their clearance receptor in the liver through apoprotein B-100, this defect also results in high LDL concentrations in the blood, and a clinical picture which closely resembles classical heterozygous familial hypercholesterolaemia. The two disorders can be distinguished clearly only by genetic tests. The approach to treatment is the same.

Polygenic hypercholesterolaemia is a term used to lump together patients with raised serum cholesterol concentrations, but without one of the monogenic disorders above. They exist in the right-hand tail of the normal distribution of cholesterol concentration. The precise nature of the polygenic variation in plasma cholesterol concentration remains unknown. Variations in the apoprotein E gene (chromosome 19) appear to contribute towards the problem in some individuals in this heterogeneous group.

Disorders of **HDL** - normal total cholesterol and triglycerides

Tangier disease

Tangier disease is an autosomal recessive disorder characterized by a low HDL cholesterol concentration. Cholesterol accumulates in reticuloendothelial tissue **and** arteries causing enlarged orange-coloured tonsils **and** hepatosplenomegaly. Cardiovascular disease, corneal opacities and a polyneuropathy also occur. This has been shown to be due to a mutation in the ATP-binding cassette transporter 1 gene *(ABC1* gene - see HDL physiology above) which normally promotes cholesterol uptake from cells by HDL particles.

Other mutations in this gene have been found in a few families with autosomal dominant HDL deficiency. It is as yet unknown whether abnormalities of this gene contribute to the low HDL cholesterol concentrations commonly seen in cardiovascular disease patients.

Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)

The most common patient group is a polygenic combined hyperlipidaemia. Patients have an increased cardiovascular risk due to both high LDL concentrations and suppression of HDL by the hypertriglyceridaemia.

Familial combined hyperlipidaemia

This is relatively common, affecting 1 in 200 of the general population. The genetic basis for the disorder has not yet been characterized. It is diagnosed by finding raised cholesterol and triglyceride concentrations in association with a typical family history. There are no typical physical signs.

Remnant hyperlipidaemia

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to accumulation of LDL remnant particles and is associated with an extremely high risk of cardiovascular disease. It may be suspected in a patient with raised total cholesterol and triglyceride concentrations by finding xanthomas in the palmar creases (diagnostic) and the presence of tuberous xanthomas, typically over the knees and elbows (Fig. 19.21). Remnant hyperlipidaemia is almost always due to the inheritance of a variant of the apoprotein E allele (apoprotein E2) together with an aggravating factor such as another primary hyperlipidaemia. When suspected clinically the diagnosis can be confirmed using ultracentrifugation of plasma, or phenotyping apoprotein E.

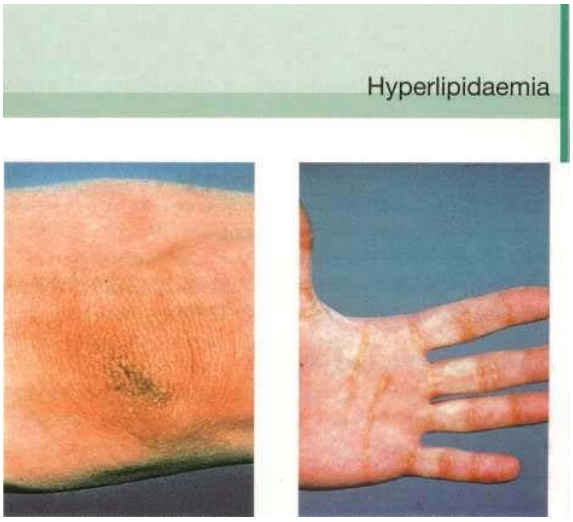

Fig. 19.21 Tuberous xanthomata behind the elbow and lipid deposits in the hand creases in a patient with remnant hyperlipidaemia.

THERAPIES AVAILABLE TO TREAT HYPERLIPIDAEMIA

The lipid-lowering diet

Studies have shown that dietitians helping patients to adjust their own diet to meet the nutritional targets set out below produce a better lipid-lowering effect than does the issuing of standard diet sheets and advice from a doctor. The main elements of a lipid-lowering diet are set out below.

Reduce the total fat intake

Dairy products and meat are the principal sources of saturated fat in the diet. Intake of these products should therefore be reduced, and fish and poultry should be substituted. Visible fat and skin should be removed before cooking and preparing meat dishes. Meat products including sausages and reconstituted meats (such as 'luncheon meat') should be avoided since the concentration of fat is unknown and often high. Baking and grilling of meats reduces the fat content and is preferred to frying. Low-fat or cottage cheese and skimmed or semi-skimmed milk should be substituted for the standard full-fat varieties. Pastries and cakes contain large quantities of fat and should be avoided. The overall aim should be to decrease fat intake such that it is providing approximately 30% of the total energy intake in the diet. Further reduction in fat intake is unacceptable to many patients.

Substitution with monounsaturates and polyunsaturates

Monounsaturated oils, particularly olive oil, and polyunsaturated oils such as sunflower, safflower, corn and soya oil, should be used in cooking instead of saturated fat-rich alternatives.

Reduce the dietary cholesterol intake

Liver, offal and fish roes should be avoided. Although eggs and prawns are rich in cholesterol their total contribution to the body's cholesterol pool is small and they can still be part of a balanced lipid-lowering diet.

Increase the intake of fibre (non-starch polysaccharides, NSPs)

Foods high in soluble fibre, such as pulses, legumes, root vegetables, leafy vegetables, and unprocessed cereals, help reduce circulating lipid concentrations. These

should be substituted in the diet in the place of higher-fat alternatives.

Reduce alcohol consumption
Excess alcohol is a cause of secondary hyperlipidaemia, and may worsen primary lipid disorders.

Achieve an ideal bodyweight
Treatment of obesity is part of the management of hyperlipidaemia, both because it will help the lipid disorder itself, and because obesity is an independent cardiovascular risk factor.

Consider foods containing stanol esters
Plant stanols reduce the absorption of cholesterol from the intestine by competing for space in the micelles that deliver lipid to the mucosal cells of the gut. They are largely unabsorbed and excreted in the stool. Increasing the amount of plant stanol in the diet 10-fold by using a margarine (e.g. Benecol) containing added stanol esters lowers LDL cholesterol by approximately 0.35-0.5 mmol/L. A reduction in the risk of heart disease of about 25% would be expected if this reduction in LDL cholesterol was applied to a population.

Drugs

The classes of drugs used to treat hyperlipidaemia are listed in Table 19.17.

MANAGEMENT OF SPECIFIC HYPERLIPIDAEMIAS

Screening

Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Many are discovered during the screening of high-risk individuals. Whose lipids should be measured?

There are great doubts as to whether blanket screening of plasma lipids is warranted. Selective screening of people at high risk of cardiovascular disease should be undertaken, to include those with:

- a family history of coronary heart disease (especially below 50 years of age)
- a family history of lipid disorders
- the presence of a xanthoma
- the presence of xanthelasma or corneal arcus before the age of 40 years
- obesity
- diabetes mellitus
- hypertension
- acute pancreatitis
- those undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder such as familial hypercholesterolaemia (1 in 500 of the population), siblings and children must have their plasma lipid concentrations measured. It is also worth screening the prospective partners of any patients with this heterozygous monogenic lipid disorder because of the small risk of producing children homozygous for the condition.

Acute severe illnesses such as myocardial infarction can derange plasma lipid concentrations for up to 3 months. Plasma lipid concentrations should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur) or 3 months later.

Serum cholesterol concentration does not change significantly after a meal and as a screening test a random blood sample is sufficient. If the total cholesterol concentration is raised, HDL cholesterol, triglyceride, and LDL cholesterol concentrations should be quantitated on a fasting sample. If a test for hypertriglyceridaemia is needed, a fasting blood sample is mandatory.

Hypertriglyceridaemia

A serum triglyceride concentration below 2.0 mmol/L is normal. In the range 2.0-6.0 mmol/L no specific intervention will be needed unless there are coincident cardiovascular risk factors, and in particular a strong family history of early cardiovascular death. In general, patients should be advised that they have a minor lipid problem, offered advice on weight reduction if obese, and advice on correcting other cardiovascular risk factors.

If the triglyceride concentration is above 6.0 mmol/L there is a risk of pancreatitis and retinal vein thrombosis. Patients should be advised to reduce their weight if overweight and start a formal lipid-lowering diet (see below). A proportion of individuals with *hypertriglyceridaemia* have livers which respond *to even moderate* degrees of alcohol intake by allowing accumulation or excess production of VLDL particles. If hypertriglyceridaemia persists, lipid measurements should be repeated before and after a 3-week interval of complete abstinence from alcohol. If a considerable improvement results, lifelong abstinence may prove necessary. Other drugs, including thiazides, oestrogens and glucocorticoids, can have a similar effect to alcohol in susceptible patients.

If the triglyceride concentration remains elevated above 6.0 mmol/L, despite the above measures, drug therapy is warranted. A fibric acid derivative is the agent of first choice. Nicotinic acid may be used in addition but its side-effects are often a problem. Fish oil capsules which contain co-3 long-chain fatty acids are also effective in lowering triglyceride concentrations.

The severe hypertriglyceridaemia associated with the rare disorders of lipoprotein lipase deficiency and apoprotein C-II deficiency may require restriction of dietary fat to 10-20% of total energy intake and the use of special preparations of medium-chain triglycerides in cooking in place of oil or fat. Medium-chain triglycerides are not absorbed via chylomicrons (see p. 296).

Table 19.17 **Drugs used in the management of hyperlipidaemia**

Drug	Mechanism of action	Contraindications and adverse reactions	Expected therapeutic effect	Long-term safety
Statins e.g. Simvastatin Pravastatin Fluvastatin Atorvastatin	Inhibit the rate-limiting step in cholesterol synthesis (HMG CoA reductase)	***Contraindications:*** Active liver disease, pregnancy, lactation ***Adverse effects:*** Derangement of liver biochemistry, diarrhoea biochemical tests: periodically during treatment. Myositis. Raise cidosporin level in blood	30-60% reduction in LDL cholesterol Modest triglyceride lowering Tiny effect on HDL cholesterol Atorvastatin and particularly rosuvastatin have the most potent cholesterol-lowering effects	Simvastatin, Atorvastatin and Pravastatin have good long-term safety in large-scale trials and in clinical practice
Cholesterol absorption inhibitors e.g. Ezetimibe	Inhibition of gut absorption of cholesterol from food and also from bile. Mechanism of this inhibition is currently unclear	***Contraindications:*** Lactation ***Adverse effects:*** Occasional diarrhoea, abdominal discomfort	Reduce LDL cholesterol by additional 10-15% if given with a statin Triglyceride concentrations reduced by 10% Increase HDL cholesterol by 5%	Mostly act in gut and little is absorbed. Short term safety good. Not available long enough for medium- or long-term safety to be known
Cholesterol-binding resins e.g. Colestyramine Colestipol	Bind bile acids in the gut preventing enterohepatic circulation. Liver makes more bile acids fromcholesterol, depleting the cholesterol pool	***Adverse effects:*** Gastrointestinal side-effects predominate. Palatability is a problem. ***Counselling:*** Other drugs bind to resins and should be taken 1 h before or 4 h afterwards	8-15% reduction in LDL Little or no effect on HDL cholesterol 5-15% rise in triglyceride concentration	Not systemically absorbed. Safety profile is good and resins are of low risk in women of childbearing age. Fat-soluble vitamin supplements may be required in children, pregnancy and breast-feeding
Fibric acid derivatives e.g. Gemfibrozil Bezafibrate Fenofibrate Ciprofibrate	Complex and not fully understood 1. Limit substrate availability for hepatic triglyceride synthesis 2. Modulate LDL/ligand interaction 3. Promote action of lipoprotein lipase 4. Stimulate reverse transport of cholesterol	***Contraindications:*** Severe hepatic or renal impairment, gallbladder disease, pregnancy ***Adverse effects:*** Reversible myositis, nausea, predispose to gallstones, non-specific malaise, impotence	Reduction of LDL cholesterol by 10-15% and triglycerides by 25-35% HDL cholesterol concentrations increase by 10-50% (newer agents often have greater beneficial effect on HDL)	No knowledge of effect on developing fetus. Avoid in women of child-bearing age. Long-term safety appears good

Cont'd

Hypercholesterolaemia (without hypertriglyceridaemia)

Familial hypercholesterolaemia

Individuals often require treatment with diet and more than one cholesterol-lowering drug. The cholesterol absorption inhibitor ezetimibe is a logical addition to a statin and has a low side-effect profile (Table 19.17). Bile acid sequestrants are an alternative to ezetimibe, but have greater problems with tolerabiliry. Concurrent therapy with statins and fibrates is usually avoided, in view of their overlapping side-effects, but in very severe cases such mixed therapy has been undertaken under close supervision.

Primary prevention for people with risk factors

Lipid-lowering therapy using a statin, or alternatives as above, should be considered in asymptomatic individuals irrespective of the total or LDL cholesterol level in type 2 diabetes alone, or with two or more of: positive family history of cardiovascular disease, albuminuria, hypertension, smoking.

Table 19.17 (Cont'd) **Drugs used in the management of hyperlipidaemia**

Drug	Mechanism of action	Contraindications and adverse reactions	Expected therapeutic effect	Long-term safety
Nicotinic acid and derivatives e.g. Nicotinic acid Modified-release nicotinic acid Acipimox	Unclear. Probably inhibit lipid synthesis in the liver by reducing free fatty acid concentrations through an inhibitory effect on lipolysis in fat tissue	***Contraindications:*** Pregnancy, breast-feeding. ***Adverse effects:*** Value limited by frequent side-effects: headache, flushing, dizziness, nausea, malaise, itching, abnormal liver biochemistry. Glucose intolerance, hyperuricaemia, activation of peptic ulcers, hyperpigmentation may occur	Reduce LDL cholesterol by 5-10% Reduce triglycerides by 15-20% HDL cholesterol increased by 10-20%	Medium-term safety but marred by the adverse effects listed. Modified-release preparation reduces side-effect incidence
Omega-3 marine triglycerides	Reduce hepatic VLDL secretion	Occasional nausea and belching	Reduce triglycerides in severe hypertriglyceridaemia No favourable change in other lipids, and may aggravate hypercholesterolaemia in a few patients	Long-term safety is not yet known but seems unlikely to be poor

Primary prevention for people without risk factors

In the absence of risk factors, lipid-lowering therapy should be considered in asymptomatic men with total cholesterol levels persistently above 6.5 mmol/L despite dietary change. Many would use lipid-lowering therapy in an asymptomatic man with this level of total cholesterol if he had a positive family history of cardiovascular disease and no other risk factors. The situation for women is less clear.

Secondary prevention

As a generality, statin treatment is warranted for any patient with known macrovascular disease (coronary artery disease, TIA or stroke, peripheral vascular disease), irrespective of the total or LDL cholesterol level. If a statin is not tolerated, a fibrate or fibrate/cholesterol absorption inhibitor combination are alternatives.

Risk prevention tables (p. 803)

An array of risk prediction tables (see pp. 803 and 804) are available to allow quantification of the risk of a patient having a cardiovascular event within the next 10 years. Some advocate the use of these risk tables as a guide to treatment - for example if the 10-year risk reaches the 15% or the 30% level. We side with those who have reservations over their use. Such risk analyses are a useful approach in helping to decide whether to use treatments such as aspirin. Aspirin probably has no effect until the day an atherosclerotic plaque ruptures, when it may then prevent thrombosis leading to a heart attack or stroke. Furthermore it has a significant associated morbidity and mortality (from bleeding). At a 10-year cardiovascular risk level of 15% the benefit/risk ratio for aspirin becomes favourable. At the 30% level the benefits are clear.

In contrast, the use of lipid-lowering agents, if initially tolerated, has a low associated morbidity and mortality. These agents probably reduce the rate of atheroma accumulation over a period of decades. When a patient is young, the chance that atheroma will be bad enough to cause a heart attack or stroke within the next 10 years will be small, even if atheroma is accumulating at a swift rate. The level of cardiovascular risk will only rise to the 15% or 30% level when the patient gets older. Yet it seems bizarre not to treat the gradual accumulation of atheroma when the patient is young with a low 10-year risk, and then to start treatment when age causes the 10-year risk levels to rise to a particular threshold, if all other factors are the same. In choosing whether or not to prescribe, we prefer to consider 'will he/she live long enough to collect some pension and see his/her grandchildren?' rather than 'will he/she have a heart attack or stroke within the next 10 years?'. The answers to these two questions are very different.

Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)

Treatment is **the** same for all varieties of combined hyperlipidaemia. For any given cholesterol concentration the hypertriglyceridaemia found in the combined hyperlipidaemias increases the cardiovascular risk considerably. Treatment is aimed at reducing serum cholesterol below 6.5 mmol/L and triglycerides below 2.0 mmol/L. Therapy is with diet in the first instance and with drugs if an adequate response has not occurred.

Fibric acid derivatives are the treatment of choice since these reduce both cholesterol and triglyceride concentrations, and also have the benefit of raising cardioprotective HDL concentrations. The combination of a fibric acid derivative and ezetimibe or a bile acid-binding resin is of considerable use when a fibrate alone produces an insufficient reduction in LDL cholesterol. Nicotinic acid can be used in addition, although its unwanted effects render it a third-line agent.

OTHER LIPID DISORDERS

Hypolipidaemia

Low lipid levels can be found in severe protein-energy malnutrition. They are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.

Hypobetalipoproteinaemia (Table 19.16) is a benign familial condition which is being increasingly recognized. The cholesterol levels are in the range 1-3.5 mmol/L.

Abetalipoproteinaemia

This is described on page 308.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Glycogen storage disease

All mammalian cells can manufacture glycogen, but the main sites of its production are the liver and muscle. Glycogen is a high-molecular-weight glucose polymer. In glycogen storage disease there is either an abnormality in the molecular structure or an increase in glycogen concentration owing to a specific enzyme defect. Almost all these conditions are autosomal recessive in inheritance and present in infancy, except for McArdle's disease, which presents in adults.

Table 19.18 shows the classification and clinical features of some of these diseases.

Galactosaemia

Galactose is normally converted to glucose. However, a deficiency of the enzyme galactose-1-phosphate uridyltransferase or, less commonly, uridine diphosphate galactase-4-epimerase results in accumulation of galactose-1-phosphate in the blood. The transferase deficiency, inherited as an autosomal recessive, is due in 70% of patients to a glutamine to arginine mis-sense mutation in Q188R. Galactose ingestion (i.e. milk) leads to inanition, failure to thrive, vomiting, hepatomegaly and jaundice, diabetes, cataracts and developmental delay. A lactose-free diet stops the acute toxicity but poor growth and problems with speech and mental development **still** occur with the transferase deficiency.

Prenatal diagnosis and diagnosis of the carrier state are possible by measurement of the level of galactose-1-phosphate in the blood.

Galactokinase deficiency also results in galactosaemia and early cataract formation.

Defects of fructose metabolism

Absorbed fructose is chiefly metabolized in the liver to lactic acid or glucose. Three defects of metabolism in the liver and intestine occur; all are inherited as autosomal recessive traits:

- *Fructosuria* is due to fructokinase deficiency. It is a benign asymptomatic condition.
- *Hereditary fructose intolerance* is due to fructose-1-phosphate aldolase deficiency. Fructose-1-phosphate accumulates after fructose ingestion, inhibiting both glycogenolysis and gluconeogenesis, resulting in symptoms of severe hypoglycaemia. Hepatomegaly and renal tubular defects occur but are reversible on a fructose- and sucrose-free diet. Intelligence is normal and there is an absence of dental caries.
- *Hereditary fructose-1,6-diphosphatase deficiency* leads to a failure of gluconeogenesis. Infants present with hypoglycaemia, ketosis and lactic acidosis. Dietary control can lead to normal growth.

Pentosuria

Pentosuria is due to reduced activity of NADP-linked sylitol dehydrogenase. It has no clinical significance.

Table 19.18 **Some glycogen storage diseases**

Type	Affected tissue	Enzyme defect	Clinical features	Tissue needed for diagnosis*	Outcome
Liver glycogenoses		Glucose-6-phosphatase	epatomegaly, ketotic hypoglycaemia, stunted growth, obesity, hypotonia	Liver DNA testing	f patients survive initial hypoglycaemia, prognosis is good; hyperuricaemia is a late complication
I (Von Gierke) (25%)	Liver, intestine, kidney				
III (Forbes) (24%)	Liver, muscle (abnormal glycogen structure)	Glycogen debranching enzyme	Like type I	Leucocytes, liver, muscle	ood prognosis but progressive neuropathy and cardiomyopathy
IV (Anderson) (3%)	Liver (abnormal glycogen structure)	Branching enzyme	ailure to thrive, hepatomegaly, cirrhosis and its complications	Leucocytes, liver, muscle	Death in first 5 years Liver transplantation
VI (Hers) (VI and VIII = 30%)	Liver	Liver phosphorylase or phosphorylase kinase	epatomegaly with hypoglycaemia in childhood	Liver	**Good**
VIII	Liver	Phosphorylase 6 kinase deficiency	epatomegaly, hypoglycaemic fatiguability	Liver, muscle	No treatment
Muscle glycogenoses		Lysosomal acid cc-glucosidase	eart failure, cardiomyopathy	Fibroblasts, muscles	Death in first 6 months Juvenile and adult variants seen
II (Pompe) (15%)	Liver, muscle, heart				
V (McArdle)	Muscle only	Phosphorylase	uscle cramps and myoglobinuria after exercise (in adults)	Muscle	lormal We-span; give sucrose prior to exercise
VII (Tarui)	Muscle	Phosphofructokinase	Like type V	**Muscle**	*Like type* ***V***

INBORN ERRORS OF AMINO ACID METABOLISM

Inborn errors of amino acid metabolism are chiefly inherited as autosomal recessive conditions. The major ones are shown in Table 19.19.

Amino acid transport defects

Amino acids are filtered by the glomerulus, but 95% of the filtered load is reabsorbed in the proximal convoluted tubule by an active transport mechanism. Aminoaciduria results from:

- abnormally high plasma amino acid levels (e.g. phenylketonuria)
- any inherited disorder that damages the tubules secondarily (e.g. galactosaemia)
- tubular reabsorptive defects, either generalized (e.g. Fanconi syndrome) or specific (e.g. cystinuria).

Amino acid transport defects can be congenital or acquired.

GENERALIZED AMINOACIDURIAS

Fanconi syndrome

This occurs in a juvenile form (De Toni-Fanconi-Debre syndrome); in adult life it is often acquired through, for example, heavy metal poisoning, drugs or some renal diseases. There is a generalized defective proximal tubular reabsorption of:

- most amino acids
a glucose
- urate
- phosphate, resulting in hypophosphataemic rickets

Table 19.19 **The major inborn errors of amino acid metabolism**

Disease	Enzyme defect	Incidence	Biochemical and clinical features	Treatment	Prognosis
Albinism	Tyrosinase	1 in 13 000	Amelanosis: whitish hair, pink-white skin, grey-blue eyes Nystagmus, photophobia, strabismus	Symptomatic	Good
Alkaptonuria	Homogentisic acid oxidase	1 in 100 000	Homogentisic acid polymerizes to produce a brown-black product that is deposited in cartilage and other tissues (ochronosis)	None	Good
Homocystinuria					
Type I	Cystathionine synthase		Homocystine is excreted in urine	-	-
			Learning difficulties	-	-
			Marfan-like syndrome	-	-
			Thrombotic episodes	-	-
Type II	Methylene tetrahydrofolate reductase		Survivors have learning difficulties	-	Many die as neonates
Phenylketonuria	Phenylalanine hydroxylase	1 in 20 000	Brain damage with learning difficulties and epilepsy Phenylpyruvate and its derivatives excreted in urine	Diet low in phenylalanine in first few months of life prevents damage	Good but some intellectual impairment
Histidinaemia	Histidase	Very rare	Learning difficulties	-	-
'Maple syrup' disease	Branched-chain ketoacid dehydrogenase	Very rare	Failure to thrive Fits, neonatal acidosis and severe cerebral degeneration Valine, isoleucine and their derivatives are excreted in urine A milder form is seen	-	Early death
Oxalosis (hyperoxaluria)	Alanine: glyoxylate aminotransferase	Very rare	Nephrocalcinosis, renal stones, renal failure due to deposition of calcium oxalate Prenatal and early diagnosis now possible	-	Liver transplantation ? Gene therapy

There are many other enzyme defects producing, for example, alaninaemia, ammonaemia, argininaemia, citrullinaemia, isovaleric acidaemia, lysinaemia, ornithinaemia or tyrosinaemia

- bicarbonate, with failure to transport hydrogen ions, causing a renal tubular acidosis that then produces a hyperchloraemic acidosis (p. 717).

Other abnormalities include:

- potassium depletion, primary or secondary to the acidosis
- polyuria
- increased excretion of immunoglobulins and other low-molecular-weight proteins.

Various combinations of the above abnormalities have been described.

The juvenile form begins at the age of 6-9 months, with failure to thrive, vomiting and thirst. The clinical features are as a result of fluid and electrolyte loss and the characteristic vitamin D-resistant rickets.

In the adult, the disease is similar to the juvenile form, but osteomalacia is a major feature.

Treatment of the bone disease is with large doses of vitamin D (e.g. 1—2 mg of la-hydroxycholecalciferol with

regular blood calcium monitoring). Fluid and electrolyte loss need to be corrected.

Lowe's syndrome (oculocerebrorenal dystrophy)

In this syndrome there is generalized aminoaciduria combined with mental retardation, hypotonia, congenital cataracts and an abnormal skull shape.

SPECIFIC AMINOACIDURIAS

Cystinuria

There is a defective tubular reabsorption and jejunal absorption of cystine and the dibasic amino acids, lysine, ornithine and arginine. Inheritance is either completely or incompletely recessive, so that heterozygotes who have increased excretion of lysine and cystine only can occur. Cystine absorption from the jejunum is impaired but, nevertheless, cystine in peptide form can be absorbed. Cystinuria leads to urinary stones and is responsible for approximately 1-2% of all urinary calculi. The disease often starts in childhood, although most cases present in adult life.

Treatment is with a high fluid intake in order to keep the urinary cystine concentration low. Patients are encouraged to drink up to 3 L over 24 hours and to drink even at night. Penicillamine should be used for patients who cannot keep the cystine concentration of their urine low.

The condition cystinosis must not be confused with cystinuria.

Hartnup's disease

There is defective tubular reabsorption and jejunal absorption of most neutral amino acids but not their peptides. The resulting tryptophan malabsorption produces nicotinamide deficiency (see p. 245). Patients can be asymptomatic, but others develop evidence of pellagra, with cerebellar ataxia, psychiatric disorders and skin lesions. Treatment is with nicotinamide, which often brings about considerable improvement.

Tryptophan malabsorption syndrome (blue diaper syndrome)

This is due to an isolated transport defect for tryptophan: the tryptophan excreted oxidizes to a blue colour on the baby's diaper.

Familial iminoglycinuria

This occurs when there is defective tubular reabsorption of glycine, proline and hydroxyproline. It seems to have *few* clinical effects.

Methionine malabsorption syndrome

This is due to failure to absorb and excrete methionine, and results in diarrhoea, vomiting and mental retardation. Patients characteristically have an oast-house smell.

LYSOSOMAL STORAGE DISEASES

Lysosomal storage diseases are due to inborn errors of metabolism which are mainly inherited in an autosomal recessive manner.

Glucosylceramide lipidoses: Gaucher's disease

This is the most prevalent lysosomal storage disease and is due to a deficiency in glucocerebrosidase, a specialized lysosomal acid (J-glucosidase. This results in accumulation of glucosylceramide in the lysosomes of the reticuloendothelial system, particularly the liver, bone marrow and spleen. Several mutations have been characterized in the glucocerebrosidase gene, the most common being a single base change (N370S) causing the substitution of arginine for serine; this is seen in 70% of Jewish patients. The typical Gaucher cell, a glucocerebroside-containing reticuloendothelial histiocyte, is found in the bone marrow, producing many cytokines such as CD14.

There are three clinical types, the most common presenting in adult life with an insidious onset of hepatosplenomegaly. There is a high incidence in Ashkenazi Jews (1 in 3000 births), and patients have a characteristic pigmentation on exposed parts, particularly the forehead and hands. The clinical spectrum is variable, with patients developing anaemia, evidence of hypersplenism and pathological fractures that are *due to* bone involvement. Nevertheless, *many have a normal* life-span.

The diagnosis is made on finding a deficiency of lysosomal B glucocerebrosidase in leucocytes. Plasma chitotriosidase (an enzyme secreted by activated macrophages) is grossly elevated in Gaucher's disease and other lysosomal disorders: it is used to monitor enzyme replacement therapy. Acute Gaucher's disease presents in infancy or childhood with rapid onset of hepatosplenomegaly, with neurological involvement owing to the presence of Gaucher cells in the brain. The outlook is poor.

Some patients with non-neuropathic Gaucher's disease show considerable improvement with infusion of human recombinant glucocerebrosidase (imiglucerase - a human recombinant enzyme). Oral miglustat (an inhibitor of glucosylceramide synthase) is used for mild to moderate Gaucher's disease.

Sphingomyelin cholesterol lipidoses: Niemann-Pick disease

The disease is due to a deficiency of lysosomal sphingomyelinase which results in the accumulation of

sphingomyelin cholesterol and glycosphingolipids in the reticuloendothelial macrophages of many organs, particularly the liver, spleen, bone marrow and lymph nodes. The disease usually presents within the first 6 months of life with mental retardation and hepatosplenomegaly; a particular type (lie) presents in adults with dementia. The gene frequency is 1 : 100 in Ashkenazi Jews. Typical foam cells are found in the marrow, lymph nodes, liver and spleen.

The mucopolysaccharidoses (MPSs)

This is a group of disorders caused by the deficiency of lysosomal enzymes (e.g. a-L-iduronidase) required for the catabolism of glycosaminoglycans (mucopolysaccharides).

The catabolism of dermatan sulphate, heparan sulphate, keratin sulphate or chondroitin sulphate may be affected either singularly or together.

Accumulation of glycosaminoglycans in the lysosomes of various tissues results in the disease. Ten forms of MPS have been described; all are chronic but progressive, and a wide spectrum of clinical severity can be seen within a single enzyme defect. The MPS types show many clinical features though in variable amounts, with dysostosis, abnormal fades, poor vision and hearing and joint dysmobility (either stiff or hypermobile) being frequently seen. Mental retardation is present in, for example, Hurler (MPS IH) and San Filippo A (MPS IIIA) types, but normal intelligence and life-span are seen in Scheie (MPS IS). L aronidase infusion reduces lysosomal storage, resulting in clinical improvement.

The GM2 gangliosidoses

In these conditions there is accumulation of GM2 gangliosides in the central nervous system and peripheral nerves. It is particularly common (1 in 2000) in Ashkenazi Jews. *Tay-Sachs disease* is the severest form, where there is a progressive degeneration of all cerebral function, with fits, epilepsy, dementia and blindness, and death usually occurs before 2 years of age. The macula has a characteristic cherry spot appearance.

Fabry's disease

This X-linked recessive condition is due to a deficiency of the lysosomal hydrolase ce-galactosidase causing an accumulation of glycosphingolipids with terminal cx-galactosyl moieties in the lysosomes of various tissues including the liver, kidney, blood vessels and the ganglion cells of the nervous system. The patients present with peripheral nerve involvement, but eventually most patients develop renal problems in adult life. Treatment is with Agalsidase Beta infusions. . ..

Diagnosis

Many of the sphingolipidoses can be diagnosed by demonstrating the enzyme deficiency, usually in peripheral blood leucocytes.

Prenatal diagnosis is possible in a number of the conditions by obtaining specimens of amniotic cells. Carrier states can also be identified, so that sensible genetic counselling can be given.

AMYLOIDOSIS

Amyloidosis is a disorder of protein metabolism in which there is an extracellular deposition of pathological insoluble fibrillar proteins in organs and tissues. Characteristically, the amyloid protein consists of [3-pleated sheets that are responsible for its insolubility and resistance to proteolysis.

Amyloidosis can be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The process for the production of these fibrils appears to be multifactorial and differs amongst the various types of amyloid.

AL amyloidosis (immunoglobulin light chain-associated)

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of particular amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains - either the dominant K or *X* isotype - which are excreted in the urine (Bence Jones proteins). This type of amyloid is often associated with lymphoproliferative disorders, such as myeloma, Waldenstrom's macroglobulinaemia or non-Hodgkin's lymphoma. It rarely occurs before the age of 40 years.

The clinical features are related to the organs involved. These include the kidneys (presenting with proteinuria and the nephrotic syndrome) and the heart (presenting with heart failure). Autonomic and sensory neuropathies are relatively common, and carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature. Sensory neuropathy is common. There is an absence of central nervous system involvement.

On examination, hepatomegaly and rarely splenomegaly, cardiomyopathy, polyneuropathy and bruising may be seen. Macroglossia occurs in about 10% of cases and periorbital purpura in 15%.

Familial amyloidoses (transthyretin-associated (ATTR))

These are autosomally dominant transmitted diseases where the mutant protein forms amyloid fibrils, starting usually in middle age. The most common form is due to a mutant - transthyretin - which is a tetrameric protein

with four identical subunits. It is a transport protein for thyroxine and retinol-binding protein and mainly synthesized in the liver. Over 80 amino acid substitutions have been described; for example, a common substitution is that of methionine for valine at position 30 (Met 30) in all racial groups, and alanine for threonine (Ala 60) in the English and Irish. These substitutions destabilize the protein, which precipitates following stimulation, and can cause disorders such as familial amyloidotic polyneuropathy (FAP), cardiomyopathy or the nephrotic syndrome. Major foci of FAP occur in Portugal, Japan and Sweden.

Other less common variants include mutations of apoprotein A-I, gelsolin, fibrinogen Aa and lysozyme.

Clinically, peripheral sensorimotor and autonomic neuropathy are common, with symptoms of autonomic dysfunction, diarrhoea and weight loss. Renal disease is less prevalent than with AL amyloidosis. Macroglossia does not occur. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease.

Other hereditary systemic amyloidoses include other familial amyloid polyneuropathies (e.g. Portuguese, Icelandic, Dutch). There is a familial Creutzfeldt-Jakob disease. In familial Mediterranean fever, renal amyloidosis is a common serious complication.

Reactive systemic (secondary AA) amyloidoses

These are due to amyloid formed from serum amyloid A (SAA), which is an acute phase protein. It is, therefore, related to chronic inflammatory disorders and chronic infection.

Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease, and untreated familial Mediterranean fever. In developing countries it is still associated with infectious diseases such as tuberculosis, bronchiectasis and osteomyelitis. AA amyloidosis often presents with renal disease, with hepatomegaly and splenomegaly. Macroglossia is not a feature and cardiac involvement is rare.

Other amyloides

Cerebral amyloidosis, Alzheimer's disease and transmissible spongiform encephalopathy

The brain is a common site of amyloid deposition, although it is not directly affected in any form of acquired systemic amyloidosis. Intracerebral and cerebrovascular amyloid deposits are seen in Alzheimer's disease. Most cases are sporadic, but hereditary forms caused by mutations have been reported. In hereditary spongiform encephalopathies several amyloid plaques have been seen. Amyloid deposits are frequently found in the elderly, particularly cerebral deposits of A4 protein. This is also seen in Down's syndrome. Apoprotein E (involved in LDL transport, see p. 1136) interacts directly with P-A4 protein in senile plaques and neurofibrillary tangles in the brain. The gene for apoprotein E is on chromosome 19 and may be susceptibility factor in the aetiology of Alzheimer's disease.

Local amyloidosis

Deposits of amyloid fibrils of various types can be localized to various organs or tissues (e.g. skin, heart and brain).

Dialysis-related amyloidosis

This is due to the (3_2-microglobulin producing amyloid fibrils in chronic dialysis patients (p. 678). It frequently presents with the carpal tunnel syndrome.

Diagnosis

This is based on clinical suspicion and, if possible, on tissue histology. Amyloid in tissues appears as an amorphous, homogeneous substance that stains pink with haematoxylin and eosin and stains red with Congo red. It also has a green fluorescence in polarized light. Tissue can be obtained from the rectum or gums. The bone marrow may show plasma cells in amyloidosis or a lymphoproliferative disorder. A paraproteinaemia and proteinuria with light chains in the urine may also be seen in AL amyloidosis. In secondary or reactive amyloidosis there will be an underlying disorder. Scintigraphy using ^{123}I-labelled serum amyloid P component is useful for the assessment of AL, ATTR and AA amyloidosis, but it is not widely available and is expensive.

Treatment

This is symptomatic or the treatment of the associated disorder. The nephrotic syndrome and congestive cardiac failure require the relevant therapies. Treatment of any inflammatory source or infection should be instituted. Colchicine may help familial Mediterranean fever. Chemotherapy (similar to myeloma, p. 578) is showing some efficacy in AL amyloidosis. In ATTR amyloidosis where transthyretin is predominantly synthesized in the liver, liver transplantation (when there would be a disappearance of the mutant protein from the blood) is considered as the definitive therapy.

THE PORPHYRIAS

This heterogeneous group of rare inborn errors of metabolism is caused by abnormalities of enzymes involved in the biosynthesis of haem, resulting in overproduction of the intermediate compounds called 'porphyrins' (Fig. 19.22). The porphyrias show extreme

/nas

Fig. 19.22 **Porphyrin metabolism showing the various porphyrias.** ALA synthase is the rate-limiting enzyme. Deficiencies of the other seven enzymes (crosses) cause the different porphyrias:
1 X-linked sideroblastic anaemia
2 ALA dehydrogenase porphyria (ADP)
3 Acute intermittent porphyria (AIP)
4 Congenital erythropoietic porphyria (CEP)
5 Porphyria cutanea tarda (PCT) and hepatoerythropoietic porphyria (HEP)
6 Hereditary coproporphyria (HCP)
7 Variegate porphyria (VP)
8 Erythropoietic protoporphyria (EPP).

genetic heterogeneity. For example, in acute intermittent porphyria more than 90 mutations have been identified in the porphobilinogen deaminase gene. One mutation has a high prevalence in patients in northern Sweden, suggesting a common ancestor.

Structurally, porphyrins consist of four pyrrole rings. These pyrrole rings are formed from the precursors glycine and succinyl-CoA, which are converted to 5-aminolaevulinic acid (8-ALA) in a reaction catalysed by the enzyme 5-ALA synthase. Two molecules of 8-ALA condense to form a pyrrole ring.

Porphyrins can be divided into uroporphyrins, coproporphyrins or protoporphyrins depending on the structure of the side-chain. They are termed type I if the structure is symmetrical and type III if it is asymmetrical. Both uroporphyrins and coproporphyrins can be excreted in the urine.

The sequence of enzymatic changes in the production of haem is shown in Figure 19.22. The chief rate-limiting step is the enzyme 5-ALA synthase. This has two isoforms, ALA-N (non-erythroid) and ALA-E (erythroid). ALA-N is under negative feedback by haem but is upregulated by drugs and chemicals; there is no known inherited deficiency and the gene is on 3p21. Conversely ALA-E, encoded by Xpll.21, is unaffected by drugs or haem, and an inherited deficiency causes X-linked sideroblastic anaemia (Fig. 19.22 [T|).

Consequently:

- Haem (endogenous or exogenous) produces remission of hepatic porphyria.
- Chemicals and drugs can produce disease.
- Erythopoietic porphyria gives constant symptoms and is affected by sunlight.

Clinical features

All of the haem intermediates shown in Figure 19.22 are potentially toxic. Three patterns of symptoms occur in the various types of porphyria.

- neurovisceral (Table 19.20)
- photosensitive
- haemolytic anaemia.

Table 19.20 **Porphyria: neurovisceral symptoms**

Neuropsychiatric	Visceral
Neuropathy: Motor (70%) Sensory Epilepsy (15%) Psychiatric disorders (50%): Depression Anxiety Psychosis	Abdominal pain Vomiting p to 90% Constipation Diarrhoea (occasional) Fever (~ 30%) Hypertension (up to 50%) Tachycardia (up to 80%) Muscular pain (~ 50%)

The most common types of porphyria are acute intermittent (AIP), porphyria cutanea tarda (PCT) and erythropoietic porphyria (EPP).

The *diagnosis* of various types is based on urinary excretion levels of aminolaevulinic acid (ALA), porphobilinogen (PBG) and porphyrin in aliquots from a 24-hour collection. Erythrocyte PBG deaminase activity is measured for neurovisceral symptoms. Urinary and plasma porphyrin concentrations are helpful for those with photocutaneous manifestations. Faecal porphyrin analysis is helpful in confirmatory testing.

Neurovisceral

Acute intermittent porphyria (AIP) (Fig. 19.22 [3]) This is an autosomal dominant disorder. Presentation is in early adult life, usually around the age of 30 years, and women are affected more than men. It may be precipitated by alcohol and drugs such as barbiturates and oral contraceptives, but a wide range of lipid-soluble drugs have also been incriminated. Acute attacks present with neurovisceral symptoms (Table 19.20). Symptoms of the rare, autosomal recessive aminolaevulinic acid dehydrogenase porphyria (ADP) \2\ are similar.

Investigations

The urine turns red-brown or red on standing.

- Blood count. This is usually normal, with occasional neutrophil leucocytosis.
- Liver biochemical tests. There is elevated bilirubin and aminotransferase.
- Serum urea is often raised.
- ALA and PBG are raised.
- Erythrocyte PBG deaminase is decreased.

Screening

Family members should be screened to detect latent cases. Urinalysis is not adequate but measurement of erythrocyte porphobilinogen deaminase and ALA synthase is extremely sensitive.

Mixed neurovisceral and photocutaneous

Variegate porphyria (VP) (Fig. 19.22 \T\) ' This combines neurovisceral symptoms with those of a cutaneous photosensitive porphyria. A bullous eruption develops on exposure to sunlight owing to the activation of porphyrins deposited in the skin.

Investigation shows an elevated urinary ALA and PBG. Fluorescence emission spectroscopy of plasma differentiates this from other cutaneous porphyrias.

Hereditary coproporphyria (HCP) (Fig. 19.22 \6\)
This is extremely rare and broadly similar in presentation to variegate porphyria.

Photocutaneous

Porphyria cutanea tarda (cutaneous hepatic porphyria) (PCT) (Fig. 19.22 [5])
This condition, which has a genetic predisposition, presents with a bullous eruption on exposure to sunlight; the eruption heals with scarring. Alcohol is the most common aetiological agent but HCV, iron overload or HIV can also precipitate the disease. Evidence of biochemical or clinical liver disease may also be present. Polychlorinated hydrocarbons have been implicated and porphyria cutanea tarda has been seen in association with benign or malignant tumours of the liver.

Hepatoerythropoietic porphyria (HEP, Fig. 19.22 \5\) is a rare disease clinically very similar to congenital erythropoietic porphyria presenting in childhood; haemolytic anaemia occurs. The defect of HEP is similar to that ofPCT.

The diagnosis depends on demonstration of increased levels of urinary uroporphyrin. Histology of the skin shows subepidermal blisters with perivascular deposition of periodic acid-Schiff-staining material. The serum iron and transferrin saturation are often raised. Liver biopsy shows mild iron overload as well as features of alcoholic liver disease.

Congenital erythropoietic porphyria (CEP)
(Fig. 19.22 GS)
This is extremely rare and is transmitted as an autosomal recessive trait. Its victims show extreme sensitivity to sunlight and develop disfiguring scars. Dystrophy of the nails, blindness due to lenticular scarring, and brownish discoloration of the teeth also occur.

Erythropoietic protoporphyria (EPP)
(Fig. 19.22 \W\)
This is more common than congenital erythropoietic porphyria and is inherited as an autosomal dominant trait. It presents with irritation and a burning pain in the skin on exposure to sunlight. The liver is usually normal but protoporphyrin deposition can occur. Diagnosis is made by fluorescence of the peripheral red blood cells and by increased protoporphyrin in the red cells and stools.

Management of porphyrias

Neurovisceral

Acute. The management of acute episodes is largely supportive. Precipitating factors, e.g. drugs, should be stopped. Analgesics should be given (avoiding drugs that may aggravate an attack). Intravenous carbohydrates, e.g. glucose, inhibit ALA synthase activity. Intravenous haem arginate (human haemin) infusion reduces ALA and PBG excretion by having a negative effect on ALA synthase-N activity (see Fig. 19.22) and decreases the duration of an attack; this is useful in a severe attack. Calorie and fluid intake should be maintained.

Prevention in remission period. This is by avoidance of possible precipitating factors, e.g. drugs and alcohol.

Stopping smoking, treatment of infections and stress avoidance are helpful. Surgery can precipitate attacks. A high-carbohydrate diet should be maintained and haemin infusions may also help.

Photocutaneous episodes

Acute attacks following exposure to UV light can only be treated symptomatically. However, *venesection,* which reduces urinary porphyria, can be used for PCT in both acute and remission phases. Chloroquine can also aid excretion by forming a water-soluble complex with uroporphyrins.

Liver transplantation is used for severe cases.

Prevention is with avoidance of sunlight, and use of sunscreens and protective clothing.

Oral (3-carotene, which quenches free radicals, provides effective protection against solar sensitivity in EPP.

DISORDERS OF THE EAR, NOSE AND THRO

THE EAR

The ear can be divided into three parts: outer, middle and inner (Fig. 20.1).

The *outer ear* has a skin-lined tube 2.5 cm long leading down to the tympanic membrane (the ear drum). Its outer third is cartilaginous and contains hair, sebaceous and ceruminous glands, but the walls of the inner two-thirds are bony. The outer ear is self-cleaning as the skin is migratory and there are no indications to use cotton wool buds. Wax should only be seen in the outer third.

The *middle ear* is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly, and the Eustachian tube connects it to the nasopharynx medially. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, such as with a cleft palate, will prevent air entering the middle ear cleft which may then fill with fluid. Lying within the middle ear cavity are the three ossicles (malleus, incus and stapes) that transmit sound from the tympanic membrane to the inner ear. On the medial wall of the cavity is the horizontal segment of the facial nerve, which may be damaged during surgery or by direct extension of infection in the middle ear.

The *inner ear* contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a semicircular canal arranged in each body plane and these are stimulated by rotatory movement. The facial, cochlear and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem (see Fig. 21.7, p. 1185).

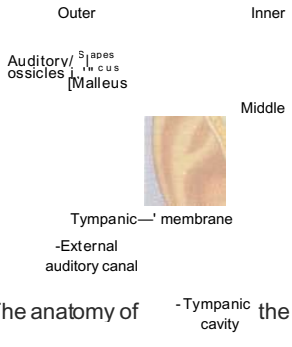

Fig. 20.1 The anatomy of the ear.

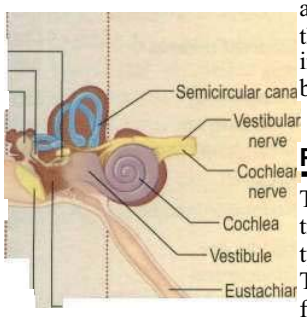

PHYSIOLOGY OF HEARING

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. They amplify the waves by about 18-fold to compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect the vibrations and transduce these into nerve impulses which pass to the cochlear nucleus and then eventually to the superior olivary nuclei

of both sides; thus lesions central to the cochlear nucleus do not cause unilateral hearing loss.

If the ossicles are diseased, sound can also reach the cochlea by vibration of the temporal bone (bone conduction).

EXAMINATION

The pinna and postauricular region should first be examined for scars or swellings. An auroscope is used to examine the external ear canal whilst the pinna is retracted backwards and upwards to straighten the canal. Look for wax, discharge or foreign bodies. The tympanic membrane should always be seen with a light reflex anteroinferiorly. Previous repeated infections may cause a thickened, whitish drum but fluid in the middle ear may show as dullness of the drum. Perforations are marginal or central.

COMMON DISORDERS

The discharging ear (otorrhoea)

Discharge from the ear is usually due to infection of the outer or middle ear.

Otitis externa is a diffuse inflammation of the skin of the ear canal. The organism may be bacterial, viral or fungal and the patient usually complains of severe pain. Gentle pulling of the pinna is tender and there may be lymphadenopathy of the preauricular nodes.

Examination may reveal debris in the canal which needs to be removed either by gentle mopping or preferably by suction viewed directly under a microscope. In severe cases the canal may be swollen and a view of the tympanic membrane impossible. Any foreign body seen should be removed with great care by trained personnel.

Treatment is with regular cleansing and topical antibiotics combined with corticosteroids; it resolves in 3-4 days.

Otitis media can also present with discharge from the middle ear through a perforation of the tympanic membrane. There are no mucous glands in the external ear canal, however, and if the discharge is serous then middle ear pathology is unlikely.

Treatment is with systemic antibiotics.

Cholesteatoma

Cholesteatoma is defined as keratinizing squamous epithelium within the middle ear cleft and can present with foul smelling otorrhoea. Examination may show a defect in the tympanic membrane full of white cheesy material. Mastoid surgery is required to remove this sac of squamous debris as it can erode local structures such as the facial nerve or even extend intracranially.

Hearing loss

Deafness can be conductive or sensorineural and these can be differentiated by the Rinne and the Weber tests (Box 20.1).

■ *Box 20.1* **Hearing loss**

Type	Defect	Rinne	Weber
			Sound heard
Conductive	Outer or middle ear	Negative	louder on the affected side
Sensorineura	Inner ear or more centrally	Positive	Sound heard louder in the normal ear

Rinne test

Normally a tuning fork, 512 Hz, will be heard as louder if held next to the ear (air conduction) compared to being placed on the mastoid bone *(Rinne positive).* If the tuning fork is perceived louder when placed on the mastoid (bone conduction), then a defect in the conducting mechanism of the external or middle ear is present *(Rinne negative).*

Weber test

A tuning fork placed on the bridge of the nose of a patient with normal hearing (or with symmetrical hearing loss) should be perceived centrally.

Conductive hearing loss may be due to many causes (Table 20.1) but wax is the commonest.

Perforated tympanic membrane

This may arise from trauma or chronic middle ear disease where recurrent infection results in a permanent defect. Surgical repair is only indicated if the patient is symptomatic with hearing loss or recurrent discharge.

Otitis media

This is an acute inflammation of the middle ear, causing severe pain (otalgia) and conductive hearing loss. This occurs because fluid accumulation in the middle ear

Table 20.1 **Deafness**

Conductive	Sensorineural
Congenital - atresia	**End organ**
Pendred's syndrome (seep. 1071)	Advancing age Occupational acoustic
Long QT syndrome (see p. 777)	trauma
	Meniere's disease Drugs (e.g.
External meatus	gentamicin, furosemide (frusemide))
Wax	
Foreign body Otitis externa Chronic suppuration	**Eighth nerve lesions**
	Acoustic neuroma Cranial trauma Inflammatory lesions:
Drum	Tuberculous meningitis
Perforation/trauma	Sarcoidosis
	Neurosyphilis
Middle ear	Carcinomatous meningitis
Otosclerosis	
Ossicular bone problems	**Brainstem lesions (rare)**
Suppuration	Multiple sclerosis Infarction

impairs sound conduction to the cochlea. It is often viral in origin, e.g. following a cold, and will settle within 72 hours without antibacterial treatment. In patients with systemic features or after 72 hours, a systemic antibiotic, e.g. amoxicillin, should be given. Topical therapy is of no value. Complications include infection of the mastoid bone.

Acute otitis media may spread to the mastoid area and if there is tenderness and swelling over the mastoid then an urgent ENT opinion should be obtained.

Secretory otitis media with effusion (also called serous otitis media or glue ear) (Fig. 20.2)

This is common in children because of Eustachian tube dysfunction. The effusion resolves naturally in the majority of cases but can persist giving hearing loss, and it predisposes to recurrent attacks of acute otitis media. A grommet is a tube that is inserted into the tympanic membrane and ventilates the middle ear cavity, i.e. it takes over the Eustachian tube's function. Grommets are extruded from the tympanic membrane as it heals (lasting from 6 months to 2 years) but if the Eustachian tube is still not working, fluid will reaccumulate in the middle ear cavity with a return of symptoms. In most children the middle third of the face grows around the age of 7-14 years and Eustachian tube dysfunction is rare after this.

Otosclerosis

This is usually a hereditary disorder where new bony deposits occur within the derivatives of the otic capsule, specifically the stapes footplate and in the cochlea. Characteristically seen in the second and third decades, it is commoner in females and can become worse during pregnancy. The hearing loss may be mixed, and treatment includes a hearing aid or replacement of the fixed stapes with a prosthesis (stapedectomy).

Presbycusis

This is the commonest cause of deafness. It is a degenerative disorder of the cochlea and is seen in old age. The onset is gradual and the higher frequencies are affected most (Fig. 20.3). Speech has two components: low frequencies (vowels) and high frequencies (consonants). When the consonants are lost, speech loses its intelligibility. Increasing the volume merely increases the low frequencies and the characteristic response of 'Don't shout. I'm not deaf!' A high-frequency-specific hearing aid will do much to ease the frustrations of both the patients and their close contacts.

Noise trauma

Cochlear damage can occur, for example, when shooting without ear protectors or from industrial noise (see p. 1030) and characteristically has a loss at 4 kHz.

Acoustic neuroma

This is a slow-growing benign Schwannoma of the vestibular nerve (p. 1245) which can present with progressive sensorineural hearing loss. Any patient with an asymmetric sensorineural hearing loss should be investigated, e.g. with an MRI scan.

Vertigo

Vertigo is usually rotatory when it arises from the ear. The presence of otalgia, otorrhoea, tinnitus or hearing loss suggests an otologic aetiology. Vestibular causes can be classified according to the duration of the vertigo:

- seconds to minutes - benign paroxysmal positional vertigo (BPPV)
- minutes to hours - Meniere's disease
- hours to days - labyrinthine or central pathology.

***Fig. 20.2* Secretory otitis media (glue ear).** Auroscopic view of tympanic membrane which is dull with loss of light reflex.

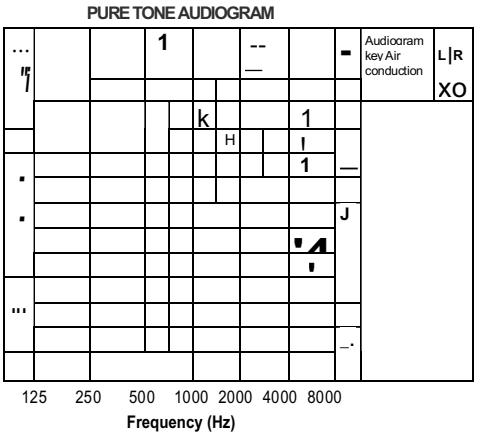

***Fig. 20.3* Audiogram showing presbycusis (high frequency loss).**

Benign paroxysmal positional vertigo (BPPV)

BPPV is thought to be due to loose otoliths in the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and may occur when turning in bed or on sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds or minutes and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause but it sometimes follows vestibular neuronitis (p. 1190), head injury or ear infection.

Diagnosis

This is made not only on the history but by precipitating an attack by carrying out a positional test in the outpatient clinic. This test, called the *Hallpike manoeuvre,* involves sitting the patient on a couch and then turning the patient's head towards the affected ear. The patient's head is supported by the examiner and the patient then lies down so that the head is just below the horizontal. Nystagmus (following a latent interval of a few seconds) is noted, as is any subjective sensation of vertigo. A positive Hallpike test confirms BPPV, which can be cured in over 90% of cases by the Epley manoeuvre. This involves gentle but specific manipulation and rotation of the patient's head to shift the loose otoliths from the semicircular canals.

A differential diagnosis is a cerebellar mass but here, positional nystagmus (and vertigo) is immediately apparent (no latent interval) and does not fatigue.

Meniere's disease

This condition is characterized by recurring episodic rotatory vertigo lasting 30 minutes to a few hours; attacks are recurrent over months or years. Classically it is associated with a low frequency sensorineural hearing loss, feeling of fullness in the affected ear, loss of balance, tinnitus and vomiting. There is a build-up of endolymphatic fluid in the inner ear, although its precise aetiology is still unclear.

Treatment involves the use of vestibular sedatives, e.g. cinnarizine in the acute phase, low-salt diet, betahistine, and avoidance of caffeine. If the disease cannot be controlled in this way, then a chemical labyrinthectomy, which involves perfusing the round window orifice with ototoxic drugs such as gentamicin is possible. Gentamicin destroys the vestibular epithelium; therefore the patient has severe vertigo for around 2 weeks until the body compensates for the lack of vestibular input on that side. The patient will happily trade occasional mild vertigo when the balance system is challenged to the unpredictable, severe and disabling attacks of vertigo of Meniere's disease.

Labyrinthine or central causes of vertigo

(see Table 21.10)

These are managed with vestibular sedatives in the acute phase. Most patients will settle over a few days but continuous true vertigo with nystagmus suggests a central lesion. A patient with a deficit of vestibular function due to viral labyrinthitis or neuronitis should be able to come off the vestibular sedatives within 2 weeks, as long-term use can give parkinsonian side-effects, delay central compensation and thus prolong the vertigo. Vestibular rehabilitation by a physiotherapist or audiological scientist can speed up the compensation process, although most patients will be able to do this themselves with time.

Tinnitus

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss. Patients describe a hissing or ringing in their ears and this can cause much distress. It usually does not have a serious cause but vascular malformation, e.g. aneurysms, or vascular tumours may be associated.

Tinnitus associated with deafness is described above.

Treatment

This is difficult. A tinnitus masker (a mechanically produced continuous soft sound) can help. A vestibular sedative, betahistine, is occasionally used.

THE NOSE

ANATOMY AND PHYSIOLOGY (Fig 20.4)

The function of the nose is to facilitate smell and respiration. Smell is a sensation conveyed by the olfactory

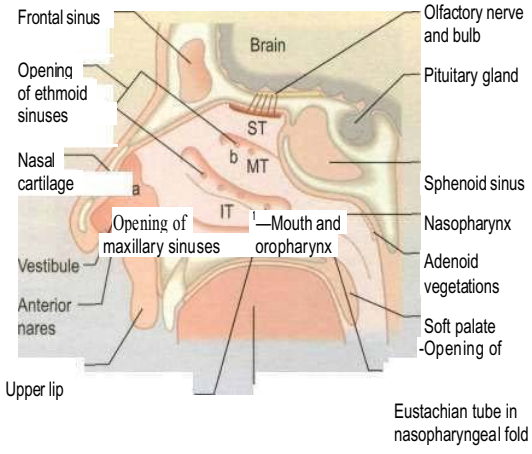

Fig. 20.4 **The anatomy of the nose in longitudinal section.** IT, inferior turbinate; MT, middle turbinate; ST, superior turbinate; a, internal ostium; b, respiratory region; c, choanae.

epithelium in the roof of the nose. The olfactory epithelium is supplied by the first cranial nerve (p. 1179). The nose also filters, moistens and warms inspired air and in doing so assists the normal process of respiration.

The external portion of the nose comprises two nasal bones attached to the rest of the facial skeleton and to the upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone. This separates the internal nose from the external nostril to the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly. The paranasal sinuses open into the lateral wall of the nose and are a system of aerated chambers within the facial skeleton.

The blood supply of the nose is derived from branches of both the internal and external carotid arteries. The internal carotid artery supplies the upper nose via the anterior and posterior ethmoidal arteries. The external carotid artery supplies the posterior and inferior portion of the nose via the superior labial artery, greater palatine artery and sphenopalatine artery. On the anterior nasal septum is an area of confluence of these vessels (Little's area) (Fig. 20.5a).

EXAMINATION

The anterior part of the nose can be examined using a nasal speculum and light source. Endoscopes are required to examine the nasal cavity and postnasal space.

COMMON DISORDERS

Epistaxis

Nose bleeds vary in severity from minor to life-threatening. Little's area (Fig. 20.5a) is a frequent site of nasal haemorrhage. First aid measures should be administered immediately, including compression of the anterior lower portion of the external nose, ice packs and leaning forward. The patient should be asked to avoid swallowing any blood running posteriorly. If the bleeding continues profusely then resuscitation in the form of intravenous access, fluid replacement or blood, and oxygen can be administered. If further intervention is necessary, consideration should be given to intranasal cautery of the bleeding vessel, or intranasal packing may be undertaken using a variety of commercially available nasal packs (Fig. 20.5b). In addition to direct treatment of the epistaxis, a cause and appropriate treatment of a cause should be sought (Table 20.2).

Table 20.2 **Aetiology of epistaxis**

Local	Idiopathic
	Trauma - foreign bodies, nose-picking and nasal fractures
	Iatrogenic - surgery, intranasal steroids
	Neoplasm - nasal, paranasal sinus and nasopharyngeal tumours
General	Anticoagulants
	Coagulation disorders (p. 469)
	Hypertension
	Osler-Weber-Rendu syndrome (familial haemorrhagic telangiectasia)

Rhinitis (see p. 895)

Nasal obstruction

Nasal obstruction is a symptom and not a diagnosis. It can significantly affect a patient's quality of life. Causes include:

- *Rhinitis* (p. 895). If an allergen is identified, then allergen avoidance is the mainstay of treatment. Topical steroids and/or antihistamines can be tried. If severe, then oral antihistamines or referral to an allergy clinic for immunotherapy may be warranted.

Fig. 20.5 **(a) Blood supply of Little's area on the septum of the nose, (b) Nasal pack.**

- *Septal deviation.* Correction of this deviation can be undertaken surgically.
- *Nasal polyps.* This condition occurs with inflammation and oedema of the sinus nasal mucosa. This oedematous mucosa prolapses into the nasal cavity and can cause significant nasal obstruction. In allergic rhinitis (p. 896) the mucosa lining the nasal septum and inferior turbinates are swollen and a dark red or plum colour. Nasal polyps can be identified as glistening swellings which are not tender. Treatment with intranasal steroids may help but if polyps are large or unresponsive to medical treatment then surgery is necessary.
- *Foreign bodies.* These are usually seen in children who present with unilateral nasal discharge. Clinical exam ination of the nose with a light source often reveals the foreign body, which requires removal either in clinic or in theatre with a general anaesthetic.
- *Sinonasal malignancy.* This is extremely rare. The diag nosis must be considered if unusual unilateral symp toms are seen, including nasal obstruction, epistaxis, pain, epiphoria, cheek swelling, paraesthesia of the cheek and proptosis of the orbit.

Sinusitis

Sinusitis is an infection of the paranasal sinuses that may be bacterial (mainly *Streptococcus pneumoniae* and *Haemophilus influenzae)* or occasionally fungal. It is most commonly associated with an upper respiratory tract infection and can occur with severe asthma. Symptoms include frontal headache, purulent rhinorrhoea, facial pain with tenderness and fever. It can be confused with a variety of other conditions such as migraine, trigeminal neuralgia, and cranial arteritis.

Treatment

Treatment for a bacterial sinusitis includes nasal decongestants, e.g. xylomethazoline, broad-spectrum antibiotics, e.g. co-amoxiclav because *H. influenzae* can be resistant to amoxicillin, anti-inflammatory therapy with topical corticosteroids such as fluticasone propionate nasal spray to reduce mucosal swelling, and steam inhalations.

If the symptoms of sinusitis are recurrent (Box 20.2) or complications such as orbital cellulitis arise, then an ENT opinion is appropriate and a CT scan of the paranasal sinuses is undertaken. Plain sinus X-rays are now rarely used to image the sinuses.

CT scan of the sinuses or an MRI scan can demonstrate soft tissue planes (Fig. 20.6).

Functional endoscopic sinus surgery (FESS) is used for ventilation and drainage of the sinuses.

Anosmia

Olfaction is mainly under the control of cranial nerve I, although irritant, unpleasant nasal sensations are carried by cranial nerves V, IX and X. Anosmia is a complete loss of the sense of smell and *hyposmia* is a decreased sense of smell. If odorant molecules do not reach the olfactory epithelium high in the nose, a *conductive deficit* of smell occurs. If the neural transmission of smell is affected then a *sensorineural loss* of smell is incurred. Some conditions may predispose to a mixed (conductive and sensorineural) loss of smell. The main cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. Other causes include sinonasal disease, old age, drug therapy and head injury/trauma. It is difficult to predict the speed and extent of recovery in the latter causes.

Idiopathic cases will account for many patients but before this diagnosis is accepted an assessment of the patient for the possibility of an intranasal tumour or intracranial mass should be undertaken.

***Box 20.2* Types of sinusitis**

Acute sinusitis	Symptoms of sinusitis lasting between 1 week and 1 month
Recurrent acute sinusitis	More than four episodes of acute sinusitis per year
Subacute sinusitis	Symptoms of sinusitis lasting between 1 and 3 months
Chronic sinusitis	Symptoms of sinusitis lasting longer than 3 months

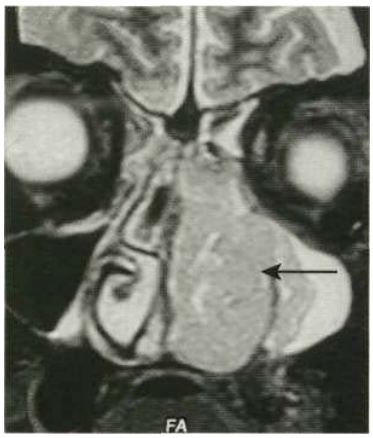

Fig. 20.6 **MRI of sinonasal tumour.** Large soft tissue swelling filling nasal cavity and sinuses on the patient's left side.

Fractured nose

Patients with a fractured nose present with epistaxis, bruising of the eyes and nasal bridge swelling. Initially, it is often difficult to assess if the bones are deviated, particularly if there is significant swelling. Reduction of the fracture should be undertaken in the first 2 weeks after injury and can be achieved by manipulation. However, if the fracture sets, a more formal rhinoplasty may have to be undertaken at a later stage. The patient should be examined for a head injury and the nose should also be checked for a septal haematoma. This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum and requires immediate drainage.

THE THROAT

ANATOMY AND PHYSIOLOGY

The throat can be considered as the oral cavity, the pharynx and the larynx. The oral cavity extends from the lips to the tonsils. The pharynx can be divided into three areas:

- nasopharynx - extending from the nasal openings to the soft palate
- orpharynx - extending from the soft palate to the tip of the epiglottis
- hypopharynx - extending from the tip of the epiglottis to just below the level of the cricoid cartilage where it is continuous with the oesophagus.

Lying within the hypopharynx is the larynx. This consists of cartilaginous, ligamentous and muscular tissue with the primary function of protecting the distal airway. The pharynx is innervated from the pharyngeal plexus. There are two vocal cords which abduct (open) during inspiration and adduct (close) to protect the airway and for voice production (phonation). The main nerve supply of the vocal cords comes from the recurrent laryngeal nerves (branches of the vagus nerve) which arise in the neck, but on the left side passes down around the aortic arch and then ascends in the tracheo-oesophageal groove to the larynx.

Normal vocal cords vibrate between 90 (male) and 180 (female) times per second, giving the voice its pitch or frequency. A healthy voice requires full closure of the vocal cords with a smooth, regular pattern of vibration, and any pathology that prevents full closure will result in air escaping between the vocal cords during phonation and a 'breathy' voice.

EXAMINATION

Good illumination is essential. Look at teeth, gums, tongue, floor of mouth and oral cavity. Tonsils, soft palate and uvula are easily seen, and a gag reflex (p. 1190) is present. The remainder of the pharynx and larynx can be inspected with a laryngeal mirror or endoscope.

Examination of the neck for lymph nodes and other masses is also performed.

COMMON DISORDERS

Hoarseness (dysphonia)

There are three essential components for voice production: an air source (the lungs); a vibratory source (the vocal cords); and a resonating chamber (the pharynx, the nasal and oral cavities). Although chest and nasal disorders can affect the voice, the majority of hoarseness is due to laryngeal pathology.

Inflammation which increases the 'mass' of the vocal cords will cause the vocal cord frequency to fall, giving a much deeper voice. Thus listening to a patient's voice can often give a diagnosis before the vocal cordsare examined.

Nodules

Nodules (always bilateral and commoner in females) and polyps (Fig. 20.7) are found on the free edge of the vocal cord preventing full closure and giving a 'breathy, harsh' voice. They are commonly found in professions that rely on their voice for their livelihood, such as teachers, singers and lawyers. They are usually related to poor technique of voice production and can usually be cured with speech therapy. If surgery is needed, great care must be taken to remain in the superficial layers of the vocal cord in order to prevent deep scarring which may leave the voice permanently hoarse.

Reinke's oedema (Fig. 20.8)

This is due to a collection of tissue fluid in the subepithelial layer of the vocal cord. The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke's oedema is associated with irritation of the vocal cords: smoking, voice abuse, acid reflux and vary rarely hypothyroidism. Treatment is to remove the irritation in most cases but surgery to thin the cords will also allow the voice to return to its normal pitch.

Acute-onset hoarseness

This, in a smoker is a danger sign. Any patient with a hoarse voice for over 6 weeks should be seen by an ENT surgeon. The voice may be deep, harsh and breathy indicating a mass on the vocal cord or can be weak suggesting a paralysed left vocal cord secondary to mediastinal disease, e.g. bronchial carcinoma.

Early squamous cell carcinoma of the larynx (Fig. 20.9) has a good prognosis. Treatment is with carbon dioxide resection or radiotherapy. Spread of the tumour can lead to referred otalgia which may then require a laryngectomy with possible neck dissection. A patient with a paralysed left vocal cord must have a chest X-ray. Medialization of the paralysed cord to allow contact with the opposite

Fig. 20.7 Vocal cord polyp.

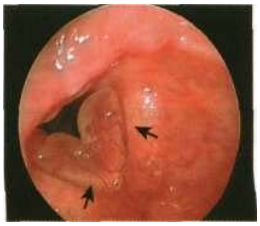

Fig. 20.8 Reinke's oedema of the vocal cords.

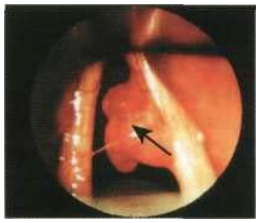

Fig. 20.9 **Carcinoma of the right cord.**

cord can return the voice and give a competent larynx. This can be done under local anaesthesia, giving an immediate result whatever the long-term prognosis of the chest pathology.

Stridor

Stridor or noisy breathing can be divided into inspiratory (source is glottic or above), expiratory (intrathoracic trachea or below) or mixed (subglottis or extrathoracic trachea). All patients with stridor, both paediatric and adult, are potentially at risk of asphyxiation and should be investigated fully. Severe stridor may be an indication for either intubation or a tracheostomy (Table 20.3). Tracheostomy tubes may be:

- *Cuffed or uncuffed.* A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.
- *Fenestrated or unfenestrated.* This is a small hole on the greater curvature of the tube (both outer and inner) allowing air to escape upwards to the vocal cords and therefore the patient can speak. This tube often has a valve which allows air to enter from the stoma but closes on expiration, directing the air through the fenestration.

Most long-term tracheostomy tubes have an inner and outer tube. The inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is crusting of its distal end with dried secretions and this arrangement allows the inner tube to be removed, cleaned and replaced as frequently as required, without disrupting the outer tube.

When to decannulate a patient is often a difficult issue if laryngeal competence is unclear. Movement of the vocal cords requires an ENT examination but owing to the risk of aspiration, a speech therapist's opinion can also be useful. The tracheostomy tube itself can also give problems due to compression of the oesophagus with a cuffed tube and by preventing the larynx from rising during normal swallowing.

Table 20.3 **Indications for tracheostomy**

Upper airway obstruction (real or anticipated)
Long-term ventilation
Bronchial lavage
Incompetent larynx with aspiration

Tonsillitis and pharyngitis

Viral infections of the throat are common and, although many practitioners are under pressure from the patient to give antibiotics, the vast majority are usually self-limiting, settling with bed rest, analgesia and encouraging fluid intake. Fungal infections, usually candidiasis, are uncommon and may indicate an immunocompromised patient or undiagnosed diabetes.

Tonsillitis

Tonsillitis, with a good history of pyrexia, dysphagia, lymphadenopathy and severe malaise is usually bacterial with P-haemolytic streptococcus the commonest organism.

Glandular fever (p. 47)

This can also present with tonsillitis, although clinically the tonsils have a white exudate, there is often a petechial rash on the soft palate and an accompanying lymphadenopathy.

Quinsy

Quinsy is a collection of pus outside the capsule of the tonsil usually located adjacent to its superior pole. The patient often has trismus making examination difficult but the pus pushes the uvula across the midline to the opposite side. The area is usually hyperaemic and smooth but unilateral tonsil ulceration is more likely to be a malignancy. In either case urgent referral to an ENT specialist is essential.

Indications for a tonsillectomy are shown in Table 20.4. This is carried out under a general anaesthetic and current surgical techniques include diathermy dissection, laser excision and coblation (using an ultrasonic dissecting probe). There are strong advocates for each technique and much will depend on the individual surgeon's preference. Some departments now carry out tonsillectomy as a day case procedure as most reactionary bleeding will occur within the first 8 hours postoperatively.

Snoring

Snoring is due to vibration of soft tissue above the level of the larynx. It is a common condition (50% of 50-year-old males will snore to some extent) and can be considered to be related to obstruction of three potential areas; the nose, the palate or/and the hypopharynx (see Fig. 14.28). An Epworth questionnaire (Table 20.5) can also assist in the discrimination of sleep apnoea (p. 907) from simple snoring. Patients with a history of habitual, non-positional, heroic (can be heard through a wall) snoring require a full ENT examination and can be investigated

Table 20.4 **Indications for tonsillectomy**

Suspected malignancy
Obstructive sleep apnoea due to tonsillar hypertrophy
Recurrent tonsillitis: five attacks a year for at least 2 years
Quinsy in a patient with a history of recurrent tonsillitis

Table 20.5 Epworth Sleepiness Scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent time. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

Situation	Chance of dozing
Sitting and reading	
Watching TV	
Sitting and inactive in a public place (theatre or meeting) As a passenger in a car for an hour without a break Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after lunch (without alcohol) In a car, while stopped for a few minutes in the traffic	
TOTAL	

Normal 5 ± 4
Severe obstructive sleep apnoea 16 (±4)
Nacrolepsy 17

by sleep nasendoscopy in which a sedated, snoring patient has a flexible nasendoscope inserted to identify the source of vibration. Nasal pathology such as polyps can be removed surgically with good results and most patients will benefit from lifestyle changes such as weight loss. Stiffening or shortening the soft palate via surgery, often using a laser, can help for palatal snorers but hypopharyngeal snorers require either a dental prosthesis at night to hold the mandible forward or continuous positive airway pressure (CPAP) via a mask (p. 982).

Dysphagia (p. 274)

Difficulty in swallowing is a common symptom but can be the presenting feature of carcinoma of the pharynx and therefore requires investigation.

A pharyngeal pouch is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (cricopharyngeus) (Fig. 20.10). An area of weakness known as Killian's dehiscence allows a pulsion diverticulum to form. This will collect food which may regurgitate into the mouth or even down to the lungs at night with secondary pneumonia. Diagnosis is made radiologically and treatment is surgical, either via an external approach through the neck where the pouch is excised or more commonly endoscopically with stapling of the party wall (Fig. 20.10c).

Foreign bodies in the pharynx can be divided into three general categories: soft food bolus, coins (smooth), bones (sharp). Soft food bolus can be initially treated conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity but sharp objects require emergency removal to avoid perforation of the muscle wall. If the patient perceives the foreign body to be to one side, then it should be above cricopharyngeus and an ENT examination will locate it; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall and valleculae. Radiology will identify coins, and it can be a clinical decision to see whether a coin will pass down to the stomach, in which case no further treatment is required as it will exit naturally. Some departments advocate the use of a metal detector to monitor the position of the coin in the patient who is usually a child or has a mental disorder. Fish can be divided into those with a bony skeleton (teleosts) and those with a cartilaginous skeleton (elasmobranchs), and therefore radiology may only be useful in some cases. Radiology can also identify air in the cervical oesophagus indicating a radiolucent foreign body lying distally.

Globus pharyngeus

This is not a true dysphagia. It is a condition with classic

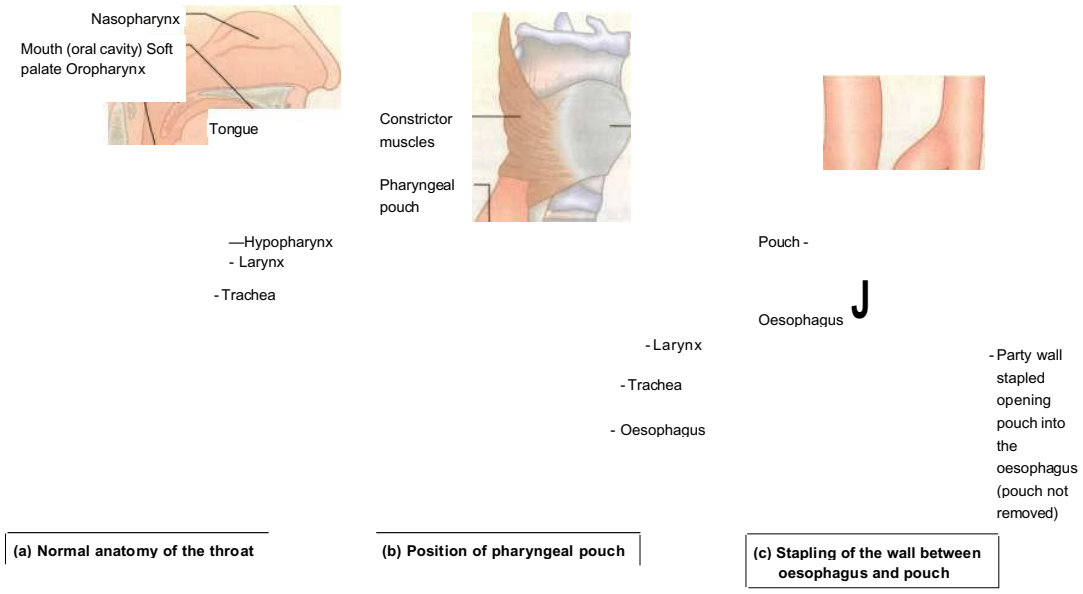

Fig. 20.10 **Pharyngeal pouch, (a)** Normal anatomy of the throat, (b) Position of pharyngeal pouch, (c) Stapling of the party wall between

oesophagus and pouch.

symptoms of an intermittent sensation of a lump in the throat. This is perceived to be in the midline at the level of the cricoid cartilage and is worse when swallowing saliva; indeed it often disappears when ingesting food or liquids. ENT examination is usually clear and normal laryngeal mobility can be felt when gently rocking the larynx across the postcricoid tissues. A contrast swallow will show not only the structures below the pharynx but also assess the swallowing dynamically. Any suspicious area will require an endoscopy with biopsy.

DISORDERS OF THE EYE

A careful and detailed history gives most of the facts needed to make a working diagnosis. The eye has only a few mechanisms by which it can convey a diseased state. Common symptoms include alteration in visual acuity, redness, pain, discharge and photophobia. It is vital that an accurate Snellen visual acuity is recorded in all patients with an eye problem.

Diabetic eye disease (p. 1124) and hypertensive eye disease (p. 860) are discussed elsewhere.

APPLIED ANATOMY AND PHYSIOLOGY

The average diameter of the human eye is 24 mm. The *cornea* occupies the central aspect of the globe and is one of the most richly innervated tissues in the body. This clear, transparent and avascular structure, measuring 12 mm horizontally and 11 mm vertically, provides 78% of the focusing power of the eye. The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor which alters the function of these cells will result in corneal oedema and cause blurred vision. The anterior surface of the cornea is lined by epithelial cells which, together with the tear film, provide a smooth and regular surface for the refraction of light. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink. In addition, the lids protect the globe and provide an outflow channel for excess tears via the punctae to the nose (Fig. 20.11).

The cornea and the sclera give mechanical strength and shape to the exposed surface of the globe. The *sclera*

Sclera covered by conjunctiva

Eyelashes of lower lid

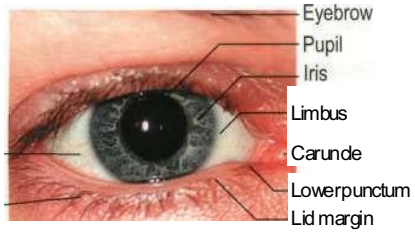

Fig. 20.11 Photograph of the right eye.

is a white opaque structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera and the optic nerve perforates it posteriorly.

The *conjunctiva* covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera and is then reflected onto the undersurface of the upper and lower lids. The area of conjunctival reflection under the lids makes up the upper and lower fornix. The conjunctiva over the sclera is referred to as the bulbar conjunctiva whilst that over the lids makes up the tarsal conjunctiva.

The *anterior chamber* is the space between the cornea and the iris, and is filled with aqueous humour (Fig. 20.12). This fluid is produced by the ciliary body (2 |iL/min) and provides nutrients and oxygen to the avascular cornea. The outflow of aqueous humour is through the trabecular meshwork and canal of Schlemm adjacent to the limbus. Any factor which impedes its outflow will increase the intraocular pressure. The upper range of normal for intraocular pressure is 21 mmHg.

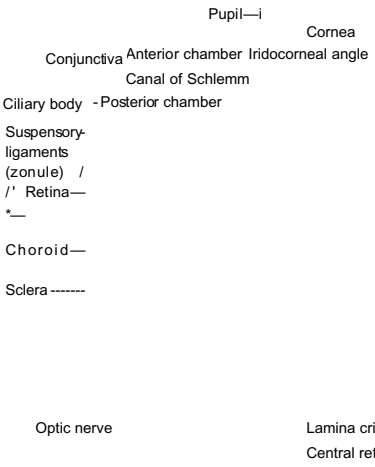

Fig. 20.12 Section of the eyeball.

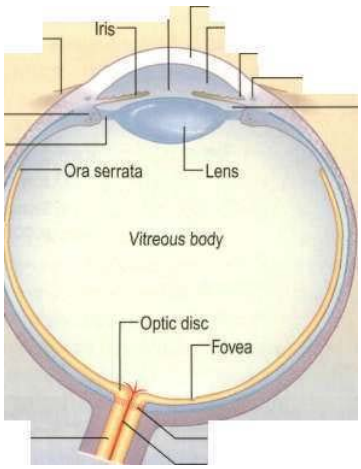

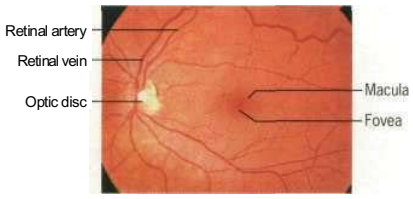

Fig. 20.13 **Fundus of the left eye.**

The *iris* is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. Immediately posterior to the pupil and anterior to the vitreous humour lies the lens of the eye. This is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape it can alter its refractive power and help to focus objects at different distances from the eye. In the fourth decade of life this ability to change shape starts to decline (presbyopia) and the need for reading glasses becomes inevitable. With age the lens starts to become less transparent and cataracts begin to develop.

The inner aspect of the *sclera* is lined by a highly vascular tissue, the choroid, and then the retina. The vitreous humour fills the cavity between the retina and the lens. The retina is the transparent light-sensitive layer, or photographic plate, of the eye. The macula is the area of the retina responsible for detailed fine vision and has the highest density of rods and cones. The axons of the ganglion cells form the optic nerve of the eye (Fig. 20.13).

The *blood supply* to the eye is via the ophthalmic artery and, in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the pre-auricular and submental nodes.

The sensory *innervation* of the eye (see p. 1185) is through the trigeminal (V) nerve. Of the six extraocular muscles the abducens (VI) nerve supplies the lateral rectus, the trochlear (IV) nerve supplies the superior oblique, whilst the rest are supplied by the oculomotor (III) nerve. The III nerve also supplies the upper lid and indirectly the pupil (parasympathetic fibres are attached to it). The facial (VI) nerve supplies the obicularis and other muscles of facial expression.

REFRACTIVE ERRORS

The eye projects a sharp and focused image onto the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic and hypermetropic eyes is shown in Figure 20.14a, b and c.

Astigmatism occurs when the eye is not of the same radius of curvature for refraction. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation the front surface of the eye is more rugby ball shaped than football shaped.

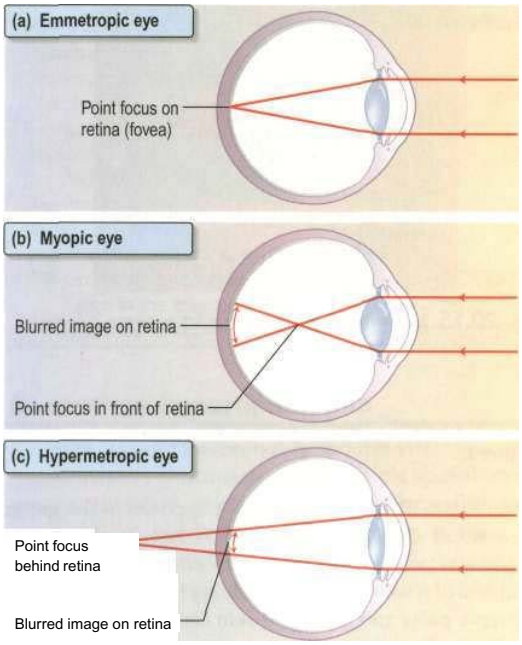

Fig. 20.14 **Refraction, (a)** Emmetropic (normal), (b) Myopic (short-sighted), (c) Hypermotropic (long-sighted).

Presbyopia is the term used to describe the normal ageing of the lens and leads to a change in the refractive state of the eye. As the lens ages it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.

Treatment

Errors of refraction can be corrected by using spectacles or contact lenses. The latter result in better quality, but carry the risk of infection. They may be the only option in some refractive states such as keratoconus. There are a number of surgical techniques available with varying degree of accuracy. Currently the most popular method is to use an excimer laser to re-profile the corneal curvature (PRK, LASIK, LASEK). Here the laser either removes corneal tissue centrally to flatten the cornea in myopia or it removes tissue from the peripheral cornea to steepen it in hypermetropia.

DISORDERS OF THE LIDS

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the punctae and lacrimal system. Malposition of the lids, factors which affect blinking or lacrimal drainage can all cause problems.

Entropion. The lid margin rolls inwards so that the lashes are against the globe (Fig. 20.15). The lashes act as a foreign body and cause irritation, leading to a red eye which can mimic conjunctivitis. Occasionally the constant rubbing of lashes against the cornea causes an abrasion.

Fig. 20.15 Lid entropion. The lower lid appears inverted.

The commonest cause is ageing and surgery is usually required.

Ectropion. The lid margin is not apposed to the globe. As a result the lacrimal puncta is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VII nerve palsy and cicatricial skin conditions. Surgery is usually required.

Dacryocystitis. This is inflammation of the lacrimal sac. Patients usually present with a painful lump at the side of the nose adjacent to the lower lid (Fig. 20.16). This should be treated with oral broad-spectrum antibiotics such as cef alexin, and patients should be watched carefully for signs of cellulites. These patients should be referred to the ophthalmologist as some may have an underlying mucocele or dilated sac, and will require surgery.

Blepharitis. This is inflammation of the lid margins. Inflammation may involve the lashes and lash follicles (Fig. 20.17) resulting in styes, or inflammation and blockage of meibomian glands (Fig. 20.18) leading to chalazia (Fig. 20.19). Treatment involves lid toilet and topical antibiotics such as chloramphenicol or fucidic acid. If there is associated cellulites then broad-spectrum oral antibiotics are required. Some patients are left with a lump once the acute inflammatory phase of the chalazion has subsided. Most of these patients find the lump cosmetically unacceptable and require incision and curettage.

Fig. 20.16 Acute dacryocystitis showing a lump on the side of the nose.

Fig. 20.17 Blepharitis. Crusty and scaly deposits on the lashes and lash bases.

Fig. 20.18 Blepharitis. Upper lid showing meibomian glands plugged with oily secretions.

Fig. 20.19 Blepharitis. Blockage of the meibomian glands leads to swelling of the lid (chalazion).

CONJUNCTIVITIS

This is the commonest cause of a red eye. Inflammation of the conjunctiva leading to a red eye can arise from a number of causes, with viral, bacterial and allergic being the commonest. Common features in all types of conjunctivitis include soreness, redness and discharge, and in general the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy and if there has been a recent history of a cold or sore throat. In the neonate it is vital to ensure there has been no associated maternal sexually transmitted disease. The differential diagnosis of conjunctivitis is shown in Table 20.6.

Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients

Table 20.6 Conjunctivitis

	Discharge	Preauricular node	Corneal involvement	Comment
Bacterial	Mucopurulent	-ve except gonococci	+ve Gonococcus	Rapid onset
Viral	Watery	+ve	+ve Adenovirus	Cold and/or sore throat
Chlamydial	Watery	+ve	+ve +ve	GU discharge
Allergic	Stringy	-ve		Itchy

it causes a sore or gritty eye in the presence of good vision. Bacterial conjunctivitis is invariably bilateral and should be suspected when conjunctival inflammation is associated with a purulent discharge. The rapidity of onset together with the severity of discharge is helpful in determining the underlying organism.

Clinical features

Gonococcal conjunctivitis should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. Gonococci are a cause of conjunctivitis giving rise to a pre-auricular node.

Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as *Haemophilus influenzae* and *Strep, pneumoniae.* Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include *Staphylococcus aureus* and *Moraxella lacunata.*

Treatment

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram stain of the conjunctival swab can quickly confirm the presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK. Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic such as chloramphenicol. Swabs should be taken if these cases do not respond to this initial treatment.

Chlamydial conjunctivitis

This is a sexually transmitted disease and is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved. It is caused by *Chlamydia trachomatis* (p. 121). Neonatal chlamydial conjunctivitis is a notifiable disease in the UK and should be suspected in newborns with a red eye. Mothers should be asked about sexually transmitted diseases. Trachoma caused by the same organism is found mainly in the tropics and the Middle East and is a very common cause of blindness in the world (p. 84).

Clinical features ;

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases the red eye is associated with a scanty mucopurulent discharge and a palpable preauricular lymph node. In chronic cases it is not unusual to see superior corneal vascularization. In neonates the onset of the red eye is typically around 2 weeks after birth, whereas gonococcal conjunctivitis occurs within days of birth. Conjunctival swabs should be taken prior to commencement of treatment.

Treatment

Topical erythromycin twice daily is commenced and patients referred to the genitourinary physicians. Neonates should be started on topical erythromycin and referred to the paediatrician as there may be associated otitis media or pneumonitis.

Viral conjunctivitis

Adenoviral conjunctivitis

This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or flu-like symptoms. The eye becomes inflamed and this is commonly associated with chemosis, lid oedema and a palpable preauricular lymph node. Some patients may develop a membrane on the tarsal conjunctiva (Fig. 20.20a, b) and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of the patients the conjunctivitis is unilateral.

Treatment

The condition is largely self-limiting in the majority of cases. Lubricants together with a cold compress can be soothing for patients. Strict hygiene and keeping towels separate from the rest of the household goes a long way in reducing the spread of the infection. Clinicians also need to ensure good hygiene practice to reduce cross-infection and infecting themselves. In patients with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

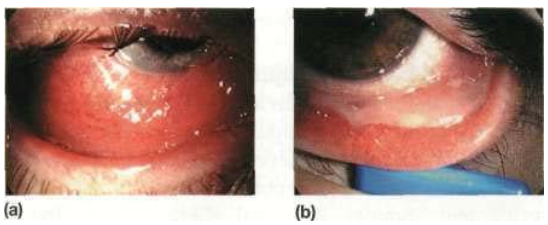

Fig. 20.20 **(a and b) Viral conjunctivitis; (b) with pseudomembrane on lower lid.**

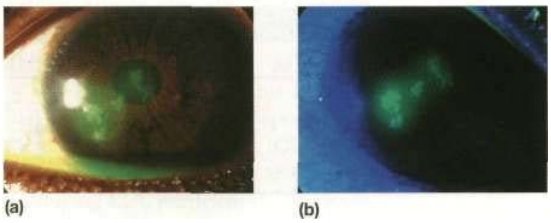

Fig. 20.21 Dendritic ulcers on the cornea, (a) Stained with fluorescein. (b) Stained with fluorescein and viewed with blue light.

Herpes simplex conjunctivitis

Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable preauricular lymph node and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority of patients. Over 50% of these patients may develop a dendritic corneal ulcer (Fig. 20.21a, b). The organism responsible for this condition is the herpes simplex virus (HSV), which is usually HSV-1 but HSV-2 can give rise to ocular infection.

Treatment

Primary ocular HSV infection is a self-limiting condition but most clinicians choose to treat it with topical aciclovir in order to limit the risk of corneal epithelial involvement.

Molluscum contagiosum conjunctivitis

This is typically unilateral and produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. A closer look at the eyelids and the margin will reveal pearly umbilicated nodules and these are filled with the DNA poxvirus. A high index of suspicion is needed to make an early diagnosis.

Treatment

This includes curetting the central portion of the lesion, freezing the centre or completely excising the lesion. If the corneal involvement is severe or the eye is very inflamed, a short course of topical steroids such as prednisolone 0.5% or dexamethasone 0.1% is helpful.

Allergic conjunctivitis

There are five main types of allergic conjunctivitis: seasonal, perennial, vernal, atopic and giant papillary. The last three are difficult to treat, chronic and can be sight-threatening. They should be referred to an ophthalmologist.

Seasonal/perennial conjunctivitis

Seasonal allergic conjunctivitis and perennial conjunctivitis affect 20% of the general population in the UK. Seasonal allergic conjunctivitis involves an allergic reaction to grass, pollen and fungal spores and occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn and includes allergens such as house-dust mites.

The main symptoms include itching, redness, soreness, watering and a stringy discharge. Occasionally the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

Treatment

Reducing the allergen load (reducing dust, p. 897) is helpful. Medical treatment includes the use of antihistamine drops such as levocabastine and emedastine together with topical mast cell-stabilizing agents such as sodium cromoglicate and nedocromil. Corticosteroid drops should be avoided. Oral antihistamines help the itching.

CORNEAL DISORDERS

Trauma

Corneal abrasions

Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur when the eye is accidentally poked with a finger, a foreign body (FB) flies into the eye or something brushes against the eye.

Clinical features

Symptoms include severe pain, due to exposure of the corneal nerve endings, lacrimation and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or amethocaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light the abrasion lights up as green. Occasionally FBs can lodge on the under surface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (Fig. 20.22a, b).

Treatment

This involves instillation of a broad-spectrum antibiotic such as chloramphenicol drops or ointment four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

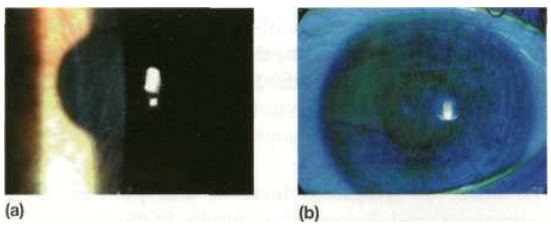

Fig. 20.22 Linear corneal abrasion, (a) Stained with fluorescein. (b) Stained with fluorescein and viewed with blue light.

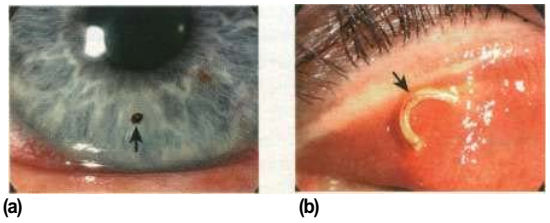

Fig. 20.23 **Foreign bodies, (a)** Corneal. (b) Subtarsal.

Corneal foreign body

Occasionally when something flies into the eye it gets stuck on the cornea (Fig. 20.23a). It may be associated with lacrimation and photophobia. Examination is best attempted following instillation of a topical anaesthetic and should include everting the upper lid (Fig. 20.23b). Corneal foreign bodies can usually be seen directly with a white light.

Treatment

The corneal FB should be removed and the patient given a topical antibiotic such as chloramphenicol four times a day for 5 days or fucidic acid twice a day for 5 days.

Trauma

In cases of high-velocity trauma corneal perforation or intraocular FB should be suspected. Examination may show a corneal laceration with or without the FB embedded in the cornea. The FB may be present on the iris or the lens. Other clues of a penetrating injury include a flat anterior chamber or the presence of blood in the anterior chamber (hyphaema) or a large subconjunctival haemorrhage. Urgent referral to the ophthalmologist is mandatory, ensuring that no drops are instilled into the eye and that a plastic shield has been placed over the eye to minimize further risk of trauma.

Blunt trauma usually results in periorbital bruising and gross lid oedema, which can make examination to exclude perforating injury difficult. These patients should be referred to the ophthalmologist for a detailed ocular examination to exclude a perforation retinal detachment or a traumatic hyphaema (Fig. 20.24).

Keratitis

This is a general term to describe corneal inflammation. Common causes include herpes simplex virus, contact lens-associated infection and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia and lacrimation. Vision is reduced if the ulcer is in the visual

Fig. 20.24 **Blunt trauma.** Hyphaema and globe rupture with iris prolapse.

Herpes simplex keratitis

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer which is typically dendritic in shape (see Fig. 20.21). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, e.g. steroid drops, or systemic immunosuppression, e.g. AIDS, can lead to the centrifugal spread of the virus such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the V nerve.

Treatment

Aciclovir ointment five times a day for 2 weeks is usually very effective.

Contact lens-related keratitis

A small number of contact lens wearers develop infective corneal ulcers which are potentially sight-threatening (Fig. 20.25a, b). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

Blepharitis

This is an extremely common condition where the lid margins are inflamed. Common underlying causes of blepharitis include meibomian gland dysfunction, seborrhoea and *Staphylococcus aureus.* Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. *Staphylococcus aureus* is frequently responsible for chronic blepharo-conjunctivitis and some patients may develop keratitis (Fig. 20.26).

Treatment

Lid hygiene is the mainstay of treatment as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol is useful in

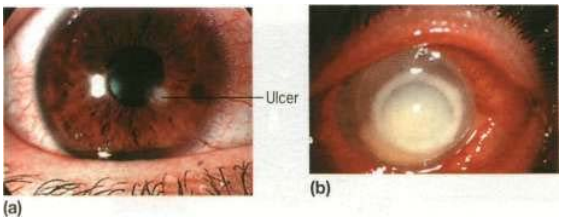

Fig. 20.25 **Contact lens-related keratitis. (a)** Corneal ulcer, (b) Severe keratitis with a corneal abscess and a hypopyon.

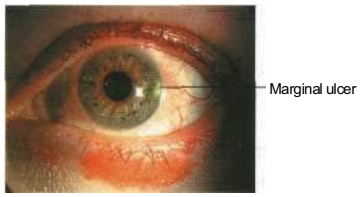

Fig. 20.26 Marginal keratitis.

chronic cases but in severe cases or cases where acne rosacea is suspected, oral doxycycline may be required. Patients with keratitis should be referred to the ophthalmologist as they will require topical steroids.

CATARACTS

Cataract (Fig. 20.27a, b) is by far the commonest cause of preventable blindness in the world with an effective surgical treatment. In the UK approximately 250 000 cataract operations are performed each year, making it the commonest surgical procedure.

Aetiology

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Table 20.7. In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted. Cataracts diagnosed in infants demand urgent referral to the ophthalmologist in order to minimize the subsequent development of amblyopia.

Clinical features

Gradual painless deterioration of vision is the commonest symptom. Other symptoms are dependent upon the type of cataract, for example a posterior capsular type would lead to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

***Table 20.7* Cataracts: aetiology**

Congenital	Maternal infection Familial
Age	Elderly
Metabolic	Diabetes, galactosaemia, hypocalcaemia, Wilson's disease
Drug-induced	Corticosteroids, phenothiazines, miotics, amiodarone
Traumatic	Post-intraocular surgery
Inflammatory	Uveitis
Disease associated	Down's syndrome (p. 175) Dystrophia mytonica (p. 1270) Lowe's syndrome (p. 1146)

Investigations

Blood glucose, serum calcium and liver biochemistry should be measured to diagnose metabolic disorders.

Treatment

Cataract extraction with the insertion of an intraocular lens is treatment of choice (Fig. 20.27c). The aetiology and density of the cataracts usually determines the technique employed. Currently, small incision surgery called phaco-emulsification is the most popular technique used for routine cases.

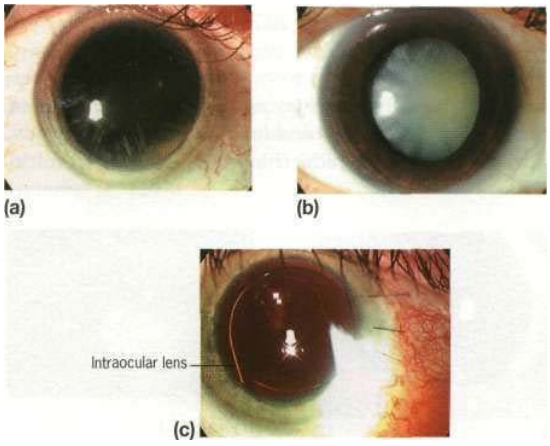

***Fig. 20.27* Cataracts, (a)** Early cataract, (b) White mature cataract, (c) Artificial intraocular lens following phacoemulsification.

GLAUCOMA

This refers to a group of diseases where the pressure inside the eye is sufficiently elevated to cause optic nerve damage and result in visual field defects (Fig. 20.28a, b). Normal intraocular pressure (IOP) is between 10 and 21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma as a disease entity is the second commonest cause of blindness word-wide and the third commonest cause of blind registration in the UK.

Primary open-angle glaucoma (POAG)

This is the commonest form of glaucoma. High intra-ocular pressures result from reduced outflow of aqueous

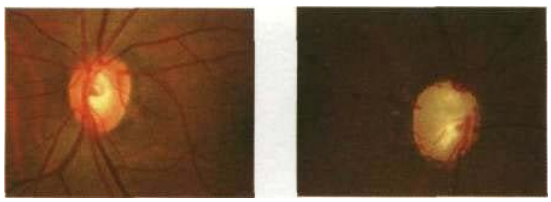

***Fig. 20.28* (a) Normal optic disc and (b) glaucomatous optic disc.** The central cup is enlarged and deepened.

Table 20.8 **Differential diagnosis of the acute red eye**

Cause	Conjuncti injection	Unilateral or bilateral	Pain	Photophobia	Vision	Pupil	Intraocular pressure
Conjunctivitis	Diffuse	Bilateral	Gritty	Occasionally with adenovirus	Normal	Normal	Normal
Anterior uveitis	Circum-corneal	Unilateral	Painful	Yes	Reduced	Constricted	Normal or raised
Acute glaucoma	Diffuse	Unilateral	Severe pain	Mild	Reduced	Mid-dilated	Raised

humour through the trabecular meshwork. The cause of this increased resistance to aqueous outflow at the level of the meshwork is not fully understood. Common risk factors include age (0.02% of 40-year-olds vs 10% of 80-year-olds), race (black Africans are at five times greater risk than whites), positive family history and myopia.

POAG causes a gradual, insidious, painless loss of peripheral visual field. The central vision remains good until the end-stage of the disease. Diagnosis is only made if the IOP is measured. The optic disc is inspected and shows an enlarged cup with a thin neuroretinal rim. Visual fields are performed and show a normal blind spot with scotomas. Most patients are identified as having glaucoma whilst undergoing a routine ophthalmic examination.

Treatment

Treatment aims to reduce the IOP and this is achieved either by reducing aqueous production or increasing aqueous drainage. Beta-blockers such as timolol, carteolol, levobunolol, reduce aqueous production and are the commonest prescribed topical agents. These drugs are contraindicated in patients with COPD, asthma or heart block. Prostaglandin analogues such as latanoprost, travoprost, increase aqueous outflow and are fast becoming the treatment of choice for POAG as they can reduce IOP by 30%. Carbonic anhydrase inhibitors such as acetazolamide reduce aqueous production and are available in both topical and oral form. In its oral form acetazolamide is the most potent drug for reducing ocular pressure. It should not be used in patients with sulphonamide allergy.

Acute angle-closure glaucoma (AACG)

This is an ophthalmic emergency. In this type of glaucoma there is a sudden rise in intraocular pressure to levels greater than 50mmHg. This occurs due to reduced aqueous drainage as a result of the ageing lens pushing the iris forward against the trabecular meshwork. People most at risk of developing AACG are those with shallow anterior chambers such as hypermetropes and women. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

AACG causes sudden onset of a red painful eye and blurred vision. Patients become unwell with nausea and vomiting and complain of headache and severe ocular pain. The eye is injected, tender and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 20.29).

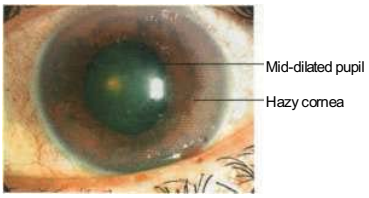

Fig. 20.29 **Acute angle-closure glaucoma.**

Table 20.8 shows the differential diagnosis of the acute red eye.

Prompt treatment is required to preserve sight and includes i.v. acetazolamide 500 mg (provided there are no contraindications) to reduce IOP, and instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork. Other topical drops such as beta-blockers and prostaglandin analogues can also be instilled if available, provided there are no contra-indications. Analgesia and antiemetics are given as required.

These patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents such as oral glycerol or i.v. mannitol can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or surgically.

UVEITIS

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body and choroid. Inflammation confined to the anterior segment of the eye (in front of the iris) is referred to as iritis or anterior uveitis, that involving the ciliary body is referred to as intermediate uveitis whilst inflammation of the choroid is termed posterior uveitis. If all three regions are involved then the term pan-uveitis is used.

The most common symptoms of uveitis are blurred vision, pain, redness, photophobia and floaters. Each symptom is determined by the location of the inflammation such that photophobia and pain are common features of iritis whilst floaters are commonly seen with posterior uveitis.

Uveitis is commonly encountered with ankylosing spondylitis and positive HLA-B27 (p. 565), arthritis, inflammatory bowel disease, sarcoid, tuberculosis, syphilis,

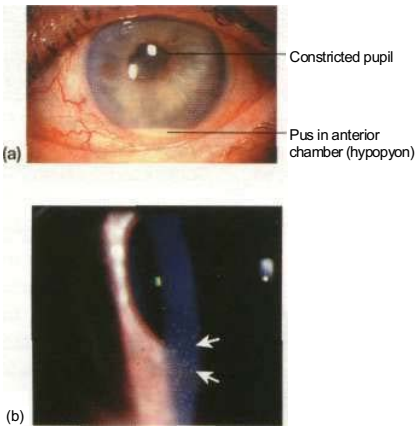

Fig. 20.30 Anterior uveitis. (a) Acute with hypopyon. (b) Showing keratic precipitates on the corneal endothelial.

toxoplasmosis, Behget's syndrome, lymphoma and viruses such as herpes, cytomegalovirus and HIV. In a number of patients no cause is found (idiopathic uveitis).

Anterior uveitis (iritis)

The classic presentation entails a triad of eye symptoms: redness, pain and photophobia. Vision can be normal or blurred depending on the degree of inflammation. The eye can be generally red or the injection can be localized to the limbus. The anterior chamber shows features consistent with inflammation including cells with keratic precipitates (KP) on the corneal endothelium, fibrin or hypopyon (pus), and the pupil may have adhered to the lens (posterior synechiae) (Fig. 20.30a, b). The IOP may be normal or raised either due to cells clogging up the trabecular meshwork or posterior synechiae causing aqueous to build up behind the iris and force the iris against the trabecular meshwork and so reduce aqueous drainage.

Treatment

This consists of reducing inflammation with the use of topical steroids such as dexamethasone 0.1% and dilating the pupil with cyclopentolate 1 % to prevent formation of anterior synechiae. Dilatation also allows fundoscopy to exclude posterior segment involvement. If the IOP is raised, this is treated with either topical beta-blockers, prostaglandin analogues, or oral or i.v, acetazolamide. These patients should be referred to the ophthalmologist.

DISORDERS OF THE RETINA

Central retinal vein occlusion (CRVO)

This usually leads to profound sudden painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots, abnormal leakage of fluid from vessels resulting in retinal oedema (Fig. 20.31). In severe cases an afferent papillary defect is usually present (p. 1182).

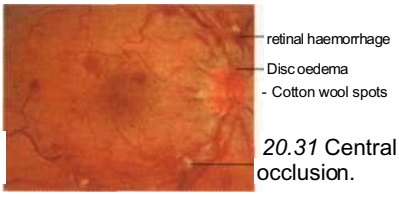

Fig. 20.31 Central retinal vein occlusion.

Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma, blood dyscrasias and vasculitis.

Treatment

Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Patients who develop iris neovascularization, rubeosis, are at risk of developing rubeotic glaucoma.

Central retinal artery occlusion (CRAO)

This results in sudden painless severe loss of vision. Retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry red spot is seen at the fovea because the choroid shows up through the thinnest part of the retina (Fig. 20.32). An afferent papillary defect is usually present (p. 1182).

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from atheromas and diseased heart valves are other causes. Giant cell arteritis (p. 1249) must be excluded.

Treatment

CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs after 90 minutes of onset. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may help in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide which acts as a vasodilator and so helps in dislodging the emboli. Other options include making a corneal paracentesis to drain off some aqueous humour, thereby reducing the intraocular pressure.

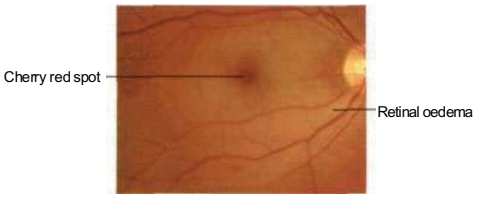

Fig. 20.32 Central retinal artery occlusion.

Fig. 20.33 **Retinal tear leading to detachment.**

Patients with CRAO should have a thorough medical evaluation to determine the aetiology of the emboli or thrombus. Some patients may present with transient loss of vision or amaurosis fugax (p. 1212). All patients with CRAO and amaurosis fugax should be started on oral aspirin if it is not medically contraindicated.

Retinal detachment

This causes a painless progressive visual field loss. The shadow corresponds to the area of detached retina. Following a tear in the retina, fluid collects in the potential space between the sensory retina and the pigment epithelium (Fig. 20.33). Patients usually report a sudden onset of floaters often associated with flashes of light prior to the detachment. These patients should be referred to an ophthalmologist for a detailed fundal examination.

Age-related macular degeneration (AMD)

This is the commonest cause of visual impairment in patients over 50 years in the western world. It is the commonest cause of blind registration in this age group. With age, the macula undergoes degenerative changes which can result in deposition of material (drusen) over the macula or involutional changes at the macula (Fig. 20.34a). Mutations in the fibulin genes (particularly 5) are being described. Not all patients with these changes will be affected visually but a number go on to develop distortion and blurring of their central vision. Some patients develop frank choroidal neovascularization at the macula leading to profound loss of central vision but continuation of good peripheral vision (Fig. 20.34b).

Patients with central distortion or with frank macular pathology should be referred to the ophthalmologist for assessment of treatment. Only a few patients will fulfil the clinical requirement to receive laser treatment or photodynamic therapy (PDT). All patients should be assessed for low-vision aids such as magnifying glasses as this may help to improve their independence. Recently, pegaptanib, an anti-vascular endothelial growth factor (anti-VEGF) has been given by intra-vitreous injection with some benefit and trials continue.

CAUSES OF VISUAL LOSS

Box 20.3 summarizes the causes of visual loss. In developing countries the common causes of blindness are similar to those in the developed world and include trauma, cataract, diabetic retinopathy, glaucoma and macular degeneration. In addition, trachoma due to *Chlamydia trachomatis* (see p. 84) accounts for 10% of global blindness and onchocerciasis (river blindness) due to *Onchocerca volvulus* (p. 108) accounts for blindness in about 1 million people, although this is decreasing with treatment. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5-10% of these. Ocular involvement is common in cerebral malaria (p. 97), although loss of vision is rare. HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye when the CD4 count falls (p. 139).

Vitamin A deficiency and xerophthalmia affects millions each year, and the WHO classification of xerophthalmia by ocular signs is shown in Table 5.10 (p. 242).

Sox *20.3* Loss of vison: summary

Painless loss of vision	Painful loss of vision
Cataract	Acute angle-closure glaucoma
Open-angle glaucoma	Giant cell arteritis (p. 1249)
Retinal detachment	Optic neuritis (p. 1181)

Neurological disease 21

EPIDEMIOLOGY

Clinical neurology is diverse and complex and the epidemiology of these conditions is discussed in individual sections. There s worldwide variation. Conditions seen in UK are summarized in Table 21.1.

Table 21.1 Incidence rates for commoner neurological conditions/100 000/year in the UK

Headaches (GP consultations)	2200
Cerebrovascular events	205
Shingles (herpes zoster)	140
Diabetic neuropathy	54
Compressive neuropathies	**49**
Epilepsy	**46**
Parkinson's disease	**19**
Post-herpetic neuralgia	11
All CNS tumours	9
Trigeminal neuralgia	8
Meningitis	7
Multiple sclerosis	7
Severe brain injury	7
Subarachnoid haemorrhage	6
Subdural haematoma	6
Presenile dementia (below 65 years)	4
Cerebral palsy	3
Guillain-Barre syndrome	3
Myasthenia gravis	3
Transient global amnesia	**3**
Motor neurone disease	**2**

HISTORY, SYMPTOMS AND SIGNS

Methods of recording history and basic examination are outside the scope of this chapter. Notes should read chronologically to portray the *story* from the patient or relative. Pattern recognition - interpretation of history, symptoms and examination - is very reliable. Practical experience is vital. There are three critical questions:

- What is/are the site(s) of the lesion(s)?
- What is the likely pathology?
- Does a recognizable disease fit this pattern?

This is the essence of clinical diagnosis. In the text that follows, several common problems are related to core neuroanatomy.

Headaches

Headache is an almost universal experience, and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease.

Mechanism

Pain receptors are located at the base of the brain in arteries and veins and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes and teeth. Curiously, brain substance is almost devoid of pain receptors.

Head pain is mediated by mechanical (e.g. stretching of meninges) and chemical receptors (e.g. 5-hydroxytryptamine and histamine stimulation). Nerve impulses travel centrally via fifth and ninth cranial nerves and via upper cervical sensory roots.

Most headaches are benign, but the diagnostic issue — and usual concern - is the question of serious disease. Here are some useful clinical pointers.

Chronic (benign) and recurrent headaches

Almost all recurring headaches lasting hours/days - band-like, generalized head pains, with a history for several years or months - are vaguely ascribed to muscle tension, and/or migraine (see p. 1247). Depression is a common accompaniment.

In localized pain of short duration (minutes to hours), sinusitis, glaucoma and migrainous neuralgia (p. 1248) should be considered. Malignant hypertension, with arterial damage and brain swelling, occasionally causes headache (see p. 859). Headaches are not caused by high blood pressure alone.

Eyestrain from refractive error does not cause headache, though new prescription lenses sometimes provoke pain.

Pressure headaches

Intracranial mass lesions displace and stretch meninges and basal vessels. Pain is provoked when these structures are shifted either by a mass or by changes in cerebrospinal fluid (CSF) pressure, e.g. coughing. Cerebral oedema around brain tumours causes further shift. These 'pressure headaches' typically become worse on lying down.

Any headache present on waking and made worse by coughing, straining or sneezing may be due to a mass lesion. Vomiting often accompanies pressure headaches. Such headaches are caused early, over days or weeks by posterior fossa masses (see hydrocephalus, p. 1247), but over a longer time scale - months or years - by hemisphere tumours.

A rare cause of prostrating headache with lower limb weakness is an intraventricular tumour causing intermittent hydrocephalus.

Headache of subacute onset

The onset and progression of a headache over days or weeks with or without features of a pressure headache should always raise suspicion of an intracranial mass or serious intracranial disease. Encephalitis (see p. 1239), viral meningitis (p. 1237) and chronic meningitis (p. 1238) should also be considered.

Headaches with scalp tenderness

Patches of exquisite tenderness overlying superficial scalp arteries are caused by giant cell arteritis (see p. 1249), almost exclusively in patients over 50.

Headache following head injury

Subdural haematoma (see p. 1218) must be considered - the majority of post-trauma headaches lasting days, weeks or months are not caused by any serious intracranial pathology.

A single episode of severe headache

This common emergency is caused by one of the following:

- subarachnoid haemorrhage
- migraine, or other benign headaches
- meningitis (occasionally).

Particular attention should be paid to suddenness of onset (suggestive of subarachnoid haemorrhage), neck stiffness and vomiting (meningeal irritation), and to the presence of a rash and/or fever (bacterial meningitis).

Difficulty walking and falls

Change in gait is a common presenting complaint in neurology (see Table 21.2). Arthritis and muscle pain also alter gait, making walking stiff and slow (antalgia). Falls, especially in the elderly, are a common cause of morbidity. The *pattern* of abnormal gait is valuable diagnostically.

Spasticity

Spasticity (see p. 1192), more pronounced in extensor muscles, with or without weakness, causes walking to be stiff and jerky. Toes of shoes become scuffed, catching level ground. Pace shortens but a narrow base is maintained. Clonus - involuntary extensor rhythmic jerking of the legs - may be noticed.

When the problem is predominantly unilateral and weakness is marked (in a hemiparesis), the stiff, weak leg drags and is circumducted.

Table 21.2 **Common neurological patterns of difficulty walking**

Spasticity/hemiparesis
Parkinson's disease
Cerebellar ataxia
Sensory loss (joint position/loss)
Distal weakness
Proximal weakness
Apraxia of gait

Parkinson's disease (see p. 1227)
There is muscular rigidity throughout extensors and flexors. Power is preserved but walking slows. The pace shortens to a shuffle; its base remains narrow. Falls occur. A stoop and diminished arm swinging become apparent. Gait becomes festinant (hurried) in small rapid steps. There is particular difficulty initiating movement and turning quickly. *Retropulsion* describes small backward steps, taken involuntarily when a patient is halted.

Cerebellar ataxia (see also p. 1195)
In disease of the lateral cerebellar lobes stance becomes broad-based, unstable and tremulous. Ataxia describes this imperfect control. Walking tends to veer towards the more affected cerebellar lobe.

In disease confined to cerebellar midline structures (the vermis) the trunk becomes unsteady without limb ataxia. There is a tendency to fall backwards or sideways - truncal ataxia.

Sensory ataxia
Peripheral sensory lesions (e.g. polyneuropathy, p. 1260) cause ataxia because there is loss of the sense of joint position - *proprioception*. Broad-based, high-stepping, stamping gait develops. This ataxia is made worse by removal of additional sensory input (e.g. vision) and is worse in the dark. First described in sensory ataxia of tabes dorsalis (p. 1240), this is the basis of Romberg's test. Ask the patient to close the eyes while standing: observe whether the patient becomes unstable (and prevent falling).

Lower limb weakness
When weakness is distal, each leg must be lifted over obstacles. When ankle dorsiflexors are weak, such as in a common peroneal nerve palsy (see p. 1260), each foot, returns to the ground with a visible and audible *slap*.

Weakness of proximal lower limb muscles (e.g. in polymyositis or muscular dystrophy) leads to difficulty in rising from sitting or squatting. Once upright, the patient walks with a waddling gait, the pelvis being ill-supported by each lower limb as it carries the full weight of the body.

Gait apraxia
With frontal lobe disease (e.g. tumour, hydrocephalus, infarction), the acquired skill of walking becomes disorganized. Leg movement is normal when sitting or lying but initiation and organization of walking fail. This is gait *apraxia* - a failure of the skilled act of walking. Shuffling small steps *(marche a petits pas),* difficulty initiating walking (gait ignition failure) or undue hesitancy may predominate. Urinary incontinence and dementia are often present with frontal lobe disease.

Falls
Falls, especially in the elderly, are a major cause of morbidity and hospital admission, e.g. following hip or upper limb fracture. Often no precise cause can be found. A multidisciplinary approach is essential, e.g. reviewing risk factors such as rugs, stairs, footwear and needs for additional home aids.

Dizziness, vertigo, blackouts, collapse and fatigue

Dizziness covers many complaints, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness felt in panic and anxiety, during palpitations, and in syncope or chronic ill-health. The real nature of this symptom must be determined.

Vertigo - an illusion of movement - is more definite. It is a sensation of rotation, or tipping. The patient feels that the surroundings are spinning or moving. It is distinctly unpleasant and often accompanied by nausea or vomiting. For causes of vertigo, see page 1188.

Blackout, like dizziness, is a descriptive term implying either altered consciousness, visual disturbance or falling. Epilepsy, syncope, hypoglycaemia, anaemia must be considered. However, commonly no sinister cause is found. A careful history, from an eye-witness, is essential.

Collapse is vague but often used. It is not a diagnosis. Avoid it in medical notes.

Fatigue is another common symptom of neurological disorders.

NEUROLOGICAL EXAMINATION

A short five-part examination is shown in Practical box 21.1, and a fuller examination in Practical box 21.2.

Formulation
Relevant findings are drawn together in a brief written diagnostic summary. This will form the basis for investigations, transfer of information, and management.

FUNCTIONAL NEUROANATOMY: AN INTRODUCTION

The neurone and synapse (Fig. 21.1)

The neurone is the functional unit of the nervous system. Its cell body and axon terminate in a synapse. The specificity, size and type of each group of neurones vary. A single a-motor neurone within an anterior horn of the

5 Assess sensation
Ask the patient

thoracic spinal cord has an axonal length over 1 metre and innervates between several hundred and 2000 muscle fibres in one leg - a motor unit. By contrast, some spinal or intracerebral internuncial neurones have axons under 100 μm long, terminating solely on one neuronal cell body.

Neurotransmitters

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters then react with postsynaptic receptors and are removed by transporter proteins. The neurotransmitter-receptor reaction increases ionic permeability and propagates a further action potential. This combination of axonal electrical activity and synaptic chemical release is the basis of all neurological function.

Neurotransmitters include acetylcholine, norepinephrine (noradrenaline), epinephrine (adrenaline), 5-hydroxytryptamine (5-HT), gamma-aminobutyric acid (GABA), opioid peptides, prostaglandins, histamine, dopamine, glutamate, nitric oxide, neuromelanin and vasoactive intestinal peptide (VIP). Of these, glutamate is the principal excitatory neurotransmitter.

The role of neurotransmitters and transporters in pathogenesis continues to be evaluated, but it is thought that a wide variety of acute and chronic neurological disease is mediated by a final common pathway of neuronal injury involving excessive stimulation of glutamate receptors.

Table 21.3 **Six grades of muscle power**

Grade	Definition
5	Normal power
4	Active movement against gravity and resistance
3	Active movement against gravity
2	Active movement with gravity eliminated
1	Flicker of contraction
0	No contraction

Practical Box 21.2
Ten-part neurological examination

2 Mental state, attitude, insight (see Box 22.5, p. 1277)

3 Cognitive function
Orientation in time and place, recall of recent and distant events (memory, level of intellect, language and speech/cerebral dominance, other disorders of skilled function, e.g. apraxia)

4 Gait and Romberg's test

5 Skull shape - circumference, bruits

6 Neck - stiffness, palpation and auscultation of carotid arteries

7 Cranial nerves (see Table 21.5)

8 Motor system
Upper limbs:
Wasting and fasciculation Posture of arms: drift, rebound, tremor Tone: spasticity or extrapyramidal rigidity Power: 0-5 scale (Table 21.3) Tendon reflexes: + or ++ normal; +++ increased: 0 absent with reinforcement

Thorax and abdomen:
Respiration
Thoracic and abdominal muscles
Abdominal reflexes Cremasteric reflexes

Lower limbs:
Wasting and fasciculation Tone, power and tendon reflexes Plantar responses

9 Coordination and fine movements

10 Sensory system
First, ask whether feeling in the limbs, face and trunk is entirely normal

Posterior columns:
Vibration (using a 128 Hz tuning fork)
Joint position Light touch
2-point discrimination (normal: 0.5 cm finger tips, 2 cm soles)

Spinothalamic tracts:
Pain: use a split orange-stick or a sterile pin
Temperature: hot or cold tubes

If sensation is abnormal, chart areas involved

Effects	Site of lesion
Frontal	Partial seizures - focal motor seizures of contralateral limbs Conjugate deviation of head and eyes away from the lesion
Temporal	Formed visual hallucinations Complex partial seizures Memory disturbances (e.g. *deja vu)*
Parietal	Partial seizures - focal sensory seizures of contralateral limbs
Parieto-occipital	Crude visual hallucinations (e.g. shapes in one part of the field)
Occipital	Visual disturbances (e.g. flashes)

Fig. 21.3 Effects of irritative cortical lesions.

Destructive lesions within the left fronto-temporo-parietal region cause various disorders of human communication:

- spoken language - *aphasia,* also called *dysphasia*
- writing - *agraphia*
- reading - *acquired alexia.*

Developmental dyslexia describes delayed and disorganized reading and writing ability in children with normal intelligence.

Aphasia

Aphasia is loss of or defective language from damage to the speech centres within the left hemisphere. Numerous varieties have been described.

Broca's aphasia (expressive aphasia, anterior aphasia)

Damage in the left frontal lobe causes reduced speech fluency with comprehension relatively preserved. The patient makes great efforts to initiate language, which becomes reduced to a few disjointed words. There is failure to construct sentences. Patients who recover from this form of aphasia say they knew what they wanted to say, but 'could not get the words out'.

Wernicke's aphasia (receptive aphasia, posterior aphasia)

Left temporo-parietal damage leaves language that is fluent but the words themselves are incorrect. This varies from insertion of a few incorrect or nonexistent words into fluent speech to a profuse outpouring of jargon (that is, rubbish with wholly nonexistent words). Severe jargon aphasia may be bizarre - and confused with psychotic behaviour.

Patients who have recovered from Wernicke's aphasia say that when aphasic they found speech, both their own and others', like a wholly unintelligible foreign language. They could neither stop themselves, nor understand themselves and others.

Nominal aphasia (anomic aphasia or amnestic aphasia)

This means difficulty naming familiar objects. Naming difficulty is an early sign in all types of aphasia. A left posterior temporal/inferior parietal lesion causes a severe, isolated form.

Global aphasia (central aphasia)

This means the combination of the expressive problems of Broca's aphasia and the loss of comprehension of Wernicke's. The patient can neither speak nor understand language. It is due to widespread damage to speech areas and is the commonest aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

Dysarthria

Dysarthria simply means disordered articulation - slurred speech. Language is intact, cf. aphasia. Paralysis, slowing or incoordination of muscles of articulation or local discomfort causes various different patterns of dysarthria. Examples are the 'gravelly' speech of upper motor neurone lesions of lower cranial nerves, the jerky, ataxic speech of cerebellar lesions, the monotone of Parkinson's disease, and speech in myasthenia that fatigues and dies away. Many aphasic patients are also somewhat dysarthric.

The non-dominant hemisphere

Disorders in right-handed patients with right hemisphere lesions are often difficult to recognize. They comprise abnormalities of perception of internal and external space. Examples are losing the way in familiar surroundings, failing to put on clothing correctly *(dressing apraxia),* or failure to draw simple shapes - *constructional apraxia.*

Memory and its disorders (see also p. 1254) Disorders of memory follow damage to the medial surfaces of both temporal lobes and their brainstem connections - the hippocampi, fornices and mammillary bodies. Bilateral lesions are necessary to cause *amnesia.* It is characteristic of all organic memory disorders that more recent events are recalled poorly, in contrast to the relative preservation of distant memories.

Memory loss (the amnestic syndrome) is part of dementia (p. 1254) but also occurs as an isolated entity (Table21.4).

Essential elements of neuroanatomy

For clinical purposes, and particularly in general medicine, the extreme complexity of neuroanatomy must be reduced to its core elements. The following sections cover:

aperture (see p. 1181), is converted to nerve action potentials by retinal rod, cone and ganglion cells. The lens, under control of the ciliary muscle (see p. 1181), produces the image (inverted) on the retina (1), i.e. an object in the lower part of the visual field is projected to the upper retina, one in a temporal field to the nasal retina. Each optic nerve (2), sheathed in pia-arachnoid meninges, carries axons from retinal ganglion cells to the lateral geniculate bodies.

At the chiasm (3), fibres travelling in the nasal portions of the optic nerves cross, join uncrossed temporal optic nerve fibres and form each optic tract. These fibres synapse at each lateral geniculate body (4). One optic tract thus carries fibres from the temporal ipsilateral retina and the nasal contralateral retina. Some optic tract fibres reaching the lateral geniculate bodies pass to the brainstem (see p. 1181) to control refraction (lens) and pupillary aperture.

From the lateral geniculate body, fibres pass in the optic radiation through the parietal and temporal lobes (5 and 6) to reach the visual, or calcarine, cortex of the occipital lobe (7 and 8). The upper retinae (lower visual fields) project in the optic radiation through the parietal lobes to the upper part of the visual cortex, and the lower retinae (upper fields) through the temporal lobes, beneath the parietal, to the lower visual cortex.

Impulses reach the cortex in strictly maintained vertical topographical order (i.e. upper field to lower retina, tract, radiation and cortex, and vice versa, lower to upper). Within the visual cortex itself there are synaptic connections between groups of cells that detect lines, orientation, shapes, movement, colour, and depth. These are processed by neighbouring visual association areas.

Visual field defects caused by lesions of each optic tract, radiation and cortex are called 'homonymous' to indicate the different (i.e. bilateral) origins of each unilateral pathway. (A homonym is the same word used to denote different things.)

Field defects are hemianopic when half the field is affected by a lesion of the optic tract, radiation or cortex and quadrantanopic when a quadrant is affected. Congruous denotes symmetry and incongruous lack of it. Bitemporal defects (damage to crossing nasal fibres) are caused by lesions of the optic chiasm.

Visual acuity

This is recorded with a Snellen chart and/ or Near Vision Reading Types and corrected for refractive errors with lenses or a pinhole. Normal acuity is 6/6 to 6/9; if less, an explanation is necessary.

Visual loss is discussed on page 1171. Causes include:

- Ocular causes, e.g. glaucoma, macular degeneration, cataract, retinal detachment, diabetic vascular disease, trachoma, leprosy, vitamin A deficiency, trauma, onchocerciasis (river blindness). All are of major inter national health and economic importance.
- Lesions of the visual neural pathway (e.g. optic nerve lesions, chiasmal compression, tract, radiation or cor tical lesions).

Visual field defects

These are checked by confrontation with white- and red-headed pins and, if abnormal or in doubt, recorded in detail with a Goldmann (or similar) screen. Examples of field defects are shown in Figure 21.4.

Retinal and local eye lesions (site 1)

Lesions of the retina produce either scotomata (small areas of visual loss) or peripheral visual loss (tunnel vision). Common causes are diabetic retinal vascular disease, glaucoma and retinitis pigmentosa. Local lesions of the eye (e.g. cataract) can also cause visual loss.

Optic nerve lesions (site 2)

Unilateral visual loss, commencing as a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex (direct and consensual) when the blind eye is illuminated (see afferent pupillary defect, p. 1182). For optic nerve lesions, see Table 21.6.

The principal pathological appearances of the visible part of the nerve (optic disc) seen on fundoscopy are:

- disc swelling and hyperaemia (papilloedema)
- pallor (optic atrophy).

Papilloedema and optic neuritis

Papilloedema simply means swelling of the papilla - the optic disc. There are many causes (Table 21.7). In all forms of disc oedema there is axonal swelling within the optic nerve, blockage of axonal transport with capillary and venous congestion. Optic neuritis means swelling of the disc with *inflammation* in the nerve.

The earliest ophthalmoscopic signs of disc swelling are pinkness of the disc followed by fuzziness and heaping up of its margins, the nasal first. There is loss within the disc of the normal, visible, spontaneous pulsation of retinal veins. The physiological cup becomes obliterated, the disc engorged and its vessels dilated. Small haemorrhages often surround the disc.

Various conditions simulate true disc oedema. Marked hypermetropic (long-sighted) refractive errors make the

Hereditary optic neuropathy
Ischaemic optic neuropathy (e.g. giant cell arteritis) Toxic optic neuropathy (e.g. methanol ingestion)
Hypervitaminosis A

Venous occlusion
Cavernous sinus thrombosis Central retinal vein thrombosis/occlusion
Orbital mass lesions

Retinal vascular disease
Malignant hypertension
Vasculitis (e.g. SLE)

Metabolic causes
Hypercapnia, chronic hypoxia, hypocalcaemia

Disc infiltration
Leukaemia, sarcoidosis, optic nerve glioma

SAH, subarachnoid haemorrhage; SLE, systemic lupus erythematosus

disc appear pink, distant and ill-defined. Opaque (myelinated) nerve fibres at the disc margin and hyaline bodies (drusen) can be mistaken for disc swelling.

Disc infiltration also causes first a prominent, then a swollen disc with raised margins (e.g. in leukaemia).

When there is doubt about disc oedema, fluorescein angiography is diagnostic. Fluorescein is injected intravenously: when there is oedema, retinal leakage is seen and photographed.

Early papilloedema from causes other than optic neuritis (for example a brain tumour) often produces few visual symptoms itself - the underlying disease is the source of the patient's complaints. However, as disc oedema progresses, enlargement of the blind spot and blurring of vision develop. The disc then becomes further engorged, its arterial blood flow falls and, then as papilloedema worsens, infarction of the optic nerve occurs. This causes sudden severe and permanent visual loss.

Optic neuritis

The most common cause of inflammation of the optic nerve is demyelination (e.g. multiple sclerosis). Disc swelling due to optic neuritis is distinguished from other causes of disc oedema by dull ocular pain with early and severe visual loss. Retrobulbar neuritis implies that the inflammatory process is within the optic nerve but behind the bulb (i.e. the eye), so that no abnormality is seen at the disc despite visual impairment.

Leber's hereditary optic neuropathy (LHON)

LHON is a cause of isolated blindness in otherwise healthy young men. Unilateral or bilateral optic nerve neuropathy develops over days or weeks. There is sometimes disc swelling and telangiectasia around the disc in the acute phase, followed by optic atrophy. Severe bilateral visual loss is usual by the age of 40. Maternal inheritance and genetic analysis point to pathogenic mitochondrial DNA mutations, many with a mutation at G11778A. Exceptional cases occur in women.

Optic atrophy

Optic atrophy means disc pallor, from loss of axons, glial proliferation and decreased vascularity that follows many pathological processes, e.g. infarction of the nerve from thromboembolism or following papilloedema, inflammation (demyelinating optic neuritis in MS, syphilis, LHON), optic nerve compression, previous trauma, toxic and metabolic causes (vitamin B_{12} deficiency, quinine and methyl alcohol ingestion). Optic atrophy is described as *consecutive* or *secondary* when it follows papilloedema, of any cause. The degree of visual loss depends upon underlying pathology.

Optic chiasm (site 3)

Bitemporal hemianopic fields are the typical defects seen when a mass compresses the chiasm. Common causes are:

- pituitary neoplasm (p. 1044)
- meningioma
- craniopharyngioma
- secondary neoplasm.

In bilateral visual loss, chiasmal compression must always be considered - and optic nerve compression in unilateral visual failure.

Optic tract and optic radiation (sites 4, 5 and 6)

Optic *tract* lesions (rare) cause field defects that are homonymous, hemianopic and often incomplete and incongruous. Optic *radiation* lesions cause homonymous quadrantanopic defects. Temporal lobe lesions (e.g. tumour or infarction) cause upper quadrantic defects; and parietal lobe, lower.

Occipital cortex (sites 7 and 8)

Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction. The macular region (of the cortex, at each occipital pole) is spared because it has a separate blood supply via the middle cerebral artery. Infarction of one occipital pole causes a small, congruous, scotomatous, homonymous hemianopia (8).

Widespread bilateral occipital lobe damage by infarction, trauma or tumour causes cortical blindness (Anton's syndrome). The patient cannot see but characteristically lacks insight into the degree of blindness and may even deny it. The pupillary responses are normal (see also p.1213).

Pupils

Sympathetic impulses dilate the pupils. Fibres in the nasociliary nerve pass to *dilator pupillae*. These arise from the superior cervical ganglion at C2. Sympathetic preganglionic fibres to the eye (and face) originate in the hypothalamus, pass uncrossed through the midbrain and lateral medulla, and emerge finally from the spinal cord

at Tl (close to the lung apex) and form the superior cervical ganglion at C2. Posfganglionic fibres leave the ganglion to form a plexus around the carotid artery bifurcation. Fibres pass to the pupil in the nasociliary nerve from part of this plexus surrounding the *internal* carotid artery. Those fibres to the face (sweating and piloerection) arise from the part of the plexus surrounding the *external* carotid artery. This arrangement has some clinical relevance in Horner's syndrome (p. 1183).

Parasympathetic impulses cause pupillary constriction. Fibres in the short ciliary nerves arise from the ciliary ganglion and pass to *sphincter pupillae,* causing constriction. Parasympathetic pathways and the light reflex mechanism are shown in Figure 21.5.

The light reflex

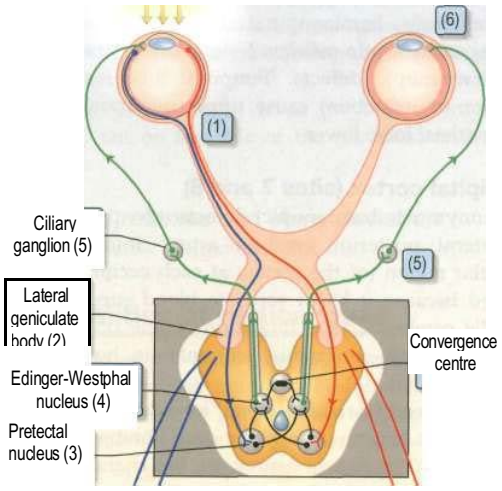
Afferent fibres (1) in each optic nerve (some crossing in the chiasm) pass to both lateral geniculate bodies (2) and relay to the Edinger-Westphal nuclei (4) via the pretectal nucleus (3).

Efferent (parasympathetic) fibres from each Edinger-Westphal nucleus pass via the third nerve to the ciliary ganglion (5) and thence to the pupil (6).

Light constricts the pupil being illuminated (direct reflex) and, by the consensual reflex, the contralateral pupil.

Light source

***Fig. 21.5* Pupillary light reflex.**



Afferent pathway
(1) A retinal image generates action potentials in the optic nerve.
(2) These travel via axons, some of which decussate at the chiasm and pass through the lateral geniculate bodies.
(3) Synapse at each pretectal nucleus.

Efferent pathway
(4) Action potentials then pass to each Edinger -Westphal nucleus of III.
(5) Then, via the ciliary ganglion.
(6) Lead to constriction of pupil.

The convergence reflex

Fixation on a near object requires convergence of the ocular axes and is accompanied by pupillary constriction. Afferent fibres in each optic nerve, which pass through both lateral geniculate bodies, also relay to the convergence centre. This centre receives la spindle afferent fibres from the extraocular muscles - principally medial recti - which are innervated by the third nerve.

The efferent route is from the convergence centre to the Edinger-Westphal nucleus, ciliary ganglion and pupils. Voluntary or reflex fixation on a near object is thus accompanied by appropriate convergence and pupillary constriction.

A darkened room makes all pupillary abnormalities easier to see.

Clinical abnormalities of the pupils

Pupillary abnormalities in coma are discussed on page 1208, and in brainstem lesions on page 989.

Physiological changes and old age

A slight difference between the size of each pupil is common (physiological anisocoria) at any age. The pupil tends to become small (3-3.5 mm) and irregular in old age (senile miosis); anisocoria is more pronounced. The convergence reflex becomes sluggish with ageing and a bright light becomes necessary to demonstrate constriction.

Afferent pupillary defect. A blind left eye, for example following complete optic nerve section, has a pupil larger than the right. The features of a left afferent pupillary defect are:

- The left pupil is unreactive to light (i.e. the direct reflex is absent).
- The consensual reflex (constriction of right pupil when the left is illuminated) is absent. Conversely, the left pupil constricts when light is shone in the intact right eye, i.e. the consensual reflex of the right eye remains intact.

Relative afferent pupillary defect (RAPD). When there has been incomplete damage to one afferent pupillary pathway (i.e. of one optic nerve *relative* to the other), the difference between the pupillary reaction, and the relative impairment on one side is called a relative afferent pupillary defect (RAPD). The sign can provide evidence of an optic nerve lesion, when, for example, retrobulbar neuritis occurred many years previously and there has been complete clinical recovery of vision (p. 1235). After previous left retrobulbar neuritis:

- Light shone in the left eye causes both left and right pupils to constrict.
- When light is shone into the intact right eye, both pupils again constrict (i.e. right direct and consensual reflexes are intact).
- When the light is swung back to the left eye, its pupil dilates slightly, relative to its previous size.

A left RAPD by the *swinging light test,* showing that the consensual reflex is stronger than the direct, indicates

T1 root	Isolated and of unknown cause
Bronchial neoplasm (apical)	
Apical tuberculosis	
Cervical rib	
Brachial plexus trauma	

residual damage in the afferent pupillary fibres of the left optic nerve.

Homer's syndrome

This collection of signs - unilateral pupillary constriction with slight ptosis and enophthalmos - indicates a lesion of the sympathetic pathway on the same side. The conjunctival vessels are slightly injected. Causes of Horner's syndrome are given in Table 21.8. There is loss of sweating of the same side of the face or body; the extent depending upon the level of the lesion:

- Central lesions affect sweating over the entire half of the head, arm and upper trunk.
- Neck lesions proximal to the superior cervical ganglion cause diminished facial sweating.
- Lesions distal to the superior cervical ganglion do not affect sweating at all.

Pharmacological tests help to indicate the level of the lesion. For example, a lesion distal to the superior cervical ganglion causes denervation hypersensitivity of the pupil, which dilates when 1:1000 epinephrine (adrenaline) is instilled. This dose has little effect on the normal pupil or a Horner's pupil from a proximal lesion. In clinical practice the test is of limited value.

Myotonic pupil (Holmes-Adie pupil)

This common cause of a dilated pupil is more frequent in females. It is usually unilateral, and the pupil is often irregular. There is no reaction (or a very slow reaction) to bright light and also incomplete constriction to convergence. This is due to denervation in the ciliary ganglion, of unknown cause. The myotonic pupil is of no more pathological significance than this, but is sometimes associated with diminished or absent tendon reflexes.

Argyll Robertson pupil

This small, irregular (3 mm or less) pupil is fixed to light but constricts on convergence. The lesion is in the brainstem surrounding the aqueduct of Sylvius.

The Argyll Robertson pupil is (almost) diagnostic of neurosyphilis. Similar changes are occasionally seen in diabetes mellitus.

III, IV, VI: OCULOMOTOR, TROCHLEAR AND ABDUCENS NERVES

Mechanisms controlling eye movement are:

- central upper motor neurone mechanisms driving normal yoked parallel eye movements (conjugate gaze)
- individual movements generated by each oculomotor, abducens and trochlear nerve and muscles they supply.

Conjugate gaze

Fast voluntary and reflex eye movements originate in each frontal lobe. Fibres pass in the anterior limb of the internal capsule and cross in the pons to end in the centre for lateral gaze (paramedian pontine reticular formation - PPRF, Fig. 21.6a), close to each sixth nerve nucleus. The PPRF also receives fibres from:

- the ipsilateral occipital cortex - a pathway concerned with tracking objects
- both vestibular nuclei - pathways linking eye movements with position of the head and neck (doll's head reflexes, p. 990).

Conjugate lateral eye movements are coordinated by the PPRF through the medial longitudinal fasciculus (MLF, Fig. 21.6b). Fibres from the PPRF pass both to the ipsilateral sixth nerve nucleus and, having crossed the midline, the opposite third nerve nucleus via the MLF. Each sixth nerve nucleus (supplying lateral rectus) and the opposite third nerve nucleus (supplying medial rectus and others) are thus linked by the MLF, driving the eyes laterally with parallel axes with the same velocity.

Abnormalities of conjugate lateral gaze

A destructive lesion of one side of the brain allows lateral gaze to be driven by the intact opposite pathway. For example, a destructive left frontal lobe lesion (e.g. an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion the eyes are often deviated past the midline to the side of the lesion, here to the left, and therefore look towards the normal limbs, as there is usually a contralateral (i.e. right) hemiparesis.

An irritative left frontal lobe lesion (e.g. an epileptic focus), stimulates the opposite, right, PPRF and drives lateral gaze away from the side of the lesion (i.e. to the right) during an attack.

In the brainstem itself a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze towards that side. There is usually a contralateral hemiparesis and lateral gaze is deviated towards the side of the paralysed limbs.

Internuclear ophthalmoplegia

Damage to one MLF causes internuclear ophthalmoplegia (1NO), one of the more common complex brainstem oculomotor signs and seen frequently in multiple sclerosis. When present bilaterally, INO is almost pathognomonic of this disease.

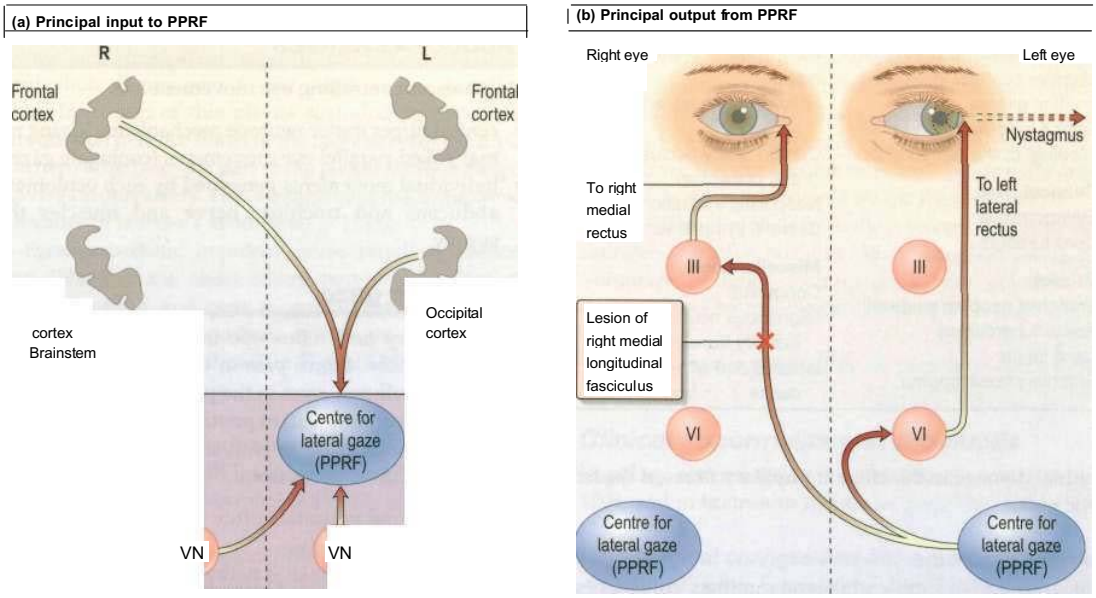

***Fig. 21.6* (a) Principal input to PPRF.** Impulses from the right frontal cortex, the left occipital cortex and both vestibular nuclei (VN) drive the left centre for lateral gaze, or paramedian pontine reticular formation (PPRF).
(b) Principal output from PPRF. Impulses from the PPRF pass via the ipsilateral VIth nerve nucleus to the lateral rectus muscle (ABduction) and via the medial longitudinal fasciculus to the IIIrd nerve nucleus and thus to the opposite medial rectus muscle (ADduction). X shows lesion with failure of ADduction of right eye and nystagmus of ABducting left eye.

Unilateral lesions are also caused by small brainstem infarcts. In a right INO there is a lesion of the right MLF (Fig. 21.6b). On attempted left lateral gaze the right eye fails to ADduct. The left eye develops coarse nystagmus in ABduction.

The side of the lesion is on the side of impaired adduction, not on the side of the (obvious, unilateral) nystagmus.

Doll's head reflexes and skew deviation

These are of some diagnostic value in coma (see p. 990).

Abnormalities of vertical gaze

Failure of up-gaze is caused by upper brainstem lesions, such as a supratentorial mass, or a brainstem tumour (e.g. a pinealoma). When the pupillary convergence reflex fails as well, this combination is called Parinaud's syndrome. Defective up-gaze also occurs in certain degenerative disorders (e.g. progressive supranuclear palsy). Some impairment of up-gaze develops as part of normal ageing.

Weakness of extraocular muscles (diplopia)

Diplopia (double vision) indicates weakness of one or more extraocular muscles. The causes are:

- lesions of the third, fourth and/or sixth cranial nerves or nuclei
- disorders of the neuromuscular junction (e.g. myasthenia gravis)
- disease of, or injury to the ocular muscles
- orbital lesions.

Squint (strabismus)

This describes the appearance of the eyes when the visual axes fail to meet at the fixation point, and is either convergent or divergent.

Paralytic squint. Paralytic or incomitant squint occurs when there is an acquired defect of movement of an eye - the usual situation in neurological disease. There is a squint (and hence diplopia) maximal in the direction of action of the weak muscle.

Non-paralytic squint. Non-paralytic or concomitant squint describes a squint dating from infancy in which the angle between the visual axes does not vary when the eyes are moved - the squint remains the same in all directions of gaze. Diplopia is almost never a symptom. The deviating eye (the one that does not fixate) usually has defective (amblyopic) vision; this is called *amblyopia ex anopsia.*

Non-paralytic squint may be latent (i.e. only visible at certain times), e.g. when tired.

The cover test. The cover test is used principally to assess non-paralytic squint and to recognize latent squint. The patient is asked to fix on a light. When there is no squint a pinpoint reflection is seen in the exact centre of each pupil. One eye that is fixing the light centrally is

Table 21.9 Common causes of an oculomotor nerve lesion

Midbrain tumour

covered quickly. If a squint has been present the other (uncovered) eye moves, to take up central fixation. The test is repeated with the opposite eye. The dominant, fixing eye will not move when the other, squinting, amblyopic eye is covered or uncovered.

III: Oculomotor nerve

The nucleus of the third nerve lies ventral to the aqueduct in the midbrain. Efferent fibres to four external ocular muscles (superior, inferior and medial recti, and inferior oblique), *levator palpebrae superioris* and *sphincter pupillae* (parasympathetic) enter the orbit through the superior orbital fissure.

The common causes of an oculomotor nerve lesion are given in Table 21.9. Signs of a complete third nerve palsy are:

- unilateral complete ptosis
- the eye facing down and out
- a fixed and dilated pupil.

Sparing of the pupil means that parasympathetic fibres that run in a discrete bundle on the superior surface of the nerve remain undamaged, and so the pupil is of normal size and reacts normally. In diabetes, infarction of the third nerve usually spares the pupil.

In a third nerve palsy the eye can still ABduct (sixth nerve) and rotate inwards or intort (fourth nerve). Preservation of intortion (inward rotation) means that the fourth (trochlear) nerve is intact. In a patient with a right third nerve palsy, when the attempt is made to converge and look downwards, the conjunctival vessels of the right eye are seen to twist clockwise, indicating that the eye is intorting and the fourth nerve is intact (see below).

IV: Trochlear nerve

This supplies the superior oblique muscle. The head is tilted away from the side of the lesion and the patient complains of torsional diplopia when attempting to look down and away from the affected side.

VI: Abducens nerve

This supplies the lateral rectus muscle that ABducts the eye. There is an evident convergent squint with diplopia maximal looking to the side of the lesion. The eye cannot be ABducted beyond the midline (see p. 1184 and Fig.21.6).

The sixth nerve has a long intracranial course The nerve can be damaged in the brainstem (e.g. MS or pontine glioma). In raised intracranial pressure it is compressed against the tip of the petrous temporal bone. The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. An isolated sixth nerve palsy due to infarction occurs in diabetes mellitus and is also a common sequel of head trauma.

Complete external ophthalmoplegia

Complete external ophthalmoplegia describes the immobile eye when III, IV and VI nerves are paralysed by disease at the orbital apex (e.g. a metastasis) or within the cavernous sinus (e.g. sinus thrombosis).

V: TRIGEMINAL NERVE

This nerve is large, mainly sensory but with some motor fibres.

Sensory fibres (Fig. 21.7; and see Figs 21.11 and 21.12) from the three divisions - ophthalmic (V_1), maxillary (V_2) and mandibular (V_3) - pass to the trigeminal (Gasserian) ganglion within the cavernous sinus at the apex of the petrous temporal bone. From here central fibres enter the brainstem. Ascending fibres transmitting light touch sensation enter the V nucleus in the pons. Descending fibres carrying pain and temperature sensation form the spinal tract of V end in the spinal V nucleus in the medulla. This nucleus extends into the upper cervical cord.

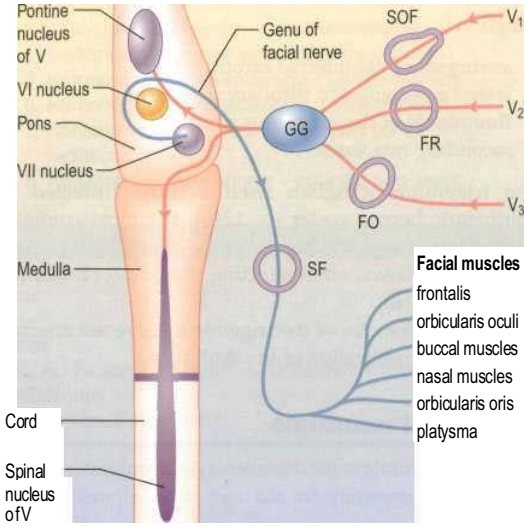

***Fig. 21.7* Sensory input of trigeminal nerve (red) and motor output of facial nerve (blue).** SOR superior orbital fissure; FO, foramen ovale; FR, foramen rotundum; GG, Gasserian ganglion; SF, stylomastoid foramen.

Motor fibres arise in the upper pons and join the mandibular branch to supply muscles of mastication.

Signs of a V nerve lesion

A complete V nerve lesion causes unilateral sensory loss on the face, tongue and buccal mucosa. When motor fibres are damaged, the jaw deviates to that side as the mouth opens. Diminution of the corneal reflex is an early, and sometimes isolated sign of a fifth nerve lesion.

Central (brainstem) lesions of the lower trigeminal nuclei (e.g. in syringobulbia, p. 1152) produce a characteristic circumoral sensory loss.

When the spinal tract (or spinal nucleus) alone is involved, sensory loss is restricted to pain and temperature sensation, i.e. dissociated (p. 1199).

Causes

Within the *brainstem,* lesions involve fifth nuclei *and* central connections, in, e.g.:

- brainstem glioma
- multiple sclerosis
- infarction
- syringobulbia.

At the *cerebellopontine angle,* the nerve is compressed by:

- acoustic neuroma
- meningioma
- secondary neoplasm.

As these lesions enlarge, the neighbouring seventh and eighth nerves become involved, producing facial weakness and deafness.

At the *apex of the petrous temporal bone,* spreading middle ear infection, or a secondary tumour, damage the nerve. The combination of a painful fifth with a sixth nerve lesion is called Gradenigo's syndrome.

Within the cavernous sinus, the trigeminal (Gasserian) ganglion is compressed by:

- aneurysm of the internal carotid artery
- lateral extension of a pituitary neoplasm
- thrombosis of the cavernous sinus
- secondary neoplasm.

The trigeminal ganglion itself becomes infected in ophthalmic herpes zoster (p. 1240), the most common lesion of the ganglion. Trigeminal postherpetic neuralgia commonly follows, often affecting the first (ophthalmic) division (p. 1240).

Peripheral branches of the trigeminal nerve are affected by neoplastic infiltration of the skull base.

Trigeminal neuralgia

Trigeminal neuralgia *(tic douloureux)* is of unknown cause, seen most commonly in old age. It is almost always unilateral.

Symptoms

Severe paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the fifth nerve. The pain tends to commence in the mandibular division (V_3) and spreads upwards to maxillary (V_2) and ophthalmic divisions (V_1). Spasms occur many times a day.

Each paroxysm is stereotyped, brought on by stimulation of one or more trigger zones in the face. Washing, shaving, a cold wind or eating are examples of trivial stimuli that provoke pain. The face may be screwed up in agony (hence the term *tic).* Pain characteristically does not occur at night. Spontaneous remissions last months or years before recurrence, which is almost inevitable.

Signs

There are no signs of trigeminal nerve dysfunction. The corneal reflex is preserved. The history alone make the diagnosis.

Treatment

The anticonvulsant carbamazepine 600-1200 mg daily reduces severity of attacks in the majority. Phenytoin, gabapentin and clonazepam are used, but are less effective.

If drug therapy fails, surgical procedures (radiofrequency extirpation of the ganglion, neurovascular decompression or sectioning of the sensory root) are useful. Alcohol injection into the trigeminal ganglion or peripheral fifth nerve branches can also be carried out.

Secondary trigeminal neuralgia

Trigeminal neuralgia occurs in MS (p. 1235), with tumours of the fifth nerve (e.g. neuroma) and with cerebellopontine angle lesions (see below). There are usually physical signs - initially a depressed corneal reflex, progressing to trigeminal sensory loss.

Idiopathic trigeminal neuropathy

A chronic isolated fifth nerve lesion sometimes develops without apparent cause. When sensory loss is severe, trophic changes (facial scarring and corneal ulceration) develop.

VII: FACIAL NERVE

The facial nerve is largely motor in function, supplying muscles of facial expression. The nerve carries sensory taste fibres from the anterior two-thirds of the tongue via the *chorda tympani.* It also supplies motor fibres to the *stapedius* muscle. The facial nerve (Fig. 21.7) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Part of each facial nucleus supplying the upper face (principally *frontalis* muscle) receives supranuclear fibres from each hemisphere. Therefore in a unilateral upper motor neurone lesion of the facial nerve the upper part of the face is usually spared.

Unilateral facial weakness

Lower motor neurone (LMN) lesions. A unilateral LMN lesion causes weakness of all muscles of facial expression on one side. The angle of the mouth falls, **and** unilateral dribbling occurs. There is weakness of frowning *(frontalis)* and of eye closure since upper facial muscles are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. The *platysma* muscle is also weak.

***Upper motor neurone (UMN)** lesions.* UMN lesions cause weakness of the lower part only of the face on the side opposite the lesion. *Frontalis* is spared. Thus the normal furrowing of the brow is preserved, and eye closure and blinking are not affected. The earliest sign is simply slowing of one side of the face, for example on baring the teeth. In UMN lesions, too, there is sometimes relative preservation of spontaneous emotional movement (e.g. smiling) compared with voluntary movement.

Causes of facial weakness

A common cause of facial weakness is a supranuclear (UMN) lesion (e.g. cerebral infarction), leading to UMN facial weakness with hemiparesis.

Lesions at four lower levels are recognized by association of LMN facial weakness with other signs.

Pons. Here the sixth (abducens) nerve nucleus is encircled by seventh nerve fibres (Fig. 21.7). The sixth nucleus is thus often involved in pontine lesions of the seventh, causing a convergent squint (lateral rectus palsy) with unilateral facial weakness.

When the neighbouring PPRF and corticospinal tract are involved, there is the triple combination of:

- LMN facial weakness
- failure of conjugate lateral gaze (towards lesion)
- contralateral hemiparesis.

Causes include pontine tumours (e.g. glioma), demyelination and vascular lesions.

The facial nucleus itself is affected unilaterally or bilaterally in poliomyelitis (see p. 49) and in motor neurone disease usually bilaterally (p. 1253) .

Cerebellopontine angle (CPA). The fifth, sixth and eighth nerves are affected with the seventh where they are clustered together in the CPA. Causes are acoustic neuroma, meningioma and secondary neoplasm.

Petrous temporal bone. The geniculate ganglion (sensory for taste) lies at the *genu* (knee) of the facial nerve (Fig. 21.7). Fibres join the facial nerve in the *chorda tympani* and carry taste from the anterior two-thirds of the tongue. The (motor) nerve to *stapedius* leaves the facial nerve distal to the *genu*. Facial nerve lesions within the petrous temporal bone cause the combination of:

- loss of taste on the anterior two-thirds of the tongue
- hyperacusis (unpleasantly loud noise distortion caused by paralysis of *stapedius).*

Causes include:

Bell's palsy
trauma
middle ear infection
herpes zoster (Ramsay Hunt syndrome, p. 1188)
tumours (e.g. glomus tumour).

Skull base, parotid gland and in the face itself. Swelling of the facial nerve within the stylomastoid foramen develops in Bell's palsy (see below). The nerve can be compressed by skull base tumours and in Paget's disease of bone. Branches of the nerve that pierce the parotid are damaged by parotid gland tumours, mumps (p. 57), sarcoidosis (p. 935) and trauma. Each facial nerve can also be involved in polyneuritis (e.g. Guillain-Barre syndrome, p. 1260), usually simultaneously.

Weakness of facial muscles is also seen in primary muscle disease and myasthenia. Weakness is usually symmetrical. Causes include:

- dystrophia myotonica (p. 1270)
- facio-scapulo-humeral dystrophy (p. 1270)
- myasthenia gravis (p. 1268).

Bell's palsy

This common, acute, isolated facial palsy is usually due to a viral (often herpes simplex) infection that causes swelling of the nerve within the petrous temporal bone and as it traverses the stylomastoid foramen in the skull base.

The patient notices sudden unilateral facial weakness, sometimes with loss of taste on the anterior two-thirds of the tongue. Pain behind the ear is common at onset. Diagnosis is made on clinical grounds. No other cranial nerves are involved.

Management and course

Weakness progresses over hours or several days. Spontaneous improvement usually begins during the second week. Thereafter, recovery continues but may take 12 months. Occasionally (fewer than 10%) patients are left with an unsightly, residual weakness.

Electrophysiological tests (EMG, p. 1203) are of some help in predicting outcome but seldom used. After the third week, absence of any evoked potential from facial muscles (the nerve is stimulated over the parotid) indicates that full recovery is unlikely.

Steroids (e.g. prednisolone 60 mg daily, reducing to nil over 10 days) with aciclovir have been shown to be more effective than either of these drugs alone.

Suturing the upper to lower **lid** (tarsorrhaphy) is essential to prevent prolonged corneal exposure if the eye cannot be closed. Adhesive tape to hold the lids closed is an invaluable temporary measure.

Severe late residual paralysis occurs in about 15% and cosmetic surgery is sometimes helpful.

Bell's palsy occasionally recurs and is very rarely bilateral.

Ramsay Hunt syndrome

This is *herpes zoster* (shingles) of the geniculate ganglion. There is a facial palsy (identical in appearance to Bell's) with herpetic vesicles in the external auditory meatus (this receives a sensory twig from the facial nerve) and/ or on the soft palate. Deafness, or a fifth nerve lesion may occur. Complete recovery is less likely than in Bell's palsy. Treatment for shingles should be given (famciclovir, p.1321).

Hemifacial spasm

This is an irregular, painless clonic spasm of the facial muscles, usually occurring after middle age, and more commonly in women. It varies froma mild inconvenience to a severe, disfiguring spasm. Causes are:

idiopathic
following Bell's palsy
acoustic neuroma
Paget's disease in the skull base
pressure from vessels in the cerebellopontine angle (postulated).

There are clonic spasms of facial muscles on one side. Mild LMN facial weakness is common.

Management

Some cases require no treatment. In others, decompression of the facial nerve in the cerebellopontine angle is sometimes helpful. Local injection of botulinum toxin into facial muscles reduces the spasm for some months, and can be repeated. Drugs are of no value.

Myokymia

Facial myokymia describes a rare, continuous, fine, sinuous or wave-like movement of the lower face that is seen in brainstem lesions (e.g. multiple sclerosis, brainstem glioma).

Myokymia is also used to describe innocent twitching around the eye.

VIII: VESTIBULOCOCHLEAR NERVE

This nerve has two parts - cochlear and vestibular.

Cochlear nerve

Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards through the medial lemnisci to the medial geniculate bodies and thence to the temporal gyri.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (see p. 1156). The deafness is called 'sensorineural' (or perceptive) deafness. Clinical detection is by tuning fork (256 Hz, not 128 Hz) tests, principally Rinne's and Webers tests, which distinguishes conductive from sensorineural deafness (see p. 1154).

Investigations of cochlear lesions

- Pure tone audiometry.
- Auditory evoked potentials. These record from scalp electrodes the response from a repetitive click. The level of the lesion may be detected from the response.

Causes of sensorineural deafness are shown in Table 20.1.

Vestibular nerve

Nerve impulses generated by movement of sensory epithelia of the three semicircular canals, saccule and utricle pass to vestibular nuclei in the pons. The vestibular nuclei are also connected to the cerebellum, nuclei of the ocular muscles, PPRF, extrapyramidal system, reticular formation, temporal lobes and spinal cord.

Balance and posture also depend upon the interaction of proprioceptive (position sense) impulses passing between the neck, spinal muscles and limbs and vestibular system.

The *main symptom* of a vestibular lesion is vertigo and loss of balance. Vomiting frequently accompanies any acute vertigo. Nystagmus is the principal physical sign.

Vertigo

Vertigo, the definite illusion of movement of the subject or surroundings, indicates a disturbance of vestibular, eighth nerve, brainstem or, very rarely cortical function. See Table 21.10.

Deafness and tinnitus accompanying vertigo indicate that its origin is from the ear or eighth cranial nerve (see p.1154).

Nystagmus

Nystagmus is a rhythmic oscillation of the eyes. It is a sign of disease of either the ocular or vestibular system and its connections. Nystagmus is classified as either *jerk*

Table 21.10 **Principal causes of vertigo**

Meniere's disease
Drugs (e.g. gentamicin, anticonvulsant intoxication)
Toxins (e.g. ethyl alcohol)
'Vestibular neuronitis'
Multiple sclerosis
Migraine
Acute cerebellar lesions
Cerebellopontine angle lesions (e.g. acoustic neuroma)
Partial seizures (temporal lobe focus)
Brainstem ischaemia or infarction
Benign paroxysmal positional vertigo

or *pendular*. For true nystagmus to be present it must be demonstrable and sustained within binocular gaze.

Jerk nystagmus

Jerk nystagmus (the usual nystagmus of neurological disease) has a fast and a slow component. It is seen in vestibular end-organ, eighth nerve, brainstem, cerebellar and (very rarely) cortical lesions. The direction of nystagmus is decided by the fast component, which can be thought of as a reflex attempt to correct the slower, primary movement.

Considerable difficulties exist when attempts are made to use the direction alone of jerk nystagmus as a localizing sign, although nystagmus is both a common and valuable indication of abnormality within the vestibular system as a whole. The following are useful diagnostic starting points:

- Horizontal jerk or rotary jerk nystagmus may be either of peripheral origin (middle ear) or central origin (eighth nerve, brainstem, cerebellum and their connections). In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo. In central lesions nystagmus is long-lasting (weeks, months or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.
- Vertical jerk nystagmus. This is caused only by central lesions.
- Down-beat jerk nystagmus. This rarity is caused by lesions around the foramen magnum (e.g. meningioma, cerebellar ectopia).

Pendular nystagmus

Pendular describes movements to and fro similar in both velocity and amplitude. Pendular nystagmus is almost always binocular, horizontal and present in all directions of gaze. Its causes are almost invariably ocular, when there is poor visual fixation (e.g. long-standing, severe visual impairment), or a congenital lesion, when it is sometimes associated with head-nodding. Exceptionally, it occurs in brainstem disease: a fine pendular, jelly-like nystagmus is a sign of a multiple sclerosis (MS) brainstem plaque, or brainstem glioma.

Investigation of vestibular lesions

MRI provides the best structural images of this region.

Caloric tests are used to assess function of the labyrinth. These record the duration of evoked nystagmus when first ice-cold, then warm, water is run into the external meatus. In the normal caloric test:

- ice-cold water in the left ear causes nystagmus with the fast movement to the right
- warm water in the left ear causes nystagmus with the fast movement to the left.

The right ear gives opposite responses. Decreased or absent nystagmus indicates ipsilateral labyrinth, eighth nerve or brainstem involvement. The technique is also used in the diagnosis of brainstem death (p. 989). There are, however, difficulties relating minor abnormalities in caloric tests to clinical symptoms of dizziness.

Vestibular and auditory lesions - central, VIIIth nerve and end organ

Drugs (e.g. anticonvulsant toxicity), alcohol and brainstem vascular disease are common central causes of vertigo. It may also be possible to recognize lesions from clinical features at six distinct levels.

Cerebral cortex. Vertigo is occasionally part of the aura of a partial (temporal lobe) seizure. Vertigo is also a psychological and perceptual sensation when experiencing unaccustomed heights, in panic attacks and agoraphobia. Deafness is very rare in acquired cortical disease; bilateral lesions are necessary.

Pons and brainstem. Vertigo is also common when lesions involve the vestibular nuclei and their connections (MS, vascular, tumour, syrinx). A sixth or seventh nerve lesion, internuclear ophthalmoplegia, lower cranial nerve lesions or contralateral hemiparesis will help localization. Nystagmus is frequently present, while deafness is rare. Transient vertigo occurs in basilar migraine (p. 1248), in syncope, and occasionally in hypoglycaemic attacks; its site of origin is often difficult to ascertain.

Cerebellum. Nystagmus, towards the side of a cerebellar mass (e.g. tumour, haemorrhage or infarct), develops. Limb ataxia is usually present. Bilateral cerebellar, or cerebellar connection disease (e.g. olivo-ponto-cerebellar degeneration) causes bilateral nystagmus. Deafness does not occur.

Cerebellopontine angle. Sensorineural deafness and vertigo occur. Sixth, seventh and fifth nerve lesions develop, followed by cerebellar signs (ipsilateral) and later pyramidal signs (contralateral). Nystagmus is often present. Causes include acoustic neuroma (p. 1245), meningioma and secondary neoplasm, carcinomatous meningitis and inflammatory lesions (Table 21.10).

Petrous temporal bone. Facial weakness (seventh nerve) often accompanies the eighth nerve lesion. Causes include trauma, middle ear infection, secondary neoplasm and Paget's disease of bone (see also Gradenigo's syndrome, p. 1186).

End organs (cochlear and semicircular canals). Causes include:

- Meniere's disease (p. 1156)
- drugs (e.g. gentamicin)
- noise (acoustic trauma, p. 1030)
- middle ear infection (p. 1154)
- mumps
- 'vestibular neuronitis'
- benign paroxysmal positional vertigo (p. 1156)

- advancing age
- intrauterine rubella
- congenital syphilis.

'Vestibular neuronitis'

This common but poorly understood syndrome describes an acute attack of isolated severe vertigo with nystagmus, often with vomiting, but without loss of hearing. It is believed to follow or accompany viral infections that affect the labyrinth or vestibular nerve.

The disturbance lasts for several days or weeks but is self-limiting and rarely recurs. Treatment is with vestibular sedatives; steroids may help. The condition is sometimes followed by benign positional vertigo. Very similar symptoms can be caused by demyelination or vascular lesions within the brainstem, but usually other abnormalities are apparent (see above).

LOWER CRANIAL NERVES IX, X, XI, XII

The glossopharyngeal (IX), vagus (X) and accessory (XI) nerves arise in the medulla and leave the skull base together through the jugular foramen. The hypoglossal (XII) also arises in the medulla but leaves through the anterior condylar foramen. All four lower cranial nerves lie close together, just outside the skull, and are related to the carotid artery and ascending sympathetic innervation to the eye.

Glossopharyngeal (IX)

This mixed nerve is largely sensory. Sensory fibres supply all sensation to the tonsillar fossa and pharynx (afferent pathway of gag reflex), and taste to the posterior third of the tongue.

Motor fibres supply the *stylopharyngeus* muscle, autonomic fibres supply the parotid gland, and a sensory branch supplies the carotid sinus.

Vagus (X)

This mixed nerve, largely motor, supplies the striated muscle of the pharynx (efferent pathway of gag reflex), larynx (including vocal cords via the recurrent laryngeal nerves) and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

Accessory (XI)

This motor nerve supplies trapezius and sternomastoid.

Hypoglossal (XII)

This motor nerve supplies the tongue.

Ninth and tenth nerve lesions

Isolated nerve lesions are most unusual, since disease at the jugular foramen affects both nerves and sometimes the accessory nerve.

Table 21.11 Principal causes of ninth, tenth, eleventh and twelfth nerve lesions

Within the brainstem
Infarction
Syringobulbia
Motor neurone disease (motor fibres)
Poliomyelitis (motor fibres)
At the skull base (jugular and anterior condylar foramina)
Carcinoma of nasopharynx
Glomus tumour
Neurofibroma
Jugular venous thrombosis (XIIth is spared)
Trauma
Within the neck and nasopharynx
Carcinoma of nasopharynx
Metastases Polyneuropathy
Trauma

A unilateral ninth nerve lesion causes diminished sensation on the same side of the pharynx. A tenth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate, which is drawn over to the opposite side.

Bilateral combined lesions of the ninth and tenth nerves cause visible weakness of elevation of the palate, depression of palatal sensation and loss of the gag reflex. The vagal recurrent laryngeal branches are involved. The cough is depressed and the vocal cords paralysed. The patient complains of difficulty in swallowing, hoarseness, nasal regurgitation and choking (particularly with fluids) - a dangerous situation. Bulbar palsy is a general term describing palatal, pharyngeal and tongue weakness of LMN or muscle origin (p. 1191).

Ninth and tenth nerve lesions often accompany eleventh and twelfth nerve lesions. Causes are given in Table 21.11.

Recurrent laryngeal nerve lesions. Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of voluntary and reflex coughing. There is no visible weakness of the palate but vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g. postoperatively) are a serious emergency and cause respiratory obstruction.

The left recurrent laryngeal nerve (which loops beneath the aorta) is more commonly damaged than the right.

Causes of recurrent laryngeal nerve lesions include:

- mediastinal primary tumours (e.g. thymoma)
- secondary spread from carcinoma of the bronchus
- aneurysm of the aorta
- trauma or surgery to the neck
- glossopharyngeal neuralgia (rare).

Glossopharyngeal neuralgia. This describes intensely painful, paroxysmal neuralgic spasms within the pharynx triggered repeatedly by swallowing. There are no physical signs. Treatment of this rare condition is with carbamazepine (see trigeminal neuralgia, p. 1186) or section of the nerve in the pharynx.

Table 21.11 shows the principal causes of lesions.

Eleventh nerve lesions

A lesion of the eleventh nerve causes weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Table 21.11 shows the principal lesions. Section of the nerve is followed by persistent neuralgic neck pain.

Twelfth nerve lesions

LMN lesions of the twelfth nerve lead to unilateral tongue weakness, wasting and fasciculation. The protruded tongue deviates towards the weaker side. For principal causes, see Table 21.11.

Bilateral supranuclear (UMN) twelfth nerve lesions (see below) produce slow, limited tongue movements; the tongue is stiff and cannot be protruded far. Fasciculation is absent.

BRAINSTEM LESIONS

Bulbar palsy

Bulbar palsy describes weakness of LMN type of muscles whose cranial nerve nuclei lie in the medulla (the 'bulb'). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei (e.g. motor neurone disease), lesions of ninth to twelfth cranial nerves (Table 21.11), malfunction of their neuromuscular junctions (e.g. myasthenia gravis, botulism), or disease of muscles themselves (e.g. muscular dystrophies).

Pseudobulbar palsy

This describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness and poverty of movement of the tongue and pharyngeal muscles. (This resembles, superficially, a bulbar palsy; hence the term *pseudobulbar.)* The findings in pseudobulbar palsy are a stiff, slow, spastic tongue (that is not wasted), dysarthria with a stiff, slow voice sounding dry and gravelly, and dysphagia. The gag and palatal reflexes are preserved. The jaw jerk is exaggerated. Emotional lability (inappropriate laughing or crying) often accompanies pseudobulbar palsy. Principal causes are:

- motor neurone disease - often both upper UMN and LMN lesions (i.e. elements of both pseudobulbar *and* bulbar palsy)
- multiple sclerosis, mainly as a late event
- cerebrovascular disease, typically in multi-infarct dementia
- following severe head injury.

Great difficulty swallowing, dysarthria and a slow tongue also develop in late stages of Parkinson's disease. This is distinct from both pseudobulbar and bulbar palsy.

MOTOR CONTROL SYSTEMS

There are three systems:

- The *corticospinal* (or pyramidal) system originates in the cerebral cortex and delivers information to spinal cord anterior horn cells. This system enables *purposive, skilled, intricate, strong* and *organized* movement to take place. Defective function is recognized by a distinct pattern of loss of skilled voluntary movement, spasticity and reflex change. This is seen, for example, in a hemiparesis or hemiplegia.
- The *extrapyramidal* system facilitates *fast, fluid* movements that the corticospinal system has generated. Defective function is recognized usually by slowness (bradykinesia), stiffness (rigidity) and/or disorders of movement (rest tremor, chorea and other dyskinesias). Frequently, one sign (e.g. stiffness, tremor or chorea) will predominate. Mixtures of these features, and lack of localized pathological anatomy makes classification difficult.
- The *cerebellum* and its connections have a role in coordinating smooth movement initiated by the corticospinal system, and in the regulation *of balance.* Cerebellar disease leads to unsteadiness and jerkiness of movement (ataxia), with characteristic physical signs of past pointing, action tremor and incoordination, with gait ataxia and/ or truncal ataxia.

Each of these three motor controllers also relies upon connections with the other two, and with sensory input, from proprioception, reticular formation, vestibular system and special senses.

CORTICOSPINAL OR PYRAMIDAL SYSTEM

The corticospinal tracts originate in neurones of the fifth cortical layer and terminate at motor nuclei of cranial nerves at the lower border of LI in spinal cord anterior horn cells. The nerve fibre pathways of particular clinical significance (Fig. 21.8) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral halves of the spinal cord as the lateral corticospinal tracts. This is the *pyramidal system,* disease of which causes upper motor neurone (UMN) lesions. *Pyramidal* is simply a descriptive term that draws together the anatomy and characteristic physical signs. It is used here interchangeably with the term UMN.

A small proportion of the corticospinal outflow remains uncrossed (the anterior corticospinal tracts) - this is of no relevance in practice.

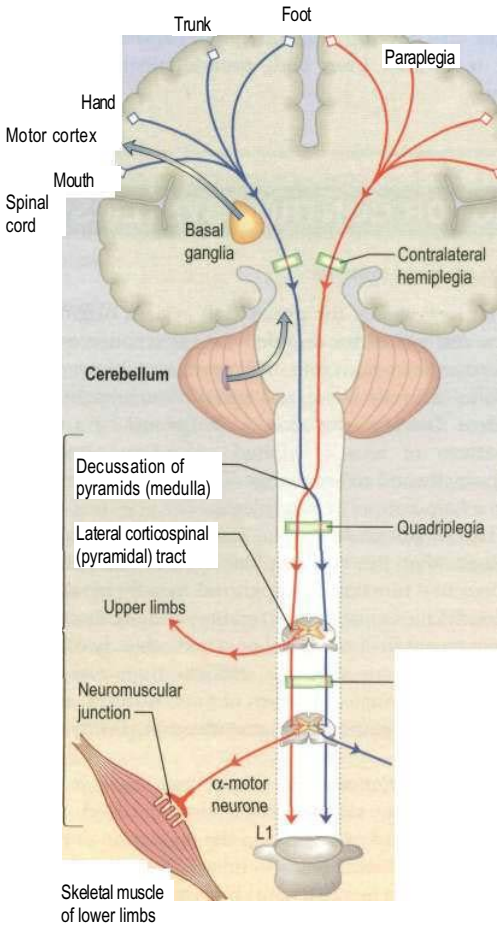

Fig. 21.8 **The motor system.** Lesions are shown on the right-hand side of the figure.

Characteristics of pyramidal lesions

(see Table 21.12)

Signs of an early pyramidal lesion may be minimal. Weakness, spasticity or changes in superficial reflexes may predominate. Absence of one group of signs does not exclude a UMN lesion.

Pyramidal drift of an upper limb

Normally, the outstretched upper limbs are held symmetrically, even when the eyes are closed. With a pyramidal (UMN) lesion, when both upper limbs are held outstretched, palms uppermost, the affected limb drifts downwards and medially. The forearm tends to pronate and the fingers flex slightly. This sign is often first to occur, sometimes before weakness or reflex changes become obvious.

Table 21.12 **Evidence of an upper motor neurone lesion**

Drift of upper limb
Weakness with a characteristic distribution
Increase in tone of spastic type
Exaggerated tendon reflexes
An extensor plantar response
Loss of fine finger/toe movements
Loss of abdominal reflexes
No muscle wasting
Normal electrical excitability of muscle

Weakness and loss of skilled movement

A unilateral pyramidal (UMN) lesion above the decussation in the medulla (e.g. an internal capsule infarct) causes weakness of the opposite limbs, i.e. contralateral hemiparesis. When acute and complete, this weakness will be immediate and dense - e.g. a hemiplegia following an internal capsule infarct. In slowly progressive lesions (e.g. a cortical glioma) a characteristic pattern of increasing weakness emerges in the hemiparetic limbs. In the upper limb flexors remain stronger than extensors, while in the lower limb extensors remain stronger than flexors. In the upper arm the weaker movements are thus shoulder abduction and elbow extension; in the forearm and hand, wrist and finger extensors and abductors are weaker than their antagonists.

In the lower limb weaker movements are hip flexion and abduction, knee flexion, and ankle dorsiflexion and eversion. In addition to weakness, there is loss of skilled movement. For example, fine finger and toe control diminishes. Muscle wasting (except from disuse) is not a feature of pyramidal lesions. Muscles remain normally excitable electrically.

When the UMN lesion is below the decussation of the pyramids, i.e. in the cervical spinal cord, the hemiparesis is on the same side as the lesion. This situation is unusual.

Increase in tone (spasticity)

An acute lesion of one pyramidal tract (e.g. the internal capsule stroke mentioned above) causes initially flaccid paralysis, and loss of tendon reflexes. Increase in tone follows within several days owing to loss of the inhibitory effect of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone affects all muscle groups on the side affected but is detectable most easily in stronger muscles. The pattern is characterized by *changing* resistance to passive movement - the sudden clasp-knife effect. The relevant tendon reflexes become exaggerated and clonus evident.

Changes in superficial reflexes

The normal flexor plantar response becomes extensor (a positive Babinski). In a severe lesion (e.g. the internal capsule infarct) this extensor response can be elicited from a wide area of the affected limb. As recovery progresses, the area that is receptive diminishes until only the posterior third of the lateral aspect of the sole is receptive. The stimulus should be unpleasant (an orange-stick is the correct instrument). An extensor plantar is certain when dorsiflexion of the great toe is accompanied by fanning (abduction) of adjacent toes. Abdominal (and cremasteric reflexes) are abolished on the affected side.

Clinical patterns of UMN disorders

There are two main patterns of UMN (pyramidal) lesions: hemiparesis and paraparesis.

Hemiparesis means a weakness of the limbs of one side; it is usually (but not always, see above) caused by a lesion within the brain. *Paraparesis* means weakness of both lower limbs and is characteristically diagnostic of a spinal cord lesion, though bilateral brain lesions occasionally can also cause a similar picture.

Hemiplegia and *paraplegia* strictly indicate total paralysis, but are often used loosely to describe severe weakness.

Hemiparesis

The level within the corticospinal tract is recognized by various accompanying features.

Motor cortex. Weakness and/ or loss of skilled movement confined to one contralateral limb (an arm or a leg - monoplegia) or part of a limb (e.g. a weak hand) is typical of an isolated motor cortex lesion (e.g. a secondary neoplasm). A defect in higher cortical function (e.g. aphasia) and focal epilepsy may occur.

Internal capsule. Since all corticospinal fibres become tightly packed as they reach the internal capsule, occupying about 1 cm^2, a small lesion causes a large deficit. For example, an infarct of a small branch of the middle cerebral artery (p. 1212) causes a sudden, dense, contralateral hemiplegia.

Pons. A pontine lesion (e.g. a plaque of multiple sclerosis) is rarely confined only to the corticospinal tract. Since adjacent structures such as the sixth and seventh nuclei, MLF and PPRF (p. 1184), are involved, there are other localizing signs - VI and VII nerve palsies, internuclear ophthalmoplegia (INO) or a lateral gaze palsy, with contralateral hemiparesis.

Spinal cord. An isolated lesion of a single lateral corticospinal tract within the spinal cord (e.g. an injury in the cervical region) causes an ipsilateral UMN lesion, the level indicated by changes in reflexes (e.g. absent biceps C5/6 jerk), presence of a Brown-Sequard syndrome (p. 1199) and muscle wasting at the level of the lesion (p. 1250).

Paraparesis (Table 21.13)

Paraparesis indicates bilateral damage to the corticospinal tracts. Spinal cord compression (p. 1250) or other cord disease is the usual cause, but cerebral lesions occasionally can produce paraparesis. Paraparesis is a feature of many neurological conditions, recognizable by additional features, making this differential diagnosis one of pivotal importance (see page 1250).

Table 21.13 **Causes of a spastic paraparesis**

Spinal lesions
Spinal cord compression (see Table 21.48)
Multiple sclerosis
Myelitis (e.g. varicella zoster virus)
Motor neurone disease
Subacute combined degeneration of the cord
Syringomyelia
Syphilis
Familial or sporadic paraparesis
Vascular disease of the cord
Non-metastatic manifestation of malignancy
Tropical spastic paraparesis (HTLV-1)
HIV-associated myelopathy
Cerebral lesions*
Parasagittal cortical lesions:
meningioma
venous sinus thrombosis
Hydrocephalus Multiple
cerebral infarction

*All are rare causes of a paraparesis
HTLV-1: human T-cell leukaemia virus

EXTRAPYRAMIDAL SYSTEM

The **extrapyramidal system is** a **general term** without an absolute definition for motor structures of the basal ganglia, i.e. corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus, substantia nigra and parts of the thalamus. In basal ganglia/ extrapyramidal disorders, either or both of two features become apparent in the limbs and axial muscles:

- reduction in speed, known as bradykinesia (slow movement) or akinesia (no movement), with muscle rigidity
- involuntary movements (e.g. tremor, chorea, hemiballismus, athetosis, dystonia).

Extrapyramidal disorders are classified broadly on clinical grounds into akinetic-rigid syndromes (p. 1227) in which poverty of movement predominates, and dyskinesias, in which there are various excessive involuntary movements (p. 1231).

The most common serious extrapyramidal disorder is Parkinson's disease.

Essential anatomy

The corpus striatum lies close **to the** substantia nigra, thalami and subthalamic nuclei. There are interconnections between these structures, cerebral cortex, cerebellum and reticular formation, cranial nerve nuclei (particularly vestibular) and spinal cord (Fig. 21.9).

Function and dysfunction

The overall function of this complex system is modulation of cortical motor activity by a series of servo loops, between cortex and basal ganglia (Fig. 21.9).

In many involuntary movement disorders there are substantial and specific changes in neurotransmitters (Table 21.14) rather than anatomical lesions discernable on imaging or at autopsy. The main neurotransmitters in

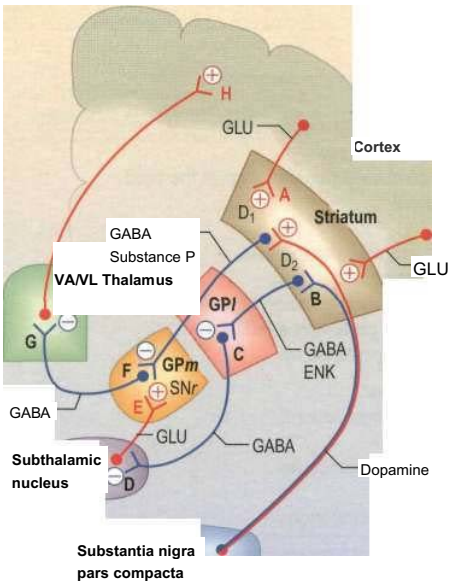

Fig. 21.9 **Extrapyramidal system: scheme of connections and neurotransmitters.** GLU, glutamate; ENK, enkephalin; GABA, gamma-aminobutyric acid; VA, ventral anterior; VL, ventrolateral; GP/, lateral globus pallidus; GPm, medial globus pallidus; SNr, substantia nigra pars reticulata.

Table 21.14 **Changes in the major neurotransmitter profile in Parkinson's and Huntington's diseases**

Condition	Site	Neurotransmitter
Parkinson's disease	Putamen	Dopamine 4 90%
		Norepinephrine (noradrenaline) 4 60%
		5-HT 4 *60%*
	Substantia nigra	Dopamine 4 90%
		GAD + GABA 44
	Cerebral cortex	GAD + GABA 44
Huntington's disease	Corpus striatum	Acetylcholine 44
		GABA 44 Dopamine: normal GAD + GABA 44

GABA, y-amino butyric acid; GAD, glutamic acid decarboxylase, the enzyme responsible for synthesizing GABA; 5-HT, 5-hydroxytryptamine

extrapyramidal pathways are outlined in Figure 21.9; changes in Parkinson's disease, chorea and hemiballismus are discussed below. The complexity of the situation is evident.

A proposed model of principal basal ganglia pathways

1. Direct pathway from striatum to medial globus pallidus (GPm) and substantia nigra pars reticulata (SNr). Inhibitory synapse F, GABA and substance P.
2. Indirect pathway from striatum to globus pallidus; via lateral globus pallidus (GP/; inhibitory synapse C, GABA, enkephalin) and subthalamic nucleus inhibitory synapse D, GABA). Terminates in GPm-SNr (in excitatory synapse E, glutamate).
3. Direct pathways, both inhibitory and excitatory from substantia nigra pars compacta (SNc) to striatum. Synapse A, dopamine, D_1, excitatory; and synapse B, D_2, inhibitory.
4. GPm and SNr to thalamus. Synapse G, GABA.
5. Thalamus to cortex. Excitatory, synapse H.
6. Cortex to striatum. Excitatory, glutamate.

The model helps explain how basal ganglia disease can either reduce excitatory thalamo-cortical activity at synapse H, i.e. movement - causing bradykinesia, or increase it, causing hyperkinesia.

Parkinson's disease. This condition is characterized by slowness, stiffness and rest tremor (p. 1227). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

Also in Parkinson's disease, in the indirect pathway dopamine deficiency results in disinhibition of neurones synapsing at C. This leads to reduced activity at D, and to increased activity of neurones in the subthalamic nucleus. There is excess stimulation at synapse E, enhancing further inhibitory output of GPm-SNr.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa used in Parkinson's disease (p. 1229) induces its *unwanted dyskinesias by increasing <&3p&n?ifi>?* activity at synapses A and B, reversing the sequences in both direct and indirect pathways.

Huntington's disease. This is an inherited dementia (p. 1231) with progressive jerky movements (chorea). Chorea results from damage to neurones (GABA, enkephalin) in the indirect pathway from striatum to GP/, reducing activity at synapse C. In turn, there is increased inhibition of subthalamic neurones at D, reduced stimulation at E and decreased inhibition of VA/VL at G. Cortical activity at H increases.

Hemiballismus. This describes wild, flinging limb movements usually caused by a small infarct in the subthalamic nucleus. This reduces excitatory activity at synapse E, causing reduction of inhibition at G with increased activity of thalamo-cortical neurones and increased activity at H.

CEREBELLUM

The third system of motor control modulates coordination, rather than speed. Ataxia, i.e. unsteadiness, is characteristic when it malfunctions.

The cerebellum receives afferent fibres from:

- proprioceptive receptors in joints and muscles
- vestibular nuclei
- basal ganglia
- the corticospinal system
- olivary nuclei.

Efferent fibres pass from the cerebellum to:

- each red nucleus
- vestibular nuclei
- basal ganglia
- corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

Cerebellar lesions

Expanding mass lesions within the cerebellum obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting and papilloedema. Coning of the cerebellar tonsils (p. 1245) through the foramen magnum and respiratory arrest occur, often within hours. Rarely, tonic seizures (sudden attacks of limb stiffness) occur.

Lateral cerebellar lobes

A lesion within one cerebellar lobe (e.g. a tumour or infarction) causes disruption of the normal sequence of movements (dyssynergia) on the same side. Ataxia and other signs develop.

Neurotransmitter changes in cerebellar disease are poorly understood.

Posture and gait. The outstretched arm is held still in the early stages of a cerebellar lesion (cf. the drift of a pyramidal lesion) but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic; the patient falters towards the lesion.

Tremor and ataxia. Movement is imprecise in direction, in force and in distance (dysmetria). Rapid alternating movements (tapping, clapping or rotary hand movements) are clumsy and disorganized (dysdiadochokinesis). Intention tremor (action tremor, with past-pointing) is seen. Speed of movement is preserved, cf. extrapyramidal disease. ■ . ■ ■ .

Nystagmus. Coarse horizontal nystagmus (p. 1189) develops with lateral cerebellar lobe lesions - the fast component towards the lesion.

Dysarthria. A halting, jerking dysarthria occurs - the scanning speech of cerebellar lesions (usually bilateral).

Other signs. Titubation - rhythmic head tremor in either to and fro ('yes-yes') movements or rotary ('no-no') movements - also occurs, mainly when cerebellar connections are involved (e.g. in essential tremor and MS, pp. 1231 and 1235). Hypotonia (floppy limbs) and depression of reflexes (and slow, pendular reflexes) are also sometimes seen with cerebellar disease, though of little value as localizing signs.

Table 21.15 **Principal causes of cerebellar lesions**

Tumours	Haemangioblastoma

	Ataxia telangiectasia
	Essential tremor
	Multiple sclerosis
Inherited	Hydrocephalus
	Postinfective cerebellar syndrome of childhood
	Hypothyroidism
	Non-metastatic manifestation of malignancy
Miscellaneous	Cerebral oedema of chronic hypoxia

Midline cerebellar lesions

Midline cerebellar vermis lesions have a dramatic effect on trunk and axial musculature—difficulty standing and sitting unsupported, with a rolling, broad, ataxic gait (truncal ataxia). Lesions of the flocculonodular region of the cerebellum cause vertigo, vomiting and gait ataxia if they extend to the roof of the fourth ventricle.

Table 21.15 summarizes the main causes of cerebellar disease.

TREMOR

Tremor means a regular and sinusoidal oscillation. Different varieties are outlined below. Pathological anatomy and neurotransmitter changes remain largely unknown.

Postural tremor

Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8-12 Hz. This is

increased with anxiety, caffeine, hyperthyroidism and certain drugs (sympathomimetics, sodium valproate, lithium) or in mercury poisoning. A coarser, postural tremor is seen in benign essential tremor (usually at 5-8 Hz) and in chronic alcohol abuse. Postural tremor does not worsen on movement, though it may become more obvious.

Intention tremor

Tremor exacerbated by action, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesis), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation and nystagmus may be present.

Rest tremor

This tremor occurs typically in Parkinson's disease, and is noticeably worst at rest, usually between 4 and 7 Hz - 'pill-rolling' between thumb and index finger.

Other tremors

Coarse tremor is seen following lesions of the red nucleus (e.g. infarction, demyelination) and rarely with frontal lobe lesions.

LOWER MOTOR NEURONE (LMN) LESIONS

The LMN is the motor pathway from anterior horn cell (or cranial nerve nucleus) via peripheral nerve to motor endplate.

The motor unit consists of a single anterior horn cell, the single fast-conducting motor nerve fibre that leaves the spinal cord via the anterior root, and the group of muscle fibres (100-2000) being supplied via the mixed peripheral nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- extrapyramidal system
- cerebellum
- afferent fibres from posterior roots.

Signs of lower motor neurone lesion

These are seen in voluntary muscles, which depend upon an intact nerve supply to produce movement *and* for metabolic integrity. Signs follow rapidly if the LMN is interrupted (Table 21.16). Muscle wasting appears within 3 weeks. Fasciculation (visible twitching) occurs - due to contractions of denervated single motor units. Fibrillation potentials are seen when denervated muscle is sampled electrically (p. 1203).

Causes

Examples of LMN lesions at various levels are:

- cranial nerve nuclei and anterior horn cell — Bell's palsy, motor neurone disease, poliomyelitis

***Table 21.16* Signs of a lower motor neurone lesion**

Weakness
Wasting
Hypotonia
Reflex loss
Fasciculation

Trophic' changes in skin and nails
long term effects

NB: Fibrillation potentials can be detected electromyographically, see page 1203.

- spinal root - cervical and lumbar disc protrusion, neuralgic amyotrophy (see p. 1264)
- peripheral (or cranial) nerve - nerve trauma or entrapment (see p. 1259), mononeuritis multiplex (p. 1260).

SPINAL REFLEX ARC

Components of the spinal reflex arc are illustrated in Figure 21.10. The stretch reflex is the physiological basis for all tendon reflexes. For example, in the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurones pass directly to LMNs (L3 and L4) that contract quadriceps.

Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (Table 21.17).

Reinforcement

Distraction of the patient's attention, clenching teeth or pulling interlocked fingers enhances reflex activity. Such

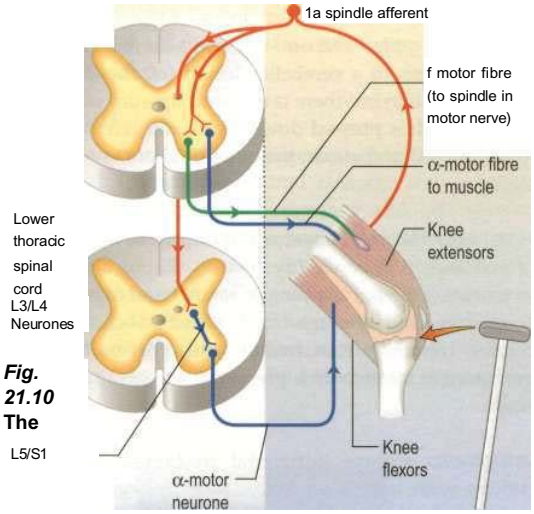

***Fig. 21.10* The knee jerk: a spinal reflex arc.** Sudden stretching of a tendon generates sensory action potentials in 1a muscle spindle afferents. These synapse with y motor fibres (to spindles) and a motor fibres. Motor action potentials generated cause muscle contraction. There is also inhibition of knee flexion.

Table 21.17 Spinal levels of tendon reflexes

Spinal level	Reflex

C5-6	Biceps
C7	Triceps
L3-4	Knee
S1	Ankle

reinforcement manoeuvres should be done before a reflex is recorded 'absent'.

SENSORY PATHWAYS AND PAIN

Peripheral nerves and spinal roots

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal root ganglia and thus to the cord. The sensory distribution of spinal roots (dermatomes) is shown in Figure 21.11.

Spinal cord (Fig. 2112)

Posterior columns

Axons in the posterior columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla carry the sensory modalities of vibration sense, joint position (proprioception), light touch and two-point discrimination. Axons from second-order neurones then cross the midline in the brainstem to form the medial lemniscus and pass to the thalamus.

ANTERIOR POSTERIOR

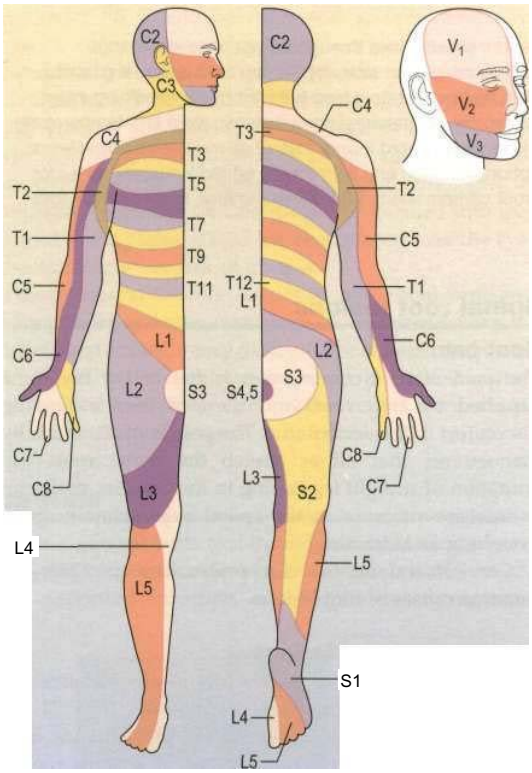

Fig. 21.11 **Dermatomes of spinal roots and ophthalmic (V_1), maxillary (V_2) and mandibular (V_3) divisions of the trigeminal nerve.**

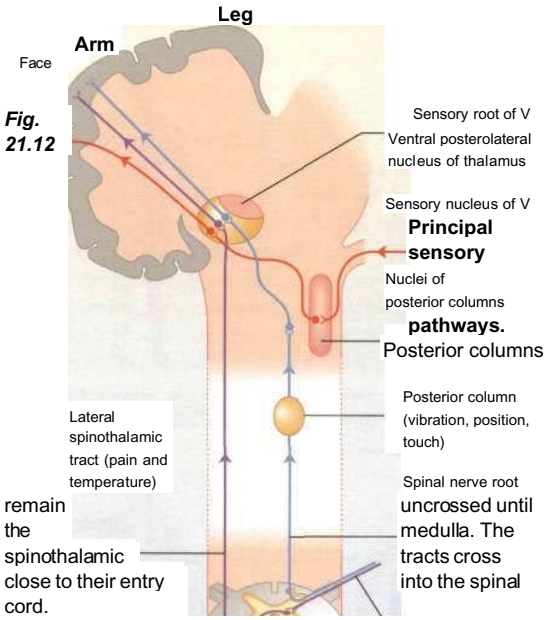

Fig. 21.12

remain uncrossed until the spinothalamic medulla. The tracts cross close to their entry into the spinal cord.

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross the cord and pass as the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

The projection of fibres from the thalamus to the sensory cortex of the parietal region is shown in Figure 21.12. Connections also exist between the thalamus and the motor cortex.

LESIONS OF THE SENSORY PATHWAYS

(Kg- 21.13^ _____ ^ ^

Altered sensation (paraesthesia), tingling, clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern usually suggests the site *of* pathology.

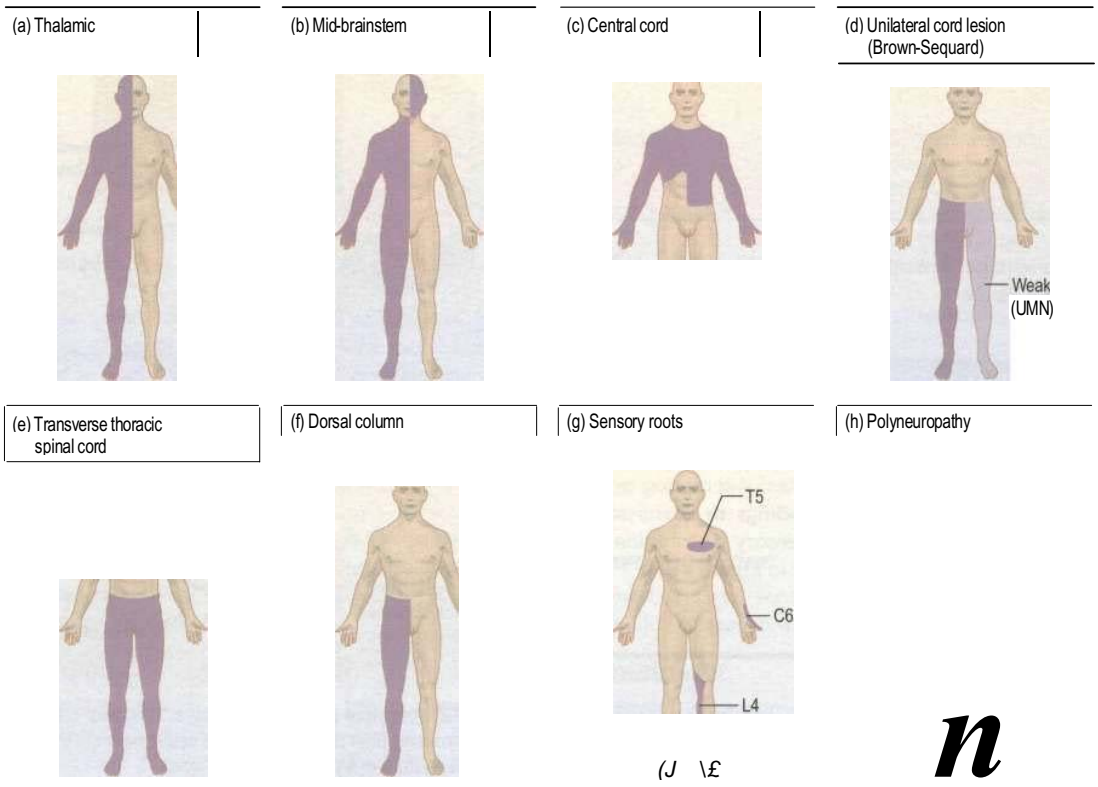

***Fig. 21.13* Principal patterns of loss of sensation, (a)** Thalamic lesion: sensory loss throughout opposite side (rare). (b) Brainstem lesion (rare): contralateral sensory loss below face and ipsiiateral loss on face, (c) Central cord lesion, e.g. syrinx: 'suspended' areas of loss, often asymmetrical and 'dissociated', i.e. pain and temperature loss but light touch remaining intact. (d) 'Hemisection' of cord or unilateral cord lesion = Brown-Sequard syndrome: contralateral spinothalamic (pain and temperature) loss with ipsiiateral weakness and dorsal column loss below lesion, (e) Transverse cord lesion: loss of all modalities below lesion. (f) Isolated dorsal column lesion, e.g. demyelination: loss of proprioception, vibration and light touch, (g) Individual sensory root lesions, e.g. C6 (cervical root compression), T5 (shingles), L4 (lumbar root compression), (h) Polyneuropathy: distal sensory loss.

Peripheral nerve lesions

Symptoms are felt in the distribution of the affected peripheral nerve (p. 1259).

Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (p. 1259) causes numb ness, pain and tingling. Tapping the site of compression sometimes causes a sharp, elecfric-shock-like pain in the distribution of the nerve, e.g. Tinel's sign in carpal tunnel syndrome (p. 1260).

Neuralgia

Neuralgia refers to local pain of great severity in the distribution of a damaged nerve. Examples are:

- trigeminal neuralgia (p. 1186)
- postherpetic neuralgia (p. 1240)
- complex regional pain syndrome type II (causalgia) - a chronic burning pain that occasionally follows nerve section (seen after amputation).

Spinal root lesions

Root pain

The pain of root compression is felt in the myotome supplied by that root, and there is also a tingling discomfort in the dermatome. The pain is made worse by manoeuvres that either stretch the nerve root (e.g. limitation of straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining).

Cervical and lumbar disc protrusions (p. 1265) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation in the appropriate dermatome (Fig. 21.11). However, the overlap with adjacent dermatomes may make it difficult to detect anaesthesia if a single root is destroyed.

Lightning pains. Tabes dorsalis (now rare in UK) is a form of neurosyphilis that causes low-grade inflam-

mation of dorsal roots and root entry zones in the spinal cord. Irregular, sharp, momentary stabbing pains (like lightning) involve one or two spots, typically in a calf, thigh or ankle.

Spinal cord lesions

Posterior column lesions

These cause:

- tingling
- electric-shock-like sensations
- clumsiness
- numbness
- band-like sensations.

These symptoms though lateralized are often felt vaguely without a clear sensory level. On examination, position sense, vibration sense, light touch and two-point discrimination are lost below the lesion. Loss of position sense produces the stamping gait of sensory ataxia (p. 1175).

Lhermitte's phenomenon

An electric-shock-like sensation radiates down the trunk and limbs when the neck is flexed. This indicates a cervical cord lesion. Lhermitte's sign is common in acute exacerbations of MS (p. 1253). It also occurs in cervical spondylotic myelopathy (p. 1264), subacute combined degeneration of the cord (p. 1263), radiation myelopathy (p. 1252), and occasionally in cord compression.

Spinothalamic tract lesions

Pure spinothalamic lesions cause isolated contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called *dissociated* sensory loss - pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central spinal cord (p. 1252).

The spinal level is modified by the lamination of fibres within the spinothalamic tracts. Fibres from the lower spinal roots lie superficially and are therefore damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g. a midthoracic extradural meningioma; Fig. 21.14) enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central lesion of the cord (e.g. a syrinx, p. 1252) affects deeper fibres first.

Spinothalamic tract lesions cause loss of pain and temperature perception (e.g. painless burns). Perforating ulcers and neuropathic joints (Charcot joints) develop.

Spinal cord compression (Fig. 21.14)

Cord compression causes a progressive spastic paraparesis (or tetraparesis/quadriparesis) with sensory loss below the level of compression. Sphincter disturbance is common.

Root pain is frequent but not invariable. It is felt characteristically at the level of compression. With thoracic cord compression (e.g. an extradural meningioma), pain radiates around the chest and is made worse by coughing and straining, as the meningeal root sheaths are stretched.

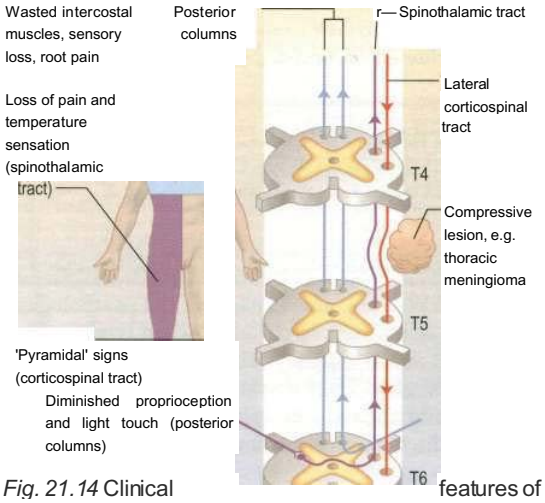

Fig. 21.14 Clinical features of spinal cord compression.

Involvement of one spinothalamic tract (contralateral loss of pain and temperature) with one corticospinal tract is known as the Brown-Sequard syndrome or hemisection of the cord. The patient complains of numbness on one side and weakness on the other. Paraparesis/spinal cord disease is discussed further on page 1250.

Pontine lesions

Since lesions in the pons (e.g. an MS plaque) lie above the decussation of the posterior columns, and the medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of III, IV, V, VI and VII cranial nerve nuclei are often also involved (Fig. 21.12) and indicate a level.

Thalamic lesions

Thalamic pain, also called thalamic syndrome, usually follows a small thalamic infarct. A patient has a stroke (hemiparesis and sensory loss). The weakness recovers partially or completely but there develops constant very severe deep-seated burning pain in the paretic limbs. This continues night and day. Extreme anguish is usual and the secondary depression may lead to suicide. Thalamic lesions may also produce loss of sensation on the opposite side of the body; this is a less usual clinical picture.

Parietal cortex lesions

Sensory loss, neglect of one side, apraxia (p. 1175) and subtle disorders of sensation occur. Pain is not a feature of

destructive cortical lesions. Irritative phenomena (e.g. partial sensory seizures from a glioma) arising in the parietal cortex cause tingling sensations in a limb, or elsewhere.

Donaghy M (1997) *Neurology - Oxford Core Texts.* Oxford: Oxford University Press.

PAIN

Pain is an unpleasant, unique physical and psychological experience. Acute pain serves a biological purpose (e.g. withdrawal) and is typically self-limiting, ceasing when healing is complete. There is sympathetic hypersensitivity. Some forms of chronic pain (e.g. causalgia, p. 1198) last many months, outlasting the time for healing.

Essential physiology of pain

Pain perception is mediated by free nerve endings, terminations of finely myelinated A-delta and of non-myelinated C fibres. Chemicals released following injury either produce pain by direct stimulation or by sensitizing nerve endings. A-delta fibres give rise to perception of sharp, immediate pain, followed by slower-onset, more diffuse and prolonged pain mediated by slower-conducting C fibres.

Sensory impulses enter the cord via dorsal spinal roots. Within it, impulses ascend either in each dorsal (posterior) column or in each spinothalamic tract. The grey matter neurones in the cord are arranged in laminae labelled I to X (dorsal to ventral). A fibres terminate in laminae I and V and excite second-order neurones which send fibres to the contralateral side via the anterior commissure and via the anterolateral column of the direct spinothalamic tract. C fibres mostly terminate in the *substantia gelatinosa* (laminae II and III). A series of short fibres give rise to long axons which pass through the anterior commissure to the contralateral side and up the spino-reticulo-thalamic tract.

The spinothalamic tracts carry impulses that localize pain. Thalamic pathways to and from the cortex mediate emotional components.

Sympathetic activity increases pain, e.g. hyperaemia in a painful limb.

The gate theory of pain

Gate theory, a useful way of thinking about pain, proposes that entry of afferent impulses is monitored first by the substantia gelatinosa. This gate determines whether or not sufficient activity penetrates to fire secondary neurones in the dorsal horn. This, and subsequent gates are influenced by brain and cord 'regulators' that alter how far a gate remains open.

Animal studies show that 'downstream regulatory elements' binding to calcium-regulated transcription factors control CNS endogenous opiate (endorphin) precursors (e.g. pro-dynorphin). These modulate pain.

Endogenous opiates

The endorphin peptides have opioid activity and probably account for placebo effects, the effects of stress, acupuncture and may explain in part why some patients develop 'chronic pain syndromes'. Endorphins are CNS neurotransmitters acting at inhibitory synapses via δ, κ and μ receptors. Dynorphin, from its precursor (above), is believed to modulate nociceptive (pain) impulses entering the spinal cord.

Management of chronic pain (see also p. 524)

Chronic pain is gravely disabling and distressing, and taxing to treat. Multidisciplinary pain-relief clinics are helpful in providing specific and supportive therapy. Pain control should, however, be part of all doctors' skills.

A management plan for intractable pain has seven components:

Diagnostic

Rigorous attention must be paid to the question of diagnosis, reviewing the history (first hand), investigations and radiology. A specific surgical approach may then become apparent (e.g. spinal stenosis, trigeminal neuralgia, glossopharyngeal neuralgia, or syringomyelia).

Psychological

Chronic pain influences quality of life. Depression (p. 1288) is commonly associated with pain when the pathology is benign and antidepressant drugs help. Only a third of patients suffering pain from secondary cancer are clinically depressed, despite the gravity of their disease.

Analgesics (see p. 549)

Perseverance and compliance with therapy is an invariable issue. The WHO analgesic ladder is useful for management of chronic pain.

Co-analgesics

Co-analgesics have a primary use other than for pain but also help either alone or added to analgesics. Examples are tricyclic antidepressants and anticonvulsants (p. 525). Calcium-channel blockers (nifedipine) improve sympathetically mediated pain in, for example, Raynaud's disease. Muscle relaxants (spasticity), antibiotics (infection) and steroids (inflammatory arthropathy) each reduce pain in appropriate situations.

Stimulation

Acupuncture, ice, heat, ultrasound, massage, transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation all achieve analgesia by a gating effect on large myelinated nerve fibres.

Nerve blocks

Pain pathways can be blocked either temporarily by local anaesthetic or permanently with phenol, or radiofrequency lesions:

- somatic blocks:
  (a) peripheral nerve and plexus injections
  (b) epidural and spinal analgesia
- sympathetic blocks:
  (a) sympathetic ganglia and nerve ending injections
  (b) central epidural and spinal sympathetic blockade.

Neurosurgery

Highly specialized and sometimes controversial techniques have a place alongside pharmacological remedies. Examples are dorsal rhizotomy, sympathectomy, cordotomy and neurostimulation.

CONTROL OF THE BLADDER AND SEXUAL FUNCTION

Changes in micturition and failure of normal sexual activity are diagnostic symptoms in sacral, spinal cord and cortical disease.

Essential anatomy and function

The three efferent LMN pathways to the bladder are shown in Table 21.18.

Afferent fibres (T12-S4) record changes in pressure within the bladder and tactile sensation in the genitalia. When the bladder is distended, continence is maintained by reflex suppression of the parasympathetic outflow, and reciprocal activation of the sympathetic, both being subject to cortical (voluntary) control. Voiding takes place by parasympathetic activation of the detrusor muscle, and relaxation of the internal sphincter.

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

Table 21.18 **The three efferent pathways to the bladder and genitalia**

Nerve supply	Function
Sympathetic	Bladder wall relaxation
T12-L2	Internal sphincter contraction Orgasm, ejaculation
Parasympathetic	Bladder wall contraction
S2-4	Internal sphincter relaxation Penis and clitoris erection/ engorgement
Pudendal nerves (somatic)	External sphincter (skeletal muscle)

Disorders of micturition: incontinence

All **three neurological patterns of bladder dysfunction** cause urinary incontinence. These may be hard to separate clinically.

Cortical:

- Frontal lesions cause socially inappropriate micturition.
- Pre-central lesions cause difficulty initiating micturition.
- Post-central lesions cause loss of sense of bladder fullness.

Spinal cord. Bilateral UMN lesions (pyramidal tracts) cause frequency of micturition and incontinence. The bladder is small and unusually sensitive to small changes in intravesical pressure (hypertonic bladder). Frontal lobe lesions also sometimes cause a hypertonic bladder.

Lower motor neurone. Sacral lesions (conus medullaris, sacral roots and pelvic nerve lesions - must be bilateral) cause a flaccid, atonic bladder, that overflows unexpectedly.

Male erectile dysfunction

Failure of **penile** erection **often has a mixed** aetiology, i.e. an organic and psychological cause. Depression is a common cause and a common effect. Endocrine aspects of sexual dysfunction are discussed on page 1055. Erectile dysfunction is treated with phosphodiesterase type 5 inhibitors, e.g. sildenafil by mouth.

NEUROLOGICAL INVESTIGATION!

NEURORADIOLOGY

Skull and spinal X-rays

These show:

- fractures of the skull vault or base
- skull lesions (e.g. metastases, osteomyelitis, Paget's disease, abnormal skull foramina, fibrous dysplasia)
- enlargement or destruction of the pituitary fossa - intrasellar tumour, raised intracranial pressure
- intracranial calcification - tuberculoma, oligodendroglioma, wall of **an** aneurysm, cysticercosis.

Spinal X-rays show fractures, congenital bone lesions (e.g. cysts), destructive lesions (infection, metastasis) or spondylosis (degenerative change).

Imaging of the brain and spinal cord

Brain CT is now widely available world-wide and MRI is rapidly becoming a standard test.

Computed tomography: CT

A collimated X-ray beam moves synchronously across a slice of brain between 2 mm and 13 mm thick. Transmitted X-irradiation from a pixel, an element < 1 mm^2, is computer-processed and a Hounsfield number assigned to its density (air = -1000 units; water = 0; bone = +1000 units).

Differences in attenuation (density) between bone, brain and CSF enable recognition of normal and infarcted tissue, tumour, extravasated blood, and oedema.

Enhancement with i.v. contrast media delineates areas of increased blood supply.

Contrast CT imaging of the spinal cord (myelography) and cerebral ventricles (ventriculography) is occasionally performed.

CT is safe apart from occasional systemic reactions to contrast; the irradiation involved is small.

Value of CT

CT scanning demonstrates:

- cerebral tumours
- intracerebral haemorrhage (see p. 1217) and infarction
- subdural and extradural haematoma
- free blood in the subarachnoid space (subarachnoid haemorrhage, see p. 1218)
- lateral shift of midline structures and displacement/ enlargement of the ventricular system
- cerebral atrophy
- spinal trauma (with CT myelography)
- skull and scalp lesions.

CT imaging, within its limitations, shows that the brain is anatomically normal, and gives reassurance.

Limitations of CT

- Lesions under 1 cm diameter may be missed.
- Lesions with attenuation close to that of bone may be missed if near the skull.
- Lesions with attenuation similar to that of brain are poorly imaged (e.g. MS plaques, isodense subdural haematoma).
- CT sometimes misses lesions within the posterior fossa.
- The spinal cord is not imaged directly by CT (contrast is necessary).
- Cooperation is required - a general anaesthetic is occasionally needed.

Magnetic resonance imaging: MRI

The hydrogen nucleus is a proton whose electrical charge creates a local electrical field. These protons are aligned by sudden strong magnetic impulses. Protons are then imaged with radiofrequency waves at right angles to their alignment. The protons resonate and spin, then revert to their normal alignment. As they do so, images are made at different phases of relaxation, known as Tl, T2, T2 'STIR', diffusion-weighted imaging (DWI) and other sequences. From these sequences, referred to as different weightings, recorded images are compared. Gadolinium is used as an intravenous contrast medium. :

Advantages of MRI

- MR distinguishes between brain white and grey matter.
- Spinal cord and nerve roots are imaged directly.
- Pituitary imaging.
- MRI has greater resolution than CT (around 0.5 cm).
- No radiation is involved.
- Magnetic resonance angiography (MRA) images blood vessels without contrast.
- It is useful in muscle disease, e.g. myositis. ■ -

Tumours, infarction, haemorrhage, clot, MS plaques, posterior fossa, foramen magnum and spinal cord are demonstrated well on MRI.

Limitations of MRI are principally time and cost. Imaging one region takes about 20 minutes. Patients do need to cooperate. Claustrophobia is an issue but 'open' machines are available. A general anaesthetic may be necessary. Patients with pacemakers or with metallic bodies in the brain cannot be imaged. MR imaging for some days after lumbar puncture (p. 1204) frequently shows diffuse meningeal enhancement with gadolinium.

Doppler studies

B-mode and colour ultrasound are valuable in the detection of stenosis of the carotid arteries.

Digital cerebral and spinal angiography

In many centres where advanced MRI is available, these techniques are little used. Contrast is injected intra-arterially or intravenously. These studies carry a mortality and risk of stroke (<1%). Sequences of the aorta, carotid and vertebral arteries demonstrate occlusion, stenoses, atheroma and aneurysms. Spinal angiography images cord arteriovenous malformations.

Isotope bone scanning

[^{99m}Tc]-pertechnetate is injected intravenously, it is of value in detection of vertebral and skull lesions (e.g. metastases). ..._, .. :;. ;

Positron emission tomography (PET) and single proton emission computed tomography (SPECT)

These techniques image function more than anatomy by tracking the uptake and metabolism of radioisotopes.

chiefly to confirm previous retrobulbar neuritis (p. 1181), which leaves a permanently delayed latency despite clinical recovery.

Similar techniques exist for auditory and somatosensory potentials (from a limb) and are also used to monitor brain and cord during neurosurgery.

Examination of the cerebrospinal fluid

(CSF) (TableZUgand_Practical box 213)

Indications for lumbar puncture (LP) are:

- diagnosis of meningitis and encephalitis
- diagnosis of subarachnoid haemorrhage (sometimes)
- measurement of CSF pressure, e.g. idiopathic intracranial hypertension (p. 1246)
- removal of CSF therapeutically, e.g. idiopathic intracranial hypertension
- diagnosis of miscellaneous conditions, e.g. MS, neurosyphilis, sarcoidosis, Behget's disease, neoplastic involvement, polyneuropathies
- intrathecal injection of contrast media and drugs.

Meticulous attention should focus on microbiology in suspected CNS infection. Close liaison between clinician and microbiologist is essential. Specific techniques (e.g. polymerase chain reaction to identify bacteria) can be invaluable. Repeated CSF examination is often necessary in chronic infections, such as TB. Headache, worse on standing is a common complaint for several days (or more) following LP. Prolonged post-LP headaches can be treated by an autologous intrathecal 'blood patch' - injection of 20 mL of the patient's venous blood.

Table 21.19 **The normal CSF**

Appearance	Crystal clear, colourless
Pressure	60-150 mm of H_2O with patient recumbent
Cell count	< 5/mm^3 No polymorphs Mononuclear cells only
Protein	0.2-0.4 g/L
Glucose	% to V_2 of blood glucose
IgG	< 15% of total CSF protein
Oligoclonal bands	Absent

Serpell MG, Rawal N (2000) Headaches after diagnostic dura! punctures. *British Medical Journal* 321: 973-974.

Biopsy

Interpretation of brain, muscle and nerve histology requires a specialist neuropathology service.

Practical Box 21.3 Lumbar puncture

Lumbar puncture should *not* be performed in the presence of raised intracranial pressure or when an intracranial mass lesion is a possibility. The procedure should be explained carefully to the patient, and consent obtained.

Technique

- The patient is placed on the edge of the bed in the left lateral position with the knees and chin as close together as possible.
- The third and fourth lumbar spines are marked. The fourth lumbar spine usually lies on a line joining the iliac crests.
- Using sterile precautions, 2% lidocaine (lignocaine) is injected into the dermis by raising a bleb in either the third or fourth lumbar interspace.

B The special lumbar puncture needle is pushed through the skin in the midline. It is pressed steadily forwards and slightly towards the head, with the head and spine bolstered horizontally with pillows.

H When the needle is felt to penetrate the dura mater, the stylet is withdrawn and a few drops of CSF are allowed to escape.

- The CSF pressure can now be measured by connecting a manometer to the needle. The patient's head must be on the same level as the sacrum. Normal CSF pressure is 60-150 mmH_20. It rises and falls with respiration and the heart beat, and rises on coughing.
- Specimens of CSF are collected in three sterilized test-tubes and sent to the laboratory. An additional sample in which the sugar level can be measured, together with a simultaneous blood sample for blood sugar measurement, should be taken when relevant (e.g. in meningitis).
- Record the naked-eye appearance of the CSF: clear, cloudy, yellow (xanthochromic), red.

* Patients are usually asked to lie flat after the procedure to avoid a subsequent headache, but this manoeuvre is probably of little value.

- Analgesics may be required for post-LP headaches.

Contraindications for lumbar puncture

- Suspicion of a mass lesion in the brain or spinal cord. Caudal herniation of the cerebellar tonsils ('coning') may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF.
  Any cause of raised intracranial pressure. Local infection near the site of puncture. Congenital lesions in the lumbosacral region (e.g. meningomyelocele).
  Platelet count below 40 x 10^9/L and other clotting abnormalities, including anticoagulant drugs.
  Unconscious patients and those with papilloedema must have a CT scan before lumbar puncture.

Notes

These contraindications are relative. There are circumstances when lumbar puncture is carried out in spite of them.

The composition of the normal CSF is shown in Table 21.19.

Brain

Brain biopsy (e.g. of a non-dominant frontal lobe) is sometimes used to diagnose inflammatory and degenerative brain diseases. CT- and MR-guided stereotactic biopsy of intracranial mass lesions are now standard procedures.

Muscle

Biopsy, with light microscopy, electron microscopy and biochemical analysis where appropriate, elucidates diagnosis of inflammatory, metabolic and dystrophic disorders of muscle (p. 1267).

Peripheral nerve

Biopsy, usually of one sural nerve (ankle) or superficial branch of a radial nerve aids diagnosis in polyneuropathies (e.g. vasculitis).

Psychometric assessment

Psychometric testing is valuable for measuring cognitive function. Preservation of verbal IQ (a measure of past attainments) in the presence of deterioration of performance IQ (a measure of present abilities) is an indicator of decline of cognitive function, for example following brain injury or in dementia. Low subtest scores (e.g. for block design, various aspects of memory, visual, speech and constructional skills) indicate impaired function of specific brain regions.

The main limitation is that depression and lack of attention also reduce scores. Also, opinions sometimes vary greatly between clinical psychologists about interpretation of agreed numerical values of tests, particularly after brain injury - thus limiting the clinical value of the tests.

Routine tests

See Table 21.20.

Table 21.20 Value of routine investigations in neurology

Test	Yield	Condition
Urinalysis	Glycosuria	Polyneuropathy
	Ketones Bence	Coma
	Jones protein	Cord compression
Blood picture	TMCV	B_{12} deficiency
	TESR	Giant cell arteritis
Blood glucose	Hypoglycaemia	Coma
	Hyperglycaemia	Coma
Serum electrolytes	Hyponatraemia	Coma
	Hypokalaemia	Weakness
Serum calcium	Hypocalcaemia	Tetany, spasms
Serum creatine phosphokinase	Raised	Muscle disease
Chest X-ray	Lytic bone or mass lesion	Bronchial cancer, thymoma

Specialized tests in specific diseases

Certain tests are employed in the diagnosis of individual (and often rare) neurological diseases. Examples

anticardiolipin and lupus anticoagulant antibody and detailed clotting studies in stroke (p. 534)
antibody to acetylcholine receptor protein in myasthenia gravis (p. 1269)
serum copper and caeruloplasmin in Wilson's disease (p. 387)
blood lactate studies (failure to rise on exercise) in McArdle's syndrome (p. 1144)
serum phytanic acid (elevated) in Refsum's disease (p. 1262)
serum long-chain fatty acid (present) in adrenoleucodystrophy (p. 1235)
genetic studies - e.g. Huntington's disease, hereditary sensorimotor neuropathies (p. 1263).

UNCONSCIOUSNESS AND COMA

The central ascending reticular formation (or reticular activating substance), extending from lower brainstem to thalamus, influences the state of arousal. Our state of consciousness is the product of complex interactions between parts of the reticular formation itself, cortex and brainstem, and all sensory stimuli.

Disturbed consciousness: definitions

Each term simply describes a *recognizable* state, either normal or pathological.

- **Consciousness** means a state of wakefulness with awareness of self and surroundings.
- **Clouding of consciousness** - used more in psychiatry than neurology - means reduced wakefulness and/or self-awareness, sometimes with confusion.
- **Confusion** means altered consciousness - the subject is bewildered and misinterprets his/her surroundings.
- **Delirium** is a state of high arousal (typically *delirium tremens,* p. 1309). There is confusion and often visual hallucination.
- **Sleep** is *normal* mental and physical inactivity from which the subject can be roused.
- **Stupor** is an *abnormal,* sleepy state from which the subject can be aroused by vigorously or repeated stimuli - also used for various psychiatric states, e.g. catatonic and depressive stupor (p. 1307).
- **Coma** means unrousable unresponsiveness. The Glasgow Coma Scale for head injury is shown in Table 21.21.

Table 21.21 Glasgow Coma Scale

	Score		Score
Eye opening (E)		**Verbal response (V)**	
Spontaneous	4	Orientated	5
To speech	3	Confused conversation	4
To pain	2	Inappropriate words	3
No response	1	Incomprehensible sounds	2
		No response	1
Motor response	*M*		
Obeys	6		
Localizes	5		
Withdraws	4		
Flexion	3		
Extension	2		
No response	1		

Glasgow Coma Scale = *E* + *M* + *V*
(QCS minimum = 3: maximum = 15)

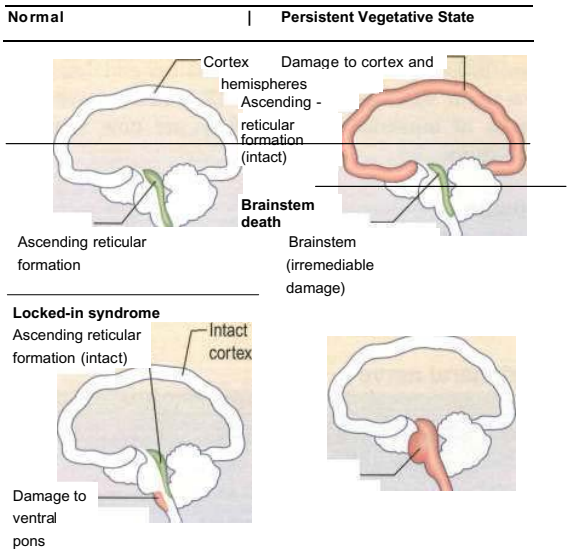

Fig. 21.17 **Basic anatomy of altered consciousness.** Adapted from Bates D Coma and brainstem death *Medicine* 2000; **28:7:** 65-70 with kind permission of the Medicine Publishing Company.

Mechanisms of coma

Altered consciousness is produced by three mechanisms affecting brainstem, reticular formation and cerebral cortex.

- *Diffuse brain dysfunction.* Generalized severe metabolic or toxic disorders (e.g. alcohol abuse, sedative drugs, uraemia and septicaemia) depress/inhibit overall brain function.
- *Direct effect within the brainstem.* A lesion within the brainstem itself damages/inhibits the reticular activating system.
- *Pressure effect on the brainstem. A* mass lesion within the brain compresses the brainstem, inhibiting the ascending reticular activating system.

A single focal hemisphere (or cerebellar) lesion does not produce coma unless it compresses or damages the brainstem. Oedema frequently surrounds masses, contributing to their effects.

Other states of unresponsiveness must be distinguished from coma; this sometimes causes difficulty. The features of these are shown in Table 21.22 and illustrated in Figure 21.17.

Differential diagnosis of the vegetative state

Vegetative state (VS) is a sequel of, for example, widespread cortical damage after head injury. Brainstem function is normal. VS implies loss of sentient behaviour. The patient perceives little or nothing but lies apparently awake, breathing spontaneously. *Minimally conscious state* (MCS) describes patients with *some* sentient behaviour, e.g. apparent, vague, pain perception. A patient may emerge from VS into MCS. *Locked-in syndrome* is a state of unresponsiveness due to massive brainstem damage below the level of the third nerve nuclei. The patient has a functioning cerebral cortex and is thus unlike a PVS patient, *fully aware* but cannot move or communicate except by vertical eye movement.

- *Brainstem death* is discussed on page 989.

Distinction between these states is essential before addressing major issues of prognosis, quality of life, and cessation of supportive care.

Unresponsiveness of psychological origin is also a cause of apparent coma.

Causes

Principal causes of coma and stupor are in Table 21.23. A common cause of coma in the UK is self-poisoning. World-wide, cerebral malaria is a frequent cause of coma.

THE UNCONSCIOUS PATIENT

Immediate assessment

Actions that take seconds save lives (Table 21.24).

Get a history from witnesses, paramedics or police. Many people on corticosteroids, with diabetes, epilepsy or hypoadrenalism, carry identification.

Further examination

- Record depth of coma (Table 21.21).
- Full general and neurological examination.

General examination

Many clues point to the cause.

Temperature

Body temperature is raised in infection and hyperpyrexia, and subnormal in hypothermia.

Table 21.22 **Differential diagnosis of the vegetative state**

Condition	Vegetative state	Minimally conscious state	Locked-in syndrome	Coma	Death confirmed by brainstem tests
Awareness	Absent	Present	Present	Absent	Absent
Sleep-wake cycle	Present	Present	Present	Absent	Absent
Response to noxious stimuli	±	Present	Present (in eyes only)	±	Absent
Glasgow Coma Scale score	E4, M1-4, V1-2	E4, M1-5, V1-4	E4, M1.V1	E1-2, M1-4, V1-2	E1.M1-3, V1
Motor function	No purposeful movement	Some consistent or inconsistent verbal or purposeful motor behaviour	Volitional vertical eye movements or eyeblink preserved	No purposeful movement	None or only reflex spinal movement
Respiratory function	Typically preserved	Typically preserved	Typically preserved	Variable	Absent
EEG activity	Typically slow wave activity	Insufficient data	Typically normal	Typically slow wave activity	Typically absent
Cerebral metabolism (PET)	Severely reduced	Insufficient data	Mildly reduced	Moderately to severely reduced	Severely reduced or absent
Prognosis	Variable: if permanent, continued vegetative state or death	Variable	Depends on cause but full recovery unlikely	Recovery, vegetative state, or death within weeks	Already dead

NB: EEG and measures of cerebral metabolism are not *required* to make these clinical diagnoses
EEG, electroencephalography; PET, positron emission tomography
From: The vegetative state: guidance on diagnosis and management. *Clinical Medicine* 2003 3: 251, with permission from Elsevier.

Table 21.23 **Examples of mechanisms of principal causes of coma**

Diffuse brain dysfunction
Drug overdose, alcohol abuse
CO poisoning, anaesthetic gases
Hypoglycaemia, hyperglycaemia
Hypoxic/ischaemic brain injury
Hypertensive encephalopathy (p. 859)
Severe uraemia (p. 699)
Hepatocellular failure (p. 368)
Respiratory failure with CO_2 retention (p. 902)
Hypercalcaemia, hypocalcaemia
Hypoadrenalism, hypopituitarism and hypothyroidism (Ch. 18)
Hyponatraemia, hypernatraemia Metabolic acidosis Hypothermia, hyperpyrexia Trauma (following closed head injury) Epilepsy (following a generalized seizure) Encephalitis, cerebral malaria, septicaemia Subarachnoid haemorrhage Metabolic rarities (e.g. porphyria)
Cerebral oedema from chronic hypoxia (p. 980)
Direct effect within brainstem Brainstem haemorrhage or infarction Brainstem neoplasm (e.g. glioma) Brainstem demyelination Wernicke-Korsakoff syndrome Trauma
Pressure effect on brainstem Hemisphere tumour, infarction, abscess, haematoma, encephalitis or trauma
Cerebellar mass lesions

Table 21.24 **The unconscious patient: immediate actions**

Examine	Findings	Potential action
Airway	Clear?	Maintain; intubate?
Pulse	Absent?	Cardiopulmonary resuscitation
Pupils	Fixed, dilated?	
Head	Trauma	Observe and investigate
Spinal	Trauma	Immobilize

Skin and skull

Look for cyanosis, jaundice, purpura, rashes, pigmentation, injection marks, trauma. Skin is coarse and dry in hypothyroidism.

Breath

Sniff - for ketones, alcohol, hepatic and uraemic fetor.

Respiration

Depressed but regular respiration occurs in many states of stupor and light coma. As coma deepens, and in normal deep sleep, respiration becomes irregular. *Patterns* of abnormal respiration are of importance:

- *Cheyne-Stokes (periodic) respiration* is alternating hyperpnoea and apnoea. In brain disease this points to bilateral cerebral dysfunction, usually deep in the hemispheres or in the upper brainstem. This pattern, a sign of incipient coning — also occurs slightly in some normal people during sleep, in metabolic comas, with CO_2 retention, and chronic hypoxia at high altitude.

Kussmaul (acidotic) respiration is deep, sighing hyperventilation seen in diabetic ketoacidosis and uraemia.

- *Central neurogenic (pontine) hyperventilation* describes sustained, rapid, deep breathing seen with pontine lesions. It may switch abruptly on and off.
- *Ataxic respiration* is shallow, halting, irregular respiration. It frequently precedes death. The medullary respiratory centre is damaged.
- *Vomiting, hiccup and excessive yawning* sometimes indicate a lower brainstem lesion in stupor.

Neurological examination in coma

Head, neck and spine

Note trauma, skull burr-holes and bruits, neck stiffness.

Pupils

Record size and reaction to light.

- *Dilatation of one pupil* that becomes fixed to light, indicates compression of the third nerve as the temporal lobe uncus herniates (coning). This is a neurosurgical emergency (e.g. an extradural haematoma).
- *Homer's syndrome* (ipsilateral pupillary constriction and ptosis, p. 1183) occurs with hypothalamic damage and also, rarely, in coning.
- *Bilateral mid-point reactive pupils* (i.e. normal pupils) are characteristic of metabolic comas and following most CNS-depressant drugs except opiates.
- *Bilateral light-fixed, dilated pupils* are a cardinal sign of brainstem death. They also occur in deep coma of any cause, but particularly in coma due to barbiturate intoxication or hypothermia.
- *Bilateral pinpoint,* light-fixed pupils occur with pontine lesions (e.g. a pontine haemorrhage) that interrupt sympathetic pathways, and with opiate drugs.
- *Bilateral mid-position light-fixed or slightly dilated light-fixed pupils* (4-6 mm), which are sometimes irregular, are seen when brainstem damage interrupts the light reflex.

Mydriatic drugs can confuse diagnosis (see also p. 1004). Previous pupillary surgery can also cause diagnostic difficulty.

Fundi

Look for papilloedema and retinal haemorrhage.

Ocular movements

The ocular axes are usually slightly divergent in coma. In light coma, slow, roving, side-to-side eye movements are seen.

Vestibulo-ocular reflexes. Passive head turning produces conjugate ocular deviation away from the direction of rotation (doll's head reflex). This reflex disappears in very deep coma and is absent in brainstem lesions, and thus in brainstem death. Its real value in coma is somewhat limited.

Calorics. Slow tonic ocular deviation towards the irrigated ear is seen when ice-cold water is run into the external auditory meatus - the caloric or vestibulo-ocular reflex. This indicates an intact brainstem. The test is used in the diagnosis of brainstem death (p. 989).

Abnormalities of conjugate gaze (p. 1183):

- *Sustained conjugate lateral deviation* occurs towards a destructive frontal lesion ('eyes look towards normal limbs'). Rarely, an irritative lesion in one frontal lobe (e.g. an epileptic focus from a glioma) 'drives the eyes away', so conjugate deviation is away from that side. In a pontine, brainstem lesion, when one paramedian pontine reticular formulation (PPRF) itself is damaged (p. 1184), sustained conjugate lateral deviation occurs away from the lesion, towards the paralysed limbs, because the opposite PPRF is active.
- *Skew deviation* (one eye deviated up and the other down) indicates a brainstem or cerebellar lesion.
- *Ocular bobbing* describes sudden, brisk, downward-diving eye movements seen in pontine (or cerebellar) haemorrhage.

Other spontaneous eye movements (other than roving eye movements) are distinctly unusual in true coma.

Lateralizing signs. Coma makes it difficult to recognize focal signs. The following are helpful:

- *Response to visual threat* in a stuporose patient. Asymmetry suggests hemianopia.
- *Facial appearance.* Drooping of one side, unilateral dribbling, or blowing in and out of the paralysed cheek.
- *Tone.* Unilateral flaccidity or spasticity may be the only sign of hemiparesis.
- *Asymmetrical response to painful stimuli.*

m *Asymmetry of plantar responses.* Both are often extensor in deep coma of any cause.

- *Asymmetry of tendon reflexes.*

m *Asymmetry of decerebrate and decorticate posturing.*

Investigations

Often, the cause for coma becomes evident (e.g. head injury, cerebral haemorrhage, self-poisoning). If the explanation remains unclear, further investigations are needed.

Blood and urine

m *Drugs screen* (e.g. salicylates, diazepam, narcotics, amfetamines)

- *Routine biochemistry* (urea, electrolytes, glucose, calcium, liver biochemistry)
- *Metabolic and endocrine studies* (TSH, serum cortisol)
- *Blood cultures*

m *Rarities,* such as cerebral malaria (thick blood film) or porphyria, are often forgotten.

Imaging

CT or MR brain imaging may indicate an otherwise unsuspected mass lesion or intracranial haemorrhage.

CSF *examination*

Lumbar puncture should be performed in coma only after careful risk assessment. It is usually contraindicated when an intracranial mass lesion is a possibility. CT is necessary to exclude this. CSF examination is likely to alter therapy only if undiagnosed meningoencephalitis or other identifiable infection is present.

Electroencephalography

EEG is of some value in the diagnosis of metabolic coma and encephalitis.

Management

Comatose or stuporose patients - be they at home or outside, on an A&E trolley, in a general ward, or ITU - need immediate careful nursing, meticulous attention to the airway, and frequent monitoring of vital functions. Longer-term requirements are:

- skin care - turning, removal of jewellery, avoidance of pressure sores and pressure palsies
- oral hygiene - mouth washes, suction
- eye care - taping of lids, prevention of corneal damage, irrigation
- fluids - intragastric or i.v. fluids
- calories - liquid diet through a fine intragastric tube, 1255 kj (3000 kcal) daily
- sphincters - catheterization only when essential (Paul's tubing if possible); avoid constipation (evacuate rectum).

FURTHER READING

Royal College of Physician's Working Party Report (2003) The vegetative state: guidance on diagnosis and management. *Clinical Medicine* 3: 249-254.

CEREBROVASCULAR DISEASE AND STROKE

Stroke is the third commonest cause of death in developed countries. The age-adjusted annual death rate from strokes is 116 per 100 000 population in the USA and some 200 per 100 000 in the UK, some 12% of all deaths. It is higher in black African populations than in Caucasian. Stroke is uncommon below the age of 40 and is more common in males. Death rate following stroke is around 25%. Hypertension is the most treatable risk factor. Stroke is decreasing in the 40-60 age range as hypertension is treated. In the elderly, it remains a major cause of mor bidity and mortality. Thromboembolic infarction (80%), cerebral and cerebellar haemorrhage (10%) and sub-arachnoid haemorrhage (about 5%) are the major cerebro-vascular problems. ...■. ^

Definitions

These, though valuable clinically, are arbitrary:

- Stroke. To the public, stroke means weakness, either permanent or transient on one side, often with loss of speech. Stroke is *defined* as the clinical syndrome of rapid onset of cerebral deficit (usually focal) lasting more than 24 hours or leading to death, with no apparent cause other than a vascular one. Hemiplegia following middle cerebral arterial thromboembolism is the typical example.
- **Completed stroke** means the deficit has become maximal, usually within 6 hours.
- **Stroke-in-evolution** describes progression during the first 24 hours.
- **Minor stroke.** Patients recover without significant deficit, usually within a week.
- **Transient ischaemic attack (TIA).** This means a focal deficit, such as a weak limb, aphasia or loss of vision lasting from a few seconds to 24 hours. There is *complete* recovery. The attack is usually sudden. TIAs have a tendency to recur, and may herald thrombo embolic stroke.

That vague term 'cerebrovascular accident' should be avoided.

Pathophysiology

Different pathological processes may cause similar clinical events in cerebrovascular disease.

Completed stroke

One of three mechanisms is usual:

- arterial embolism from a distant site (usually the carotid, vertebral or basilar arteries) and subsequent brain infarction
- arterial thrombosis causing occlusion in atheromatous carotid, vertebral or cerebral artery with subsequent brain infarction
- haemorrhage into the brain (intracerebral or subarachnoid).

Less commonly, other processes cause stroke, or look like a common stroke:

- venous infarction
- carotid or vertebral artery dissection
- polycythaemia (hyperviscosity syndromes)
- fat and air embolism (see diving, p. 1028)
- multiple sclerosis - a demyelinating plaque
- mass lesions (e.g. brain tumour, abscess, subdural haematoma)
- rarities: arteritis, neurosyphilis, systemic lupus erythematosus, mitochondrial disease.

Transient ischaemic attack (TIA) (p. 1211) TIAs are *usually* the result of microemboli, but as in stroke different mechanisms produce similar clinical events. For example, TIAs may be caused by a fall in cerebral per-fusion (e.g. a cardiac dysrhythmia, postural hypotension or decreased flow through atheromatous carotid and vertebral arteries). Infarction is usually averted by autoregulation (p. 1211). Small areas of brain infarction following thrombosis or haemorrhage may occasionally cause a clinical TIA. Rarely, brain tumours and subdural

Table 21.25 **Reducing stroke risk**

Risk factor	Intervention	Reduction in stroke risk		
		Cerebral infarction	Cerebral haemorrhage	Subarachnoid haemorrhage
Hypertension	Treat	**++**	++	Possible
Smoking	Stop	++	+	Probable
Lifestyle	More active	+	0	0
Alcohol	Moderate intake	+	0	**0**
Hypercholesterolaemia	Statin therapy	+	**0**	0
Raised haematocrit	Reduce	+	0	0
Atrial fibrillation	Anticoagulate	+	(Possibly increased risk)	0
Sleep apnoea	Treat	+	0	0
Obesity	Weight reduction	Probable	Probable	0
Diabetes	Good control	Probable	0	**0**
Carotid artery stenosis	Surgery	++	0	**0**

++, major correlation with reduced risk; +, moderate correlation with reduced risk

haematomas cause episodes indistinguishable from thromboembolic TIAs. A clinical TIA is thus not an entirely reliable indicator of thromboembolism. Principal sources of emboli to the brain are cardiac thrombi and atheromatous plaques/thrombi within the great vessels, and carotid and vertebral systems. Cardiac thrombi (mural and valvular) follow atrial fibrillation, itself often secondary to valvular disease, or myocardial infarction. A total high red cell volume (e.g. polycythaemia) is also a cause.

Thromboembolism from sources outside the brain generates 70% of all strokes and 80% of TIAs.

Risk_jffactors_ancl prevention

The principal accepted risk factors and effects of altering them are shown in Table 21.25.

The following measures reduce stroke incidence:

- treatment of hypertension (of vital importance)
- cessation of smoking; 50% reduction within 1 year reaching normal risk after 5 years
- active lifestyle (recommend 30-60 min exercise, four to six times per week)
- moderate alcohol consumption
- statin therapy (p. 1141) reduces cerebrovascular disease by up to a third even in people with a low cholesterol level (see Table 19.17)
- anticoagulation in atrial fibrillation
- weight reduction in obesity (see Table 5.14)
- treating polycythaemia.
- surgery for carotid stenosis (see p. 1215).

Low-dose aspirin in symptomless populations and postmenopausal HRT has shown no protective effect.

Cerebral and cerebellar haemorrhage

Hypertension, bleeding disorders, pre-existing cerebral aneurysm, anticoagulant and antiplatelet drug therapy are risk factors.

Rarer risk factors and other causes of stroke

- Thrombocythaemia and thrombophilia (protein C deficiency, factor V Leiden) areweakly associated with arterial stroke but predispose to cerebral venous thrombosis.
- Polycythaemia predisposes to stroke.
- Anticardiolipin and lupus anticoagulant antibodies (i.e. antiphospholipid syndrome p. 577) causes arterial thrombotic stroke in young patients.
- Endocarditis (p. 828) - thromboembolic stroke may be the presenting feature.
- Low-dose oestrogen-containing oral contraceptives do not increase stroke risk significantly in healthy women but probably do so with other risk factors, e.g. uncontrolled hypertension or smoking.
- Migraine is a rare cause of cerebral infarction (p. 1247).
- Vasculitis (SLE, polyarteritis nodosa, giant cell arteritis, granulomatous CNS angiitis) is a rare cause of stroke.
- Amyloidosis can present as recurrent cerebral haemorrhage (p. 1147).
- Hyperhomocysteinaemia predisposes to thrombotic strokes. Folic acid therapy does not reduce the incidence.
- Drugs - illicit drugs, e.g. cocaine and over-the-counter 'cold' remedies containing vasoconstrictors. Chronic use of COX II inhibitors is associated with an increased incidence of stroke (p. 550).

CADASIL (cerebral dominant arteriopathy with subcortical infarcts and leucoencephalopathy) is a rare inherited cause of stroke/vascular dementia. There is a defect in the *NOTCH3* gene on chromosome 19. Characteristic damage to small brain arterioles follows with multiple infarcts. Familial migraine and depression in youth occur, progressing to TIA and stroke in the third and fourth decades, and to dementia in the sixth.

Vascular anatomy (Figs 21.18-21.20)

Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main syndromes.

The circle of Willis is supplied by the two internal carotid arteries and by the basilar. The distribution of the

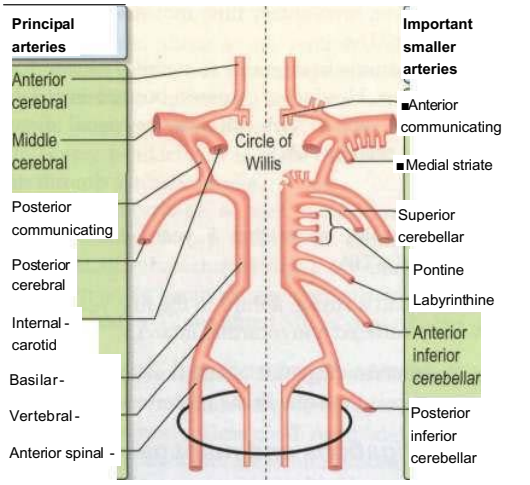

Fig. 21.18 Diagram of arteries supplying the brain.

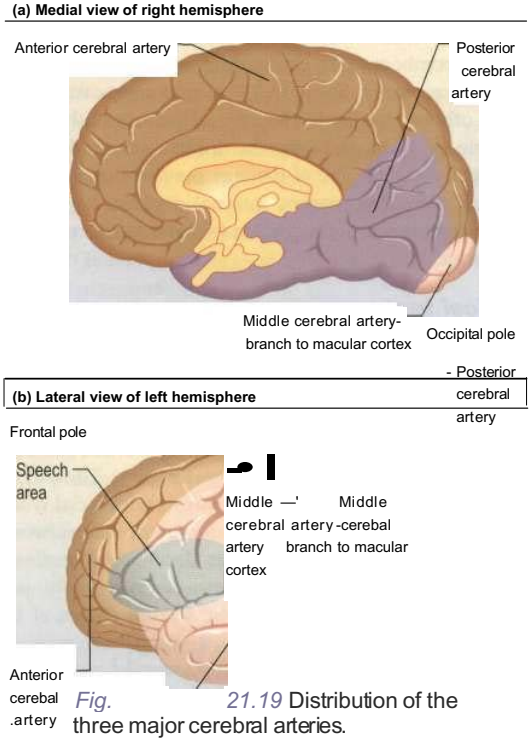

Fig. 21.19 Distribution of the three major cerebral arteries.

anterior, middle and posterior cerebral arteries that supply the cerebrum is shown in Figure 21.19.

Stenoses and plaques proximal to the circle of Willis are common at five sites (positions 1-4 are shown in Fig. 21.20):

- origins of common carotid arteries (1)
- origins of internal carotid arteries (2)

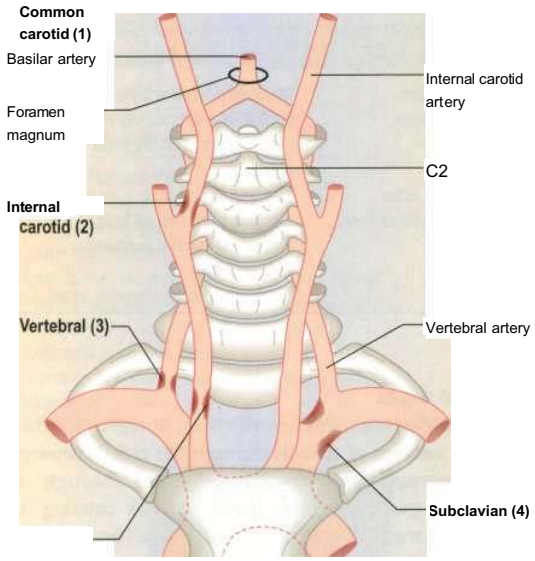

Fig. 21.20 Principal sites of atheromatous stenoses in extracerebral arteries: common carotid (1); internal carotid (2); vertebral (3); subclavian (4).

- carotid artery syphon - within the cavernous sinus
- origins of vertebral arteries (3)
- subclavian vessels (4).

Autoregulation

Smooth muscle of small intracerebral arteries responds directly to changes in pressure gradient. In the normal situation, constant cerebral blood flow (CBF) is maintained by mean arterial blood pressures between 60 and 120 mmHg, i.e. CBF is independent of perfusion pressure. In disease, CBF autoregulation may fail. Contributory causes are:

- severe hypotension with systolic BP < 75 mmHg
- severe hypertension with systolic BP > 180 mmHg
- increase in blood viscosity, e.g. polycythaemia
- raised intracranial pressure
- increase in arterial Pco_2 and/or fall in arterial Po_2.

TRANSIENT ISCHAEMIC ATTACKS

Symptoms

TIAs cause sudden loss of function, usually within seconds, and last for minutes or hours (but by definition < 24 hours). The site is often suggested by the type of attack.

Features

Clinical features of principal forms of TIA are given in Table 21.26. Hemiparesis and aphasia are the commonest but two other events are mentioned briefly here.

Table 21.26 Features of transient ischaemic attacks

Anterior circulation	Posterior circulation
Carotid system	***Vertebrobasilar system***
Amaurosis fugax	Diplopia, vertigo, vomiting
Aphasia Hemiparesis	Choking and dysarthria
Hemisensory loss	Ataxia
Hemianopic visual loss	Hemisensory loss
	Hemianopic visual loss
	Transient global amnesia
	Tetraparesis
	Loss of consciousness (rare)

Amaurosis fugax

This is a sudden transient loss of vision in one eye. When due to the passage of emboli through the retinal arteries, arterial obstruction is sometimes visible through an ophthalmoscope during an attack. A TIA causing an episode of amaurosis fugax is often the first clinical evidence of internal carotid artery stenosis - and forerunner of a hemiparesis. Amaurosis fugax also occurs as a benign event in migraine.

Transient global amnesia

Episodes of amnesia lasting several hours, occurring principally in people over 65, and followed by complete recovery are presumed to be caused by posterior circulation ischaemia. The exact pathology of this striking but unusual event is unknown. Episodes rarely recur.

Clinical findings in TIA

Diagnosis of TIA is often based solely upon its description. It is unusual to witness an attack. Consciousness is usually preserved in TIA.

There may be clinical evidence of a source of embolus, such as:

- carotid arterial bruit (stenosis)
- atrial fibrillation or other dysrhythmia
- valvular heart disease/endocarditis
- recent myocardial infarction
- difference between right and left brachial BP.

An underlying condition may be evident:

- atheroma
- hypertension
- postural hypotension
- bradycardia or low cardiac output
- diabetes mellitus
- rarely, arteritis, polycythaemia
- antiphospholipid syndrome (p. 577).

Differential diagnosis

TIAs must be distinguished, usually on clinical grounds, from other transient episodes (p. 1226). Occasionally, events identical to TIAs are produced by mass lesions. Focal epilepsy is usually distinguishable by its 'positive' features (e.g. limb jerking) and characteristic progression over minutes. In a TIA, deficit is usually apparent immediately. However, involuntary limb movements do occur occasionally in TIAs.

A focal prodrome in migraine sometimes causes diagnostic confusion. Headache, common but not invariable in migraine, is rare in TIA. Migrainous visual disturbances are not seen in TIA.

Prognosis

Prospective studies show that 5 years after a single thromboembolic TIA:

- 30% have had a stroke, a third in the first year
- 15% have suffered a myocardial infarct.

TIA in the anterior cerebral circulation carries a more serious prognosis than one in the posterior circulation.

TIA: investigations and management

These are discussed with stroke on page 1215.

TYPICAL STROKE SYNDROMES

Cerebral infarction

Major thromboembolic cerebral infarction usually causes an obvious stroke. Some small infarcts may cause TIAs, while others are silent. The clinical picture is thus very variable and depends on the infarct site and extent. Whilst the general site of damage may be deduced from physical signs (e.g. cortex, internal capsule, brainstem), clinical estimation of the precise vascular territory is often inaccurate.

Clinical features

The most common stroke is caused by infarction in the internal capsule following thromboembolism in a middle cerebral artery branch. A similar picture is caused by internal carotid occlusion (Fig. 21.20). Limb weakness on the opposite side to the infarct develops over seconds, minutes or hours (occasionally longer). There is a contralateral hemiplegia or hemiparesis with facial weakness. Aphasia is usual when the dominant hemisphere is affected. Weak limbs are at first flaccid and areflexic. Headache is unusual. Consciousness is usually preserved. Exceptionally, an epileptic seizure occurs at the onset.

After a variable interval, usually several days, reflexes return, becoming exaggerated. An extensor plantar response appears. Weakness is maximal at first; recovery occurs gradually over days, weeks or many months.

Carotid and vertebral artery dissection

Dissection accounts for under one-fifth of strokes below age 40 and is sometimes a sequel of head or neck trauma. Stroke, TIA or migraine-like symptoms occur, often with neck pain at the site of dissection.

Brainstem infarction

This causes complex signs depending on the relationship of the infarct to cranial nerve nuclei, long tracts and brainstem connections (Table 21.27).

Table 21.27 Features of brainstem infarction

Clinical feature	Structure involved
Hemiparesis or tetraparesis	Corticospinal tracts
Sensory loss	Medial lemniscus and spinothalamic tracts
Diplopia	Oculomotor system Fifth nerve nuclei Seventh nerve nucleus
Facial numbness	
Facial weakness (lower motor neurone)	
Nystagmus, vertigo	Vestibular connections Ninth and tenth nerve nuclei
Dysphagia, dysarthria	
Dysarthria, ataxia, hiccups, vomiting	Brainstem and cerebellar connections
Horner's syndrome Altered consciousness	Sympathetic fibres Reticular formation
Ipsilateral	**Contralateral**

The lateral medullary syndrome, also called posterior inferior cerebellar artery (PICA) thrombosis, or Wallenberg's syndrome, is a common example of brainstem infarction presenting as acute vertigo with cerebellar and other signs (Table 21.28 and Fig. 21.21). It follows thrombo-embolism in the PICA or its branches, vertebral artery thrombo-embolism or dissection. The clinical picture depends on the precise structure damaged.

Coma follows damage to the brainstem reticular activating system.

The locked-in syndrome is caused by upper brainstem infarction (p. 1207).

Pseudobulbar palsy (p. 1191) is caused by lower brainstem infarction.

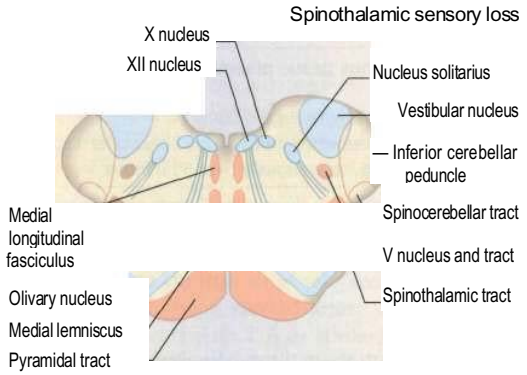

***Fig. 21.21* Cross-section of medulla: structures at risk after brain-stem infarction.**

Table 21.28 Clinical signs in the lateral medullary syndrome (PICA thrombosis)

Facial numbness (Vth)
Diplopia (VIth)
Nystagmus
Ataxia (cerebellar)
Horner's syndrome
IXth and Xth nerve lesions

Other patterns of infarction

Lacunar infarction

Lacunes are small (<1.5cm^3) infarcts seen on MRI or at autopsy. Hypertension is commonly present. Minor strokes (e.g. pure motor stroke, pure sensory stroke, sudden unilateral ataxia and sudden dysarthria with a clumsy hand) are syndromes caused typically by single lacunar infarcts. Lacunar infarction is also often symptomless.

Hypertensive encephalopathy (see also p. 859) This describes the neurological sequelae of malignant hypertension. Severe headaches, TIA, stroke, and rarely subarachnoid haemorrhage occur. Papilloedema may develop, either as part of an ischaemic optic neuropathy or following brain swelling due to multiple acute infarcts.

Multi-infarct dementia (vascular dementia)

(see also p. 1255)

Multiple lacunes or larger infarcts cause generalized intellectual loss seen with advanced cerebrovascular disease. The condition tends to occur with a stepwise progression over months or years with each subsequent infarct. There is eventually dementia, pseudobulbar palsy and a shuffling gait with small steps - the *marche a petits pas,* sometimes called atherosclerotic parkinsonism. There may be confusion clinically with idiopathic Parkinson's disease. *Binswanger's disease* is an imaging term describing low attenuation in cerebral **white** matter, **with** dementia, TIAs and stroke episodes in hypertensive patients.

Infarction in the visual cortex

Posterior cerebral artery infarction or infarction of the middle cerebral artery macular branch causes combinations of hemianopic visual loss and cortical blindness (Anton's syndrome, Fig. 21.19).

Weber's syndrome

This is ipsilateral third nerve paralysis with contralateral hemiplegia due to an infarct in one side of the midbrain. Paralysis of upward gaze is usually present.

Watershed (or borderzone) cerebral infarction

This describes the multiple cortical infarcts that follow prolonged periods of very low perfusion (e.g. from hypotension after massive myocardial infarction or cardiac bypass surgery). Borderzone infarcts occur between areas supplied by the anterior, middle and posterior cerebral arteries. Cortical visual loss, memory loss and intellectual impairment are typical. In severe cases a persistent vegetative state or minimal conscious state develops (p. 1207).

Management of cerebral infarction

The possible sources of embolus should be sought (e.g. carotid bruit, atrial fibrillation, valve lesion, evidence of endocarditis, previous emboli or TIA) and hypertension and postural hypotension assessed. The brachial blood pressure should be measured in each arm; a difference of

more than 20mmHg is suggestive of subclavian artery stenosis. The neurological deficit should be carefully documented.

Stroke: immediate care and thrombolysis

(Box 21.1)

Dedicated units with multidisciplinary, organized team care deliver a higher standard of care than a general ward, reducing stroke mortality and long-term disability. Evidence-based guidelines have contributed to management by establishing clear protocols.

After a stroke, immediate, continued and meticulous attention to the airway and to swallowing is essential. The initial decision to admit a stroke patient to hospital depends upon the clinical state and facilities available. Table 21.29 outlines the current proposals for stroke thrombolysis - unfortunately rarely carried out in the UK. Aspirin 300 mg daily should be given as soon as a diagnosis of ischaemic stroke or thromboembolic TIA is confirmed, reducing to 75 mg after several days.

Management of the unconscious patient is described on page 1209.

Investigations

The purpose of investigations in both stroke and TIA is:

- to confirm clinical diagnosis
- to distinguish between haemorrhage and thrombo embolic infarction
- to look for underlying causes of disease and to direct therapy, either medical or surgical.

Sox *21.1* Stroke: immediate management issues

1. **Admit to multidisciplinary hospital stroke unit if possible.**
2. **General medical measures**
   Care of the unconscious patient (p. 1209)
   Oxygen by mask
   Assessment of swallowing
   Check BP and look for source of emboli.
3. **Is thrombolysis to be considered?**
   If so (see text and Table 21.29) immediate brain imaging is essential.
4. **Brain imaging**
   CT scans will usually be the only emergency imaging available. This will indicate whether there has been brain infarction, haemorrhage or other pathology.
5. **Cerebral infarction**
   If CT shows infarction, give aspirin (300 mg/day initially) antiplatelet therapy if no contraindications, give alteplase thrombolysis, which must be started within 3 hours (aim for 90 min) of stroke; informed consent is essential.
6. **Cerebral haemorrhage**
   If CT shows haemorrhage, do not give any therapy that may interfere with clotting. Neurosurgery may be required.

Table 21.29 Thrombolysis in acute ischaemic stroke

Eligibility
Age > 18 years
Clinical diagnosis of acute ischaemic stroke Assessed by experienced team Measurable neurological deficit Timing of symptom onset well established CT or MRI and blood test results available CT or MRI consistent with diagnosis Treatment could begin within 180 minutes of symptom onset
Exclusion criteria
Symptoms minor or improving rapidly
Haemorrhage on pretreatment CT or MRI
Suspected subarachnoid haemorrhage
Active bleeding from any site
Gastrointestinal or urinary tract haemorrhage in last 21 days
Platelet count < 100 x 10^9/litre Recent treatment with heparin and activated partial thromboplastin time above normal Recent treatment with warfarin and INR elevated Major surgery or trauma in last 14 days Recent post-myocardial infarction pericarditis Neurosurgery, serious head trauma or stroke in last 3 months
History of intracranial haemorrhage (any time)
Known arteriovenous malformation or aneurysm
Recent arterial puncture at non-compressible site
Recent lumbar puncture Blood pressure consistently > 185 systolic or > 110 diastolic
Abnormal blood glucose (< 3 mmol/litre or > 20 mmol/litre)
Suspected or known pregnancy Active pancreatitis Epileptic seizure at stroke onset
Dose of intravenous tissue plasminogen activator (alteplase)
Total dose 0.9 mg/kg (maximum 90 mg)
10% of total dose as initial intravenous bolus over 1 minute
Remainder infused intravenously over 60 minutes

Source: National Institute of Neurological Disorders and Stroke protocol; from *Medicine* (2000) 28(7): 62

Routine investigations in thromboembolic stroke and TIA with their potential yields are listed in Box 21.2.

Imaging TIA and stroke patients

CT and MRI. CT imaging will demonstrate haemorrhage immediately (p. 1217) while a patient with an infarct may have a normal scan. Infarctions are usually detectable at 1 week (Fig. 21.22) although 50% are never detected on CT. CT or MRI should be carried out urgently in the majority of cases.

Diffusion-weighted imaging (DWI) MR can identify infarcted areas within a few minutes of onset. Conventional T2 weighting is no better than CT. Imaging will also show the unexpected, e.g. subdural haematoma, tumour or abscess.

Box 21.2 **Stroke: further investigation and management**

Further investigation

Routine bloods (for polycythaemia, infection, vasculitis, thrombophilia, syphilitic serology, clotting studies, autoantibodies, lipids)
- Chest X-ray
- ECG
- Carotid Dopplers
- Angiography

Further management
- Appropriate drugs for hypertension, heart disease, diabetes, other medical conditions
- Other antiplatelet agents, e.g. dipyridamole
- Question of endarterectomy
- Question of anticoagulation - Table 21.30
- Speech therapy, dysphagia care, physiotherapy, occupational therapy
- Specific neurological issues, e.g. epilepsy, pain, incontinence
- Preparations for future care

Fig. 21.22 **CT: Massive middle cerebral artery infarct.**

Carotid Doppler and duplex scanning. Ultrasound studies are of value in screening for arterial stenosis and occlusion: in skilled hands they demonstrate accurately the degree of internal carotid artery stenosis.

Vascular imaging. Magnetic resonance angiography or digital subtraction angiography is valuable in anterior circulation TIAs to confirm surgically accessible arterial stenoses, mainly internal carotid artery stenosis. Most normotensive patients with TIA or stroke in the anterior circulation - who recover well - should have vascular imaging if ultrasound suggests carotid stenosis. The results of endarterectomy are given below.

Lumbar puncture. This is indicated only in unusual circumstances, such as when blood syphilitic serology is positive.

Long-term management

Medical therapy

All risk factors (Table 21.25) should be identified and, if possible, treated.

Antihypertensive therapy

Recognition and control of high blood pressure in the population is the single most important factor in primary stroke prevention. Transient hypertension often seen after acute stroke usually does not require treatment provided diastolic pressure does not rise higher than lOOmmHg. Sustained severe hypertension needs treatment (p. 864), but the pressure must be lowered slowly to avoid a sudden fall in cerebral perfusion.

Antiplatelet therapy (also p. 478)

Long-term soluble aspirin (75 mg daily) reduces substantially the incidence of further infarction after thromboembolic TIA or stroke. Aspirin inhibits cyclo-oxygenase, which converts arachidonic acid to prostaglandins and thromboxanes. The predominant therapeutic effect is to reduce platelet aggregation. Clopidogrel, dipyridamole and ticlopidine are also used (p. 478). Combined aspirin 75 mg daily and dipyridamole 200 mg twice daily is probably the best prophylaxis against further thromboembolic stroke or TIA.

Anticoagulants

Heparin and warfarin should be given when there is atrial fibrillation, other paroxysmal dysrhythmias or when there are cardiac valve lesions (uninfected) or cardiomyopathies. Brain haemorrhage must be excluded by CT/MRI. All patients on anticoagulants must be aware of the small risk of cerebral (and other) haemorrhage. The drugs are potentially dangerous in the 2 weeks following cerebral infarction because of the risk of provoking cerebral haemorrhage. There are wide differences in clinical practice here. Table 21.30 outlines the issues in secondary stroke prevention.

Other measures

Polycythaemia and clotting abnormalities should be treated if found (p. 453).

Surgical approaches

Internal carotid endarterectomy

Surgery is recommended in TIA or stroke patients shown to have internal carotid artery stenosis greater than 70%. Successful surgery reduces the risk of further TIA/stroke by approximately 75%. Endarterectomy has a mortality around 3%, and a similar risk of stroke. Percutaneous transluminal angioplasty (stenting) is an alternative procedure. Surgery for asymptomatic patients is advocated for some.

Strokes in the elderly

The yield of investigation in stroke falls with age. Age itself is, however, no barrier to recovery, and elderly patients benefit most from high standards of rehabilitation. Consider social isolation in elderly patients, preexisting cognitive impairment, their nutrition, skin and sphincter care, and reassess swallowing. Carotid endarterectomy over 75 carries little more risk than in younger cases.

Table 21.30 **Stroke prevention: indications for considering anticoagulants**

Indication	Comment
Valvular heart disease	Heparin/warfarin is of clear benefit in chronic rheumatic heart disease, particularly mitral stenosis
Recent MI Intracardiac thrombus	Heparin/warfarin should be given if there is evidence of intracardiac thrombus
Atrial fibrillation	Anticoagulants long term reduce stroke incidence in atrial fibrillation
Acute internal carotid artery thrombus Acute basilar artery thrombus Internal carotid artery dissection Extracranial vertebral artery dissection	Anticoagulants are reserved for imaging-confirmed cases of arterial thrombosis or dissection. They have not been shown to be beneficial in stroke prevention after thromboembolism from carotid or vertebrobasilar sources
Prothrombic states, e.g. protein C deficiency	Consider anticoagulation in consultation with a haematologist
Recurrent TIAs or stroke on full antiplatelet therapy	If no remediable cause, a trial of anticoagulants may be justified
Cerebral venous thrombosis including sinus thrombosis	Benefits of anticoagulation outweigh risks of haemorrhage

Modified from Brown M (2000) *Medicine* 28(7): 64

Rehabilitation: physiotherapy and speech therapy

Skilled physiotherapy has particular value in the first few weeks after stroke. It relieves spasticity, prevents contractures and teaches patients to use walking aids. The benefit of physiotherapy for the longer-term outcome is still inadequately researched. Baclofen (a GABA agonist) is sometimes helpful in the management of severe spasticity following stroke.

In aphasia, the speech therapist has a vital understanding of the patient's problems and frustration. It is, however, possible that spontaneous return of speech is hastened as much by normal conversation with a relative as by a therapist. If the patient cannot swallow safely without the risk of aspiration, either nasogastric feeding or percutaneous gastrostomy will be needed. Videofluoroscopy while attempting to swallow is helpful.

Both physiotherapy and speech therapy have an undoubted psychological role. Stroke is frequently devastating and, particularly when it occurs during working life, radically alters the patient's remaining years. Many become unemployable, lose independence and are financially embarrassed. Loss of self-esteem makes depression common.

Following early recovery, aids and modifications may be necessary at home. For example: stair rails, portable lavatories, bath rails, hoists, sliding boards, wheelchairs, tripods, altering doorways and sleeping arrangements, stair lifts and kitchen modifications. Liaison between a hospital-based neurology community care team, locally based therapists and primary care physician is valuable.

Prognosis

Twenty-five per cent of patients die within 2 years of a stroke. Around 30% of this group die in the first month. This early mortality is lower for thromboembolic infarction (death in under a quarter) than for intracerebral haemorrhage (death in around three-quarters). A poor outcome is likely when there is coma, a defect in conjugate gaze and severe hemiplegia. Many complications that lead to early death, particularly in the elderly, are preventable — for example, aspiration. Coordinated care reduces risks.

Recurrent strokes are, however, common (10% in the first year) and many patients die subsequently from myocardial infarction. Of initial stroke survivors, some 30-40% remain alive at 3 years.

Gradual improvement usually follows stroke, although the late residual deficit may be severe. Of those who survive, about one-third return to independent mobility and one-third have serious disability requiring permanent institutional care.

The outlook for recovery of language is variable. If, in general, the stroke patient is intelligible at 3 weeks, prognosis for fluent speech is good - but many are left with word-finding difficulties.

Intracranial haemorrhage

This comprises:

- intracerebral and cerebellar haemorrhage
- subarachnoid haemorrhage
- subdural and extradural haemorrhage/haematoma.

Intracerebral haemorrhage

Aetiology

Intracerebral haemorrhage causes around 10% of strokes. Rupture of microaneurysms (Charcot-Bouchard aneurysms, 0.8-1.0 mm diameter) and degeneration of small deep penetrating arteries are the principal pathology. Such haemorrhage is usually massive, often fatal and occurs in chronic hypertension and at well-defined sites - basal ganglia, pons, cerebellum and subcortical white matter.

In normotensive patients, particularly over 60 years, *lobar* intracerebral haemorrhage occurs - in the frontal, temporal, parietal or occipital cortex. Cerebral amyloid angiopathy (rare) is the cause in some of these haemorrhages, and the tendency to rebleed is associated with particular apolipoprotein E genotypes.

Recognition

At the bedside, there is no entirely reliable way of distinguishing between intracerebral haemorrhage and thromboembolic infarction. Both produce stroke. Intracerebral haemorrhage, however, tends to be dramatic with severe headache. It is more likely to lead to coma than thromboembolic stroke.

Brain haemorrhage is seen on CT imaging immediately (cf. infarction, p. 1214) - as intracerebral, intraventricular, or subarachnoid blood. MR imaging may not identify an acute haemorrhage correctly in the first few hours. Thereafter T2 weighted MR is very reliable.

Management: haemorrhagic stroke

The principles are those for cerebral infarction. The immediate prognosis is less good. Antiplatelet drugs and, of course, anticoagulants are contraindicated. Control of hypertension is vital. Urgent neurosurgical clot evacuation is sometimes considered when there is deepening coma and coning (occasionally in lobar haemorrhage but particularly in cerebellar haemorrhage, see below). The outlook is usually poor.

Cerebellar haemorrhage (Fig. 21.23)
There is headache and rapid reduction of consciousness with signs of brainstem origin (e.g. nystagmus, ocular palsies). Gaze deviates towards the haemorrhage. Skew deviation (p. 1183) may develop. There are unilateral or bilateral cerebellar signs, if the patient is awake. Cerebellar haemorrhage sometimes causes acute hydrocephalus. Emergency surgical clot evacuation is often necessary after imaging.

Subarachnoid haemorrhage
Subarachnoid haemorrhage (SAH) means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically by its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100 000.

Causes

The causes of SAH are shown in Table 21.31, though it is unusual to find any contributing disease.

Saccular (berry) aneurysms (Fig. 21.24)
Saccular aneurysms develop on the circle of Willis and adjacent arteries. Common sites are at the following arterial junctions:

- between posterior communicating and internal carotid artery - posterior communicating artery aneurysm
- between anterior communicating and anterior cerebral artery - anterior communicating artery aneurysm
- at a bifurcation or at the trifurcation of the middle cerebral artery - middle cerebral artery aneurysm.

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid and ophthalmic arteries. Saccular aneurysms are an incidental finding in 1 % of autopsies and can be multiple.

Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the commonest cause of a painful third nerve palsy (p. 1185).

Arteriovenous malformation (AVM)
This is a collection of arteries and veins of developmental origin, usually within the hemisphere. An AVM may also cause epilepsy, often focal. Once an AVM has ruptured the tendency is to rebleed -10% will then do so annually. Cavernous haemangiomas ('cavernomas') are common (< 0.5% of population) and consist of collections of capillary vessels; they are frequently symptomless

Table 21.31 Underlying causes of subarachnoid haemorrhage

Saccular ('berry') aneurysms	70%
Arteriovenous malformation (AVM)	10%
No lesion found	20%

Rare associations
Bleeding disorders
Mycotic aneurysms (endocarditis)
Acute bacterial meningitis
Brain tumours (e.g. metastatic melanoma)
Arteritis (e.g. systemic lupus erythematosus)
Spinal AVM (spinal haemorrhage only)
Coarctation of the aorta
Marfan's syndrome, Ehlers-Danlos syndrome
Polycystic kidneys

Fig. 21.23 **CT: Cerebellar haemorrhage.**

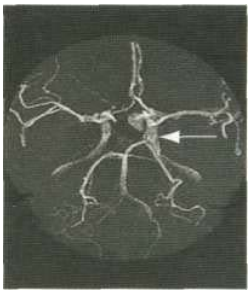

Fig. 21.24 **Digital subtraction angiogram of posterior communicating artery aneurysm.**

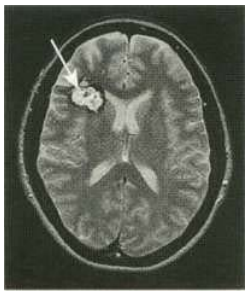

Fig. 21.25 MR (T2): Symptomless cavernous haemangioma (arrow).

(Fig. 21.25). Cavernomas sometimes have a genetic basis, with linkage to two loci on chromosome 7q. Rarely cavernomas cause seizures or bleed; exceptionally they cause sudden death from massive haemorrhage. Surgery is rarely appropriate.

Clinical features of SAH

There is a sudden devastating headache, often occipital. This is usually followed by vomiting and often by coma. The patient remains comatose or drowsy for several hours to several days, or longer. Less severe headaches cause difficulty (p. 1174), but SAH is a *possible* diagnosis in any sudden headache.

After major SAH there is neck stiffness and a positive Kernig's sign. Papilloedema is sometimes present and accompanied by retinal and subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs, but almost invariably headache.

Investigations

CT imaging is the initial investigation of choice (Fig. 21.26). Subarachnoid or intraventricular blood is usually seen. Lumbar puncture is not necessary if SAH is confirmed by CT, but should be performed if doubt remains. The CSF becomes yellow (xanthochromic) several hours after SAH. Visual inspection of the supernatant CSF is usually sufficiently reliable for diagnosis, but there is a move to use spectrophotometry to estimate bilirubin released from lysed cells to define

Fig. 21.26 CT: Subarachnoid haemorrhage showing blood around the brain stem (arrow).

with certainty SAH in doubtful cases. MR angiography is usually performed in all potentially fit for surgery, i.e. generally below 65 years and not in coma. In some cases, no aneurysm is found despite a definite SAH.

Differential diagnosis

SAH must be differentiated from severe migraine. This is sometimes difficult. *Thunderclap headache* is a term used (confusingly) to describe either SAH or a sudden headache for which no cause is ever found. The onset of acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures. Subarachnoid bleeding also occasionally occurs at the onset of acute bacterial meningitis.

Complications

Blood in the subarachnoid space can lead to obstruction of CSF flow and hydrocephalus. This can be asymptomatic but may cause deteriorating consciousness after SAH. Diagnosis is by CT. Shunting may be required.

Severe arterial spasm (visible on cerebral angiography and a cause of coma or stroke) sometimes complicates SAH. It is a poor prognostic sign.

Management

Immediate treatment of SAH is bed rest and supportive measures. Hypertension should be controlled. Dexamethasone is often prescribed, to reduce cerebral oedema; it also is believed to stabilize the blood-brain barrier. Nimodipine, a calcium-channel blocking agent, reduces mortality.

All surviving SAH cases should be discussed urgently with a specialist neurosurgical centre. Nearly half SAH cases are either dead or moribund before they reach hospital. Of the remainder, a further 10-20% rebleed and die in the next several weeks. Delay or failure to diagnose SAH without coma (e.g. mistaking it for migraine) contributes to this mortality.

Patients who remain comatose or with persistent severe deficits have a poor prognosis. In others, where angiography demonstrates aneurysm, a direct neurosurgical approach to clip the neck of the aneurysm is carried out. In selected cases the results of surgery are excellent. Invasive radiological techniques, such as inserting a fine wire coil into an aneurysm are also used. Direct surgery, microembolism and focal radiotherapy ('gamma **knife') are** used in AVM.

Subdural and extradural haemorrhage and haematoma

These cause death after head injury unless treated **promptly.**

Subdural haematoma (SDH) (Fig. 21.27)

SDH means accumulation of blood in the subdural space following rupture of a vein. It usually follows a head injury, which may be trivial. The interval between injury and symptoms may be days, weeks or months. Chronic, unsuspected or spontaneous SDH is common in the elderly and in alcohol abuse.

Fig. 21.27 **MR (T1): Bilateral subdural haematomas.**

Headache, drowsiness and confusion are common; symptoms are indolent and often fluctuate. Focal deficits such as hemiparesis or sensory loss develop. Epilepsy occasionally occurs. Stupor, coma and coning may follow, but there is a tendency for SDH to resolve spontaneously.

Extradural haemorrhage

This follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Blood accumulates rapidly over minutes/hours in the extradural space. The most characteristic picture is of a head injury with a brief duration of unconsciousness followed by a lucid interval of recovery. The patient then develops a progressive hemiparesis and stupor, and rapid transtentorial coning, with first an ipsilateral dilated pupil, followed by bilateral fixed dilated pupils, tetraplegia and respiratory arrest. An acute *subdural* haemorrhage presents in a similar way.

Management

Suspected extradural or subdural haemorrhage needs immediate imaging.

Extradural bleeding requires urgent neurosurgery. If performed early, the outlook is excellent. When far from specialist neurosurgical help (e.g. in wartime or at sea), surgical drainage through a skull burr-hole has been lifesaving when an extradural has been diagnosed on clinical grounds alone.

Subdural bleeding may allow; more conservative management - even large subdural collections can resolve. Progress is assessed with serial imaging, but close liaison with a neurosurgeon remains essential.

CORTICAL VENOUS THROMBOSIS AND DURAL VENOUS SINUS THROMBOSIS

Intracranial venous thromboses are usually (85%) associated with a pro-thrombotic risk factor e.g. oral contraceptives, pregnancy, genetic and acquired pro-thrombotic states. Head injury is also a cause but infection e.g. from the paranasal sinus is unusual (6-12%). They may arise apparently de novo.

Cortical venous thrombosis

The venous infarct leads to headache, focal signs (e.g. hemiparesis) and/or epilepsy. There is often a fever.

Dural venous sinus thromboses

Cavernous sinus thrombosis causes ocular pain, fever, proptosis and chemosis. An external and internal ophthalmoplegia with papilloedema develop.

Sagittal and lateral sinus thrombosis cause raised intracranial pressure with headache, fever, papilloedema and often epilepsy.

Management

MRI, MRA and the venous phase of angiography show occluded sinuses and/or veins. Treatment is with heparin initially although its value has been questioned. This is followed by warfarin for six months. Anticonvulsants and anticoagulants are given if necessary.

EPILEPSY AND CAUSES OF LOSS OF CONSCIOUSNESS

EPILEPSY

A seizure is a convulsion or transient abnormal event resulting from a paroxysmal discharge of cerebral neurones. Epilepsy is the continuing tendency to have seizures, even if a long interval separates attacks. A

generalized convulsion (i.e. a grand mal fit) is the most common recognized event. Epilepsy is common. Over 2% of the population have two or more seizures during their lives, and in 0.5% epilepsy is an active problem and hence a common one in general practice. In the UK approximately 65 people suffer their first seizure each day. Often no clear cause is found for seizures. Sometimes (though unusually) epilepsy is caused by a brain tumour or follows a stroke. Around 250 000 people take anticonvulsant drugs, the mainstay of treatment. Neurosurgery (temporal lobectomy) is also valuable in carefully selected cases.

Mechanisms

Spread of electrical activity between neurones is normally restricted and *synchronous discharge* of neurones takes place in restricted groups producing the normal EEG rhythms. During a seizure, large groups of neurones are activated repetitively, unrestrictedly and hypersynchronously. Inhibitory synaptic activity between neurones fails. This produces high-voltage spike-and-wave EEG activity, the electrophysiological hallmark of epilepsy.

A partial seizure is epileptic activity confined to one area of cortex with a recognizable clinical pattern (Fig. 21.28). This activity either remains focal or spreads to generate epileptic activity in both hemispheres - and thus a generalized seizure. This spread is called secondary generalization. The focal onset of a seizure may not be apparent. This means that a generalized tonic-clonic seizure may either have started as a focal seizure, or be a primary generalized major convulsion. Brain becomes epileptogenic either because neurones have a predisposition to be hyperexcitable, for example following abnormal neuronal migration patterns in utero, or because the cells acquire this hyperexcitable tendency. Trauma or brain neoplasms are examples of acquired conditions that alter neuronal seizure threshold.

Seizure threshold

Each individual has a seizure threshold. Experimentally some chemicals (e.g. pentylenetetrazol, a toxic gas) induce seizures in everyone. People who are more likely to have seizures in response to flashing lights, for example, have *low seizure thresholds* - a concept, not a measurement.

Classification

Various classifications of seizures are confusing. Seizures are described here by clinical pattern (Table 21.32).

- *Generalized* implies bilateral abnormal electrical activity, with bilateral motor manifestations and impaired consciousness.
- *A partial (focal) seizure* means a localized seizure:
  (a) simple - without loss of consciousness, e.g. jerking of a limb
  (b) complex - with loss of awareness, e.g. an absence attack.
- *Unclassifiable seizure.*

Generalized seizure types

Tonic-clonic seizures (grand mal seizures, generalized major convulsions)

Following a vague warning, the tonic phase commences. The body becomes rigid, for up to a minute. The patient utters a cry and falls, sometimes suffering serious injury.

Fig. 21.28 **Seizure types, (a)** Partial (focal) seizure. (b) Primary generalized seizure, (c) Partial seizure with secondary generalization.

Table 21.32 **The commoner types of epilepsy**

Abridged from International League against Epilepsy

1. **Generalized seizure types**
   - A Absence seizures
     - (a) Typical absences with 3 Hz spike-and-wave discharge *(petit mal)*
     - (b) Atypical absences with other EEG changes
   - B Myoclonic seizures
   - C Tonic-clonic seizures *(grand mal,* major convulsion)
   - D Tonic seizures E Akinetic seizures
2. **Partial seizure types**
   These start by activation of a group of neurones in one part of one hemisphere. They are also called 'focal seizures'
   - A Simple partial seizures (without impairment of consciousness) (e.g. Jacksonian seizures)
   - B Complex partial seizures (impairment of consciousness)
   - C Partial seizures evolving to tonic-clonic seizures
   - D Apparent generalized tonic-clonic seizures, with EEG but not clinical evidence of focal onset
3. **Unclassifiable seizures**
   Seizures which do not fit one of the above categories

The tongue is usually bitten. There may be incontinence of urine or faeces.

The clonic phase then begins, a generalized convulsion, with frothing at the mouth and rhythmic jerking of muscles. This lasts from a few seconds to several minutes. Seizures are usually self-limiting, followed by drowsiness, confusion or coma for several hours.

Typical absences (petit mat)

This generalized epilepsy almost invariably begins in childhood. Each attack is accompanied by 3 Hz spike-and-wave EEG activity (Fig. 21.15, p. 1203). Activity ceases, the patient stares and pales slightly for a few seconds. The eyelids twitch; a few muscle jerks may occur. After an attack, normal activity is resumed. Typical absence attacks are never due to acquired lesions such as tumours. They are a developmental abnormality of neuronal control. Children with typical absence attacks tend to develop generalized tonic-clonic seizures in adult life (known as *primary generalized epilepsy). Petit mal* describes only these 3 Hz absence seizures. Clinically similar absence attacks are also caused by partial seizures of temporal lobe origin, a source of some confusion.

Other generalized seizure types

Myodonic seizures describe isolated muscle jerking. *Tonic* seizures describe intense stiffening of the body not followed by convulsive jerking. *Atonic* seizures cause sudden loss of tone, with falling and loss of consciousness.

Partial seizure types

Partial seizures (focal seizures)

A partial or focal seizure (simple or complex, see above) implies that an area of brain (e.g. a temporal lobe) has generated abnormal electrical activity. The seizure frequently has clinical features that provide evidence of its site.

An aura describes the effects of initial focal electrical events, such as an unusual smell, tingling in a limb or a strange inner feeling often recognized as a warning of an impending seizure.

Jacksonian, or focal motor seizures

These simple partial seizures originate in the motor cortex. Jerking movements typically begin at the angle of the mouth or in the hand, spreading to involve the limbs on the side opposite the epileptic focus. Clinical evidence of this spread of activity is called the *march* of the seizure. With a frontal lesion, conjugate gaze (p. 1183) and the head deviate away from the irritative epileptic focus - known as an adversive seizure. Weakness of the convulsing limbs for several hours sometimes follows a seizure - *Todd's paralysis.*

Temporal lobe seizures

These partial seizures, either simple or complex, describe feelings *of* unreality *(jamais vu)* or undue familiarity *(deja vu)* with the surroundings. Absence attacks, vertigo, visual hallucinations (i.e. visions or faces) are other examples of temporal lobe seizures.

Table 21.33 **Aetiological and precipitating factors in epilepsy**

Genetic predisposition
Developmental, e.g. hamartomas, neuronal migration abnormalities
Trauma and surgery
Pyrexia
Intracranial mass lesions, e.g. tumour, neurocysticercosis
Vascular, e.g. cerebral infarction, arteriovenous malformation
Drugs and drug withdrawal Encephalitis and inflammatory conditions Metabolic abnormalities, e.g. porphyria, hypocalcaemia Neural degenerative disorders Provoked seizures, e.g. photosensitivity, sleep deprivation

Many other types of partial seizure occur, such as autonomic disturbances with piloerection, flushing, and overbreathing, strange smells (frontal cortex), sensory disturbances (parietal cortex), crude visual shapes (occipital cortex), or strange sounds (auditory cortex).

Aetiology and precipitants (Table 21.33)

A definite cause for epilepsy is found in under a third of cases in UK community surveys: cerebrovascular disease accounts for some 15%, cerebral tumours for 6%, alcohol-related seizures for 6% and post-traumatic epilepsy 2%. Rarer causes are hippocampal sclerosis (resection may be possible), malformations of cortical development, vascular malformations, hamartomas, brain abscesses and tuberculomas.

Genetic predisposition and developmental anomalies

Over 200 genetic disorders list epilepsy among their features, giving rise to complex syndromic classifications. These account for < 2% of epilepsy cases. About 30% of epilepsy patients have first-degree relatives with seizures. Usually the mode of inheritance is uncertain. A low seizure threshold appears to run in some families. Generalized typical absence seizures *(petit mal,* 3 Hz spike-and-wave) and primary generalized epilepsy are often inherited as an autosomal dominant trait with variable penetrance. Primary epilepsies are due to complex developmental abnormalities of neuronal control. There are abnormalities in synaptic connections, and anomalies in neurotransmitter distribution and release. Neuronal migration defects in utero, dysplastic areas of cerebral cortex and hamartomas contribute to seizures both in infancy and adult life.

Trauma, hypoxia and surgery

Perinatal trauma (cerebral contusion and haemorrhage) and fetal anoxia are common causes of childhood seizures. Hypoxic damage to the hippocampi (mesial temporal sclerosis) is another childhood cause of epilepsy. Brain injury is sometimes followed by epilepsy within the first week (early epilepsy) or many months or years

later (late epilepsy). To cause epilepsy, the injury must (usually) be sufficient to cause coma. Early epilepsy, a depressed skull fracture, penetrating brain injury, cerebral contusion, dural tear or intracranial haematoma increases the incidence of late post-traumatic epilepsy.

Seizures follow some 10% of neurosurgical operations on the cerebral hemispheres.

Pyrexia

Convulsions sometimes occur when children under 5 years have high fevers (febrile convulsions). In the majority there is no recurrence. Partly for social reasons, febrile convulsions are not usually labelled as epilepsy.

Brain tumours (and abscesses)

Mass lesions in the cortex cause epilepsy - either partial or secondary generalized seizures. If epilepsy develops in adult life, the chance of finding an unsuspected tumour is around 3%.

Hydrocephalus (p. 1247) also lowers seizure threshold.

Vascular

Seizures sometimes follow cerebral infarction, especially in the elderly - there is a peak in incidence late in life. A brain arteriovenous malformation may present with seizures and occasionally a subarachnoid bleed.

Alcohol, drugs and drug withdrawal

Chronic alcohol abuse is a common cause of seizures. These occur either while drinking heavily or during periods of withdrawal. Alcohol-induced hypoglycaemia also provokes attacks (p. 1134).

Phenothiazines, monoamine oxidase inhibitors, tricyclic antidepressants, amfetamines, lidocaine, propofol and nalidixic acid sometimes provoke fits, either in overdose or at therapeutic doses in individuals with a low seizure threshold.

Withdrawal of anticonvulsant drugs (especially phenobarbital) and benzodiazepines may provoke seizures.

Encephalitis and inflammatory conditions

Seizures are frequently presenting features of encephalitis, cerebral abscess, cortical venous thrombosis, and neurosyphilis. They also occur in chronic meningitis (e.g. tuberculosis) and may rarely be the first sign of bacterial meningitis. In countries where the tapeworm is endemic, e.g. India, neurocysticercosis is a frequent cause of seizures.

Metabolic abnormalities

Seizures are seen with: .

- hypocalcaemia, hypoglycaemia, hyponatraemia
- acute hypoxia
- uraemia, hepatocellular failure .,
- mitochondrial disease, porphyria.

Degenerative brain disorders

Seizures can occur in Alzheimer's disease and in many degenerative diseases. Epilepsy is three times commoner in multiple sclerosis patients than in the general population.

Provoked seizures (e.g. photosensitivity)

Seizures are occasionally precipitated by flashing lights or a flickering television screen. Photosensitivity can be recorded on occipital EEG electrodes. Rarely other stimuli (e.g. music) provoke attacks.

Sleep deprivation

A convulsion sometimes follows missing a night's sleep in a susceptible person.

Diagnosis

The history from a witness is crucial, and usually enables one to distinguish other causes of disturbed consciousness (p. 1226). The onset, setting, and stages of attacks are of importance. Neurological examination may be normal or point to a clinical diagnosis (e.g. hemiparesis and papilloedema in a hemisphere tumour). General medical screening, including serum calcium and an ECG should be carried out.

Electroencephalography

The EEG remains a useful test, despite limitations. It should be performed after a first fit.

- *During a seizure* the EEG is almost invariably abnormal, because spikes reach the brain surface.
- EEG *evidence of seizure activity* is shown typically by focal cortical spikes (e.g. over a temporal lobe) or by generalized spike-and-wave activity. Epileptic activity is continuous in *status epilepticus.*
- *3 Hz spike-and-wave activity* occurs specifically in *petit mal* (Fig. 21.15, p. 1203). This is always present during an attack and is frequently seen in between attacks.
- *A normal EEG between attacks* (interictal) does not in any way exclude epilepsy. Many people with epilepsy have normal interictal EEGs.
- *An abnormal interictal EEG* does not prove that one particular attack was epileptic.
- *EEG videotelemetry* is used to study attacks of uncertain nature (e.g. non-epileptic attack disorder, p. 1226).

CT and/or MR imaging

The trend is towards sophisticated imaging of all new cases of epilepsy when resources permit. In practice, CT is a reasonable screening test for tumours in adults but MR is used routinely if available.

Treatment

Emergency measures

When faced with a seizure it is best simply to ensure that the patient comes to as little harm as possible, and that the airway is maintained both during a prolonged seizure and in post-ictal coma. Wooden mouth gags, tongue forceps and physical restraint cause injury.

Most seizures last only minutes and end spontaneously. A prolonged seizure - longer than 3 minutes - or repeated seizures outside hospital are best treated with rectal diazepam (10 mg), or intravenous diazepam. If there is any suspicion of hypoglycaemia, take blood for glucose and give i.v. glucose. Serial epilepsy describes repeated

seizures with brief periods of recovery. These may lead to status epilepticus. Sudden death in a seizure is unusual but does occur.

Status epilepticus

This medical emergency means continuous seizures without recovery of consciousness. It should be considered if prolonged serial seizures (two or more) occur with incomplete recovery of consciousness. Status has a mortality of 10-15%. Over 50% of cases occur without a previous history of epilepsy. However, about 25% with apparent refractory status have *pseudostatus* (non-epileptic attack disorder). The iatrogenic morbidity here is significant.

Focal status also occurs. In absence status, for example, status is non-convulsive - the patient is in a continuous, distant, stuporose state. *Epilepsia partialis continua* is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

Management. See Practical box 21.4.

Anticonvulsant drugs

Drugs are indicated when there is a firm clinical diagnosis of recurrent seizures, or a substantial risk of recurrence. Anticonvulsant use carries the stigma of epilepsy. Concordance is essential, and understanding of potential unwanted effects. For both partial and generalized seizures, prescribe monotherapy with an established anticonvulsant (Table 21.34). The dose is increased until control is achieved or tolerance exceeded. If control is not achieved, a second drug is added. Despite many new anticonvulsants (Table 21.35), there remain different

Practical Box 21.4 **Management of Status Epilepticus**

Several treatment schedules exist. Issues of prime importance are the speed with which convulsive activity is treated, the accuracy of diagnosis and need for continued monitoring and cardiorespiratory support - this must be available. An ITU is essential for optimum management.

- At home, give immediate diazepam 10-20 mg i.v. at 5 mg/min and repeat once. If immediate i.v. access is impossible, give rectally diazepam or paraldehyde.
- Arrange immediate admission to hospital.
- Administer oxygen, monitor ECG, BR routine bloods (include alcohol, calcium, magnesium, drug screen, anticonvulsant levels). Exclude hypoglycaemia: treat if present.
- Give thiamine i.v. (250 mg) if nutrition poor or alcohol abuse suspected. (In the UK parenteral vitamin B and C, one pair of high-potency i.v. ampoules over 10 minutes.)
- *Anticonvulsants:*
  1. Give lorazepam i.v. 4 mg at 2 mg/min. Respiratory depression, hypotension and cardiac dysrhythmias may occur. (Lorazepam 4 mg vial.)
  2. Reinstate previous anticonvulsant drugs. Establish whether the patient has had adequate phenytoin recently. Measure levels as an emergency if service available.
  3. If seizures continue, consider i.v. phenytoin or fosphenytoin (if patient is not already loaded with these drugs).
     - Phenytoin: give 15 mg/kg i.v. diluted to 10 mg/mL in normal saline into a large vein at less than 50 mg/min. (Phenytoin sodium 250 mg 5 ml_ ampoule.)
     - Fosphenytoin: this is a pro-drug of phenytoin and can be given faster than phenytoin. Doses are expressed in phenytoin equivalents (PE): fosphenytoin 1.5 mg = 1 mg phenytoin.
     - Give 15 mg/kg (PE) fosphenytoin (15 mg x 1.5 = 22.5 mg) diluted to 10 mg/mL in normal saline at 50-100 mg (PE)/min. (Fosphenytoin sodium 750 mg 10 mL ampoule.)
  4. If status continues, give phenobarbital 10 mg/kg diluted 1 in 10 in water for injection at < 100 mg/min. (Phenobarbital 200 mg/mL 1 mL vial in propylene glycol 90% with water for injection 10%.) Intravenous clonazepam, paraldehyde and clomethiazole are also used.
  5. If, despite these measures, status persists > 90 minutes, use thiopental or propofol anaesthesia with assisted ventilation.

EEG monitoring is valuable if there is doubt about the nature of status.

CT scanning may reveal an underlying cause for status.

Remember: 25% of apparent status turns out to be *pseudostatus.*

Remember: potential unwanted effects of the drugs (e.g. hypotension, cardiac arrest) and the need for continuous cardiorespiratory monitoring.

Table 21.34 **Principal antiepileptic drugs and common seizure types**

Drug	Partial	2° Generalized	Tonic-clonic	3 Hz absence	Myoclonic
Carbamazepine					
Ethosuximide					
Phenobarbital					
Phenytoin					
Primidone					
Valproate					

+, efficacy proven/probable; 0, ineffective; - worsens seizures; ?, unknown
After Brodie MJ (2000) *Lancet* 356: 324

ante-natal screening (p. 191) is required. Vitamin K 20 mg orally should also be taken daily during the week before delivery to prevent neonatal haemorrhage (caused by inhibition of vitamin K transplacental transport).

Contraception. Anticonvulsants that induce enzymes (e.g. carbamazepine, phenytoin and phenobarbital) reduce the efficacy of oral contraceptives; valproate does not. A combined contraceptive pill containing either ethinylestradiol 50 u.g or mestranol 50 |ig provides greater contraceptive security at the risk of side effects. An IUCD or barrier methods of contraception are an alternative.

Breast-feeding. Mothers taking the established drugs (Table 21.34) need not in general be discouraged from breast-feeding - though drug manufacturers are often hesitant in assuring that there is no risk to the baby.

Drug withdrawal

Epilepsy, when controlled, may remain in remission. Drug withdrawal is sometimes possible, and this question often raised. Successful withdrawal is only achieved in less than 50%. Recurrence of seizures can cause considerable difficulty, e.g. when a driving licence has been regained. The UK Driving Licensing Authority (DVLA Swansea) recommend that patients do not drive while anticonvulsants are reduced and for 6 months after stopping them. Careful discussion and full explanation is necessary. Withdrawal should not usually be considered until all fits have been absent for at least 2-3 years.

Neurosurgical treatment

Several surgical approaches are used in epilepsy. Amputation of the non-dominant anterior temporal lobe can be performed in a patient with uncontrolled seizures and hippocampal sclerosis defined by imaging and confirmed by EEG. In these highly selected cases (under 1 % of epilepsy patients) in specialist centres this surgical treatment is highly effective - with cure rates (complete seizure cessation) over 50%. Section of the corpus callosum and hemispherectomy are also used.

Social consequences

The majority of patients with epilepsy are managed by a general practitioner or as a hospital outpatient, and suffer infrequent seizures. In a very small minority who have exceedingly frequent seizures, treatment in hospital or even residential care is necessary.

There remains, however, a considerable stigma attached to the word epilepsy and this must be realized when the nature of attacks is uncertain. Employers are reluctant to accept people with epilepsy.

Both adults and children with epilepsy should be encouraged to lead lives as unrestricted as reasonably possible, though with simple, sensible provisos such as avoiding swimming alone and dangerous sports such as rock-climbing or solo canoeing. Domestic issues include leaving the bathroom or lavatory door unlocked. Support groups and information services are valuable.

Driving and epilepsy

It is illegal to drive a motor vehicle if any form of seizure or any episode of unexplained loss of consciousness has occurred during the previous year. There is some variation between different countries. In the UK those who have suffered from epilepsy cannot legally hold a Group 1 driving licence (for a car or motorcycle) unless they satisfy the following legal criteria, whether on or off treatment. The regulations state:

- A person who has suffered an epileptic attack whilst awake must refrain from driving for 1 year from the date of the attack before a driving licence may be issued.
- A person who has suffered a single epileptic attack whilst asleep must also refrain from driving for 1 year from the date of that attack, unless they have had attacks exclusively whilst asleep over a period of 3 years and no awake attacks, i.e. attacks occurring exclusively in sleep must be shown to have occurred over a 3-year period.
- In any event, the driving of a vehicle by such a person should not be likely to cause danger to the public.

For UK Group 2 drivers (vocational and for truck drivers) regulations are stricter. Persons with previous seizures must meet *all* these three criteria:

- They must have been free of attacks for at least 10 years.
- They must not have taken anticonvulsants during this 10 years.
- They do not have any continuing liability to seizures.

Stringent regulations also exist for potential aircraft pilots, sea captains, divers and other similar activities. The correct diagnosis of an attack at any age is therefore of major social and legal importance. It is an essential medical requirement to inform patients of the law. In the UK the patient should then write to the licensing authorities.

OTHER ATTACKS OF DISTURBED CONSCIOUSNESS; FALLS (Table 21.38)

Episodes of transient disturbance of consciousness and falls are common clinical problems. It is usually possible to distinguish between a fit (i.e. a seizure), a faint (i.e. syncope), and other types of attack from the description and an eye-witness account. Falls must be distinguished from episodes of disturbed consciousness. The precise cause of falls in the elderly, with their sequelae such as a femoral fracture, often remains ill-defined. Falls without loss of awareness are common in extrapyramidal disease. 'Collapse' is non-diagnostic and the term should be avoided.

Syncope; vasovagal attacks; drop attacks

The simple faint that over half the population experience at some time (particularly in childhood, in youth or in pregnancy) is due to sudden reflex bradycardia with vasodilatation of both peripheral and splanchnic vasculature. This simple syncope (also known as neurocardiogenic syncope) is a common response to prolonged standing, fear, venesection or pain. Syncope almost never occurs in the recumbent posture. The subject falls to the ground and is unconscious for less than 2 minutes. Recovery is rapid. Jerking movements can occur. Incontinence of urine is exceptional.

Syncope occurs with severe anaemia at any age.

Syncope occurs after *micturition in men,* particularly at night, and in either sex when the venous return to the heart is obstructed by breath-holding and severe coughing. *Effort syncope* (on exertion) is of cardiac origin.

Postural hypotension (p. 734) also occurs in autonomic neuropathy, with phenothiazines, levodopa or tricyclic antidepressants. Carotid sinus problems (p. 734) and cardiac arrhythmias (p. 734) cause syncopes.

Transient cerebral {posterior circulation) ischaemia also leads to loss of consciousness and patients sometimes faint during a severe 'basilar' migraine.

Drop attacks are instant unexpected episodes of lower limb weakness with falling, largely in women over 60 years. They are due to sudden change in lower limb tone, presumably of brainstem origin, rather than thromboembolism. Awareness is preserved. Sudden attacks of leg weakness also occur in hydrocephalus.

Table 21.38 Causes of attacks of disturbed consciousness and falling

Epilepsy
Syncope (situational or vasovagal)
Simple faints
Cough
Effort
Micturition
Carotid sinus
Autonomic failure
Basilar migraine Cardiac dysrhythmias Drop attacks
Hydrocephalus Transient ischaemic attacks Panic attacks
Non-epileptic attacks (pseudoseizures)
Hyperventilation Night terrors Breath-holding in children
Hypoglycaemia
Hypocalcaemia
Vertigo
Choking
Drug reactions
Carcinoid syndrome
Phaeochromocytoma

Syncope: investigation and management

Syncope and related conditions can usually be distinguished from epilepsy on clinical grounds. A witness account is extremely valuable: persistent jerking movements, incontinence and post-episode confusion with amnesia are very suggestive of a fit, and unusual in a faint. Cardiac monitoring is used to detect dysrhythmia. Tilt testing (p. 749) is sometimes diagnostic in syncope.

The immediate management of syncope, or impending syncope, is to lay the patient down, to lift the legs and to record the pulse. In rare circumstances where cerebral blood flow cannot be restored (e.g. propped upright in a dentist's chair), cerebral infarction can follow syncope.

Other conditions

Panic attacks; hyperventilation; non-epileptic attacks.

Panic attacks are usually associated with an autonomic disturbance, such as tachycardia, sweating and piloerection. Consciousness is usually preserved and attacks often easily recognized. Hyperventilation is common and (see Box 22.11, p. 1298) overbreathing causes alkalosis. This leads to light-headedness, anxiety and sometimes circumoral and peripheral tingling and tetany, e.g. carpopedal spasm (p. 1095). Occasionally there is loss of consciousness.

Non-epileptic attacks (pseudoseizures) regularly cause difficulty. Attacks often resemble grand mal fits. Usually there are bizarre limb movements, but on occasion there is extreme difficulty in separating these attacks from

epilepsy. EEG videotelemetry is valuable. Apparent *status epilepticus* can be seen. The serum prolactin level is of some diagnostic value: it rises during a true grand mal seizure but not during a pseudoseizure (or a partial seizure).

Hypoglycaemia (see also p. 1133). Hypoglycaemia causes attacks of loss of consciousness, sometimes with a convulsion. There is often some warning, with hunger, malaise, shaking and sweating. Prompt recovery occurs with i.v. (or oral) glucose. Prolonged hypoglycaemia causes widespread cerebral damage. Hypoglycaemic attacks unrelated to diabetes are rare (but see p. 1133). Feeling faint after fasting or in the early morning does not indicate anything serious.

Hypocalcaemia (see also p. 1094). A grand mal fit may accompany hypocalcaemia - seizure threshold is lowered.

Vertigo. Acute vertigo can be sufficiently severe to cause prostration: a few seconds' unconsciousness sometimes follows.

Choking causes intense coughing and laryngeal spasm when obstruction is partial. However, when a large food bolus completely blocks the larynx, the person becomes blue and silent. Death may follow if the blockage is not relieved promptly, e.g. by the Heimlich manoeuvre (p. 899), or gravity - holding the person upside down.

***Drug** reactions.* Acute dystonic reactions (oculogyric crises, p. 1231) are sometimes mistaken for epilepsy. Consciousness is preserved.

***Carcinoid** syndrome, phaeochromocytoma and scombroid poisoning* (pp. 309 and 1098). Flushing and palpitation is sometimes mistaken for anxiety, allergy or possibly a partial seizure.

*Paroxysmal **dyskinesias.*** These are rare causes of attacks of abnormal limb movement.

SLEEP AND ITS DISTURBANCES

(see also p. 1287)

Sleep is required on a **regular basis. It preserves recent** memory, refreshing cognitive and emotional equilibrium, and avoids neurotransmitter depletion. Poorly understood neurotransmitter pathways - including those involving hypothalamic hypocretin (orexin) neuropeptides — between cortex and reticular formation are involved in the sleep-waking cycle.

In *insomnia,* sleep is fitful (p. 1288). Less time than usual is spent in REM sleep. In old age, sleep requirement falls - sometimes to 4 hours a night. In practice, insomnia is rarely a feature of neurological disease.

Narcolepsy and cataplexy

Narcoleptic attacks are periods of irresistible sleep, i.e. excessive daytime drowsiness, in inappropriate circumstances. Episodes occur when there is little distraction, after meals, while travelling in a vehicle, or sometimes without obvious cause (see Table 20.5, p. 1161). Genetically, narcolepsy is strongly associated with HLA-DR2 and HLA-DQBl*0602 antigens. There are suggestions that narcolepsy patients positive for these antigens have subnormal CSF hypocretin 1 (orexin) levels. It is thought to have an autoimmune basis.

Cataplexy is sudden loss of lower limb tone - falling with intact awareness. Attacks are often set off by sudden surprise or emotion.

The two conditions sometimes coexist and are accompanied by vivid hypnagogic hallucinations (on falling asleep), hypnopompic hallucinations (on waking), with sleep paralysis - a frightening inability to move. The EEG remains normal during and between attacks.

Treatment

Methylphenidate, dexamfetamine, modafinil, or small doses of tricyclic antidepressants, particularly clomipramine, are used, rarely with great success. Siberian ginseng *(Elenthrococcus serticosus)* and St John's Wort *(Hypericum perforatum)* are also used.

Central sleep apnoea

This occurs at the onset of sleep and is due to impairment of central ventilatory control due to brainstem pathology. It is seen in the non-obese patient with no history of snoring.

MOVEMENT DISORDERS

Disorders of movement form a substantial part of neurodegenerative diseases. They divide broadly into akinetic-rigid syndromes; slowed movement with increased tone (also called parkinsonism), and dyskinesias - added, uncontrollable movements. Precise anatomical and neurotransmitter profile changes are hard to define. Both parkinsonism and dyskinesia may coexist, leading to confusing classifications. Table 21.39 outlines the principal clinical varieties: idiopathic Parkinson's disease (an akinetic-rigid syndrome) and essential tremor (a dyskinesia) are much the commonest movement disorders.

AKINETIC-RIGID SYNDROMES

Idiopathic Parkinson's disease

In 1817, James Parkinson, a physician in Hoxton, London, published *The Shaking Palsy,* describing this common

Table 21.39 Movement disorders

world-wide condition, with prevalence of 150/100 000 increasing sharply in those over 70 years. Parkinson's disease is clinically and pathologically distinct from other parkinsonian syndromes.

There are few real clues as to the cause of idiopathic Parkinson's disease (PD). The relatively uniform world-wide prevalence suggests that an environmental agent is not responsible. Some factors possibly involved are:

Nicotine. Several epidemiological studies confirm the curious fact that PD is less prevalent in tobacco smokers than in lifelong abstainers.

MPTP. Minute doses of the pyridine compound, methylphenyltetrahydropyridine (MPTP) cause severe parkinsonism. The link between this and idiopathic PD is tenuous. Suggestions that environmental MPTP-like herbicides are implicated are entirely unsubstantiated.

Encephalitis lethargica. Some survivors of the epidemic, presumed viral encephalitis lethargica, developed severe parkinsonism. However, it is not thought that idiopathic Parkinson's disease is related to an infective agent.

Genetic factors. Whilst not usually familial, there is clustering of early-onset Parkinson's disease in some families. Mutations of the alpha-synuclein gene and ubiquitin carboxyl-terminal hydrolase LI (UCHL1), on chromosomes 2pl3 and 4pl4-16.3 respectively, account for occasional cases. Mutations in the parkin gene on chromosome 6 have been found in families with autosomal recessive cases of PD and some young apparently sporadic cases. Parkin mutations probably account for most PD cases with onset below the age of 40. Mutant parkin proteins are unable to interact, and ubiquinate forms of oc-synuclein accumulate. The relevance to the common sporadic older PD cases remains doubtful.

Pathology

In the *pars compacta* of the *substantia nigra,* progressive cell degeneration and neuronal eosinophilic inclusion bodies (Lewy bodies) are seen. These contain protein filaments of ubiquitin and alpha-synuclein. Degeneration also occurs in other basal ganglia nuclei. Biochemically there is loss of dopamine (and melanin) in the striatum. This correlates well with cell loss and with the degree of akinesia.

Clinical symptoms

The combination of tremor, rigidity and akinesia develops slowly, over months or several years, together with changes in posture. The most common initial symptoms are tremor and slowness. Patients complain that limbs and joints feel stiff. They ache. Fine movements become difficult. Slowness causes characteristic difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, and tends to tail off. Relatives often notice other features - slowness and an impassive face. Idiopathic PD is almost always initially more prominent on one side.

Clinical signs

Diagnosis is usually evident from the overall appearance.

Tremor

The characteristic 4-7 Hz pill-rolling (movements between thumb and finger) rest tremor usually decreases with action. Tremor is often asymptomatic at first.

Rigidity

Stiffness develops throughout the range of limb movement and is equal in opposing muscle groups - in sharp contrast to the selective increase in tone found in spasticity. This 'lead pipe' increase in tone is usually more marked on one side. It is also present in the neck and axial muscles.

This plastic rigidity is more easily felt when a joint is moved slowly and gently. When one arm is being examined, its tone increases when the opposite arm moves actively. When stiffness occurs with tremor, smooth 'lead-pipe' rigidity is broken up into a jerky resistance to passive movement - known as cogwheeling, or cogging.

Akinesia

Poverty and slowing of movement (bradykinesia) is an additional handicap, distinct from rigidity. There is difficulty initiating movement. Rapid fine finger movements, such as piano-playing, become indistinct, slow and tremulous. Facial immobility gives a mask-like semblance of depression. The frequency of spontaneous blinking is reduced, producing a 'serpentine' stare.

Postural changes

A stoop is characteristic. Gait becomes, hurrying (festinant) and shuffling with poor arm swinging. The posture is sometimes called 'simian' to describe the ape-like forward flexion, immobility and lack of animation. Balance deteriorates, but despite this the gait retains a narrow base. Falls are common in later stages of PD, the sufferer toppling like a falling tree.

Speech
Pronunciation is initially a monotone but progresses to characteristic tremulous slurring dysarthria, the result of combined akinesia, tremor and rigidity. Speech may eventually be lost completely (anarthria).

Gastrointestinal and other symptoms
These include heartburn, dribbling, dysphagia, constipation and weight loss. Urinary difficulties are common, especially in men. Skin is greasy and sweating excessive.

Natural history and other features
Parkinson's disease worsens over some years, beginning as a mild inconvenience but slowly progressing. Remissions are unknown except for rare and remarkable short-lived periods of release. These tend to occur at times of great emotion, fear or excitement, when the sufferer is released for seconds or minutes and able to move quickly.

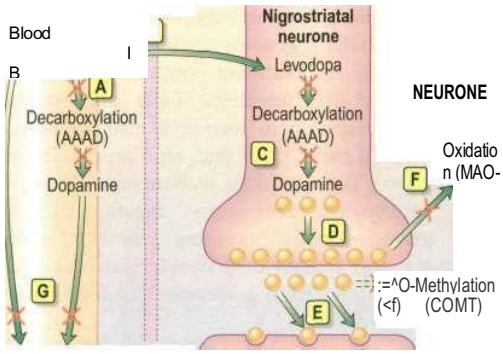
While bradykinesia and tremor worsen, power remains normal until immobility makes its assessment difficult. Patients often complain bitterly of limb and joint discomfort. There is no sensory loss. The reflexes are brisk; their asymmetry follows the increase in tone. The plantar responses remain flexor. Cognitive function is preserved, at least early on. Dementia often develops in the late stages. Anxiety and depression are common.

The rate of progression is very variable, with a benign form running over several decades. Usually the course is over 10-15 years, with death resulting from bronchopneumonia.

Diagnosis
There is no laboratory test - the diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other parkinsonian syndromes. Conventional imaging (MR) is normal. Dopamine transporter imaging (available in some specialist centres) discriminates poorly - both between normal and pathological and between PD and other akinetic-rigid syndromes.

Other diffuse and multifocal brain diseases can cause features of parkinsonism, i.e. the slowing, rigidity and tremor seen in idiopathic PD. Examples are Alzheimer's disease, multi-infarct dementia, sequelae of repeated head injury (e.g. in boxers, p. 1250), and the late effects of severe hypoxia or carbon monoxide poisoning. Slowing also occurs in hypothyroidism, and in depression.

Treatment
While no drugs alter the course of Parkinson's disease, levodopa and/or dopaminergic agonists produce striking initial symptomatic improvement. These drugs should be avoided until they are clinically necessary because of delayed unwanted effects (see below). Catechol-O-methyl transferase inhibitors are also used as supplementary therapy. Older treatments such as the antimuscarinic trihexyphenidyl (benzhexol) helped little and frequently caused confusion; they are of some value in severe tremor. Selegeline, a monoamine oxidase B inhibitor, may delay the need for levodopa therapy by



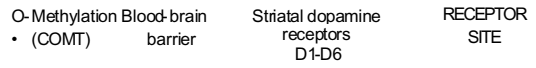


Fig. 21.29 **Drugs in Parkinson's disease: a nigrostriatal neurone and striatal dopamine receptors.**
Levodopa crosses the blood-brain barrier, enters a neurone and is converted to dopamine.

A. Carbidopa and benserazide reduce peripheral conversion of levodopa to dopamine by AAAD, thus reducing side-effects of excess circulating dopamine.
B. Dietary amino acids from a high-protein meal may inhibit active transport into brain by competing with levodopa.
C. Levodopa is converted (AAAD) to dopamine in nigrostriatal neurones.
D. At the nerve terminal, amantadine enhances dopamine release.
E. Dopamine agonist drugs react with dopamine receptors.
F. Selegeline, the MAO-B inhibitor, blocks dopamine breakdown.
G. Entacapone, a COMT inhibitor, prolongs dopamine activity by blocking breakdown.

AAAD, aromatic amino acid decarboxylase; COMT, catechol-O-methyl transferase.

some months. Antioxidants are also used with this aim, but their value is unproven. A scheme for the mechanism of action of drugs in Parkinson's disease is shown in Figure 21.29.

Levodopa

Levodopa is combined with an aromatic amino acid decarboxylase inhibitor - benserazide (co-beneldopa, as Madopar) or carbidopa (co-careldopa, as Sinemet). The decarboxylase inhibitor reduces peripheral side-effects, principally nausea, of levodopa and its metabolites. Levodopa treatment is commenced (co-beneldopa 62.5 mg or co-careldopa 110 mg, one tablet three times daily) and gradually increased.

The great majority of patients with idiopathic PD (but not other parkinsonian syndromes) improve initially with levodopa. The response in severe, previously untreated idiopathic PD is sometimes dramatic.

Unwanted effects of levodopa therapy

Nausea and vomiting are the most common immediate symptoms of excess levodopa. Confusion, formed visual pseudo-hallucinations and chorea also occur. There are difficult issues with long-term therapy (e.g. levodopa-

induced involuntary movements). After several years levodopa gradually becomes ineffective, even with increasing doses. As treatment continues, episodes of immobility develop (freezing). Falls are common. Fluctuation in response to levodopa also appears, its effect apparently turning on and off, causing freezing alternating with dopa-induced dyskinesias, chorea and dystonic movements. Levodopa's duration of action shrinks, with dyskinesia becoming prominent several hours after a dose (end-of-dose dyskinesia). The patient also begins to suffer from a chronic levodopa-induced movement disorder.

Levodopa therapy does not alter the natural progression of idiopathic PD. After 5 years' treatment, around half of Parkinson's patients suffer from minor or major unwanted effects of therapy. The more distressing problems are often largely insoluble. Approaches to treatment of these complications include:

- Shortening the interval between levodopa doses and increasing each dose.
- Selegiline, a type B monoamine oxidase inhibitor, inhibits catabolism of dopamine in the brain. This sometimes smoothes out the response to levodopa.
- Dopaminergic agonists (see below) are added, or replace levodopa.
- Entacapone (a catechol-O-methyl transferase inhibitor) is used.
- Drug holidays - periods of drug withdrawal - are occasionally helpful. They require close supervision since severe relapse may follow levodopa withdrawal.

Dopamine receptor agonists

Bromocriptine, lisuride, pergolide, cabergoline (ergot derivatives), pramipexole and ropinirole are oral directly acting dopamine receptor agonists, acting principally on D_1 and D_2 receptors, and also on receptors D_{3-5}. These are used as an alternative or an addition to levodopa therapy. The ergot derivatives are associated with pulmonary, retroperitoneal and pericardial fibrotic reactions.

Apomorphine, a potent D_1 and D_2 agonist given by subcutaneous metered infusion is an effective method of smoothing out fluctuations in response to levodopa. Skilled nursing is required to train patients and relatives to set up the infusion pump. Vomiting is common. Haemolytic anaemia is an unusual side-effect.

Dopamine receptor agonists are in general less effective than levodopa in treating symptoms in Parkinson's disease, but cause fewer late unwanted dyskinesias.

There is much variation in clinical practice between different regimens of levodopa and dopamine receptor agonists. There is a trend towards the use of receptor agonists as primary treatment (before levodopa) and to delaying starting any drugs until it is clinically essential. Directly acting agonists are usually used below the age of 70, and levodopa for older cases.

Other agents

Antioxidant compounds such as vitamins C and E (possible neuroprotective agents) are sometimes suggested. Their role is uncertain. Amantadine, originally marketed as an antiviral drug, occasionally has a modest effect. Rivastigmine is helpful for the dementia.

Stereotactic neurosurgery

Stereotactic lesions, usually unilateral in the ventrolateral nucleus of the thalamus (thalamotomy) or in the globus pallidus (pallidotomy), were used widely before levodopa. Surgery still provides effective, if temporary improvement in tremor and dyskinesia with minor relief of bradykinesia. Thalamic stimulation is also used. There has been a revival of interest in surgery in the last decade.

Tissue transplantation

Despite early promise and suggestive laboratory studies in rats with MPTP-induced parkinsonism, tissue transplantation is little used. Experimental transplantation of fetal or autologous dopamine-containing adrenal medulla and glial cell-line neurotrophic releasing factor (GDNF) into the cerebral ventricles or basal ganglia, does not produce any sustained improvement.

Physiotherapy and physical aids

Skilled and determined therapy can improve gait and help overcome particular problems. Practical guidance is of value:

clothing - avoid zips, fiddly buttons and lace-up shoes
cutlery - use built-up handles chairs - high upright rather than deep, low chairs rails - near lavatory and bath
shoes — should be easy to put on and have smooth soles

- flooring - vinyl is safer than loose carpets.

Walking aids are often a hindrance early on, but later a frame or a tripod may help. All efforts must be made to avoid falls.

Psychiatric aspects

Depression is common as PD progresses. Selective serotonin reuptake inhibitors (SSRIs) are the drugs of choice. Tricyclic antidepressants (e.g. amitriptyline) have extrapyramidal side-effects. Type A monoamine oxidase inhibitors (e.g. phenelzine) are absolutely contraindicated with levodopa.

All antiparkinsonian drugs can cause visual hallucinations, especially at night, and exacerbate cognitive impairment.

^OTHERAJKINETIC-RIGID SYNDROMES

Drug-induced parkinsonism

Reserpine and methyldopa (drugs once used to treat hypertension), phenothiazines and butyrophenones induce parkinsonism, with slowness and rigidity but usually little tremor. Tricyclic antidepressants also cause some slowing. These unwanted effects tend not to progress and settle when a drug is stopped. They respond negligibly to levodopa.

Neuroleptics and movement disorders

Neuroleptics (i.e. phenothiazines and butyrophenones) also produce movement disorders.

- **Akathisia.** This is a restless, repetitive and irresistible need to move.
- **Acute dystonic reactions.** These occur (dramatically and unpredictably) after single doses of neuroleptics and related drugs widely used as antiemetics and vestibular sedatives (e.g. metoclopramide and prochlorperazine). Spasmodic torticollis, trismus and oculogyric crises (i.e. episodes of sustained upward gaze) occur. These acute dystonias respond promptly to i.v. antimuscarinics, e.g. benzatropine (1-2 mg) or procyclidine 5-10 mg. The offending drug (and all similar) should be avoided forever.
- **Chronic tardive dyskinesias.** These are mouthing and lip-smacking grimaces, disabling disorders that occur several years after commencing neuroleptics. They often become temporarily worse when the neuroleptic dose is reduced. Resolution seldom occurs, even if treatment ceases.

Post-encephalitic parkinsonism and MPTP (see p. 1228)

Parkinsonism-plus

This describes rare disorders in which there is parkinsonism with additional features and pathology. *Progressive supranuclear palsy* (Steele-Richardson-Olzewski syndrome) is the commonest. It consists of parkinsonism, axial rigidity, falls, dementia, and inability to move the eyes vertically or laterally. Other examples are multiple system atrophies, such as olivo-ponto-cerebellar degeneration and primary autonomic failure (Shy-Drager syndrome).

These are progressive, unresponsive to levodopa and usually cause death within a decade.

Akinetic-rigid syndromes in children

Several extremely rare disorders cause akinetic-rigid syndromes with onset under 20 years.

Wilson's disease

This rare but treatable disorder of copper metabolism is inherited as an autosomal recessive. Copper deposition occurs in the brain, particularly in the basal ganglia, in the cornea and liver (p. 387), where it causes cirrhosis. All young patients either with an akinetic-rigid syndrome or with cirrhosis should be screened for Wilson's disease. Neurological damage is reversible with early treatment. This akinetic-rigid syndrome and/or dyskinesias is followed by progressive intellectual impairment. Diagnosis and treatment with the chelating agent penicillamine is discussed on page 388.

Athetoid cerebral palsy

Writhing movements, sometimes with progressive dystonia, occur in cerebral palsy following kernicterus. This is now rare following prophylactic eradication of rhesus haemolytic disease with anti-D immunoglobulin.

DYSKINESIAS

Benign essential tremor

This common condition, often inherited as an autosomal dominant trait, causes 5-8 Hz tremor, usually worse in the upper limbs. The head is often tremulous (titubation) and also the trunk. Pathologically there is patchy neuronal loss in the cerebellum and its connections. Tremor develops when the hands adopt a posture, such as holding a glass or a spoon. Essential tremor occurs at any age but occurs most frequently in the elderly. It is slowly progressive but rarely produces severe disability. Writing is shaky and untidy: micrographia is absent. Anxiety exacerbates the tremor, sometimes dramatically. In essential tremor, shaking occasionally occurs at rest, as in Parkinson's disease, or on action, as in cerebellar disease.

Treatment is often unnecessary, and unsatisfactory. Many patients are reassured to find they do not have Parkinson's disease, with which essential tremor is often confused.

Small amounts of alcohol, (3-adrenergic blockers (propranolol) and the anticonvulsant primidone may help the tremor: sympathomimetics (e.g. salbutamol) make it worse. The antidepressant mirtazapine has some effect. Stereotactic thalamotomy and thalamic stimulation are used in severe cases.

Chorea

Chorea means jerky, quasi-purposive, explosive, fidgety movements, flitting around the body - causes are listed in Table 21.40.

Huntington's disease

Relentlessly progressive chorea and dementia, usually in middle life but sometimes in childhood, are hallmarks of this inherited disease. Prevalence world-wide is about 5 in 100 000. Inheritance is as an autosomal dominant trait with full penetrance: children of an affected parent have a

Table 21.40 **Causes of chorea**

Huntington's disease Sydenham's chorea Benign hereditary chorea Abetalipoproteinaemia (see p. 308) with chorea Chorea associated with:
- Drugs - phenytoin, levodopa, alcohol
- Thyrotoxicosis, pregnancy and oral contraceptive pill
- Systemic lupus erythematosus
- Polycythaemia vera
- Encephalitis lethargica
- Stroke (basal ganglia)
- Rarities (tumour, trauma, subdural haematoma, following carbon monoxide poisoning, paroxysmal choreoathetosis, Wilson's disease, dentato-rubro-pallido-luysian atrophy)

50% chance of developing Huntington's disease. Previous family history is often concealed, sometimes deliberately. A mutation occurs in the distal short arm of chromosome 4 (4pl6.3) with a variable expansion of a CAG-repeat sequence located in exon 1 of a large gene containing 67 exons. This results in translation of an extended glutamine sequence in *huntingtin,* the protein product of the gene. Huntingtin is expressed throughout the body. Its function is unclear. Most adult-onset HD cases have CAG expansions of 40-55 repeats, while greater expansions (> 70 repeats) are seen in childhood-onset HD.

Pathology

Cerebral atrophy progresses, with marked loss of small neurones in the caudate nucleus and putamen. Changes in neurotransmitters occur:

- *reduced* acetylcholine synthesis (due to reduced choline acetyl transferase) and GABA in the striatum
- *increased* transglutaminase (catalyses aggregates of *huntingtin)* in cortex, cerebellum and corpus striatum
- *depleted* GABA, angiotensin-converting enzyme and met-enkephalin in substantia nigra
- *high* somatostatin levels in the corpus striatum.

These may be secondary to cell damage. In contrast to Parkinson's disease, dopamine and tyrosine hydroxylase remain normal.

Management and course

Other causes of chorea should be investigated. Imaging in Huntington's, if practical with the chorea, shows caudate nucleus atrophy. There is steady progression, of both dementia and chorea. While nothing arrests this, phenothiazines (e.g. sulpiride) and tetrabenazine reduce chorea. Death usually occurs 10-20 years from the onset. Mutation analysis is used for presymptomatic testing. Test centres have a national protocol for counselling families and addressing the ethical issues.

Sydenham's chorea (St Vitus's dance)

This transient postinfective chorea occurs largely in children and young adults. Streptococcal infection is one cause: under half the cases follow within 3 months of rheumatic fever (p. 76). Sydenham's may recur, or appear, in adult life, during pregnancy as chorea gravidarum and with hormonal contraceptives. There is a diffuse mild encephalitis.

The onset is gradual over a few weeks. Irritability, emotional lability, and inattentiveness herald fidgetiness, sometimes mainly unilateral. A minority of patients become confused. Rheumatic heart disease is sometimes found. Fever is unusual. Antistreptolysin-O (ASO) titre and ESR are typically normal. Sedation may be needed. Recovery occurs spontaneously within weeks or months. Phenoxymethylpenicillin should continue to the age of 20 to prevent rheumatic heart disease. ■.•:■■■■

HemibalMsmuS (see p. 1194 and Fig. 21.9)

Hemiballismus (also called hemiballism) describes violent swinging movements of one side caused usually by infarction or haemorrhage in the contralateral subthalamic nucleus.

Myoclonus

Myoclonus is sudden, involuntary jerking of a single muscle or a group of muscles. It occurs in a wide range of disorders and is sometimes provoked by sudden stimuli such as loud noise. Piracetam is used for cortical myoclonus.

Benign essential myoclonus

Nocturnal myoclonus - sudden jerking (often with a feeling of falling) on dropping off to sleep - is common and not pathological. Periodic limb movements (repetitive dorsiflexion of the great toe or plantar flexion of the foot during Stage I or II sleep) are brief and occur in restless leg syndrome (p. 666).

Paramyoclonus multiplex describes widespread, random muscle jerking usually occurring in adolescence. Fits do not occur.

Myoclonus in epilepsy

Muscle jerking occurs in many different forms of epilepsy. An antiepileptic drug, e.g. valproate, may be helpful.

Progressive myoclonic epilepsies

These rare conditions include familial and metabolic disorders where myoclonus accompanies progressive encephalopathy. *Lafora body disease* is one example, consisting of myoclonus, epilepsy, dementia, with mucopolysaccharide inclusions in neurones, liver cells and intestinal mucosa.

Static myoclonic encephalopathy

Non-progressive myoclonus sometimes develops following recovery from severe cerebral anoxia.

Non-organic muscle jerking.

This is sometimes volitional, or seen in psychiatric conditions, e.g. somatization, non-epileptic attacks and malingering.

Tics

Some idiosyncratic movement of the face, neck or hand is part of our normal motor gestures. Patients or relatives seek advice when movements become frequent or irritating. Simple transient tics (e.g. sniffing or a particular facial grimace) are common in childhood, but may persist. The borderland between normal and pathological is vague.

Gilles de la Tourette syndrome

This describes multiple tics (motor and speech) with behavioural problems including the attention-deficit-hyperactivity disorder (ADHD) and the obsessive-compulsive disorder (OCD). This develops in childhood or adolescence, more commonly in males, and is lifelong. There is sometimes explosive barking and grunting of obscenities and gestures. The cause is believed to be an

Table 21.41 A classification of dystonias

Generalized dystonia
Primary torsion dystonia (PTD) Dopamine-responsive dystonia (DRD) Drug-induced dystonia (e.g. metoclopramide)
Symptomatic dystonia (e.g. after encephalitis lethargica or in Wilson's disease) Paroxysmal dystonia (very rare, familial, with marked fluctuation)

Focal dystonia
Spasmodic torticollis
Writer's cramp
Oromandibular dystonia
Blepharospasm
Hemiplegic dystonia (e.g. following stroke)
Multiple sclerosis

inherited disorder of synaptic transmission. Haloperidol is sometimes helpful.

Torsion dystonias

Dystonia means movement caused by prolonged muscular contraction - part of the body is thrown into spasm. A brief explanatory classification of these unusual basal ganglia conditions is given in Table 21.41. Their causes are largely unknown.

Primary torsion dystonia (dystonia musculorum deformans)

Dystonia affecting gait and posture in childhood progresses, spreading to all parts of the body over one to four decades. Cognitive function is not impaired. Spontaneous remissions occur occasionally. This rare disease is usually inherited as an autosomal dominant. A PTD gene has been located on chromosome 9 (9q34); this is a deletion of three base pairs encoding an ATP-binding protein torsin A.

Dopamine-responsive dystonia (DRD)

This lower limb dystonia is almost completely abolished by small doses of levodopa. Typically dystonic walking begins in childhood - and may resemble a spastic paraparesis. The usual form is autosomal dominant DRD with a point mutation of the GTP cyclohydrolase 1 gene on chromosome 14q22.3. Patients with other odd dystonic gaits are sometimes given test doses of levodopa.

Spasmodic torticollis

Dystonic spasms gradually develop around the neck, usually in the third to fifth decade. These cause the head to turn (torticollis) or to be drawn backwards (retrocollis) or forwards (antecollis). Minor dystonic movements often also affect the trunk and limbs. A curious feature in some patients is a single trigger area, often on the jaw. A gentle touch with a finger tip at this specific site relieves the spasm temporarily. Torticollis may remit but often persists indefinitely. Similar features are sometimes seen when no organic disease is present.

Writer's cramp

This is a specific inability to perform a previously highly developed repetitive skilled movement, e.g. writing. The movement provokes dystonic posturing. Writer's cramp occurs in those who spend many hours each day *writing,* and is thus seen less frequently than in years past. Other functions of the hand remain normal. There are no other neurological signs. Prolonged rest sometimes helps but the dystonia can cause substantial disability. Similar dystonias occur in other occupations.

Blepharospasm and oromandibular dystonia

These consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g. lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

Treatment

All dystonic movement disorders are particularly difficult to help. Butyrophenones (e.g. haloperidol and sulpiride) and antimuscarinics (e.g. trihexyphenidyl (benzhexol)) are sometimes helpful. Botulinum toxin carefully sited by injection can help, temporarily, blepharospasm, torticollis and writer's cramp. Neurosurgical treatment, principally stereotactic thalamotomy for torticollis, or neurostimulation brings some temporary alleviation in selected cases.

MULTIPLE SCLEROSIS (MS)

MS is a chronic inflammatory disorder of the central nervous system. There are multiple plaques of demyelination within the brain and spinal cord. Plaques are 'disseminated in time and place', hence the old name disseminated sclerosis.

Prevalence

MS prevalence varies widely, being directly proportional to distance of residence from the equator. At latitudes of 50-65° N (roughly from southern England to Iceland) prevalence is 60-100 per 100 000; at latitudes less than 30° N prevalence is below 10/100 000. At the equator MS is a rarity. Dietary factors, e.g. high animal fat consumption, had been suggested for this geographical distribution but there is little evidence for this. In the southern hemisphere this trend is similar - increasing prevalence with distance from the equator. Overall, in Europe and N America the annual incidence is 2-10 per 100 000, making it the most common neurological disease in young adults.

Aetiopathogenesis

Although the precise mechanism is unknown, there is an inflammatory process against self molecules in the white matter of the brain and spinal cord mediated by CD4 T cells. In the active lesions (plaques) there is an increase in inflammatory cells, active myelin degradation and phagocytosis. Lymphocytes and monocytes gain access to the brain parenchyma from the circulation by adhering to vascular endothelial cells via the glycoprotein $a_4p"i$, integrin expressed on their surface. This integrin (also known as very late antigen VLA_4) is also a regulator of immune-cell activation.

An initial inflammatory demyelinating event may prime autoreactive cellular and humoral immune responses against myelin. Antibody-mediated demyelination, e.g. against myelin basic protein, may present early in MS. Antibodies against myelin oligodendrocyte glycoprotein (MOG) - a protein which is specific to the CNS - have also been found in vitro.

Familial incidence, HLA linkage and migration

First-degree relatives of a patient have an increased chance of developing MS, without a clear-cut pattern of inheritance.

The concordance rate is 31% in monozygotic twins.

In Caucasians in northern Europe and the USA, there is a weak association between MS and antigens HLA-A3, B7, D2 and DR2.

Immigrants from low to high prevalence zones (e.g. from the equator to northern Europe) *acquire* the prevalence of their destination, provided they arrive before the age of10.

Infection

Efforts to transmit MS experimentally have been uniformly unsuccessful. However, an abnormal immune response in many MS patients produces increased titres of serum and CSF antibodies to many common viruses, particularly measles. Some epidemic transmissible zoonoses, such as scrapie (demyelinating disease in sheep), have some similarities to MS. In man, human T-cell leukaemia virus 1 (HTLV-1) causes tropical spastic paraparesis, but no other features seen in MS. Chlamydia has been questioned as a cause. No known links exist between MS and any infection.

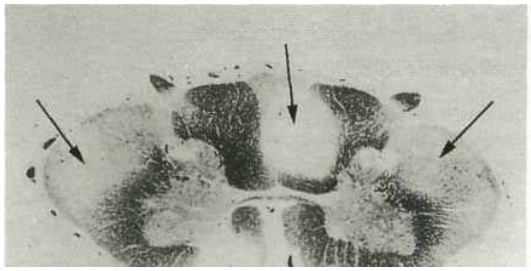

Fig. 21.30 Multiple sclerosis. Cross-section of the spinal cord showing demyelination (arrows) in the posterior column and lateral corticospinal tracts. Courtesy of Professor WI Macdonald.

Pathology (Fig. 21.30)

Plaques of demyelination, initially 2-10 mm in size are the cardinal features. Plaques are perivenular with a predilection for distinct CNS sites: optic nerves, the periventricular region, brainstem and its cerebellar connections and the cervical spinal cord (corticospinal tracts and posterior columns).

Acute relapses are caused by focal inflammatory demyelination, which causes a conduction block. Inflammation induces local production of nitric oxide by macrophages, which damages central nerve fibres. *Remission* follows as inflammation subsides. Remyelination occurs and helps recovery. When damage is severe, secondary permanent axonal destruction occurs. In the cord, plaques rarely destroy large groups of anterior horn cells - thus focal muscle wasting (e.g. small hand muscles) is unusual. MS plaques are not seen in myelin sheaths of peripheral nerves.

Clinical features

The commonest age of onset is between 20 and 45 years, a diagnosis before puberty or after 60 years is rare. MS is more common in women. No single group of signs or symptoms is absolutely diagnostic. Despite this, MS is often recognizable clinically by different patterns:

- relapsing and remitting MS (80-90%)
- primary progressive MS (10-20% of cases)
- secondary progressive MS - this follows on from relapsing/remitting disease
- occasionally (< 10%) MS runs a fulminating course over some months (fulminant MS).

Three characteristic common presentations of relapsing and remitting MS are described below.

Optic neuropathy (ON)

Symptoms

Blurring of vision in one eye develops over hours or days, varying between a 'looking through frosted glass' sensation to severe unilateral visual loss, but rarely complete blindness. Mild ocular pain is usual. Recovery

occurs, typically within 2 months. Bilateral ON occasion ally occurs. . . . . .

Signs

The optic disc appearance depends upon the site of the plaque within the optic nerve. When the lesion is in the nerve *head* there is disc swelling (optic neuritis, p. 1181). If the lesion is several millimetres *behind the disc* there are often no ophthalmoscopic abnormalities - 'the doctor sees nothing and the patient sees nothing'. This is *retrobulbar neuritis* (p. 1181).

Worsening of vision in ON during a fever, hot weather or after exercise is known as Uthoff's phenomenon - central conduction is slowed by an increase in local body temperature.

Disc swelling from optic neuritis causes early visual acuity loss, thus distinguishing it from disc swelling from raised intracranial pressure - the latter causes little or no visual loss early on, but sudden visual loss in advanced stages.

A relative afferent pupillary defect (p. 1182) in optic neuropathy is often found, and persists after recovery.

Late sequelae of optic neuropathy

There is often no residual loss of vision, but small scotomata and defects in colour vision can be found. Following optic neuropathy, disc pallor appears (optic atrophy), first on the temporal side. Visual evoked responses (VER) remain abnormal (see below and page 1203).

Brainstem demyelination

Acute MS in the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria or dysphagia. Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. This lasts for some weeks before recovery. Diplopia in MS is produced by many lesions - a sixth nerve lesion and internuclear ophthalmoplegia (INO, p. 1183) are two examples.

Spinal cord lesion

Spastic paraparesis developing over days or weeks (p. 1192) is a typical result of a plaque in the cervical or thoracic cord, causing difficulty in walking and numbness. Lhermitte's sign may be present (p. 1199). Urinary symptoms are common.

Unusual presentations

Epilepsy and trigeminal neuralgia (p. 1186) occur more commonly in MS patients than in the general population. Tonic spasms (brief spasms of one limb) are other unusual presentations. Organic psychosis is occasionally seen in early MS.

End-stage multiple sclerosis

Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g. bilateral INO), pseudobulbar palsy, and urinary incontinence. Dementia is common. Death follows from uraemia and/or bronchopneumonia.

Differential diagnosis

Few other neurological diseases follow a similar relapsing and remitting course. Thromboembolism causes events with more sudden onset. Other degenerative conditions, such as Friedreich's ataxia, are gradually progressive. Following an isolated neurological event it is often impossible to be sure, even with MR imaging, whether or not MS is the diagnosis. The pattern of subsequent lesions leads to the diagnosis. Remissions may last for several or more years; their length is unpredictable and the mechanism of relapse and remission unclear.

Individual plaques (e.g. in optic nerve, brainstem or cord) must be distinguished from mass, vascular or other inflammatory lesions. Of the latter, CNS sarcoidosis, SLE and Behget's syndrome may mimic relapsing MS. Adrenoleucodystrophy (an inherited disorder of saturated fatty acid deposition in lipid-containing tissues) can cause a progressive paraparesis identical to chronic progressive MS (p. 1234).

Investigations

- *MRI* of brain and spinal cord is the definitive investigation. Multiple plaques are visible, principally in the periventricular region (Fig. 21.31), brainstem, and cervical cord. Head MRI scans show lesions in 85% of patients with clinical MS. Typical lesions are multifocal with 10 or more lesions seen in a clinical relapse. Plaques are rarely visible on CT.
- *CSF examination* is often unnecessary with diagnostic MR and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in 80% of cases but these are not specific as they simply indicate immunoglobulin production within the CNS in response to an unknown antigen. The CSF cell count is raised (5-60 mononuclears/ mm^3).
- *Electrophysiological tests.* Delay in visual-evoked responses (VER) is seen in optic neuropathy. Some ON attacks are subclinical: a delayed VER provides evidence of a previous optic nerve lesion. This is helpful for diagnosis if there had been, for example, an undiagnosed and apparently solitary spinal cord lesion. Brainstem and somatosensory evoked poten-

Fig. 21.31 MR (T2): Multiple sclerosis. The arrows point to the demyelinating lesions.

tials become delayed when these pathways have been damaged. Peripheral nerve studies are normal and EEG unhelpful.

- *Blood/urine* tests are unhelpful.

Management and prognosis

Once diagnosed, practical decisions need to be taken about employment, home and plans for the future in the face of a potentially disabling disease. There is no curative treatment.

The course of MS is unpredictable but a florid MR1 lesion load at first presentation is a strong predictor of future disability. There is wide variation in severity. Many patients continue to live self-sufficient, productive lives: others become gravely disabled.

Straightforward advice, tempered with reassurance of the benign course of many cases of MS is necessary. The MS Society, a national UK charity, and others have helpful literature.

MS therapies

Many forms of treatment have been marketed, among them cryotherapy, pyrotherapy, radiotherapy, various vaccines, purified TB protein derivative (PPD), transfer factor, electrical stimulation, gluten-free diets, sunflower seed oil, arsenicals, vitamins and hyperbaric oxy gen. None has been shown to improve outcome.

- *Acute relapses.* Short courses of corticosteroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used widely in relapses and do sometimes reduce severity. They do not influence long-term outcome.
- *Preventing relapse and disability.* Beta-interferon (both INF-pib and la) by self-administered injection is used in relapsing and remitting disease. This is defined as at least two attacks of neurological dysfunction over the previous 2 or 3 years followed by a reasonable recovery. IFN-fSlb is also now licensed for secondary progressive MS. Interferon reduces the relapse rate in some patients and prevents an increase in lesions seen on MR1. Long-term outcome seems unaltered. Unwanted effects are flu-like symptoms and irritation at injection sites. Cost—benefit analyses are serious issues: beta-interferons are expensive.
- *Immunosuppressants* (azathioprine, cyclophosphamide) are also used, but controlled trials have shown no benefit
- *Other therapies,* such as glatiramer acetate, reduce relapse frequency. Mitoxantrone is also being evaluated.

The rehabilitative approach in MS

Much can be done for someone with any chronic disabling disease. Practical advice at work, on walking aids, wheelchairs, car conversions, alterations to houses and gardens is needed, from professionals with experience of rehabilitation. Wide-ranging support - for fear, reactive depression and sexual difficulties - is also helpful. Multidisciplinary team liaison between patient, carers, doctors and therapists is essential.

Treat all infections. Urinary infection frequently exacerbates symptoms. Urinary incontinence may be helped by oxybutinin and/or intermittent self-catheterization.

Physiotherapy is of particular value in reducing pain and discomfort of spasticity, particularly lower limb flexor spasms. Muscle relaxants (e.g. baclofen, benzodiazepines, dantrolene and tizanidine) are sometimes helpful. Injected botulinum toxin is used for severe spasticity. Cannabis is used by many patients for painful spasms. Cannabis extracts (e.g. Sativea) are being evaluated. Prevention of pressure sores is vital. Amantadine is sometimes used for general fatigue.

CNS INFECTION AND INFLAMMATION^

MENINGITIS

Meningitis means inflammation but usually implies serious infection of the meninges (Table 21.42). Microorganisms reach the meninges either by direct extension from the ears, nasopharynx, cranial injury or congenital meningeal defect, or by bloodstream spread. Immunocompromised patients (e.g. HIV, cytotoxic drugs) are at risk of infection by unusual organisms. Non-infectious causes of inflammation include malignant cells, drugs and blood following subarachnoid haemorrhage.

Pathology

In acute bacterial meningitis, the pia-arachnoid is congested with polymorphs. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus.

In chronic infection (e.g. TB), the brain is covered in a viscous grey-green exudate with numerous meningeal

*Streptococcus pneumoniae**
Staphylococcus aureus
Streptococcus Group B
Listeria monocytogenes Gram-negative bacilli *Mycobacterium tuberculosis Treponema pallidum*

Viruses
Enteroviruses:
ECHO
Coxsackie
Mumps
Herpes simplex HIV
Epstein-Barr virus

Fungi
Cryptococcus neoformans
Candida
(Coccidioides immitis, Histoplasma capsulatum, Blastomyces dermatitidis in USA)

'These organisms account for 70% of acute bacterial meningitis outside the neonatal period. A wide variety of infective agents are responsible for the remaining 30% of cases. *Haemophilus influenzae* b (Hib) has been eliminated as a cause in many countries by immunization

Table 21.43 Clinical clues in meningitis

Clinical feature	Probable cause
Petechial rash Skull fracture Ear disease Congenital CNS lesion	Meningococcal infection
Immunocompromised patients	Pneumococcal infection
Rash or pleuritic pain	HIV opportunistic infection
International travel	Enterovirus infection
Occupational history (working in drains, canals, polluted water, recreational swimming): prostration, myalgia, conjunctivitis, jaundice	Poliomyelitis Malaria Leptospirosis

tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis.

In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs or adhesions; there is little or no cerebral oedema unless encephalitis develops.

Clinical features

The meningitic syndrome

This is a simple triad: headache, neck stiffness and fever. Photophobia and vomiting are often present. In acute bacterial infection there is usually intense malaise, fever, rigors, severe headache, photophobia and vomiting. This develops within hours or minutes. The patient is irritable and often prefers to lie still. Neck stiffness and positive Kernig's sign usually appear within hours.

In less severe cases (e.g. many viral meningitides) there are less prominent meningitic signs, but fatal bacterial infection may also be indolent, with a deceptively mild onset. Clinical pictures that are apparently mild are unreliable and lead to fatal misjudgements.

In uncomplicated meningitis, consciousness remains intact, although anyone with high fever may be delirious. Progressive drowsiness, lateralizing signs and cranial nerve lesions indicate complications such as venous sinus thrombosis (p. 1219), severe cerebral oedema, hydrocephalus, or an alternative diagnosis such as cerebral abscess (p. 1243) or encephalitis (p. 1239). Papilloedema may develop.

Specific varieties of meningitis

Clinical clues point to the diagnosis (Table 21.43). If there is access to the subarachnoid space via skull fracture (recent or old) or occult spina bifida, bacterial meningitis can be recurrent — and the infecting organism usually pneumococcus.

Acute bacterial meningitis

Onset is typically sudden, with rigors and high fever. *Meningococcal* meningitis is often heralded by a petechial or other rash, sometimes sparse (see Emergency box 21.1). The meningitis may be part of a generalized meningococcal septicaemia (p. 75). Acute septicaemic shock may develop in any bacterial meningitis.

Viral meningitis

This is almost always a benign, self-limiting condition lasting 4-10 days. Headache may follow for some months. There are no serious sequelae.

Chronic meningitis (see below)

Differential diagnosis

It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever and in any sudden headache. Neck stiffness should be assessed carefully - it may not be obvious. Chronic meningitis sometimes resembles an intracranial mass lesion, with headache, epilepsy and focal signs. Cerebral malaria often mimics bacterial meningitis.

Management (Emergency Box 21.1) Recognition and immediate treatment of acute bacterial meningitis is vital. Minutes save lives. Bacterial meningitis is lethal. Even with optimal care, mortality is around 15%. When meningococcal meningitis is diagnosed clinically by the petechial rash, immediate i.v antibiotics should be given; lumbar puncture is unnecessary. In other causes of meningitis a lumbar puncture is performed if

Emergency Box 21.1 **Meningococcal meningitis and meningococcaemia: emergency treatment**

Suspicion of meningococcal infection is a medical emergency requiring treatment *immediately* medical contact takes place. In meningococcal meningitis, fever, headache and neck stiffness are accompanied or heralded by a petechial, or non-specific blotchy red rash. However, all these features may not be present - and meningococcal infection may sometimes begin like any intercurrent non-serious viral infection.

The ***immediate*** management of suspected meningococcal infection is benzylpenicillin 1200 mg (adult dose) either by slow i.v. injection or intramuscularly, prior to investigations. Cefotaxime 1 g i.v. is an alternative in cases of penicillin allergy. In meningitis, minutes count: delay is unacceptable.

On arrival in hospital, routine tests including blood cultures should be carried out *immediately,* and a close lookout kept for the emergence of septicaemic shock. For further management and prophylaxis, see text.

Table 21.44 **Antibiotics and acute bacterial meningitis**

Organism	Antibiotic	Alternative (e.g. allergy)
Unknown pyogenic	Cefotaxime	Benzylpenicillin and chloramphenicol
Meningococcus	Benzylpenicillin	Cefotaxime Penicillin
Pneumococcus	Cefotaxime	Chloramphenicol
Haemophilus	Cefotaxime	

there is no clinical suspicion of a mass lesion (p. 1245). If the latter is suspected an immediate CT scan must be performed because coning of the cerebellar tonsils may follow. Typical CSF changes are shown in Table 21.45. CSF pressure is characteristically elevated. If a presumptive diagnosis of the organism can be made (e.g. pneumococcus is likely with skull fracture or sinus infection), targeted treatment should be started immediately. A scheme for immediate antibiotic treatment in acute bacterial meningitis is in Table 21.44.

Blood should be taken for cultures, glucose and routine tests, and chest and skull films if appropriate.

CSF stains demonstrate organisms (e.g. Gram-positive intracellular diplococci - pneumococcus; Gram-negative cocci - meningococcus). Ziehl-Neelsen stain demonstrates acid-fast bacilli (TB), though TB organisms are rarely numerous. Indian ink stains fungi.

It cannot be emphasized enough that meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques (e.g. polymerase chain reaction for meningococci and other bacteria) are invaluable. Syphilitic serology should always be carried out.

The clinical picture and CSF examination should thus yield a presumptive cause for acute meningitis within hours. Antibiotics must be started before the actual organism is identified.

If bacterial meningitis is diagnosed, further discussion with the microbiologist should include antibiotics, drug resistance, recent infections in the locality, barrier nursing and prophylaxis.

In bacterial meningitis in children, the use of dexamethasone has declined since the introduction of Hib vaccination. In adults it is recommended for pneumococcal meningitis.

Intrathecal antibiotics are no longer used in meningitis.

Local infection (e.g. paranasal sinus) should be treated surgically if necessary. Repair of depressed skull fracture or meningeal tear may be required.

Prophylaxis

Meningococcal infection should be notified to public health authorities, and advice sought about immunization and prophylaxis of contacts, e.g. with rifampicin or ciprofloxacin. *MenC,* a meningococcal C conjugate vaccine, is part of childhood UK immunization and often given to case contacts. A combined A and C meningococcal vaccine is sometimes used prior to travel to endemic regions, e.g. Africa, Asia; and a quadrivalent ACWY vaccine for specific events, e.g. Hajj and Umrah in Mecca. There is no vaccine for Group B.

A polyvalent pneumococcal vaccine is used after recurrent meningitis, e.g. after a CSF leak following skull fracture.

Hib (Haemophilus influenzae) vaccine is given routinely in childhood in the UK, virtually eliminating a common cause of fatal meningitis.

Chronic meningitis

Tuberculous meningitis (TBM) and cryptococcal meningitis commence typically with vague headache, lassitude, anorexia and vomiting. Acute meningitis can occur but is unusual. Meningitic signs usually take some weeks to develop. Drowsiness, focal signs (e.g. diplopia,

Table 21.45 **Typical CSF changes in meningitis**

	Normal	Viral	Pyogenic	Tuberculosis
Appearance	Crystal-clear	Clear/turbid	Turbid/purulent	Turbid/viscous
Mononuclear cells	< 5 mm^3	10-100 mm^3	< 50 mm^3	100-300 mm^3

Protein	0.2-0.4 g/L	0.4-0.8 g/L	0.5-2.0 g/L	0.5-3.0 g/L
Glucose	% > V_2 blood glucose	> Y_2 blood glucose	< V_2 blood glucose	< V_2 blood glucose

"Some polymorph cells may be seen in the early stages of viral meningitis and encephalitis

papilloedema, hemiparesis) and seizures are common. Syphilis, sarcoidosis and Behget's syndrome also cause chronic meningitis. In some chronic meningitis an organism is never identified.

Management of TBM

TMB is a common and serious disease world-wide. Brain imaging may show meningeal enhancement, hydrocephalus and tuberculomas (p. 1243), though it may remain normal. See Table 21.45 for CSF changes. In many cases the sparse TB organisms cannot be seen on Ziehl-Neelsen staining. Repeated CSF examination is often necessary and it will be some weeks before cultures are confirmatory. Treatment with anti-TB drugs (p. 932) - rifampicin, isoniazid and pyrazinamide - must commence on a presumptive basis and continue for at least 9 months. Ethambutol should be avoided because of its eye complications. Relapses and complications (e.g. seizures, hydrocephalus) are common in TBM. The mortality remains over 60% even with early treatment.

Malignant meningitis

Malignant cells can cause a subacute or chronic non-infective meningitic process. A meningitic syndrome, cranial nerve palsies, paraparesis and root lesions are seen, often in confusing and fluctuating patterns. The CSF cell count is raised, with high protein and low glucose. Treatment with intrathecal cytotoxic agents is rarely helpful.

Cells in a sterile CSF

Difficulties arise with a raised CSF cell count without evident infecting organism. CSF pleocytosis, a mixture of lymphocytes and polymorphs is the usual situation. See Table 21.46.

Table 21.46 **Causes of sterile CSF (pleocytosis)**

Partially treated bacterial meningitis Viral meningitis Tuberculosis or fungal infection	Cerebral venous thrombosis Cerebral infarction Following subarachnoid haemorrhage
Neoplastic meningitis Parameningeal foci (e.g. paranasal sinus)	Encephalitis, including HIV Rare causes (e.g. cerebral malaria, sarcoidosis, Behcet's syndrome, Lyme disease, endocarditis, cerebral vasculitis/ angitis)
Syphilis Intracranial abscess

Meningitis Trust: http://www.meningitis-trust.org.uk

ENCEPHALITIS

Encephalitis means inflammation of brain parenchyma, usually viral. Brain inflammation also develops in bacterial and fungal meningitis.

Acute viral encephalitis

The usual organisms cultured from adult UK cases are herpes simplex, ECHO, Coxsackie, mumps and Epstein-Barr viruses. Adenovirus, varicella zoster, influenza, measles and other viruses are rarer. Often, viral aetiology is presumed but never confirmed.

Epidemic and endemic viral encephalitides occur world-wide:

- Japanese encephalitis in South East Asia
- Ross River fever in Australia
- California encephalitis in the USA
- Omsk haemorrhagic fever in Russia
- Tick-borne flavivirus encephalitis in Sweden and Central Europe
- West Nile encephalitis in Egypt and Sudan.

Epidemic viral encephalitides with unusual organisms are common. For example, encephalitis caused by Nipah-virus, hitherto not known to cause human disease, occurred in 1998 in abattoir workers in Malaysia; in New York in 1999 West Nile virus caused an encephalitis epidemic. In Southern India in 2003 there was an outbreak of encephalitis in children due to the chandipura virus. Rabies (p. 58) is a variety of sporadic viral encephalitis.

Clinical features

Many encephalitides are mild and recovery occurs. In a minority, serious illness develops with high fever, headache, mood change and drowsiness over hours or days. Focal signs, seizures and coma ensue. Death, or brain injury follows. Herpes simplex virus (HSV-1) accounts for many severe cases in Britain. Mortality remains around 20%. In SE Asia, Japanese encephalitis (arbovirus) is more usual, causing a serious illness with higher mortality than HSV-1.

Differential diagnosis

This includes:

- bacterial meningitis with cerebral oedema
- cerebral venous thrombosis
- cerebral abscess
- acute disseminated encephalomyelitis (see below)

cerebral malaria
- toxic confusional states
- septicaemia, febrile illness, vasculitis
- endocarditis.

Investigations

CT and MR imaging show diffuse areas of oedema, often in the temporal lobes. EEG shows characteristic slow waves, which are useful in some cases; a normal EEG is exceptional. CSF shows a raised cell count. Viral serology (blood + CSF) is helpful. Brain biopsy is occasionally performed.

Treatment

Suspected herpes simplex encephalitis is treated immediately with intravenous aciclovir, the active form of which inhibits DNA synthesis. Phosphorylation of aciclovir is dependent upon viral thymidine kinase; the drug is thus specific for herpesvirus infections. A poor outlook usually follows coma whether or not aciclovir has been given. Supportive measures are required for comatose patients; seizures are treated with anticonvulsants. Prophylactic immunization against Japanese encephalitis is advised for travellers to endemic areas in Asia.

Editorial (2000) Exotic diseases close to home. *Lancet* 354: 1221. Whitley RJ, Gnann JW (2002) Viral encephalitis. *Lancet* 359: 507-514.

Acute disseminated encephalomyelitis (ADEM)

ADEM follows many viral infections (e.g. measles, varicella zoster, mumps and rubella) and rarely immunization against rabies, influenza or pertussis. The syndrome is often similar to acute viral encephalitis, with focal brainstem and/or spinal cord lesions due to demyelination (see also MS, p. 1235). Viral particles are not present in these lesions, which are well seen on T2 MR images. Prognosis is variable. Mild cases recover completely. When there is coma, mortality remains c. 25%. Survivors often have permanent brain damage. Treatment is supportive, with steroids and anticonvulsants.

MYELITIS

Myelitis means spinal cord inflammation causing paraparesis or tetraparesis. This occurs with varicella zoster or ADEM. Poliomyelitis is a specific spinal cord anterior horn cell enterovirus infection (p. 49). Transverse myelitis is mentioned on page 1252.

HERPES ZOSTER (SHINGLES)

This is recrudescence of varicella-zoster infection within dorsal root ganglia, the original virus infection having been chickenpox many years previously. Chickenpox and shingles viruses are identical.

Clinical features

For shingles rashes, see page 46.

In the cranial nerves, herpes zoster has a predilection for the fifth and seventh nerves. 'Ophthalmic' herpes is infection of the first division of the fifth nerve. This can lead to corneal scarring and secondary panophthalmitis (p. 1167). Geniculate herpes (geniculate ganglion of Vllth nerve) is also called Ramsay Hunt syndrome (p. 1188). Local complications are secondary bacterial infection, very rarely local purpura with necrosis *(purpum fulminans),* generalized zoster, and postherpetic neuralgia. Myelitis, meningoencephalitis and motor radiculopathy (usually lumbar or brachial) also follow varicella-zoster. Treatment is with aciclovir or its pro-drug valaciclovir.

Postherpetic neuralgia

Postherpetic neuralgia is pain in a previous shingles zone; this occurs in some 10% of patients (often elderly). Burning, continuous pain responds poorly to analgesics. Depression is almost universal. Treatment is unsatisfactory but there is a trend towards gradual recovery over 2 years. Amitryptyline is commonly used. Methylprednisolone intrathecally is sometimes helpful.

FURTHER READING

Johnson RW, Dworkin RH (2003) Treatment of herpes zoster and postherpetic neuralgia. *British Medical Journal* 326: 748-750.

NEUROSYPHILIS

Syphilis is described on page 122. A variety of syndromes occur, sometimes mixed.

Asymptomatic neurosyphilis

This describes positive CSF serology without signs.

Meningovascular syphilis

This causes:

- subacute meningitis with cranial nerve palsies and papilloedema
- a gumma — a chronic expanding intracranial mass
- paraparesis caused by a spinal meningovasculitis.

Tabes dorsalis

Demyelination in dorsal roots causes a complex deafferentation syndrome. The elements of tabes are:

- lightning pains (p. 1198)
- ataxia, stamping gait, reflex and sensory loss, muscle wasting
- neuropathic joints (Charcot joints)
- Argyll Robertson pupils (p. 1183)
- ptosis and optic atrophy.

General paralysis of the insane (GPI)

The grandiose title describes madness and weakness. GPI dementia is, however, often similar to Alzheimer's (p. 1254). Progressive cognitive decline, seizures, brisk reflexes, extensor plantars and tremor develop. Death

follows within 3 years. Argyll Robertson pupils are usual. GPI and tabes are now rarities.

Other forms of neurosyphilis

In *congenital* neurosyphilis (acquired in utero), features of combined tabes and GPI develop in childhood - taboparesis.

In *secondary* syphilis, a meningeal reaction occurs: this may be symptomless or cause a self-limiting subacute meningitis.

Treatment

Benzylpenicillin 1 g daily by injection for 10 days in primary infection eliminates the risk of neurosyphilis. Established neurological disease can be arrested but not reversed - parenteral penicillin is given for 2-3 weeks. Allergic reactions (Jarisch-Herxheimer reactions) can occur; high-dose steroid cover is usually given with penicillin (p. 124) but there is little evidence of its value.

NEUROCYSTICERCOSIS

The adult pork tapeworm, *Taenia solium,* is endemic in Latin America, India, non-Muslim African countries and rural areas of SE Asia. It is a major global health problem (p. 115).

Epilepsy is a major feature of neurocysticercosis. Other neurological patterns include brainstem dysfunction, cerebellar ataxia, hydrocephalus, and rarely dementia, arachnoiditis, and vasculitis. Most infected people remain symptomless.

Brain CT and MRI are helpful, but not diagnostic. Serological tests indicate infection but not activity. Biopsy of a lesion may be necessary.

Management is primarily the control of seizures with anticonvulsants. The place of anthelminthics (praziquantel and albendazole) is controversial. Neurosurgery is sometimes necessary for giant inflammatory lesions or hydrocephalus.

Prevention (see p. 116)

Maguire JH (2004) Tapeworms and seizures. *New England Journal of Medicine* 350: 215-217.

HIV AND NEUROLOGY (p. 133)

HIV-infected individuals frequently present with or develop neurological conditions. Immunosuppression leads to indolent, atypical clinical patterns. HIV patients also have a high incidence of stroke. These conditions have been dramatically reduced in countries where HAART is available.

Brain and meningeal disease

Meningitis

Acute aseptic meningitis is a primary HIV infection, with spontaneous recovery.

Chronic meningitis occurs with fungal infections (e.g. *Cryptococcus neoformans* or *Aspergillus),* TB, *Listeria, E. coli* or other organisms. Aggressive treatment is essential.

Diffuse encephalopathies

AIDS-dementia complex (ADC). This diffuse, progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where anti-retroviral therapy is unavailable.

Encephalitis and brain abscess. Toxoplasma, cytomegalovirus, herpes simplex, and other organisms cause severe encephalitis, commonly with multiple brain abscesses.

CNS lymphoma. This neoplasm has a poor prognosis (p. 516).

Progressive multifocal leucoencephalopathy. PML is due to papovavirus (JC virus p. 48).

Spinal cord disease

Paraparesis with HIV occurs in several settings:

- acute transverse myelitis - primary HIV myelitis with spontaneous recovery
- myelopathy due to infection, e.g. herpes simplex, zoster, cytomegalovirus or TB
- CNS lymphoma (cord compression or malignant meningitis).

Peripheral nerve disease

Neuropathies (particularly sensory) occur:

- mononeuropathy (e.g. a common peroneal nerve lesion)
- mononeuritis multiplex (p. 1260)
- polyneuropathy (p. 1260).

Autonomic neuropathy also occurs, (p. 1264).

These neuropathies are often a complication of treatment (see Table 2.53).

Management of HIV

See page 143. The incidence of many HIV-related neurological conditions is reduced with HAART.

OTHER INFECTIONS

Many other infections involve the CNS and are discussed in Chapter 2, e.g. rabies, tetanus, botulism, Lyme disease, leprosy and poliomyelitis.

Transmissible spongiform encephalopathy (Creutzfeldt-Jakob disease (CJD)) (p. 60)

This rare, progressive dementia is recognized pathologically by spongiform changes in the brain. CJD, a prion (proteinaceous infectious particle, PrP) disease, occurs world-wide and is transmitted by an agent resistant to many sterilization processes. All PrP diseases are associated with accumulation of a disease-related protein isoform, PrP^{50}, derived from a normal cellular precursor, PrP^{c}.

Sporadic, iatrogenic ***and familial forms.*** Sporadic CJD cases are usually single. Symptoms develop, usually over the age of 50 years.

Iatrogenic CJD is transmitted from surgical specimens, autopsy, transplant material (e.g. corneal grafts), and human growth hormone. Iatrogenic CJD has a long incubation period, up to 5 years. Death is invariable within 6 months of clinical onset in both sporadic and iatrogenic forms. Quinarine is being used in trials. There is a rare familial form of CJD. CJD pathology is very similar to that of bovine spongiform encephalopathy (BSE, 'mad cow disease'), recognized first in the UK in the early 1980s and in 2003 in the USA.

Incidence. Sporadic CJD occurs world-wide with an annual incidence < 1 per million; some 30-55 cases occur annually in the UK. Numbers have not been rising. Iatrogenic CJD is rarer - 0-6 UK cases annually. Familial CJD cases - 0-4 annually in Britain - are associated with PrP gene mutations. An even rarer form, Gerstmann-Straussler-Scheinker syndrome, is an inherited autosomal recessive condition, typified by chronic progressive ataxia and terminal dementia, with duration 2-10 years.

Variant CJD (vCJD) was noted in Britain in 1995. Numbers are not increasing. vCJD cases are younger than sporadic cases with a mean age of 29. Early symptoms are neuropsychiatric, followed by ataxia, and dementia with myoclonus or chorea. Diagnosis can be confirmed by tonsillar biopsy and CSF gel electrophoresis. vCJD has a longer course than sporadic CJD - up to several years. vCJD and BSE are caused by the same prion strain, giving rise to speculation that transmission from animal to human food chain occurred, i.e. infection from BSE-infected cattle to humans (p. 60). Transmission via blood transfusion may occur.

Kuru

This dementia and cerebellar ataxia, another prion disease, is described on page 61. Spongiform change occurs, very similar to those in CJD.

OTHER INFLAMMATORY CONDITIONS

Subacute sclerosing panencephalitis (SSPE)

Persistence of measles antigen in the CNS causes this rare late sequel of measles. Progressive mental deterioration, fits, myoclonus and pyramidal signs develop, typically in a child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against SSPE, which is now almost eliminated in the UK.

Progressive rubella encephalitis

Some 10 years after primary rubella infection, this syndrome, which is even rarer than SSPE, causes progressive mental impairment, fits, optic atrophy, cerebellar and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It has not been seen as a complication of rubella immunization.

Reye's syndrome (see also p. 395)

This severe encephalitic illness of children is accompanied by fatty infiltration of liver with hypoglycaemia.

Mollaret's meningitis

This is recurrent self-limiting episodes of aseptic meningitis (i.e. no bacterial cause found) over many years. Viral (herpes simplex) infection is postulated.

Vogt-Koyanagi-Harada syndrome

This obscure recurrent inflammation of cells of neural crest origin causes uveitis, meningoencephalitis, vitiligo, deafness and alopecia.

Progressive multi-focal leucoencephalopathies (PMFL)

PMFL is usually seen in patients with HIV, is due to the JC virus and is described on page 48. It is also seen in other immunosuppressed patients.

In leucoencephalopathy there is demyelination of the white matter of the cerebral hemispheres. It can also be due to vascular lesions, e.g. CADASIL (p. 1210); toxic and metabolic causes, e.g. drugs (cocaine, Ecstasy), heavy metals, chemotherapy and other immunosuppressive agents (e.g. ciclosporin) when it may be reversible; hereditary factors, e.g. adrenoleucodystrophy; autoimmune and inflammatory causes, e.g. SLE, multiple sclerosis; tumours, e.g. gliomas; and other infections, e.g. Lyme disease, varicella zoster.

Whipple's disease

Whipple's disease is characterized by myoclonus, dementia and supranuclear ophthalmoplegia. It is described on page 305.

Neurosarcoidosis

Neurosarcoid with or without systemic sarcoidosis causes chronic meningoencephalitis, spinal cord lesions, cranial nerve palsies, particularly bilateral seventh nerve lesions, polyneuropathy, and myopathy (p. 935).

Behcet's syndrome (see also p. 584)

Behget's three principal features are; recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis, see p. 1169) and neurological syndromes. Brainstem and cord lesions, aseptic meningitis (p. 1239) encephalitis and cerebral venous thrombosis also occur.

Granulomatous (isolated, or primary cerebral) angiitis

In this rare condition there is necrotizing inflammation in the brain and leptomeningeal vessels. Stroke, seizures and confusional states develop. There is some response to steroid and immunosuppressive therapy.

BRAIN AND SPINAL ABSCESSES

Brain abscess (see Fig. 21.32)

Focal bacterial infection behaves as any expanding mass (p. 1245). Typical bacteria are *Streptococcus angiosus,* and *Bacteroides* species (from paranasal sinuses and teeth) and staphylococci (from penetrating trauma). Mixed infections are common. Multiple abscesses develop, particularly in HIV patients. Fungi also cause brain abscesses. A parameningeal infective focus (e.g. ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g. lung, heart, abdomen) may be present. Frequently no underlying cause is found. An abscess is 10 times rarer than a brain tumour in the UK.

Clinical features

Headache, focal signs (e.g. hemiparesis, aphasia, hemianopia), epilepsy and raised intracranial pressure develop. Fever, leucocytosis and raised ESR are usual though not invariable. Abscesses may also be indolent, developing over weeks, particularly in the cerebral hemispheres. Cerebellar abscesses tend to develop rapidly over days or hours, producing hydrocephalus.

Management

Urgent imaging is essential. A contrast enhanced T2 weighted MR shows a thin rim of low signalling which is virtually diagnostic of an abscess. The search for a local focus of infection should include a detailed examination of the skull, ears and paranasal sinuses; also include distant foci, such as the heart and abdomen. Lumbar puncture is dangerous and usually unhelpful. Aspiration with stereotactic guidance allows the infective organism to be identified.

Treatment requires liaison between neurosurgeon and microbiologist. Streptococcal and anaerobic infections are treated with cefuroxime 1.5 g IV plus metronidazole 500 mg IV 8 hourly. For staphylococcal infections, flucloxacillin 2-3 g IV 6 hourly with cefuroxime is given. Other bacteria are treated appropriately. Surgical decompression may be necessary if parenteral antibiotics are unsuccessful. Despite treatment, mortality remains high at around 25%. Epilepsy is common in survivors.

Fig. 21.32 MR: Pyogenic brain abscess showing the ring enhancing lesion with surrounding oedema.

Brain tuberculoma

TB bacilli cause chronic caseating intracranial granulomas - tuberculomas. These are the most common intracranial masses in countries where TB is common (e.g. India). Brain tuberculomas either present as mass lesions de novo or develop during tuberculous meningitis. They can be found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. For treatment, see p. 932.

Subdural empyema and intracranial epidural abscess

Intracranial subdural empyema is a collection of subdural pus, usually secondary to local skull or middle ear infection. Features are similar to those of a cerebral abscess. Imaging is diagnostic.

In intracranial epidural abscess, a thin (1-3 mm) layer of pus tracks along the epidural space causing sequential cranial nerve palsies, typically without evidence of raised intracranial pressure. There is usually evidence of local infection, e.g. in the middle ear. MRI outlines the pus and is the investigation of choice, as CT imaging is sometimes normal. Drainage is required, with appropriate antibiotics.

Spinal epidural abscess

Staphylococcus aureus is the usual organism, reaching the spine via the bloodstream, possibly from a boil. Fever and usually back pain are followed by paraparesis and/ or root lesions. Emergency imaging and antibiotics are essential. Surgical decompression is often necessary.

BRAIN TUMOURS

Primary intracranial tumours account for some 10% of neoplasms. The most common tumours are outlined in Table 21.47. In the UK, metastases are the commonest

Table 21.47 Common brain tumours

Tumour	Approximate relative frequency
Metastases	**50%**
Bronchus	
Breast	
Stomach	
Prostate

Fig. 21.34 **MR (T1): Glioblastoma.**

intracranial tumours (Fig. 21.33). Symptomless meningiomas are also found regularly on imaging or at autopsy.

Gliomas (Fig. 21.34)
These malignant tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem or cord. Their cause is unknown. Glioma is occasionally associated with neurofibromatosis. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

Astrocytomas
These gliomas arise from astrocytes. They are classified histologically into grades I-IV. Grade I astrocytomas grow slowly over many years, while grade IV tumours (glioblastoma) cause death within several months. *Cystic* astrocytomas of childhood are relatively benign, and usually cerebellar. . . , ▮ . ▮ , ▮

Oligodendrogliomas
These arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common.

Meningiomas (Figs 21.35-21.37)
These benign tumours arise from the arachnoid membrane and may grow to a large size, usually over years. Those close to the skull erode bone. They often occur along the intracranial venous sinuses, which they may invade. They are rare below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa and skull base.

Neurofibromas (Schwannomas)
These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they arise from the eighth nerve sheath (acoustic neuroma, p. 1189).

Other neoplasms
Other less common neoplasms include cerebellar haemangioblastoma, ependymoma of the fourth ventricle.

Fig. 21.35 **CT: Frontal meningioma.**

Fig. 21.36 **MR (T1): Falx (occipital) meningioma.**

colloid cyst of the third ventricle, pinealoma, chordoma of the skull base, glomus tumour (of the jugular bulb), medulloblastoma (a cerebellar childhood tumour), craniopharyngioma (p. 1044) and cerebral lymphoma.

Pituitary tumours

These are discussed on page 1044.

Clinical features

Mass lesions within the brain produce symptoms and signs by three mechanisms:

- by direct effect - brain is either destroyed locally or function is impaired
- by secondary effects of raised intracranial pressure and shift of intracranial contents (e.g. papilloedema, vomiting, headache)
- by provoking either generalized or partial seizures.

Although neoplasms, either secondary or primary, are the commonest mass lesions in the UK, cerebral abscess, tuberculoma, subdural and intracranial haematoma can also produce features that are clinically indistinguishable.

Direct effects of mass lesions

The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:

- *A left frontal meningioma* caused a frontal lobe syndrome over several years - vague disturbance of personality, apathy and impaired intellect. Expressive aphasia developed, followed by progressive right hemiparesis as the corticospinal pathways became involved. As the mass enlarged further, pressure headaches and papilloedema developed.
- *A right parietal lobe glioma* caused a left homonymous field defect (optic radiation). Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) developed.
- *A left eighth nerve sheath neurofibroma* (an acoustic neuroma, Schwannoma) in the cerebellopontine angle caused, over 3 years, progressive perceptive deafness (VIII), vertigo (VIII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side. Papilloedema was a late sequel.

With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions: its effect is difficult to distinguish from that of the tumour itself.

Raised pressure and shift of intracranial contents

Raised intracranial pressure causing headache, vomiting and papilloedema is a relatively unusual presentation of a mass lesion. These symptoms often imply hydrocephalus - obstruction to CSF pathways. Typically this is produced early by posterior fossa masses (that obstruct the aqueduct and fourth ventricle) but later with lesions above the tentorium. Shift of the intracranial contents produces features that coexist with the direct effects of any expanding mass:

- *Distortion of the upper brainstem,* as midline structures are displaced either caudally or laterally by a hemisphere mass (Fig. 21.34). This causes impairment of consciousness.
- *Compression of the medulla,* by herniation of the cerebellar tonsils caudally through the foramen magnum - an example of coning. This causes impaired consciousness, respiratory depression, bradycardia, decerebrate posturing and death.
- *False localizing signs* — false only because they do not point directly to the site of the mass.

Three examples of false localizing signs are:

- *A sixth nerve lesion,* first on the side of a mass and later bilaterally - as the VI nerve is compressed during its long intracranial course.
- *A third nerve lesion* develops as the temporal lobe uncus herniates caudally, compressing the third nerve against the petroclinoid ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.
- *Hemiparesis on the same side as a hemisphere tumour* (i.e. the side you would not expect) produced by compression of the contralateral cerebral peduncle within the brainstem on the free edge of the tentorium.

These false localizing signs, though unusual, are of importance because they indicate that shift of brain has occurred.

Seizures

Partial seizures, simple or complex, that may evolve into generalized tonic-clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of partial seizure is of localizing value (p. 1221).

Investigations

CT and MR imaging

Imaging is mandatory when a tumour is suspected, though it has limitations. Brain abscess and infarction, benign and malignant tumours have characteristic, but not entirely reliable, appearances.

Technetium brain scan

This is of value in diagnosis of destructive skull vault (e.g. metastases) and skull base lesions.

EEG (p. 1203)

This rarely helps. An exception is cerebral abscess, where characteristic focal slow waves are sometimes seen.

Skull films (p. 1201)

In hemisphere tumours, plain films have no value. With metastases, skull vault lesions may be seen; and with pituitary tumours, enlargement of the pituitary fossa.

Routine tests

Since metastases are common, routine tests, e.g. chest X-ray, should be performed.

More specialized neuroradiology

MR angiography and MR spectroscopy are occasionally used to define changing size or blood supply. Positron emission tomography (PET) is helpful in grading gliomas or locating an occult primary.

Lumbar puncture

Lumbar puncture is initially contraindicated when there is any possibility of a mass, and CSF examination rarely yields useful information in this situation. Withdrawing CSF may provoke immediate herniation of the cerebellar tonsils. LP should be done only after imaging, but is rarely necessary.

Biopsy and tumour removal

Stereotactic biopsy via a skull burr-hole is usually carried out to ascertain the histology of a suspected malignancy. With a symptomatic meningioma, open exploration (craniotomy) is usually performed.

Management

Cerebral oedema surrounding a tumour is rapidly reduced by corticosteroids; i.v. or oral dexamethasone is given. Intravenous mannitol, an osmotic diuretic, is also used to reduce oedema. Epilepsy is treated with anticonvulsants.

Whilst complete surgical removal of a brain tumour is an objective, it is not always possible, nor is surgery always necessary. Follow-up with serial imaging is sometimes preferable. At surgical exploration, some benign tumours can be entirely removed (e.g. acoustic neuromas, some parasagittal meningiomas). With a brain malignancy it is rarely possible to remove an infiltrating mass. Biopsy and debulking are achieved.

Within the posterior fossa, tumour removal is often necessary because of raised pressure and the danger of coning. Overall mortality for posterior fossa exploration remains around 10%.

Radiotherapy is usually given to gliomas and metastases, and improves survival. An isolated posterior fossa metastasis can sometimes be excised successfully. Chemotherapy has little real value in the majority of primary or secondary brain tumours. Vincristine, procarbazine and temozolamide are used. Temozolamide has an active metabolite that interrupts DNA replication by methylation of the 06 position of guanine. Most malignant brain tumours continue to have a poor prognosis despite advances in imaging, surgery, chemotherapy and radiotherapy - less than 50% survival for high-grade gliomas at 2 years. The management involves multidisciplinary care.

Benign (idiopathic) intracranial hypertension (BIH, IIH)

This syndrome, once called *pseudotumor cerebri,* is included with tumours because marked papilloedema develops. There is neither a mass nor an increase in ventricular size. BIH develops mainly in obese young women with vague menstrual irregularities. Headaches and visual blurring (caused by papilloedema) are common. A sixth nerve palsy may develop - a false localizing sign (p. 1185). CSF pressure is elevated with normal constituents. Imaging is normal. Steroid therapy is sometimes thought to be a cause: many other drugs have occasionally been implicated. Other causes of papilloedema should be excluded. Sagittal sinus thrombosis can cause a similar picture.

BIH is benign in the sense that it is not fatal: it is usually self-limiting. However, optic nerve infarction can follow, with consequent blindness when papilloedema is severe and long-standing. Repeated LP, acetazolomide, and thiazide diuretics are used to reduce the intracranial pressure. Weight reduction is helpful. Surgical decompression or shunting is sometimes necessary.

FURTHER READING

Behin A et al. (2003) Primary brain tumours in adults. *Lancet* 361: 323-331. Whittle IR et al. (2004) Meningioma. *Lancet* 363: 1535-1543.

HYDROCEPHALUS

Hydrocephalus means an excessive volume of CSF within the skull. In practice hydrocephalus usually describes different syndromes in which there is, or has been, obstruction to CSF outflow with consequent high pressure and dilatation of the cerebral ventricles. Also, exceptionally an increase in CSF production occurs.

Infantile hydrocephalus

Head enlargement in infancy occurs in 1 in 2000 live births. There are several anatomical causes:

- *Arnold-Chiari malformation.* There is elongation of the medulla. Cerebellar tonsils descend into the cervical canal. Associated spina bifida is common. Syringomyelia may develop (p. 1251).
- *Dandy-Walker syndrome.* There is cerebellar hypoplasia and obstruction to fourth ventricle outflow foramina.
- *Stenosis of the aqueduct of Sylvius* (Fig. 21.38). 'Aqueduct stenosis' is either congenital or acquired following

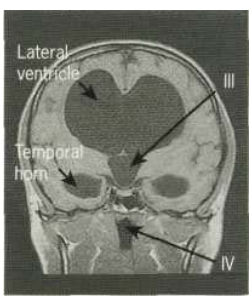

Fig. 21.38 MR (T1): Communicating hydrocephalus.

neonatal meningitis/ haemorrhage. Often no evident cause is found.

Hydrocephalus in adult life

Hydrocephalus is often an unsuspected symptomless finding on imaging. However, infantile hydrocephalus can become apparent in adult life (e.g. aqueduct stenosis). Combinations of headache, cognitive impairment, vomiting, papilloedema, ataxia and bilateral pyramidal signs develop. Hydrocephalus may develop in other circumstances:

- *Posterior fossa and brainstetn tumours* obstruct the aqueduct or fourth ventricular outflow.
- *Following subarachnoid haemorrhage, head injury or meningitis* (particularly tuberculous).
- *A third ventricle colloid cyst* causes lateral ventricle enlargement, headache and papilloedema. These rare intraventricular tumours also sometimes produce intermittent hydrocephalus - recurrent prostrating headaches with episodes of lower limb weakness.
- *Choroid plexus papilloma* (extremely rare) secretes CSF.

Treatment

Ventriculo-atrial or ventriculo-peritoneal shunting is necessary when progressive hydrocephalus causes symptoms. Neurosurgical removal of tumours is carried out when appropriate, sometimes urgently.

Normal pressure hydrocephalus

This describes enlarged cerebral ventricles, dementia, urinary incontinence and gait apraxia, usually in the elderly. CSF constituents and pressure are normal. There is now doubt about its existence as a true separate entity from dementia. Ventriculo-peritoneal shunting is occasionally carried out.

HEADACHE, MIGRAINE AND FACIAL PAIN

'Tension' headache

The vast majority of chronic and recurrent headaches are believed to be produced by 'neurovascular irritation' and tension within scalp muscles. Despite universal occurrence, precise mechanisms of common headache remain obscure. Tight band sensations, pressure behind the eyes, throbbing and bursting sensations are common. What is clear is that almost all headaches with these features are benign.

There may be obvious precipitating factors such as worry, noise, concentrated visual effort or fumes. Depression is also a frequent underlying feature. Tension headaches are often attributed to cervical spondylosis, refractive errors or high blood pressure. Evidence for such associations is poor. Headaches also follow even minor head injuries. Tenderness/tension in neck and scalp muscles are the only physical signs.

Management

This involves:

firm reassurance (imaging is often needed)
avoiding evident causes, e.g. bright lights
analgesic withdrawal
physical treatments - massage, icepacks, relaxation
antidepressants - when indicated
drugs for recurrent headache/migraine.

Migraine

Migraine is recurrent headache associated with visual and gastrointestinal disturbance. The borderline between migraine and tension headaches is vague. Over 12% of any population world-wide report these symptoms.

Mechanisms

Precise mechanisms of migraine remain unknown. Genetic factors play some part - a rare form of familial migraine is associated with mutation in the alpha-1 subunit of the P/Q-type voltage-gated calcium channel on chromosome 19. The release of the neuropeptide calcitonin-gene-related peptide (CGRP) is thought to play a central role as it is a potent dilator of cerebral and dural vessels.

The headache of migraine, often throbbing, is due to vasodilatation or oedema of blood vessels, with stimulation of nearby nerve endings. Release of vasoactive substances such as nitric oxide has a role. Serum 5-hydroxytryptamine rises with prodromal symptoms and falls during the headache. Magnesium deficiency, neural excitation by glutamate and aspartate, changes in the hypothalamic-pituitary axis and in endogenous opioids have all been suggested.

Cerebral features, such as tingling limbs, aphasia and weakness, are caused by focal depression of cortical function.

Some patients recognize precipitating factors:

- week-end migraine (a time of relaxation)
- chocolate (high in phenylethylamine)
- cheese (high in tyramine)
- noise and irritating lights
- with premenstrual symptoms.

Migraine is common around puberty and at the menopause and sometimes increases in severity or frequency with hormonal contraceptives, in pregnancy and with the onset of hypertension. There is no reason to suppose that the development of migraine is suggestive of any serious intracranial lesion. However, since migraine is so common, an intracranial mass and migraine sometimes occur together by coincidence. Migraine sometimes follows a blow to the head - often minor.

Clinical patterns

Migraine attacks vary from intermittent headaches indistinguishable from tension headaches to discrete episodes that mimic thromboembolic cerebral ischaemia. Distinction between variants is somewhat artificial. Migraine can be separated into phases:

well-being before an attack (occasional)
- prodromal symptoms
- the main attack (headache, nausea, vomiting)
- sleep and feeling drained afterwards.

Migraine with aura (classical migraine)
Prodromal symptoms are usually visual and related to depression of visual cortical function or retinal function. Unilateral patchy scotomata (retina), hemianopic symptoms (cortex), teichopsia (flashes) and fortification spectra (jagged lines resembling battlements) are common. Transient aphasia sometimes occurs, with tingling, numbness, vague weakness of one side and nausea. The prodrome persists for a few minutes to about an hour. Headache then follows. This is occasionally hemicranial (i.e. splitting the head) but often begins locally and becomes generalized. Nausea increases and vomiting follows. The patient is irritable and prefers a darkened room. Superficial temporal arteries are engorged and pulsating. After several hours the migraine settles, sometimes with a diuresis. Deep sleep often ensues.

Migraine without aura (common migraine)
This is the usual variety. Prodromal visual symptoms are vague. There is recurrent headache accompanied by nausea and malaise.

Basilar migraine
Prodromal symptoms include circumoral and tongue tingling, vertigo, diplopia, transient visual disturbance (even blindness), syncope, dysarthria and ataxia. These occur alone or progress to a typical migraine.

Hemiparetic migraine
This rarity is classical migraine with hemiparetic features, i.e. resembling a stroke but with recovery within 24 hours. Exceptionally, cerebral infarction (stroke) occurs.

Ophthalmoplegic migraine
This rarity is a third nerve, or exceptionally a sixth nerve, palsy with a migraine - and difficult to diagnose without investigation to exclude other conditions.

Facioplegic migraine
This is unilateral facial weakness during a migraine.

Differential diagnosis

The sudden headache may resemble meningitis or SAH.

Hemiplegic, visual and hemisensory symptoms must be distinguished from thromboembolic TIAs (p. 1211). In TIAs maximum deficit is present immediately and headache is unusual.

Unilateral tingling or numbness may resemble sensory epilepsy (partial seizures). In epilepsy, distinct march (progression) of symptoms is usual.

Management

General measures include:
- reassurance and relief of anxiety
- avoidance of dietary factors - rarely helpful.

Patients taking hormonal contraceptives may benefit from a brand change, or trying without. Premenstrual migraine may respond to diuretics. Depot oestrogens are sometimes used. Severe hemiplegic symptoms are an indication for stopping hormonal contraceptives.

During an attack. After ruling out any serious cause for a sudden headache (p. 1174), paracetamol or other simple analgesics should be given, with an antiemetic such as metoclopramide if necessary. Repeated use of analgesics leads to further headaches. Triptans (5-HT, agonists) are also helpful. In some 30% of cases, where there is recurrent severe migraine, sumatriptan, zolmitriptan, naratriptan and rizatriptan are of value either by prompt self-administered subcutaneous injection, or orally by wafer or inhaler. Triptans should be avoided when there is vascular disease, and not overused. A recent study has shown that an i.v. CGRP antagonist was effective in treating severe attacks.

Prophylaxis. It is difficult to discern placebo effects of prophylactic drugs. The following are used when attacks are frequent:

- pizotifen (antihistamine and 5-HT antagonist) 0.5 mg at night for several days, increasing to 1.5 mg (common side-effects: weight gain and drowsiness)
- propranolol 10 mg three times daily, increasing to 40-80 mg three times daily
- amitriptyline: 10 mg (or more) at night.

Sodium valproate, methysergide, SSRIs, verapamil, topiramate, nifedipine and naproxen are also used.

Facial pain

The face has many pain-sensitive parts - teeth, gums, sinuses, temporomandibular joints, jaw and eyes, all of which can cause pain. Facial pain is also caused by specific neurological conditions.

Trigeminal neuralgia (p. 1186), trigeminal nerve lesions (p. 1186) and postherpetic neuralgia (p. 1240) are described elsewhere.

Cluster headache (migrainous neuralgia)

'Cluster', clinically distinct from migraine despite its name, describes recurrent bouts of excruciating unilateral pain that typically wake the patient. Attacks *cluster* around one eye. 'Cluster' affects adults, mostly males between 30 and 40. Alcohol sometimes provokes an attack, and also experimentally, nitroglycerin. There are changes in grey matter density on functional imaging in the posterior hypothalamus. Intense pain rises to a worse crescendo over half an hour, lasting for several hours. Vomiting occurs. One cheek and nostril feel congested. Transient ipsilateral Horner's syndrome is common.

Despite intense pain there are no serious sequelae. Attacks recur at intervals over several years but tend to

disappear after the age of 55. Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice. Alternatively oxygen inhalation 7.12 L/min may abort an attack. Most prophylactic migraine drugs are unhelpful. Verapamil, topiramate and lithium carbonate sometimes prevent'cluster'. ■■■.

Paroxysmal hemicrania

Episodic paroxysmal hemicrania is a rare condition describing unilateral sudden, brief (< 20 min) pains with some characteristics of cluster headaches. Paroxysms may occur many times each day, and typically respond to indometacin.

Atypical facial pain

Facial pain for which no cause can be found is seen in the elderly, mainly in women. It is believed to be a somatic equivalent of depression. Tricyclic antidepressants are sometimes helpful.

Other causes of facial pain

Facial pain occurs in variants of migraine and in giant cell arteritis (see below).

Giant cell arteritis (GCA) - cranial or temporal arteritis (see also p. 582)

This granulomatous arteritis is described on page 582.

Clinical features

Headache

Headache is almost invariable in GCA. Pain develops over inflamed superficial, temporal or occipital arteries. Touching the skin over an inflamed vessel (e.g. combing hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.

Facial pain

Pain in the face, jaw and mouth is caused by inflammation of facial, maxillary and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Opening the mouth and protruding the tongue becomes difficult. A painful, ischaemic tongue occurs rarely.

Visual problems

Visual loss from arterial inflammation and occlusion occurs in 25% of untreated GCA cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy in three-quarters of these. Other mechanisms are central retinal artery occlusion, cilioretinal artery occlusion and posterior ischaemic optic neuropathy. There is sudden monocular visual loss (partial or complete), usually painless. Amaurosis fugax (p. 1212) may precede permanent blindness.

When the posterior ciliary vessels are affected, ischaemic optic neuropathy causes the disc to become swollen and pale; retinal branch vessels usually remain normal. When the central retinal artery is occluded, there is sudden permanent unilateral blindness, disc pallor and visible retinal ischaemia. Bilateral blindness may develop, with the second eye being affected in 1-2 weeks.

Rare complications

Brainstem ischaemia, cortical blindness, ischaemic microangiopathic neuropathy of peripheral or cranial nerves, and involvement of the aorta, coronary, renal and mesenteric arteries sometimes occur.

Management

The ESR is greatly elevated and the diagnosis should be established immediately by superficial temporal artery biopsy, because of the risk of blindness. Immediate high doses of steroids (prednisolone, initially 60-100 mg daily) should be started in a patient with typical features, even before biopsy (see p. 583). Since the risk of visual loss persists over many years, neurologists and ophthalmologists tend to recommend long-term treatment.

TRAUMATIC BRAIN INJURY

In most western countries head injury accounts for about 250 hospital admissions per 100 000 population annually. Traumatic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100 000 people, 10 die annually following TBI; 10-15 are transferred to a neurosurgical unit - the majority of these require rehabilitation for a prolonged period of 1-9 months. The *prevalence* of survivors with a major persisting handicap is around 100 per 100 000. Road traffic accidents and alcohol abuse are the principal etiological factors in this major cause of morbidity and mortality.

Skull fractures

Linear skull fracture of the vault or base is one indication of the severity of a blow, but is itself not necessarily associated with any brain injury. Healing takes place spontaneously. *Depressed* skull fracture is followed by a high incidence of post-traumatic epilepsy - surgical elevation and debridement are usually necessary. Principal local complications of skull fracture are:

- *meningeal artery rupture* - causing extradural haematoma (p. 1219)
- *dural vein tears* - causing subdural haematoma (p. 1218) or CSF rhinorrhoea/otorrhoea (risk of meningitis).

Mechanisms of brain damage

Older classifications attempted to separate *concussion* (transient coma for hours followed by apparent complete clinical recovery) from brain *contusion* (prolonged coma, focal signs and lasting brain damage). Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:

- axonal and neuronal damage - shearing and rotational stresses on decelerating brain, often at sites opposite impact *(contracoup* effect)
- axonal and neuronal damage from direct trauma
- brain oedema and raised intracranial pressure
- brain hypoxia
- brain ischaemia.

Clinical course

In a mild TBI a patient is stunned or dazed for a few seconds or minutes. Following this the patient remains alert with little or no post-traumatic amnesia. Complete recovery is usual. In more serious injuries duration of unconsciousness and particularly of post-traumatic amnesia (PTA) helps grade severity. PTA over 24 hours indicates severe TBI. The Glasgow Coma Scale (GCS, p. 1206) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies severe injury; 50% of such patients die or remain in a persistent vegetative or minimal conscious state (p. 1207). However, prolonged coma of up to several weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks/months. During the first few weeks, patients are often intermittently restless or lethargic and have focal deficits, such as hemiparesis or aphasia. Gradually they become more aware, though may remain in post-traumatic amnesia, being unable to lay down any continuous memory despite being awake. This amnesia may last some weeks or more, and may not be obvious clinically. PTA is one predictor of outcome. PTA over 2 weeks implies that persistent organic cognitive deficit is almost inevitable, although return to unsupported paid work may be possible.

Late sequelae

Sequelae of TBI are major causes of morbidity and have important social and medicolegal consequences. They include:

- *Incomplete recovery* - e.g. cognitive impairment, hemiparesis.
- *Post-traumatic epilepsy* (p. 1221).
- *The post-traumatic (post-concussional) syndrome.* This describes the vague complaints of headache, dizziness and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged.
- *Benign paroxysmal positional vertigo* (BPPV, p. 1156).
- *Chronic subdural haematoma* (p. 1218).
- *Hydrocephalus* (p. 1247).
- *Chronic traumatic encephalopathy* - follows repeated (and often minor) injuries. This 'punch drunk' syndrome is cognitive impairment, extrapyramidal and pyramidal signs, seen typically in professional boxers.

Immediate management

Attention to the airway is vital. If there is coma, depressed fracture or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential. Indications for CT imaging vary - from imaging all minor head injuries in some US centres to more considered/stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. Intracranial pressure monitoring is valuable. Care of the unconscious patient is described on page 1209. Prophylactic anticonvulsant treatment has been shown to be of no value in prevention of late post-traumatic epilepsy (p. 1221).

Rehabilitation

TBI cases require skilled, prolonged and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes intensive physiotherapy and care from a multidisciplinary team with both physical and psychological skills. Many survivors are left with cognitive problems - amnesia, neglect, disordered attention and motivation, and behavioural/emotional problems - temper dyscontrol, depression and grief reactions. Long-term support for both patients and families is necessary.

SPINAL CORD DISEASE

The cord extends from Cl (its junction with the medulla) to the vertebral body of LI where it becomes the conus medullaris. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by vertebral arteries, thyrocervical trunk and several branches from lumbar and intercostal vessels.

SPINAL CORD COMPRESSION (Table 2148)

Principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the level of compression, and sensory loss below the compression.

Table 21.48 Causes of spinal cord compression

Spinal cord neoplasms	*Rarities*
Disc and vertebral lesions:	Paget's disease, scoliosis
Chronic degenerative	and vertebral anomalies
Trauma	Epithelial, endothelial and
Inflammatory:	parasitic cysts Aneurysmal
Epidural abscess	bone cyst Vertebral angioma
Tuberculosis	Haematomyelia, arachnoiditis
Granuloma	Osteoporosis with fracture
Vertebral neoplasms:	Arteriovenous malformation
Metastases	
Myeloma Epidural haemorrhage	

For example, in compression at T4 (see Fig. 21.14) a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months, days or hours, depending upon underlying pathology. Numbness commencing in the feet rises to the level of compression. This is called the *sensory level*. Retention of urine and constipation develop.

Cord compression is a medical emergency. It is sometimes difficult on clinical grounds alone to distinguish chronic progressive cord compression from other (non-surgical) causes of worsening paraparesis and tetraparesis. One reason for this is that pain at the level of compression can be absent.

Spinal cord neoplasms (Table 21.49) Extramedullary tumours, both extradural and intradural, cause cord compression (Fig. 21.39) gradually over weeks to months, often with root pain and a sensory level (p. 1198).

The rarer intramedullary tumours (e.g. glioma) typically progress slowly over many years. Sensory disturbances similar to syringomyelia may appear (p. 1252).

Table 21.49 Principal spinal cord neoplasms

Extradural	**Extramedullary**
Metastases:	Meningioma
Bronchus	Neurofibroma
Breast	Ependymoma
Prostate	
Lymphoma	**Intramedullary**
Thyroid	Glioma
Melanoma	Ependymoma
	Haemangioblastoma
	Lipoma
	Arteriovenous malformation
	Teratoma

Fig. 21.39 **MR (T2): Thoracic meningioma (cord compression).**

Tuberculosis

Spinal TB is the commonest cause of cord compression in countries where TB is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis - Pott's paraplegia.

Disc and vertebral lesions

Central cervical disc and thoracic disc protrusion causing cord compression are considered on page 1265.

Spinal epidural abscess

This is described on page 1243.

Epidural haemorrhage and haematoma

These are rare sequelae of anticoagulant therapy, bleeding disorders, trauma and after lumbar puncture when clotting is abnormal. A rapidly progressive cord lesion develops.

Management

Early recognition of cord compression is vital. Plain spinal films show degenerative bone disease and destruction of vertebrae by infection or neoplasm. Routine tests (e.g. chest X-ray) may indicate a primary neoplasm or infection. Spinal MR identifies most lesions and has entirely replaced contrast myelography. Surgical exploration is frequently necessary. If decompression is not performed sufficiently promptly, irreversible cord damage may follow. Results are excellent if benign tumours are removed early.

OTHER CAUSES OF PARAPARESIS

Paraparesis (and tetraparesis) occurs in many conditions recognizable by their clinical patterns. The elucidation of the cause of paraparesis has a pivotal place in neurology (see Table 21.13).

Syringomyelia and syringobulbia

The *syrinx,* a fluid-filled cavity within the cervical or thoracic spinal cord, is the essential feature. Syringobulbia means a cavity in the brainstem.

Aetiology and mechanism

Classical syringomyelia is associated with the Arnold-Chiari malformation (see p. 1257). The anatomical abnormality at the foramen magnum probably allows normal pulsatile CSF pressure waves to be transmitted to the fragile tissues of the cervical cord and brainstem, causing secondary cavity formation. The syrinx is in continuity with the central canal of the cord.

Pathological anatomy

The expanding cavity in the cord gradually destroys spinothalamic neurones, anterior horn cells, and lateral corticospinal tracts. In the medulla (syringobulbia), trigeminal nuclei, sympathetic trunk, ninth, tenth, eleventh and twelfth nerve nuclei and the vestibular system are destroyed by the expanding syrinx.

Clinical features

Patients with classical syringomyelia with the Arnold-Chiari malformation usually develop symptoms around the age of 20-30. Upper limb pain exacerbated by exertion or coughing is typical. Spinothalamic sensory loss (pain and temperature) leads to painless upper limb burns, and trophic changes. Difficulty in walking with paraparesis develops. The following are typical signs of a substantial cervical syrinx (Fig. 21.40):

- *Areas of 'dissociated' sensory loss,* i.e. spinothalamic loss without loss of light touch. Bizarre patterns are seen.
- *Loss of upper limb reflexes.*
- *Muscle wasting* in the hand and forearm.
- *Spastic paraparesis* - initially mild and symptomless.
- *Neuropathic joints,* trophic skin changes (scars, nail dystrophy) and ulcers.
- *Brainstem signs* - as the syrinx extends into the brainstem (syringobulbia), there is tongue atrophy and fasciculation, bulbar palsy, nystagmus, Horner's syndrome, hearing loss and impairment of facial sensation.

Course, investigation and management

Syringomyelia is gradually progressive over several decades. Sudden deterioration sometimes follows minor trauma, or spontaneously. MR imaging demonstrates the cavity and herniation of cerebellar tonsils.

There is no curative treatment. Surgical decompression of the foramen magnum sometimes slows deterioration.

Other causes of syrinx formation are bony anomalies at the foramen magnum, spina bifida (p. 1257), arachnoiditis, hydrocephalus (p. 1247), intrinsic cord tumours (e.g. glioma and ependymoma) and trauma.

Fig. 21.40 **MR:** Cervical syrinx (cavity, arrow).

Metabolic and toxic cord disease

Vitamin B_{12} deficiency (p. 432)

Subacute combined degeneration of the cord resulting from vitamin B_{12} deficiency is the most common example of metabolic disease causing spinal cord damage. Cord lesions probably due to multiple B vitamin deficiencies are also seen in severe malnutrition.

Lathyrism

This curiosity is an endemic spastic paraparesis of central India caused by the toxin beta-(N)-oxalylamino-L-alanine. It occurs when excessive quantities of a drought-resistant pulse, *Lathyrus sativa,* are consumed.

Konzo; tropical ataxic neuropathy

In West Africa and the West Indies inadequate preparation of *cassava* root allows ingestion of cyanogenic glycosides. A subacute spastic paraparesis follows - called *konzo. Tropical ataxic neuropathy* consists of sensory ataxia, loss of reflexes, deafness and optic atrophy, probably due to chronic low-level exposure to these glycosides.

Acute transverse myelopathy (transverse myelitis)

This term is used to describe a cord lesion and paraparesis (or paraplegia) occurring with viral infections, MS, mixed connective tissue disease and other inflammatory and vascular disorders - e.g. HIV, sarcoid, syphilis, radiation myelopathy, and anterior spinal artery occlusion. MRI is usually required to exclude cord compression.

Anterior spinal artery occlusion

Cord infarction, causing an acute paraplegia or tetraplegia, (or paresis) occurs in many thrombotic or embolic vascular diseases - for example, endocarditis, severe hypotension, atheroma, diabetes mellitus, polycythaemia, syphilis and polyarteritis. Cord infarction sometimes occurs during surgery to the posterior mediastinum, or follows aortic dissection and trauma. It also occurs as an isolated event.

Radiation myelopathy

A mild paraparesis with sensory loss sometimes develops within several weeks to a year after radiotherapy. Care is taken to shield the cord during radiotherapy.

MANAGEMENT OF PARAPLEGIA

General considerations

General health and morale should be reviewed carefully and regularly. Any intercurrent infection is potentially dangerous and should be treated early. Chronic renal failure is a common cause of death. The paraplegic patient needs skilled and prolonged nursing care and training to be aware of problems. Particular issues are discussed below.

Bladder
Catheterization is usually necessary initially. Many patients self-catheterize, or develop reflex bladder emptying, helped by abdominal pressure. Free urinary drainage is essential to avoid stasis, subsequent infection and calculi.

Bowel
Constipation and faecal impaction must be avoided. Manual evacuation is necessary following acute paraplegia, but reflex rectal emptying develops later.

Skin care
The risk of pressure sores and their sequelae is great. Meticulous attention must be paid to cleanliness and to turning the patient every 2 hours. The sacrum, iliac crests, greater trochanters, heels and malleoli should be inspected frequently (see p. 1355). Ripple mattresses and water beds are useful. If pressure sores develop, plastic surgical repair should be considered. Pressure palsies (e.g. of ulnar nerves) must be avoided.

Lower limbs
Passive physiotherapy helps to prevent contractures in paralysed limbs. Severe spasticity, with flexor or extensor spasms, may be helped by baclofen, diazepam, dantrolene, tizanidine or botulinum toxin injections.

Rehabilitation
Many patients with traumatic paraplegia or tetraplegia return to full or partial self-sufficiency despite a wheelchair existence. Specialist advice from a skilled rehabilitation unit is necessary. Lightweight, specially adapted wheelchairs are available. 'Paraplegics' have demanding practical, psychological, sexual and social needs.

DEGENERATIVE NEURONAL DISEASES

Degenerative underlines our incomplete understanding of these progressive nervous system diseases. Their molecular and genetic basis is the subject of intense study.

Motor neurone disease (MND)

In this common disease seen world-wide there is progressive degeneration of lower and upper *motor* neurones in the spinal cord, in cranial nerve motor nuclei and within the cortex. Most MND is sporadic and of unknown cause. It is thought that relentless degeneration of motor nerve cells may be programmed genetically. Abnormal mRNA splicing of the excitatory amino-acid transporter *(EAAT2)* gene, a major glial transporter, was once thought to be specific for MND, but is sometimes found in normal people. Oxidative neuronal damage, aggregation of abnormal neuronal proteins, glutamate mishandling and abnormalities of neurofilament-mediated axonal transport are also involved. Apoptosis and prolonged neuronal caspase activity (p. 162) are the final mechanisms of cell destruction.

There is a familial form of MND in which there are mutations in the gene (chromosome 21q) encoding the free radical scavenging enzyme copper/zinc superoxide dismutase (SOD-1).

Incidence of the sporadic form is around 2/100 000/ year, with a slight male predominance and onset in middle life.

Clinical features
The sensory system is not involved. In the common, sporadic form of MND, four broad patterns are seen:

- progressive muscular atrophy
- amyotrophic lateral sclerosis (ALS)
- progressive bulbar and pseudobulbar palsy
- primary lateral sclerosis (rare).

Although useful as a means of recognizing MND, these are not distinct aetiological or pathological variants and usually merge as MND progresses. Other classifications are also used.

Progressive muscular atrophy
Wasting beginning in the small muscles of one hand (or both) spreads inexorably. Although it may commence unilaterally, wasting soon follows on the opposite side. Fasciculation is common. It is due to spontaneous firing of abnormally large motor units formed by branching fibres of surviving axons that are striving to innervate muscle fibres that have lost their nerve supply. Cramps may occur. Pain does not.

Physical signs are of wasting and weakness, with fasciculation - often widespread. Tendon reflexes are lost when the reflex arc is interrupted by anterior horn cell loss, but are preserved or exaggerated when there is loss of corticospinal motor neurones.

Amyotrophic lateral sclerosis (ALS)
Lateral sclerosis means disease of the lateral corticospinal tracts (i.e. one cause of spastic paraparesis). Amyotrophy means 'muscle atrophy', i.e. wasting, which is unusual in most other forms of spastic tetraparesis or paraparesis. The course is progressive spastic tetraparesis or paraparesis with added lower motor neurone signs and fasciculation. ALS is the term used for MND in the USA.

Progressive bulbar and pseudobulbar palsy
Here the brunt falls initially upon lower cranial nerve nuclei and their supranuclear connections. Dysarthria, dysphagia, nasal regurgitation of fluids and choking are common symptoms. For reasons unknown, this form of MND is more common in women. Characteristic features are of a bulbar and pseudobulbar palsy, (p. 1191), with mixed UMN and LMN signs in the lower cranial nerves - for example, a wasted fibrillating tongue with a spastic weak palate. Eye movements remain unaffected in all

forms of MND. There are neither cerebellar nor extrapyramidal signs. Awareness is preserved and dementia unusual. Sphincter disturbance occurs late, if at all.

Primary lateral sclerosis

This describes a rare form of MND confined to upper motor neurones. There is progressive tetraparesis with terminal pseudobulbar palsy.

Diagnosis

There are no specific tests. Diagnosis is clinical. Usually MND is easily identifiable and confirmed by EMG and nerve conduction studies. Exclusion of other conditions is necessary in atypical cases. Cervical radiculopathy with myelopathy, syringomyelia, and the rare (almost extinct) syphilitic cervical pachymeningitis can cause diagnostic difficulty. Motor neuropathies and spinal muscular atrophies sometimes resemble the progressive muscular atrophy form of MND - their course is more prolonged. Kennedy's syndrome, an X-linked bulbar and spinal muscular atrophy, sometimes causes confusion: UMN signs are not seen in this condition.

Bulbar myasthenia gravis (p. 1269) may sometimes appear similar in the early stages.

Multifocal motor neuropathy (p. 1260) causes distal weakness with LMN signs; antibodies to GM, ganglioside are present and conduction block is seen on electrophysiological studies.

Denervation, a feature of all forms of MND except primary lateral sclerosis, is confirmed by electromyography. Chronic partial denervation with preserved motor conduction velocity is characteristic. CSF constituents are normal.

Course and management

Remission is unknown. MND progresses, spreading gradually, and causes death, often from bronchopneumonia. Survival > 3 years is unusual, although there are rare MND cases who survive for a decade or longer.

No treatment has been shown to influence outcome. Riluzole, a sodium-channel blocker that inhibits glutamate release, slows progression slightly, particularly with disease of bulbar onset. Spasticity may be helped by baclofen, and drooling by propantheline or amitriptyline. Ventilatory support and feeding via gastrostomy helps prolong survival. Giving accurate advice to MND patients is particularly difficult. Shared-care protocols between patient, primary care physician, carers and support groups are helpful.

Spinal muscular atrophies

These rare genetic disorders of motor neurones give rise to slowly progressive, usually symmetrical, muscle wasting and weakness. An acute infantile type (Werdnig-Hoffmann disease), a chronic childhood type (Kugelberg-Welander disease) and adult forms are recognized. Clinically these conditions may be confused with muscular dystrophies (p. 1269), hereditary neuropathies or MND.

Dementia

Dementia is used to describe progressive decline of cognitive function, i.e. loss of mind, usually affecting the cerebral cortex as a whole, though sometimes patchily. Memory is especially affected; intellect gradually fails. There is loss of emotional control, a deterioration of social behaviour and loss of motivation. There are many causes of this clinical syndrome, which is common in later life (Table 21.50). Dementia is a very substantial cause of morbidity in any ageing population, with profound social and economic effects. It affects some 10% of any population over 65, and 20% over 80. The commonest causes are Alzheimer's disease, vascular and dementia with Lewy bodies (DLB). In practice it is difficult to recognize the particular *type* of dementia, and to define landmarks that separate the mild decline in memory and cognitive function often accepted as part of normal ageing.

Differential diagnosis

This includes a depressive disorder with pseudodementia, in which many of the features of an early dementia (especially memory impairment, slowed thinking and lack of spontaneity) are apparent. Patients with pseudodementia often have a previous history of depression or a family history of mood disorder. Successful treatment of the mood disorder results in restoration of intellectual function. Delirium and mild or moderate learning difficulties are also differential diagnoses.

Alzheimer's disease

This is the commonest dementia, accounting for over 65% of dementia in any age group. It is a primary

degenerative disease of the cerebral cortex. The cardinal clinical features are:

- progressive loss of ability to learn, retain and process new information (memory loss)
- decline in language — difficulty in naming and in understanding what is being said (various aphasias, p. 1178)
- apraxia - impaired ability to carry out skilled motor activities (p. 1175)
- agnosia - failure to recognize objects (e.g. clothing), places or people
- progressive loss of executive function - organizing, planning and sequencing
- behavioural change - agitation, aggression, wandering and persecutory delusions
- loss of insight, relative or complete, into the above
- depression - though severe depression is unusual, because of loss of insight.

The onset is gradual. Alzheimer's disease is rare below the age of 50 but increasingly common thereafter. Disturbance of gait, motor and sensory abnormalities and seizures occur late. The course is progressive over several to 10 or more years, with death in a state of extreme cognitive decline.

Neuropathology and neurochemical changes

Loss of neurones, neurofibrillary tangles, senile plaques and amyloid angiopathy are seen, especially within the frontal, temporal and parietal cortex, hippocampi, substantia innominata and locus ceruleus.

Neurofibrillary tangles in neuronal cell bodies are made up of the microtubular-associated *tau* protein in paired helical filaments. Ubiquitin is also seen in association with tangles. Aggregation of beta-amyloid (A(3) appears to play a central role, developing progressively in extracellular senile plaques. These plaques contain deposits of amyloid fi-protein, produced by enzymes, |3 and *y* secretase. Apoptosis follows, leading to cell death with a marked reduction in choline acetyltransferase, acetylcholine itself, norepinephrine (noradrenaline) and serotonin.

Aetiology

The cause of Alzheimer's disease (AD) is unknown. No environmental toxin has been found. Incidence is increased in Down's syndrome. Increase in free radical formation and failure of antioxidant defences may contribute to neuronal degeneration. Superoxide dismutase (SOD), the free radical defence enzyme is reduced by some 25% in AD frontal cortex and hippocampi.

AD is occasionally familial. Genetic studies have shown linkage between familial (presenile) AD (FAD) and loci on chromosome I (presenilin, PS1 gene), chromosome 14 (presenilin, PS2 gene) and chromosome 21 (amyloid (3-protein precursor, APP gene).

Late-onset AD (the great majority) is a heterogeneous disorder. Evidence suggests a link between AD and atherosclerosis, inflammation and cholesterol. A linkage has been found in some cases to a gene locus on chromosome 19q. The gene encoding apolipoprotein E is a possible candidate. This has three alleles, e2, e3 and e4. The e4 allele is a major risk factor for Alzheimer's disease and the *el* allele is under-represented. It is possible that beta-amyloid accumulation is more extensive in those with the e4 allele than in those lacking it.

Dementia with Lewy bodies (DLB)

This accounts for some 25% of all dementias and is characterized by fluctuating cognition with pronounced variation in attention and alertness. Prominent or persistent memory loss may not occur in the early stages. Impairment in attention, frontal, subcortical and visuospatial ability is often prominent. Depression and sleep disorders occur. Recurrent formed visual hallucinations (e.g. strange faces, frightening creatures) are a feature. Parkinsonism (e.g. slowing, rigidity) is common, with repeated falls. Delusions and transient loss of consciousness occur. Cortical Lewy bodies are prominent at autopsy. These inclusions were first described in idiopathic Parkinson's disease, but are a hallmark of DLB. These patients are particularly sensitive to neuroleptic drugs and these should not be used.

Vascular dementia (multi-infarct dementia)

This common cause of dementia is distinguished from Alzheimer's disease by its clinical features and course. There is usually a history of transient ischaemic attacks with brief impairment of consciousness, fleeting pareses or visual loss. The dementia may follow a succession of acute cerebrovascular events or, less commonly, a single major stroke. Vessel occlusion is the most common cause of vascular dementia, and this may produce a variety of cognitive deficits depending on the site of ischaemic damage. Multi-infarct dementia results from involvement of several vessels supplying the cerebral cortex and subcortical structures and is typically associated with signs of cortical dysfunction.

Frontotemporal dementia

Progressive deterioration of social behaviour (disinhibition) and personality develops in middle life, followed by decline in memory, intellect and language. This accounts for some 3% of dementias. Imaging shows selective atrophy of frontal and temporal lobes. There is no excess of either senile plaques or neurofibrillary tangles (both are seen in normal ageing and typically in AD). Cytoplasmic inclusion bodies (silver-staining, Pick's bodies) are seen. These changes separate this condition pathologically from AD.

Other dementias

Subcortical encephalopathies comprise disorders that affect *subcortical* structures such as the basal ganglia. They include dementia occurring in idiopathic Parkinson's disease, Huntington's disease, progressive supranuclear palsy (p. 1231) and dementia occurring in rarities such as cerebral vasculitis.

Rare neuropsychiatric conditions such as Creutzfeldt-Jakob disease (p. 1242) and Wilson's disease (p. 387) cause

Table 21.51 **Tests in dementia**

Blood tests Full blood count ESR, C-reactive protein Urea and electrolytes Blood glucose Liver biochemistry Serum calcium Vitamin B_{12}, folate TSH, T_3, T_4 Syphilis serology HIV antibodies	**Imaging** Chest X-ray CT scan MRI **Other** EEG CSF Brain biopsy

progressive dementia. In these conditions, there are usually evident clinical features, e.g. parkinsonism, chorea and/or pseudobulbar palsy. Dementia also occurs commonly in the late stages of multiple sclerosis (p. 1235). Dementia is only a part of the clinical features in these conditions.

Primary progressive aphasia - a language-based dementia - is increasingly recognized; there is a relentless deterioration of language skills with relative preservation of memory.

Investigations

Dementia is diagnosed from the history and basic examination, especially cognitive testing (p. 1277), and confirmed by psychometric testing (e.g. the Wechsler scale). The history should be taken from someone who has known the patient for a long time.

In later life, few cases of dementia are investigated. Defined medical conditions should be excluded (Table 21.51). Investigations in younger cases of dementia include detailed CT, MR and PET imaging, psychometry, EEG, CSF examination and brain biopsy. The latter is usually only carried out in units specializing in the study of dementia.

Management and social consequences

It is rare that a treatable cause for dementia is found, for example hypothyroidism.

Management is supportive, to preserve dignity and to provide care for as long as possible in the familiar home environment. The burden of illness falls frequently on relatives. In an ageing population, medical problems of the carers themselves deserve particular attention.

Recent evidence suggests that participation in cognitively demanding leisure activities in late life can protect against dementia.

Treatment with antioxidants (mainly vitamin E) have shown some slight benefit. Other drugs, principally anticholinesterase inhibitors (donepezil, rivastigmine and galantamine) and memantine, an N-methyl D-aspartate (NMDA) receptor antagonist that affects glutamate transmission, have been shown to slow, slightly, the rate of cognitive decline in AD. Whilst there is dispute about the place for these drugs (all are costly), they contribute in some cases to a patient with dementia being able to remain at home for some months. However, the AD2000 randomized controlled trial showed no significant difference between donepezil and placebo. There are thus complex cost—benefit arguments.

CONGENITAL AND INHERITED DISEASES

CEREBRAL PALSY

This describes disorders apparent at birth or in childhood due to neonatal brain damage. Deficits are non-progressive. Learning problems, mild to severe are frequent, though not exclusive - physical disability is independent of cognitive impairment.

The precise cause of damage in an individual child may be difficult to determine. The following are responsible:

- hypoxia in utero and/or during parturition
- neonatal cerebral haemorrhage and/or infarction
- trauma, neonatal or during parturition
- prolonged seizures - *status epilepticus* or hypoglycaemia
- kernicterus (now rare, with maternal Rh immunization).

Clinical features

Failure to achieve normal milestones is often the earliest feature. More specific motor syndromes become apparent later in childhood or, rarely, in adult life.

Spastic diplegia

This is spasticity (predominantly of lower limbs) with scissoring of gait.

Athetoid cerebral palsy

This is described on page 1231, and now rare.

Infantile hemiparesis

Hemiparesis may be noted at birth or later. One hemisphere is hypotrophic and the contralateral, hemiparetic limbs small (hemiatrophy).

Congenital ataxia

This is incoordination and hypotonia of limbs and trunk.

DYSRAPHISM

Failure of normal fusion of the fetal neural tube leads to a group of congenital anomalies. Folate deficiency during pregnancy is contributory: supplements should always be given (p. 247). Anticonvulsant drugs (e.g. valproate) are also implicated (p. 1224). Bacterial meningitis may follow if there is access to the subarachnoid space.

Anencephaly

This is absence of brain and skull - incompatible with life.

Meningoencephalocele

Brain and meninges extrude through a midline skull defect — protrusion can be minor or massive.

Spina bifida

There is failure of lumbosacral neural tube fusion. Several varieties occur.

Spina bifida occulta

This is isolated failure of vertebral arch fusion (usually lumbar), often seen on X-rays (3% of population). A dimple or a tuft of hair may overlie the anomaly. Clinical abnormalities are rare.

Meningomyelocele with spina bifida

Meningomyelocele consists of elements of spinal cord and lumbosacral roots within a meningeal sac. This herniates through a vertebral defect. In severe cases both lower limbs and sphincters are paralysed. The lumbosacral defect is visible at birth. Meningocele is a meningeal defect alone.

BASILAR IMPRESSION OF SKULL (PLATYBASIA)

This is usually a congenital anomaly. There is invagination of the foramen magnum and skull base upwards. Lower cranial nerves, medulla, upper cervical cord and roots are affected. A syrinx may be present. The *Arnold-Chiari malformation* may coexist, with aberrant cerebellar tonsils extending through the foramen magnum. Basilar invagination also develops in Paget's disease and rarely in osteomalacia (p. 601). Clinical features are spastic tetraparesis, cerebellar and lower brainstem signs.

NEUROECTODERMAL SYNDROMES

Tissue derived from ectoderm forms tumours and hamartomas, with lesions in the skin, eye and nervous system.

Neurofibromatosis (von Recklinghausen's disease)

This is characterized by multiple skin neurofibromas and pigmentation. The neurofibromas arise from the neurilemmal sheath. One new case occurs in every 4000 live births. The mode of inheritance is autosomal dominant with complete penetrance.

Clinical features (see also p. 1345)

Clinically neurofibromatosis is divided into type 1 (peripheral > 70%) and type 2 (central). The abnormal gene for NFl is on chromosome 17 (qll.2) and for NF2 on chromosome 22 (ql2.2) (Table 3.4, p. 179). The main application for these genetic markers is potential antenatal diagnosis and counselling. A wide variety of abnormalities occur.

Peripheral (NF1)

Skin neurofibromas present as subcutaneous, soft, sometimes pedunculated, tumours (p. 1345). They increase in numbers throughout life. Multiple cafe-au-lait patches are present (p. 1358).

Central (NF2) (see Table 3.4)

The abnormal protein (merlin or schwannomin) is a cytoskeletal protein. Many neural tumours occur:

- meningioma
- acoustic neuroma
- glioma (including optic nerve glioma)
- plexiform neuroma (massive cutaneous overgrowth)
- cutaneous neurofibroma.

Rarely, the benign tumours undergo sarcomatous change.

Associated abnormalities

- Scoliosis
- Orbital haemangioma
- Local gigantism of a limb
- Phaeochromocytoma and ganglioneuroma
- Renal artery stenosis
- Pulmonary fibrosis
- Obstructive cardiomyopathy
- Fibrous dysplasia of bone.

Treatment

Tumours causing pressure symptoms within the nervous system require excision, if feasible.

Tuberous sclerosis (epiloia)

This rare autosomal dominant condition comprises adenoma sebaceum (p. 1345), epilepsy and cognitive impairment (often severe). Retinal phakomas (glial masses), renal tumours, glial overgrowth in brain and gliomas occur.

Sturge-Weber syndrome (encephalofacial angiomatosis)

There is an extensive port-wine naevus on one side of the face (usually in the distribution of a division of the fifth nerve) and a leptomeningeal angioma. Epilepsy is common. Familial occurrence is exceptional.

von Hippel-Lindau syndrome (retinocerebellar angiomatosis)

This is dominantly inherited. Retinal and cerebellar haemangioblastomas develop or, less commonly,

haemangioblastomas of the cord and cerebrum. Renal, adrenal and pancreatic tumours (and haemangioblastomas) may also be found. Polycythaemia sometimes develops.

Numerous other disorders can be included here, e.g. ataxia telangiectasia (p. 1258) and Osler-Weber-Rendu syndrome (p. 469).

SPINOCEREBELLAR DEGENERATIONS

The classification of this large group of rare inherited disorders is complex. Three conditions will be mentioned here.

Friedreich's ataxia

This is an autosomal recessive progressive degeneration of dorsal root ganglia, spinocerebellar tracts, corticospinal tracts and cerebellar Purkinje cells. Most patients are homozygous for the GAA triplet expansion in the Friedreich's ataxia gene. This gene, mapped to chromosome 9ql3, encodes a mitochondrial protein *(fraxatin)* of unknown function. There is abnormal function of mitochondrial ATP. The expression of fraxatin is decreased in Friedreich's patients. Progressive difficulty walking occurs around the age of 12. Death is usual before 40. However, with the identification of the gene, patients mildly affected have been diagnosed in middle age.

Clinical findings are:

ataxia of gait and trunk
nystagmus (25%)
dysarthria
absent lower limb joint position and vibration sense
absent lower limb reflexes
optic atrophy (30%)
pes cavus
cardiomyopathy.

Hereditary spastic paraparesis

Isolated progressive paraparesis runs in some families. Inheritance is variable. Additional features including cerebellar signs, pes cavus, wasted hands and optic atrophy are sometimes seen. The paraparesis is usually mild and progresses slowly over many years. Some cases have dystonic features and respond to levodopa.

Ataxia telangiectasia (see also p. 219)

This rare, autosomal recessive condition is a progressive ataxic syndrome in childhood and early adult life. There is striking telangiectasia of the conjunctiva, nose, ears and skin creases. There are also defects in cell-mediated immunity and antibody production. A defect in DNA repair has been demonstrated. Death is usual by the third decade, either from infection or from lymphoreticular malignancy.

PERIPHERAL NERVE DISEASE

The various nerve fibre types are shown in Table 21.52. All are myelinated except C fibres that carry impulses from pain receptors.

Mechanisms of damage to peripheral nerves

Peripheral nerves consist of two principal cellular structures - the axon and its anterior horn cell, and the myelin sheath, produced by Schwann cells between each node of Ranvier (see Fig. 21.1). Blood supply is via *vasa nervorum*. Six principal mechanisms, some coexisting, cause nerve malfunction.

Demyelination

When the Schwann cell is damaged, the myelin sheath is disrupted. This causes marked slowing of conduction, seen for example in Guillain-Barre syndrome, post-diphtheritic neuropathy and many hereditary sensori-motor neuropathies.

Axonal degeneration

The primary damage is in the axon, which dies back from the periphery. Conduction velocity tends to remain normal (cf. demyelination) because axonal continuity is maintained in surviving fibres. Axonal degeneration occurs typically in toxic neuropathies.

Wallerian degeneration

This describes the changes following nerve section. Both axon and distal myelin sheath degenerate over several weeks.

Table 21.52 **A, B and C fibres in peripheral nerves**

Diameter ((*)	Conduction velocity m/s	Function
Aa (1-20)	70-110	Motor; proprioception
Ap(5-10)	30-60	Touch
Ay (3-6)	20-30	Fusimotor, to spindles
A5 (2-5)	20-30	Sharp pain
B (<3)	5-15	Autonomic, preganglionic
C (< 1.3)	0.5-2	Slow pain

Compression
Focal demyelination at the point of compression. The myelin sheath is disrupted. This occurs typically in entrapment neuropathies e.g. carpal tunnel syndrome (p. 1260).

Infarction
Microinfarction of *vasa nervorum* occurs in arteritis, e.g. polyarteritis nodosa, Churg-Strauss syndrome (p. 938), and in diabetes mellitus. Wallerian degeneration occurs distal to the ischaemic zone.

Infiltration
Peripheral nerves are infiltrated by inflammatory cells in leprosy, by malignant cells or granulomas in sarcoidosis.

Nerve regeneration

Regeneration occurs either by remyelination, when recovering Schwann cells spin new myelin sheaths around the axon, or by axonal growth down the nerve sheath and sprouting from the axonal stump. Axonal growth takes place at a rate of up to 1 mm daily.

Definitions (Fig. 21.41)

Neuropathy means a pathological process affecting a peripheral nerve or nerves.
Mononeuropathy means a process affecting a single nerve.
Mononeuritis multiplex (multiple mononeuropathy, or multifocal neuropathy) affects several or multiple nerves.
Polyneuropathy describes diffuse, symmetrical disease, usually beginning peripherally. The course is either acute, chronic, static, progressive, relapsing or towards recovery. Polyneuropathies are motor, sensory, sensorimotor (i.e. mixed) and autonomic. They are classified broadly into demyelinating and axonal types, depending upon which principal pathological process predominates. It is often impossible to separate these clinically. Many different classifications exist. Many systemic diseases cause neuropathies. Widespread loss of tendon reflexes is typical. ■ **Radiculopathy** means disease affecting nerve roots.

Diagnosis is made by clinical pattern, electrical tests, nerve biopsy (usually sural or radial) and identification of systemic or genetic disease.

MONONEUROPATHIES

Peripheral nerve compression or entrapment (Table 21.53)

Nerve damage by compression is either acute (e.g. due to a tourniquet or other sustained pressure) or chronic, such as in entrapment neuropathy. In both, focal demyelination predominates at the site of compression, but some distal axonal degeneration also occurs. Acute compression usually affects nerves exposed anatomically, e.g. common peroneal nerve at fibula head, or the ulnar at the elbow. Entrapment develops in relatively tight anatomical passages, e.g. the carpal tunnel.

These neuropathies are recognized largely by clinical features. Diagnosis can be confirmed by nerve conduction

Table 21.53 **Nerve compression and entrapment**

Nerve	Site of entrapment or compression
Median	Carpal tunnel
Ulnar	Cubital tunnel
Radial	Spiral groove of humerus
Posterior interosseous	Supinator muscle
Lateral cutaneous of thigh (meralgia paraesthetica')	Inguinal ligament
Common peroneal Posterior tibial	Neck of fibula Flexor retinaculum (tarsal tunnel)

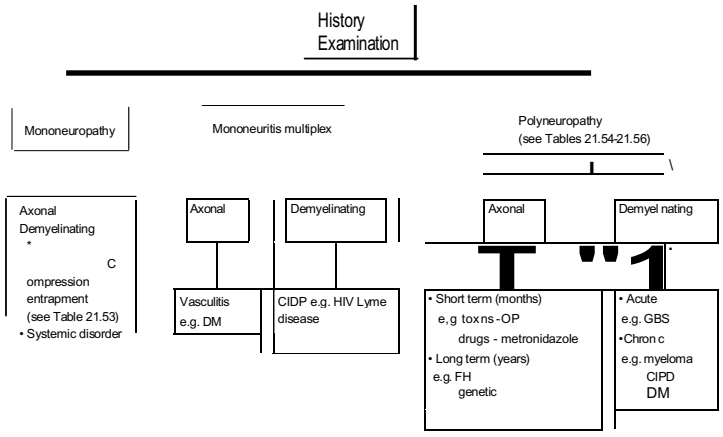

Fig. 21.41 **Peripheral neuropathies** - The type of neuropathy (axonal or demyelinating) can be assessed by electrical nerve studies (p. 1203). CIDP, chronic inflammatory demyelinating polyneuropathy; GBS, Guillain-Barre syndrome; DM, diabetes mellitus; HIV, human immunodeficiency virus; OP organophosphate insecticides; FH, family history; HSMN, hereditary sensorimotor neuropathy.

studies. The commonest are mentioned below. All are seen more frequently in people with diabetes. Where leprosy is prevalent (e.g. India) an isolated nerve lesion can occur.

Carpal tunnel syndrome (p. 539) This is the common condition of median nerve compression at the wrist. Many cases are idiopathic, but this entrapment neuropathy is sometimes seen in:

hypothyroidism
diabetes mellitus
pregnancy (third trimester) and obesity
rheumatoid arthritis
acromegaly
amyloid
renal dialysis patients
trauma.

There is nocturnal tingling and pain in the hand (and/or forearm) followed by weakness of thenar muscles. Wasting of abductor pollicis brevis develops, with sensory loss in the palm and radial three-and-a-half fingers. Tinel's sign is often present and Phalen's test positive. Tinel's sign is elicited by tapping the flexor aspect of the wrist: this causes tingling and pain. In a positive Phalen's test, symptoms are reproduced on maximal wrist flexion.

A wrist splint at night or a local steroid injection in the wrist gives relief in mild cases. In pregnancy (fluid retention), it is often self-limiting. Surgical decompression of the carpel tunnel is the definitive treatment.

Ulnar nerve compression

The nerve is compressed in the cubital tunnel (at the elbow). This follows ulnar fractures or prolonged/ recurrent pressure.

Clawing of the hand due to wasting of ulnar innervated muscles develops (hypothenar muscles, interossei and medial two lumbricals) with sensory loss in the ulnar one-and-a-half fingers. Decompression and transposition of the nerve at the elbow may be necessary.

The deep branch of the ulnar nerve (solely motor) can be compressed in the palm by recurrent trauma from tools, e.g. a screwdriver handle, crutches or cycle handlebars.

Radial nerve compression

The radial nerve is compressed acutely against the humerus, e.g. when the arm is draped over a hard chair for several hours (Saturday night palsy). Wrist drop and weakness of brachioradialis and finger extension follow. Recovery is usual, though not invariable, within 1-3 months. A rather similar picture occurs with compression of the posterior interosseous nerve in the forearm.

Meralgia paraesthetica (see p. 543)

Common peroneal nerve palsy

When the common peroneal (lateral popliteal) nerve is compressed against the head of the fibula following prolonged squatting, wearing a plaster cast, prolonged bed rest or coma, there is foot drop and weakness of ankle eversion. Frequently no cause is found. A patch of numbness on the anterolateral border of the shin or dorsum of the foot develops. Recovery is usual, though not invariable, within several months.

Multifocal neuropathy (mononeuritis multiplex, multiple mononeuropathy)

This occurs in:

diabetes mellitus
leprosy (commonest cause world-wide)
vasculitis sarcoidosis amyloidosis
malignancy neurofibromatosis HIV
infection
Guillain-Barre syndrome (usually polyneuropathy, p. 1260) ■ idiopathic multifocal motor neuropathy.

Diagnosis is largely clinical, supported by electrical studies. Several nerves become affected sequentially or simultaneously, e.g. ulnar, median, radial and lateral popliteal nerves. When multifocal neuropathy is symmetrical, there is difficulty distinguishing it from polyneuropathy.

Idiopathic multifocal motor neuropathy

A distal motor neuropathy (often asymmetrical and predominantly in the hands) of unknown cause develops gradually over months with profuse fasciculation - hence confusion with motor neurone disease (p. 1253). Conduction block and denervation are seen electrically. Antibodies to the ganglioside GM, are found in over 50% of cases. This is non-specific - they are sometimes seen in other neuropathies, e.g. Guillain-Barre syndrome.

Treatment with i.v. immunoglobulin, steroids and/ or cyclophosphamide slows the condition.

POLYNEUROPATHIES

Many toxins and diseases cause polyneuropathy, though the aetiology sometimes remains obscure. The most common presentation is an acute, chronic or subacute sensorimotor neuropathy. A classification is given in Table 21.54.

Guillain-Barre syndrome (GBS)

Clinical features

This is the most common acute polyneuropathy (3/100 000/year); it is usually demyelinating (occasionally axonal) and probably has an autoallergic basis. GBS is monophasic - it does not recur. GBS is also known as acute inflammatory or postinfective neuropathy, and acute inflammatory demyelinating polyradiculoneuropathy. It has become clear that the clinical spectrum of GBS extends to an acute motor axonal neuropathy, and

Table 21.54 Varieties of polyneuropathy

Guillain-Barre syndrome (acute postinfective polyneuropathy)
Chronic inflammatory demyelinating polyneuropathy
Diphtheritic polyneuropathy Idiopathic sensorimotor neuropathy Toxic, metabolic and vitamin deficiency neuropathies
(Table 21.55) Hereditary sensorimotor neuropathies, e.g. Charcot-Marie-Tooth
Other polyneuropathies:
Neuropathy in cancer
Neuropathies in systemic diseases
Autonomic neuropathy
HIV-associated neuropathy
Critical illness neuropathy

the Miller-Fisher syndrome - a rare proximal form causing ocular muscle palsies and ataxia.

Paralysis follows 1-3 weeks after an infection that is often trivial, and often unidentified. *Campylobacter jejuni* and cytomegalovirus infections are well-recognized causes of severe GBS. Infecting organisms induce antibody responses against peripheral nerves. 'Molecular mimicry', sharing of homologous epitopes between microorganism liposaccharides and nerve gangliosides (e.g. GMj), is the potential mechanism.

The patient complains of weakness of distal limb muscles and/or distal numbness. This ascends, progressing over several days to 6 weeks. Loss of tendon reflexes is almost invariable. In mild cases there is little disability before spontaneous recovery begins, but in some 20% respiratory and facial muscles become weak, sometimes progressing to complete paralysis. Autonomic features sometimes develop.

Diagnosis

This is established on clinical grounds and confirmed by nerve conduction studies; these show slowing of conduction in the common demyelinating form, prolonged distal motor latency and/or conduction block. CSF protein is often raised to 1-3 g/L. The cell count and sugar level remain normal.

Differential diagnosis includes other paralytic illnesses, e.g. poliomyelitis, botulism, cord compression or muscle disease.

Course and management

Paralysis may progress rapidly (hours/days) to require ventilatory support. It is essential that ventilation is monitored (vital capacity, blood gases) repeatedly to recognize emerging respiratory muscle weakness. Subcutaneous heparin (p. 480) should be given to reduce the risk of venous thrombosis.

High-dosage intravenous immunoglobulin given within the first 2 weeks reduces the duration and severity of paralysis. There is concern about using this expensive pooled blood product. Patients should be screened for IgA deficiency before immunoglobulin is given - severe allergic reactions due to IgG antibodies may occur when IgA congenital deficiency is present. Angina or myocardial infarction can be precipitated by i.v. immunoglobulin. Plasma exchange is also of proven benefit in shortening disability, though rarely used. Corticosteroids were given for many years but are valueless in GBS. Recovery begins (with or without treatment) between several days and 6 weeks from the outset. Prolonged ventilation may be necessary. Improvement towards independent mobility is gradual over many months but may be incomplete. Fifteen per cent of patients die or are left disabled; fatigue is common.

Chronic inflammatory demyelinating polyneuropathy (CIDP)

This polyneuropathy develops over weeks or months, usually with a persistent but relapsing and remitting course. CSF protein is raised and, usually, segmental demyelination is seen in peripheral nerves. CIDP responds to steroids (long term, low dose) and to i.v. immunoglobulin (for exacerbations). In some cases plaques resembling MS lesions are seen on MRI in brain and spinal cord.

Outlook is variable, but with therapy many CIDP cases run a benign course over many years. Recovery occasionally occurs. There are several CIDP varieties - the usual demyelinating form, an axonal form, and multifocal neuropathy.

Diphtheritic neuropathy (p. 65)

Palatal weakness followed by pupillary paralysis and a sensorimotor neuropathy occur several weeks after the throat infection.

Idiopathic chronic sensorimotor neuropathy

The patient complains of progressive symmetrical numbness and tingling in hands and feet, spreading proximally in glove and stocking distribution. There is distal weakness which also ascends. Rarely cranial nerves are affected. Tendon reflexes become absent. Symptoms may progress over many months, remain static or occasionally remit. Autonomic features are sometimes seen.

Nerve conduction and electromyography show either axonal degeneration or demyelination, or features of both these processes. Peripheral nerve biopsy is helpful in classifying some cases, in particular diagnosing CIDP and unsuspected vasculitis.

Cranial polyneuropathy

This means multiple cranial nerve lesions. This occurs in malignant infiltration, particularly with lymphomas, and with sarcoidosis.

Table 21.55 Toxic, metabolic and vitamin-deficiency neuropathies

Metabolic	Toxic
Diabetes mellitus	Drugs (Table 21.56) Alcohol
Uraemia Hepatic disease Thyroid disease	Industrial toxins, e.g. lead organophosphates
Porphyria	**Vitamin deficiency**
Amyloid disease	B_1 (thiamin) B_6 (pyridoxine)
Malignancy	Nicotinic acid B_{12}
Refsum's disease	
Critical illness	

Toxic, metabolic and vitamin-deficiency neuropathies

The most common are shown in Table 21.55. All are due to impaired axonal and/or myelin metabolism.

Metabolic neuropathies

Diabetes mellitus

Several varieties of neuropathy occur in diabetes:

- symmetrical sensory polyneuropathy
- acute painful neuropathy
- mononeuropathy and multiple mononeuropathy:
  - cranial nerve lesions
  - isolated peripheral nerve lesions (e.g. median)
- diabetic amyotrophy
- autonomic neuropathy.

These are discussed in more detail on page 1129.

Uraemia

Progressive sensorimotor neuropathy develops in chronic uraemia. The response to dialysis is variable but the neuropathy usually improves after renal transplantation.

Thyroid disease

A mild chronic sensorimotor neuropathy is sometimes seen in both hyperthyroidism and hypothyroidism (pp. 1074 and 1072). Myopathy also occurs in hyperthyroidism (p. 1074).

Porphyria

In acute intermittent porphyria (p. 1148) there are episodes of a severe, mainly proximal, neuropathy, sometimes associated with abdominal pain, confusion and later coma. Alcohol and barbiturates may precipitate attacks.

Amyloidosis

See page 1147. Polyneuropathy or multifocal neuropathy develops.

Refsum's disease

This is a rare condition inherited as an autosomal recessive. There is a sensorimotor polyneuropathy with ataxia, retinal damage and deafness. It is due to defective phytanic acid metabolism.

Table 21.56 Drug-related neuropathies

Drug	Neuropathy	Mode/site of action
Phenytoin	M	**A**
Chloramphenicol	S, M	**A**
Metronidazole	S, S/M	A
Isoniazid	S, S/M	A
Dapsone	**M**	A
Anti-retroviral drugs	S>M	**A**
Nitrofurantoin	S/M	**A**
Vincristine	**S>M**	**A**
Paclitaxel	**S>M**	**A**
Disulfiram	**S, M**	**A**
Cisplatin	S	**A**
Amiodarone	S, **M**	D, A
Chloroquine	S, M	**A**, D
Suramin	M>S	D, A

A = axonal; D = demyelinating; M = motor

Toxic neuropathies

Alcohol

Polyneuropathy, mainly in the lower limbs, occurs with chronic excess alcohol. Calf pain is common. Thiamine is the treatment, but the response is variable, even with complete abstention. Recurrence (and progression) occurs with even small amounts of alcohol.

Drugs and industrial toxins

Many drugs (Table 21.56) and a wide variety of industrial toxins cause polyneuropathy. Toxins include:

- lead poisoning - motor neuropathy
- acrylamide (plastics industry), trichlorethylene, hexane and other fat-soluble hydrocarbons (e.g. glue-sniffing, p. 1305) - progressive sensorimotor polyneuropathy
- arsenic and thallium - polyneuropathy, initially sensory.

Vitamin-deficiency neuropathies

Vitamin deficiencies cause nervous system diseases that are largely preventable and potentially reversible if treated early - and inexorably progressive if not. Deficiencies (often of multiple vitamins) occur in malnutrition.

Thiamin (vitamin B1)

Dietary deficiency causes *beriberi* (p. 244). Principal features are polyneuropathy and cardiac failure. Thiamin deficiency also leads to an amnestic syndrome (Wernicke-Korsakoff psychosis, p. 245 and below). Alcohol is the commonest cause in western countries and, rarely, anorexia nervosa. For other neurological consequences of alcohol, see Table 21.57.

Wernicke-Korsakoff syndrome. This thiamine-responsive encephalopathy is due to ischaemic damage in the brainstem and its connections. It consists of:

Psychobgical medicirne 22

INTRODUCTION

Psychiatry is concerned with the study and treatment of disorders of mental function. Psychological medicine, or liaison psychiatry, is the discipline within psychiatry that is concerned with psychiatric and psychological disorders in patients who have physical complaints or conditions. This chapter will primarily concern itself with this particular branch of psychiatry.

The long-held belief that diseases are either physical or psychological has been broken down by the accumulated evidence that the brain is functionally or anatomically abnormal in most if not all psychiatric disorders. Both physical and psychological factors, and their interactions must be considered. This philosophical change of approach rejects the Cartesian dualistic approach of the mind/body *medical model* and replaces it with the more holistic *biopsychosotial model.*

Epidemiology (Box 22.1)

The prevalence of psychiatric disorders in the community in the UK is about 20%, mainly composed of depressive and anxiety disorders and substance misuse (mainly alcohol). The prevalence is about twice as high in patients attending the general hospital, with the highest rates in the accident and emergency department and medical wards. The higher rates in the general hospital are due to several factors, such as admission for deliberate self-harm, a psychiatric disorder or treatment causing physical harm (e.g. alcohol-induced hepatitis or lithium-related renal failure), and physical presentations of psychiatric disorders (such as weight loss due to anorexia nervosa).

Box 22.1 **The approximate prevalence of psychiatric disorders in different populations**

	% (approx.)
Community	20%
Neuroses	16%
Psychoses	0.5%
Alcohol misuse	5%
Drug misuse	2% (an underestimate)
(total in community 20% due to comorbidity)	
Primary care	25%
General hospital outpatients	30%
General hospital inpatients	40%

Culture and ethnicity

These can alter either the presentation or the prevalence of psychiatric ill-health. Biological factors in mental illness are usually similar across cultural boundaries, whereas psychological and social factors will vary. For example, the prevalence and presentation of schizophrenia vary little between countries, suggesting that biological/genetic factors are operating independently of cultural factors. In contrast, conditions in which social factors play a greater role vary between cultures, so that anorexia nervosa is found *more often in developed cultures. Culture* can also influence the presentation of illnesses, such that

physical symptoms are more common presentations of depressive illness in Asia than in Europe.

THE PSYCHIATRIC HISTORY

The purpose of the history is to help to make a diagnosis, determine possible aetiology, and estimate prognosis. Data may be taken from several sources, including interviewing the patient, a friend or relative (usually with the patient's permission), or the patient's general practitioner. The patient interview enables a doctor to establish a relationship with the patient and is the primary way to make a psychiatric diagnosis. Box 22.2 gives essential guidance on how to safely conduct such an interview. It is very unlikely that a patient will physically harm a healthcare professional. When interviewing a patient for the first time follow the guidance outlined in Chapter 1 (see p. 14). The history consists of:

- *Reason for referral* - a brief statement of why and how the patient came to the attention of the doctor.
- *Complaints* - as reported by the patient.
- *Present illness* — a detailed account of the illness from the earliest time at which a change was noted until the patient came to the attention of the doctor.
- *Past psychiatric history* — previous episodes of psychiatric illness and their treatments, including responses and adverse reactions. Always ask after previous episodes of self-harm.
- *Past medical history* - this should include emotional reactions to illness and procedures.
- *Family history* - focusing on the way the parents or carers cared (physically and emotionally) for the patient, and the occurrence of both mental and physical illnesses in first-degree relatives.
- *Personal (biographical) history* - a short biography that covers childhood difficulties including both abuse and neglect, educational problems (e.g. bullying and truanting), qualifications (to judge premorbid intelligence), job problems, sexual relationships, children, present housing, financial situation, bereavements and life stresses. Ways of asking awkward questions might include:
  - 'Do you feel able to tell me what memory most upsets you/makes you angry?'
  - 'Are you able to say what you have done in the past that you most regret?'
  - 'How well do you get on with your partner? Are you happy in every way? Are there any problems in your sexual life that you think I should know about?'

  A *reproductive history* in women should include menstrual problems, pregnancies, terminations, miscarriages, contraception and the menopause, if relevant. *Personality* - this helps to determine prognosis and response to treatment. The doctor should find out how other people would describe the patient. Is the patient generally a worrier, shy, introverted, dependent on others, passive, aggressive, irritable, over-emotional, prone to moodiness, conscientious, or perfectionist? These are all personality traits that predict a poorer outcome in both medical and psychiatric disorders. *Drug history* - both prescribed and over-the-counter medication, the use (units per week) and abuse of alcohol, tobacco, caffeine, and illicit drugs. *Forensic history* - you should carefully explain that you need to ask about this since ill-health can sometimes lead to problems with the law.
  - 'Have you ever had any legal problems or contact with the police or courts?'

  Particularly note any violent or sexual offences. This is part of a *risk assessment* and is necessary in order to assess potential risks to those close to the patient as well as staff. Ask the patient what is the worst harm they have ever inflicted on someone else, which will give an indication of the potential for violence. A *systematic review* of physical symptoms is particularly necessary in patients complaining of physical symptoms.

Sox 22.2 The essentials of a safe psychiatric interview

Beforehand: Ask someone senior who knows the patient whether it is safe to interview the patient alone.
Access to others: If in doubt, interview in the view or hearing of others, or accompanied by another member of staff.
Setting: If safe; in a quiet room alone for confidentiality, not by the bed.
Seating: Place yourself between the door and the patient.
Alarm: If available, find out where the alarm is and how to use it.

THE MENTAL STATE EXAMINATION (MSE)

The history will already have assessed several aspects of the MSE, but the interviewer will need to expand several areas as well as test specific areas, such as cognition.

Appearance and general behaviour

State and colour of clothes, facial appearance, eye contact, posture and movement provide information about a patient's affect. Patients with *psychomotor retardation* due to a depressive illness sit with shoulders hunched, immobile, tearful, with a downcast gaze. Depressed individuals tend to wear clothes with dark colours. Agitation (seen with depressive illness) and anxiety cause an easy startle response, sweating, tremor, restlessness, fidgeting, visual scanning (for danger) and even *pacing* up and down. Patients with mania are often physically

overactive and disinhibited, wearing colourful clothes. Someone who is actively hallucinating will seem distracted and suddenly stop talking or listening and stare intently at a particular place in the room.

Mood and affect

The patient has an *emotion or feeling,* tells the doctor their *mood* and the doctor observes the patient's *affect.* In psychiatric disorders, mood may be altered in three ways:

A persistent change in mood

- *Depression* is a lowering of mood, such as feeling sad, tearful, melancholic or low in spirits. Some patients report *anhedonia,* which is a lack of positive pleasure or loss of interest. Depression is the cardinal feature of depressive illness. Sometimes the word 'depression' is used as shorthand to describe a depressive illness. *Diurnal variation* in mood, feeling worse on waking, suggests a more severe illness, whereas a *reactive mood,* in which the patient can sometimes respond positively, indicates less severity.
- *Anxiety* is a feeling of constant, inappropriate or excessive worry, fear, apprehension, tension or inner restlessness, seen in anxiety and depressive disorders and drug withdrawal.
- *Elation* is a feeling of high spirits, exuberant happiness, vitality and even ecstasy, seen in mania and acute drug intoxication.
- *Irritability* can be either expressed (as in a temper or impatience) or an internal feeling of exasperation or anger, seen in both mania and depressive illness, especially in men.
- *Blunting* of affect is a total absence of emotion, seen most commonly in chronic schizophrenia.

Fluctuating or labile mood

This occurs when different emotions rapidly follow one another, so that a patient is crying one moment and laughing the next. This can occur in mixed affective states (see p. 1288). Alternatively, the patient is easily and excessively emotional over banal events or news, but the emotion is transient. This is seen both in a pseudobulbar palsy, commonly following a cerebrovascular accident (see p. 1191), and with mild depressive illnesses.

Inconsistent or incongruous mood

This occurs when emotional expression fails to match thoughts and actions. For example, a patient may laugh when describing the death of a close relative. This can occur in schizophrenia. Such incongruity needs to be distinguished from the embarrassed laughter that indicates that someone is ill at ease when talking about a distressing subject.

Speech

Disorders *of* thinking are usually recognized *from the* patient's speech.

Disorders of the stream of thought

These are abnormalities in the amount and speed of the thoughts experienced.

Pressure of speech occurs in mania and can be recognized by loudness, rapidity, and difficulty in interrupting speech.

Poverty of speech is the opposite experience, when there appears to be an absence of any thought and patients report their minds to be empty. It occurs in depressive illness.

Thought block occurs in schizophrenia. There is an abrupt and complete interruption of the stream of thought, so the mind goes blank. Patients may interpret the experience in an unusual way (e.g. thought withdrawal; see below).

Disorders of the form of thought

Flight of ideas. The patient's thoughts rapidly jump from one topic to another, such that one train of thought is not completed before another appears. It is often produced by clang associations (the use of two or more words with a similar sound: 'sun, son, song'), punning, rhyming, and responding to distracting cues in the immediate surroundings. Flight of ideas is characteristic of mania and often accompanies pressure of speech.

Perseveration is the persistent and inappropriate repetition of the same thoughts or actions. It occurs in frontal lobe disorders.

Loosening of associations is manifested by a loss of the normal structure of thinking. The most striking impression is a lack of clarity so that it is impossible to understand what is being said. There are several forms. Knight's move or derailment denotes an illogical transition from one topic to another, in the absence of flight of ideas. When this abnormality is extreme and disrupts the grammatical structure of speech, it is termed 'word salad'.

Thought broadcast is when the patient experiences their thoughts as being understood by others without talking, as though their thoughts are literally being broadcast to all around them.

Thought insertion occurs when a patient's thought is perceived as being planted in their mind by someone else.

Thought withdrawal occurs when a patient experiences their thoughts being taken away from them, without their control.

The latter three types of thought disorders are *all first rank symptoms,* which Schneider suggested were pathognomonic of schizophrenia (see p. 1307).

Thought content

Thought content refers to the worries and preoccupations manifested by the patient and elicited at interview. Abnormal beliefs and experiences are, of course, part of the thought content, but are regarded as sufficient to be discussed separately (see below).

- An *obsessional rumination* is a recurrent, persistent thought, *impulse, image or musical theme that enters* the mind despite the individual's effort to resist it. The

individual recognizes that the obsessional thought is their own, but it is usually unpleasant and often 'out of character', such as the thought that the patient has accidentally killed someone while driving their car. Common obsessions concern dirt, contamination and orderliness.

- A *compulsion* is a repetitive and seemingly purposeful action performed in a stereotyped way, referred to as a *compulsive ritual*. Compulsions are accompanied by a subjective sense that they must be carried out (or the patient will be overwhelmed by either anxiety or a superstitious belief that something bad will occur) and by an urge to resist. Compulsive rituals are used to counteract ruminations, so patients repetitively wash their hands to diminish the fear of contamination with dirt.

Insight and illness beliefs

Insight is the degree to which a person recognizes that he or she is unwell, and is minimal in patients with a psychosis. Illness beliefs are the patient's own explanations of their ill-health, including diagnosis and causes. These beliefs should be elicited because they can help to determine prognosis and compliance with treatment, with any disease.

Abnormal beliefs

The main form of abnormal belief is the *delusion* (Box 22.3). Delusions can be primary or secondary.

- Primary delusions are rare and appear suddenly and with full conviction but without any preceding mental events. For example, a patient on being offered a glass of wine suddenly believes that this indicates that he is Jesus Christ.
- Secondary delusions are derived from a preceding morbid experience, such as a depressed mood or an auditory hallucination.

Delusions are also classified according to their content, and include persecutory delusions, delusions of reference, guilt, worthlessness, nihilism, religious delusions, and delusions of grandeur, jealousy or control. These are further defined when discussed in relation to specific conditions.

Feelings, thoughts or actions may also be interpreted by the patient as being under the control of some external power. Such *passivity* experiences are first rank symptoms and are regarded as diagnostic of schizophrenia (see p. 1307). Patients may develop secondary delusions that explain this alien control as a result of witchcraft, hypnosis, radio waves or television - so-called delusions of passivity.

Delusions should be distinguished from *overvalued ideas* - deeply held personal convictions that are understandable when the individual's background is known.

Ideas of reference that fall short of delusions are held by people who are particularly self-conscious. Such individuals cannot help feeling that people take particular notice of them in public places, laugh at them or pass comment about them. Such a feeling is not delusional in that individuals who experience it realize that it originates within themselves and that they are no more noticeable than anyone else, but nevertheless cannot dismiss the feeling.

Abnormal perceptions

- *Illusions* are misperceptions of external stimuli and are most likely to occur when the general level of sensory stimulation is reduced.
- *Hallucinations* are defined in Box 22.4. Healthy people occasionally experience hallucinations, such as in normal grief, or during the transition between sleeping and waking (hypnagogic and hypnapompic). Hallucinations can be elementary (e.g. bangs, whistles) or complex (e.g. faces, voices, music), and may affect any of the perceptions: auditory, visual, tactile, gustatory, olfactory or of deep sensation.
- *Pseudohallucinations* are usually auditory, and are either true externally sited hallucinations, but with insight into their imaginary nature, or are sited within internal space (e.g. 'I heard a voice in my head speak to me'). They can occur in mood disorders and do not indicate a psychosis.
- *Depersonalization* is a change in self-awareness such that the person feels unreal or detached from their body. The individual is aware, however, of the subjective nature of this alteration.
- *Derealization* is the unpleasant feeling that the external environment has become unreal and/or remote; patients may describe themselves as though they are in a dream-like state. Both this and depersonalization can occur in healthy people when they are tired, after sensory deprivation and when using hallucinogenic drugs. They also occur in anxiety disorders, schizophrenia and temporal lobe epilepsy.

Box 22.3 **Delusion**

Delusion is defined as an abnormal belief that is:

held with absolute conviction
not amenable to reason or modifiable by experience
not shared by those of a common cultural or social background
experienced as a self-evident truth of great personal significance
usually false.

Box 22.4 **Hallucination**

An hallucination is defined as a perception in the absence of a stimulus. It is:

a false perception and not a distortion
- perceived as inhabiting objective space
- perceived as having qualities of normal perception
- perceived alongside normal perceptions
- independent of the individual's *will*.

Deja vu is a sudden familiarity with a situation or event as having been encountered before when it is in fact novel.

Jamais vu is the reverse experience when there is failure to recognize a situation or event that has been encountered before. Deja vu experiences occur in healthy people as well as in extreme anxiety states. Both types of experience can occur in temporal lobe epilepsy (see p. 1221).

Increased sensitivity of perceptions, such as *photosensitivity* and *phonosensitivity,* occurs in anxiety disorders (e.g. increased sensitivity to the neon striplights and noise in a supermarket in agoraphobia) as well as neurological disorders such as migraine.

Cognitive state

Examination of the cognitive state is necessary to diagnose organic brain disorders, such as delirium and dementia. Poor concentration, confusion and memory problems are the most common subjective complaints. Clinical testing is a screening of cognitive functions, which may suggest the need for more formal psychometry. A premorbid estimate of intelligence can be made from asking the patient the final year level of education and the highest qualifications or skills achieved.

Testing can be divided into tests of diffuse and focal brain functions.

Diffuse functions

Orientation in time, place and person. *Consciousness* can be defined as the awareness of the self and the environment. *Clouding of consciousness* is more accurately a fluctuating level of awareness and is commonly seen in delirium.

Attention is tested by saying the months or days backwards.

Verbal memory. Ask the patient to repeat a name and address with 10 or so items, noting how many times it takes to recall it 100% accurately (normal is 1 or 2) *(immediate recall* or *registration).*

Ask the patient to try to remember it and then ask it of them again after 5 minutes (0 or 1 error is normal) *(short-term memory).*

Long-term memory. Ask the patient to recall the news of that morning or recently. If they are not interested in the news, find out their interests and ask relevant questions (about their football team or favourite soap opera). *Amnesia* is literally an absence of memory and *dysmnesia* indicates a dysfunctioning memory. .,... ■

Focal functions

Frontal, temporal and parietal function tests are covered on page 1178. *Frontal lobe skills* are difficult to test at the bedside. Note any *disinhibited behaviour* not explained by another psychiatric illness, such as mania. *Sequential tasks* are tested by asking the patient to alternate making a fist with one hand at the same time as a flat hand with the other. Ask the patient to tap a table once if you tap twice and vice versa. Note any *motor perseveration* whereby the patient cannot change the movement once established. Observe for *verbal perseveration,* in which the patient repeats the same answer as given previously for a different question. *Abstract thinking* is measured by asking the meaning of common proverbs, a literal meaning suggesting frontal lobe dysfunction, assuming reasonable premorbid intelligence.

Mini-mental state examination

Box 22.5 gives the 'mini-mental state' examination of cognitive function. This is a 5-minute bedside test that is useful as a screen and in assessing the degree of cognitive dysfunction in patients with diffuse brain disorders. It correlates well with more time-consuming Intelligence

Sox *22.5* The mini-mental state examination

Orientation

Score one point for each correct answer:

What is the: time, date, day, month, year? Maximum: 5 points

What is the name of: this ward, hospital, district, town, country? 5 points

Registration

Name three objects only once. Score up to maximum of 3 points for each correct repetition. 3 points a

Repeat the objects until the patient can repeat them accurately (in order to test recall later).

Attention and calculation

Ask the patient to subtract 7 from 100 and then 7 from the result four more times. 5 points

Score 1 point for each correct subtraction

Recall

Ask the patient to repeat the names of the three objects learnt in the registration test. 3 points

Language

Score 1 point for each of two simple objects named (e.g. pen and a watch) 2 points

Score 1 point for an accurate repetition of the phrase: 'No ifs, ands or buts' 1 point

Give a 3-stage command, scoring 1 point for each part correctly carried out; e.g. 'With the index finger of your right hand touch your nose and then your left ear' 3 points

Write 'Close your eyes' on a blank piece of paper and ask the patient to follow the written command. Score 1 point if the patient closes the eyes. 1 point

Ask the patient to write a sentence. Score 1 point if the sentence is sensible and contains a noun and a verb. 1 point

Draw a pair of intersecting pentagons with each side approximately 1 inch long. Score 1 point if it is correctly copied 1 point

TOTAL MAXIMUM SCORE 30 POINTS

From: Folstein MF, Folstein SE, McHough PR (1975) 'Mini-mental state': a practical method for grading the cognitive state of patients for the clinician. *Journal of Psychiatric Research 12:* 189-198

Quotient (IQ) tests, but it will not as easily pick up cognitive problems caused by focal brain lesions. A score of 23 or less will pick up about 90% of patients with cognitive impairments, with about 10% false positives.

Defence mechanisms

Although not strictly part of the mental state examination, it is useful to be able to identify psychological defences in ourselves and our patients. Defence mechanisms are mental processes that are usually unconscious. The defence mechanisms described below are among the most commonly used and are useful in understanding many aspects of behaviour.

- *Denial* is similar to repression and occurs when patients behave as though unaware of something that they might be expected to know. One example would be a patient who, despite being told that a close relative has died, continues to behave as though the relative were still alive.
- *Displacement* involves the transferring of emotion from a situation or object with which it is properly associated to another that gives less distress.
- *Identification* refers to the unconscious process of taking on some of the characteristics or behaviours of another person, often to reduce the pain of separation or loss.
- *Projection* involves the attribution to another person of thoughts or feelings that are in fact one's own.
- *Regression* is the adoption of primitive patterns of behaviour appropriate to an earlier stage of development. It can be seen in ill people who become child like and highly dependent.
- *Repression* is the exclusion from awareness of memories, emotions and/or impulses that would cause anxiety or distress if allowed to enter consciousness.
- *Sublimation* refers to the unconscious diversion of unacceptable behaviours into acceptable ones.

The relevant physical examination

This should be guided by the history and mental state examination. Particular attention should usually be paid to the neurological and endocrinological examinations when organic brain syndromes and affective illnesses are suspected.

Summary or formulation

When the full history and mental state have been assessed, the doctor should make a concise assessment of the case, which is termed a *formulation.* In addition to summarizing the essential features of the history and examination, the formulation includes a differential diagnosis, a discussion of possible causal factors, and an outline of further investigations or interviews needed. It concludes with a concise plan of treatment and a statement of the likely prognosis.

CLASSIFICATION OF PSYCHIATRIC DISORDERS

The classification of psychiatric disorders into categories is mainly based on symptoms, since there are currently few diagnostic tests for psychiatric disorders. The fourth edition text revision (TR) of the *Diagnostic and Statistical Manual of the American Psychiatric Association* (DSM-IV-TR) provides descriptions of diagnostic categories in order to enable clinicians and investigators to diagnose, communicate about, study and treat people with various mental disorders. This scheme has five axes:

I Psychiatric disorders
II Personality disorders, learning difficulty
III General medical conditions
IV Psychosocial and environmental problems
V Overall level of functioning

Psychiatric classifications have traditionally divided up disorders into neuroses and psychoses.

Neuroses are illnesses in which symptoms vary only in severity from normal experiences. *Psychoses* are illnesses in which symptoms are qualitatively different from normal experience, with little insight into their nature.

There are several problems with a neurotic-psychotic dichotomy. Firstly, neuroses may be as severe in their effects on the patient and their family as psychoses. Secondly, neuroses may cause symptoms that fulfil the definition of psychotic symptoms. For instance, someone with anorexia nervosa may be convinced that they are fat when they are thin, and this belief would meet all the criteria for a delusional belief. Yet we would traditionally classify the illness as a neurosis.

Another classification system - the *International Classification of Mental and Behavioural Disorders* (ICD-10) - has been published by the World Health Organization. This system has largely abandoned the traditional division between neurosis and psychosis, although the terms are still used. The disorders are now arranged in groups according to major common themes (e.g. mood disorders, schizophrenia and other delusional disorders). A classification of psychiatric disorders derived from ICD-10 is shown in Table 22.1, and this is the classification mainly used in this chapter.

Table 22.1 International classification of psychiatric disorders (ICD-10)

Organic disorders
Mental and behavioural disorders due to psychoactive substance use
Schizophrenia and delusional disorders
Mood (affective) disorders
Neurotic, stress-related and somatoform disorders
Behavioural syndromes Disorders of adult personality and behaviour Mental retardation

CAUSES OF A PSYCHIATRIC DISORDER

A psychiatric disorder may result from several causes. It is most helpful to divide causes into the three 'P's: predisposing, precipitating and perpetuating factors.

- *Predisposing factors* often stem from early life and include genetic, pregnancy and delivery, previous traumas and personality factors.
- *Precipitating (triggering) factors* may be physical, psychological or social in nature. Whether they produce a disorder depends on their nature, severity and the presence of predisposing factors. For instance a death of a close, rather than distant, family member is more likely to precipitate a depressive illness or pathological grief reaction in someone who has not come to terms with a previous bereavement.
- *Perpetuating (maintaining) factors* prolong the course of a disorder after it has occurred. Again they may be physical, psychological and/or social, and several are often active and interacting at the same time. For example, high levels of criticism at home combined with taking cannabis, as relief from the criticism, may help to maintain schizophrenia.

PSYCHIATRIC ASPECTS OF PHYSICAL DISEASE

Patients **with** physical illnesses are more likely to suffer from psychiatric disorders than those who are well. The most common psychiatric disorders in physically ill patients are mood or adjustment disorders and acute organic brain disorders (delirium). The relationship between psychological and physical symptoms may be understood in one of three ways:

- Psychological distress and disorders can precipitate physical diseases (e.g. anorexia nervosa causing cardiac arrhythmias, due to hypokalaemia).
- Physical diseases and their treatments can cause psychological symptoms or ill-health (Table 22.2).
- Physical and psychological symptoms and disorders may be independently co-morbid, particularly in the elderly.

Common psychiatric disorders in the general hospital

Delirium is **the** commonest psychosis seen in the general hospital, with *dementia* being the commonest chronic organic brain disorder seen. *Mood disorders,* particularly depressive illness, are common in patients with chronic painful conditions (severe arthritis), disabling illnesses (after a stroke), and after being given a life-threatening diagnosis, such as cancer. Other factors also increase the risk of a psychiatric disorder in someone with a physical disease (Table 22.3).

Table 22.2 **Psychiatric conditions sometimes caused by physical diseases**

Psychiatric disorders/ Physical disease symptom	
Depressive illness	Hypothyroidism Cushing's syndrome Steroid treatment Brain tumour
Anxiety disorder	Thyrotoxicosis Hypoglycaemia (transient) Phaeochromocytoma Complex partial seizures (transient) Alcohol withdrawal
Irritability	Post-concussion syndrome Frontal lobe syndrome Hypoglycaemia (transient)
Memory problem	Brain tumour Hypothyroidism
Altered behaviour	Acute drug intoxication Post-ictal state Acute delirium Dementia Brain tumour

Table 22.3 **Factors increasing the risk of psychiatric disorders in the general hospital**

Patient factors	**Physical conditions**
Previous psychiatric history	Chronic ill-health Chronic pain
Current social or interpersonal stresses	Life-threatening illness
Homeless Recent alcohol misuse	Recent bad prognostic news
	Disabling condition Brain disease Recent live birth, stillbirth or miscarriage Functional (psychosomatic) illness
Setting	**Treatment**
A&E department	Certain drugs (e.g. dopamine agonists)
Neurology, oncology and endocrinology wards	Second postoperative day
Intensive care unit Renal dialysis unit	Surgery affecting body image (e.g. emergency sfomataj

Differences in treatment

Although the basic principles are the same as in treating psychiatric illnesses in the physically healthy, there are some differences:

- *Uncertainty* regarding the physical diagnosis or prognosis, with its attendant tendency to imagine the worst, is often a triggering or maintaining factor, particularly in an adjustment or mood disorder. Good two-way communication between doctor and patient, with time taken to listen to the patient's concerns, is often the most effective 'antidepressant' available.
- A careful history may reveal the role of a *physical disease* or *treatment* exacerbating the psychiatric condition, which should then be addressed (see Table 22.2). For example, the dopamine agonist bromocriptine can precipitate a psychosis.
- When prescribing psychotropic drugs, the dose should be reduced in disorders affecting *pharmacokinetics*, e.g. fluoxetine in renal or hepatic failure.
- *Drug interactions*, e.g. lithium and non-steroidal anti-inflammatories; lithium and thiazide diuretics. Drug interactions are most likely to occur when a patient taking psychotropic is acutely admitted to hospital and prescribed analgesics.
- Sometimes a physical treatment may be planned that may exacerbate the psychiatric condition. An example would be high-dose steroids as part of the next cycle of chemotherapy in a patient with leukaemia and depressive illness. Careful thought should be given to the particular priority for the patient at that moment. It is often useful to discuss the clinical dilemma with a psychiatrist.
- Always consider the risk of *suicide* in an inpatient with a mood disorder and take steps to reduce that risk; for example, moving the patient to a room on the ground floor and/or having a registered psychiatric nurse attend the patient while at risk.

SEVERE BEHAVIOURAL DISTURBANCE

Patients with aggressive or violent behaviour cause understandable apprehension in all staff, and are most commonly seen in the accident and emergency department. Information from anyone accompanying the patient, including police or carers, can help considerably. Box 22.6 gives the main causes of disturbed behaviour.

Management of the severely disturbed patient

The primary aims of management are control of dangerous behaviour and establishment of a provisional diagnosis.

Box 22.6 **Main causes of disturbed behaviour**

Drug intoxication (especially alcohol)
Delirium (acute confusional state)
Acute psychosis Personality
disorder

Three specific strategies may be necessary when dealing with the violent patient:

- reassurance and explanation
- physical restraint
- medication.

The majority of disturbed patients are themselves frightened, as well as frightening, and may feel threatened by those around them, misinterpreting the actions of others. Staff should always explain the situation and their intentions. This simple strategy may calm a patient sufficiently to be interviewed and allow an appropriate examination.

If the behaviour remains severely disturbed, it may be necessary to restrain patients from harming themselves or others. If planned, this should be done with sufficient numbers of trained staff; at least one person per limb and another two in charge or delivering medication. Once brought under physical control, the patient should be held in the prone position, in order to protect the airway and allow access for intramuscular medication. Care must be taken to ensure that neither the airway nor breathing are impeded, by having someone always present at the head of the patient.

It is usually necessary to administer medication while the patient is restrained and they should not be released until they are visibly calmed. Management depends on the provisional diagnosis. 'Rapid tranquillization' should be employed when the patient has a psychosis, so long as the Mental Health Act has been used (see p. 1314) or the situation is so dangerous that the doctor is acting under 'common law'. A deep intramuscular injection of zuclopenthixol acetate in a dose ranging from 50-150 mg together with 0.5-1 mg. lorazepam is now the treatment of choice for rapid effect. Used in combination, they have a synergistic action. Moderate doses of a neuroleptic or benzodiazepine can also be given at regular, comparatively short intervals (30-60 minutes) intramuscularly. Another alternative regimen is intramuscular butyrophenone (haloperidol 5-10 mg) in patients under 60 years old. This dose should be reduced in the elderly and those with known cardiac or hepatic disease. The patient should be observed for up to 1 hour before a further dose is administered. Breathing, pulse rate and blood pressure should be monitored for hypotension, arrhythmias and respiratory difficulty. In the case of continuing disturbance, it may be preferable to administer an adjunctive intramuscular benzodiazepine (lorazepam 2 mg) rather than a further dose of a neuroleptic. Both neuroleptic drugs and benzodiazepines may be used as tranquillizers.

THE SICK ROLE AND ILLNESS BEHAVIOUR

The *sick role* describes behaviour usually adopted by ill people. Such people are not expected to fulfil their normal social obligations. They are treated with sympathy by others and are only obliged to see their doctor and take medical advice or treatments.

Illness behaviour is *the way in which given symptoms* may be differentially perceived, evaluated and acted (or

not acted) upon by different kinds of persons. We all have illness behaviour when we choose what to do about a symptom. Going to see a doctor is generally more likely with more severe and more numerous symptoms and greater distress. It is also more likely in introspective individuals who focus on their health.

Abnormal illness behaviour occurs when there is a discrepancy between the objective somatic pathology present and the patient's response to it, in spite of adequate medical investigation and explanation.

FUNCTIONAL OR PSYCHOSOMATIC DISORDERS: MEDICALLY UNEXPLAINED SYMPTOMS

'Functional' disorders are illnesses in which there is no obvious pathology or anatomical change in an organ (thus in contrast to 'organic') and there is a presumed dysfunction in an organ or system. The word *psychosomatic* has had several meanings, including psychogenic, 'all in the mind', imaginary and malingering. The modern meaning is that psychosomatic disorders are syndromes of unknown aetiology in which both physical and psychological factors are likely to be causative. The psychiatric classification of these disorders would be *somatoform disorders,* but they do not fit easily within either medical or psychiatric classification systems, since they occupy the hinterland between them. Medically unexplained symptoms and syndromes are very common in both primary care and the general hospital (over half the outpatients in gastroenterology and neurology clinics have these syndromes). Because orthodox medicine has not been particularly effective in treating or understanding these disorders, many patients perceive their doctors as unsympathetic and seek out complementary treatments of uncertain efficacy. Examples of functional disorders are shown in Table 22.4.

Because epidemiological studies suggest that having one of these syndromes significantly increases the risk of having another, some doctors believe that these syndromes represent different manifestations in time of *'one functional syndrome',* which is indicative of a *somatization* process. Functional disorders also have a significant association with psychiatric disorders, especially depressive and panic disorders as well as phobias. Against this view is the evidence that the majority of primary care patients with most of these disorders do not have either a psychiatric disorder or other functional disorders. It also seems that it requires a major stress or a psychiatric disorder in order for such sufferers to attend their doctor for help, which might explain why doctors are so impressed with the associations with stress and psychiatric disorders. Doctors have historically tended to diagnose 'stress' or 'psychosomatic disorders' in patients with symptoms that they cannot explain. History is full of such disorders being reclassified as research clarifies the pathology. A recent example is writer's cramp (p. 1233) which most neurologists now agree is a dystonia rather than a neurosis.

Table 22.4 **Functional or psychosomatic syndromes (medically unexplained symptoms)**

- 'Tension' headaches
- Atypical facial pain
- Atypical chest pain
- Fibromyalgia (chronic widespread pain)
- Other chronic pain syndromes
- Chronic or post-viral fatigue syndrome
- Multiple chemical sensitivity
- Premenstrual syndrome
- Irritable or functional bowel syndrome
- Irritable bladder syndrome

Chronic fatigue syndrome (CFS)

There has probably been **more controversy over the** existence and aetiology of CFS than any other functional syndrome in recent years. This is reflected in its uncertain classification as *neurasthenia* in the psychiatric classification and *myalgic encephalomyelitis* (ME) under neurological disorders. There is good evidence for this syndrome, although the diagnosis is made clinically and by exclusion of other fatiguing disorders. Its prevalence is 0.5% in **the** UK, although abnormal fatigue as a symptom occurs in 10-20%. It occurs most commonly in women between the ages of 20 and 50 years old. The cardinal symptom is chronic fatigue made worse by minimal exertion. The fatigue is usually both physical and mental, with associated poor concentration, impaired registration of memory, irritability, alteration in sleep pattern (either insomnia or hypersomnia), and muscular pain. The name myalgic encephalomyelitis (ME) is decreasingly used within medicine because it implies a pathology for which there is no evidence.

Aetiology

Functional disorders often have aetiological factors in common with each other (see Table 22.5), as well as more specific aetiologies. For instance, CFS can be triggered by certain infections, such as infectious mononucleosis and viral hepatitis. About 10% of patients with infectious mononucleosis have CFS 6 months after the infectious onset, yet there is no evidence of persistent infection in these patients. Those fatigue states which clearly do follow on a viral infection can be classified as *post-viral fatigue syndromes.* Other aetiological factors include physical inactivity and sleep difficulties. Immune and endocrine abnormalities noted in CFS may be secondary to the inactivity or sleep disturbance commonly seen in patients. Mood disorders are present in a large minority of patients, and can cause problems in diagnosis because of the large overlap in symptoms. These mood disorders may be secondary, independent (co-morbid), or primary with a misdiagnosis of CFS. The role of stress is uncertain, with some indication that the influence of stress is mediated through consequent psychiatric disorders exacerbating fatigue, rather than any direct effect.

Management

The general principles *of the management of functional* disorders are given in Box 22.7. Specific management of

Table 22.5 **Aetiological factors commonly seen in functional disorders**

Predisposing
Perfectionist, obsessional and introspective personality traits
Childhood traumas (physical and sexual abuse)
Similar illnesses in first-degree relatives

Precipitating (triggering)
Infections
Chronic fatigue syndrome (CFS)
Irritable bowel syndrome (IBS)
Psychologically traumatic events (especially accidents)
Physical injuries ('fibromyalgia' and other chronic pain syndromes) Life events that precipitate changed behaviours (e.g. going off sick) Incidents where the patient believes others are responsible

Perpetuating (maintaining)
Inactivity with consequent physiological adaptation (CFS and 'fibromyalgia') Avoidant behaviours - multiple chemical sensitivities (MCS), CFS Maladaptive illness beliefs (that maintain maladaptive behaviours) (CFS)
Excessive dietary restrictions ('food allergies')
Stimulant drugs Sleep disturbance Mood disorders Somatization disorder Unresolved anger or guilt Unresolved compensation

Box 22.7 **Management of functional disorders**

The first principle is the identification and treatment of maintaining factors (e.g. dysfunctional beliefs and behaviours, mood and sleep disorders).

Communication
Explanation of ill-health, including diagnosis and causes Education about management (including self-help leaflets) * Stopping drugs (e.g. caffeine causing insomnia, analgesics causing dependence)
m Rehabilitative therapies
Cognitive behaviour therapy (to challenge unhelpful beliefs and change coping strategies)
Supervised and graded exercise therapy for approximately 3 months (to reduce inactivity and improve fitness) «
Pharmacotherapies
Specific antidepressants for mood disorders, analgesia and sleep disturbance Symptomatic medicines (e.g. appropriate analgesia, taken only when necessary)

CFS should include a mutually agreed and supervised programme of gradually increasing activity. However, few patients regard themselves as cured after treatment. It is sometimes difficult to persuade a patient to accept what are inappropriately perceived as 'psychological therapies' for such a physically manifested condition. Antidepressants do not work in the absence of a mood disorder or insomnia.

Prognosis

This is poor without treatment, with less than 10% of hospital attenders recovered after 1 year. Outcomes are worse with increasing age, co-morbid mood disorders, and the conviction that the illness is entirely physical.

Fibromyalgia (chronic widespread pain: CWP)

This controversial condition of unknown aetiology overlaps with chronic fatigue syndrome, with both conditions causing fatigue and sleep disturbance (see p. 1281). Diffuse muscle and joint pains are more constant and severe in CWP, although the 'tender points', previously considered to be pathognomonic, are now known to be ubiquitous, associated with psychological distress, and of no diagnostic importance (p. 547). CWP occurs most commonly in women aged 40-65 years old, with a prevalence in the community of between 1 and 11%. There are associations with depressive and anxiety disorders, other functional disorders, physical deconditioning and a possibly characteristic sleep disturbance (see Table 22.5).

Management

Apart from the general principles in Box 22.7, management also consists of symptomatic analgesia, reversing the sleep disturbance, and a physically orientated rehabilitation programme. A recent meta-analysis suggests that tricyclic antidepressants that inhibit reuptake of both serotonin (5-hydroxytryptamine - 5-HT) and norepinephrine (noradrenaline) (e.g. amitriptyline, dosulepin (dothiepin)) have the greatest effect on sleep, fatigue and pain. The doses used were too low for antidepressant efficacy and the drugs may work through their hypnotic and analgesic effects.

Other chronic pain syndromes

A chronic pain syndrome is a condition of chronic disabling pain for which no medical cause can be found. The psychiatric classification would be a persistent *somatoform pain disorder,* but this is unsatisfactory since the criteria include the stipulation that emotional factors must be the main cause, and it is clinically difficult to be that certain. The main sites of chronic pain syndromes are the head, face, neck, lower back, abdomen, genitalia and all over (CWP: fibromyalgia). 'Functional' low back pain is the commonest 'physical' reason for being off sick long-term in the UK (p. 540). Quite often a minor abnormality will be found on investigation (such as mild cervical spondylosis on the neck X-ray), but this will not be severe enough to explain the severity of the pain and resultant disability. These *pains are often unremitting and respond* poorly to analgesics. Sleep disturbance is almost universal

and co-morbid psychiatric disorders are found in a large minority.

Aetiology

The perception of pain involves sensory (nociceptive), emotional and cognitive processing in the brain. Functional brain scans suggest that the brain may respond abnormally to pain in these conditions, with increased activation in response to chronic pain. This could be related to conditioned behavioural and physiological responses to the initial acute pain. The brain may then adapt to the prolonged stimulus of the pain by changing its central processing. The prefrontal cortex, thalamus and cingulate gyrus seem to be particularly affected and some of these areas are involved in the emotional appreciation of pain in general. Thus it is possible to start to understand how beliefs, emotions and behaviours might influence the perception of chronic pain (see Table 22.5).

Management

Management involves the same principles as used in other functional syndromes (Box 22.7). Since analgesics are rarely effective, and can cause long-term harm, patients should be encouraged to gradually reduce their use. It is often helpful to involve the patient's immediate family or partner, to ensure that the partner is also supported and not unconsciously discouraging progress.

Specific drug treatments are few. Nerve blocks are not usually effective. Anticonvulsants such as carbamazepine and gabapentin may be given a therapeutic trial if the pain is thought to be neuropathic (see p. 1200). The antidepressant *dosulepin (dothiepin)* is an effective treatment in half of patients with atypical facial pain, and this effect seems to be independent of dosulepin's effect on mood. Another tricyclic antidepressant, *amitriptyline,* is helpful in tension headaches, which might be related to its independent analgesic effect. Amitriptyline has the added bonus of increasing slow wave sleep, which may be why it is more effective than NSAIDs in chronic widespread pain. Tricyclic antidepressants that affect both serotonin and norepinephrine (noradrenaline) reuptake (e.g. p. 1292) seem to be more effective than more selective norepinephrine reuptake inhibitors, e.g. in neuropathic pain. There is some evidence that tricyclics are generally superior to SSRIs in chronic pain syndromes.

Irritable bowel syndrome

This is one of the commonest functional syndromes, affecting some 10-30% of the population in the UK. The clinical features and management of the syndrome and the related *functional dyspepsia* are described in more detail on page 337. Although the majority of sufferers with the irritable bowel syndrome (IBS) do not have a psychiatric disorder, depressive illness should be excluded in patients with constipation and a poor appetite. Anxiety disorders should be excluded in patients with nausea and diarrhoea. Persistent abdominal pain or a feeling of emptiness may occasionally be the presenting symptom of a severe depressive illness, particularly in the elderly, with a *nihilistic delusion* that the body is empty or dead inside (see p. 1289).

Management

This is dealt with in more detail on page 339 and in Box 22.7. Seeing a physician who provides specific education that particularly addresses individual illness beliefs and concerns can provide lasting benefit. Psychological therapies that help the more severely affected include biofeedback, hypnotherapy, cognitive behaviour therapy and brief interpersonal psychotherapy. If indicated, the choice of antidepressant should be determined by the effects of these drugs on bowel transit times, with tricyclic antidepressants normally slowing and selective serotonin reuptake inhibitors (SSRIs) (p. 1292) normally speeding up transit times.

Multiple chemical sensitivity, Candida hypersensitivity, and food allergies

Some complementary health practitioners, doctors, and patients themselves make diagnoses of multiple chemical sensitivities (MCS) (e.g. to foods, smoking, perfumes, petrol), Candida hypersensitivity, and allergies (to food, tap-water, and even electricity). Symptoms and syndromes attributed to these putative disorders are numerous and variable and include all the functional disorders, *mood disorders,* and *arthritis.* Scientific support for the existence of these disorders has been hard to acquire, particularly when double-blind methodologies have been used.

Type 1 hypersensitivities to foods such as nuts certainly exist, although they are fortunately uncommon (approximately 3 per 1000) (see p. 220). Direct specific food intolerances also occur (e.g. chocolate with migraine, caffeine with IBS).

Candidiasis can occur in the gastrointestinal tract in immunocompromised individuals, such as those with AIDS. Vaginal candidiasis can occur after antibiotic treatment in otherwise healthy women. A double-blind and controlled study of nystatin in women, diagnosed as having candidiasis hypersensitivity syndrome, showed that vaginal Candida was the only symptom relieved more by nystatin than placebo. There is little evidence of Candida having a systemic role in other symptoms. In spite of this evidence, the patient is often convinced of the legitimacy and usefulness of these diagnoses and their treatments.

Aetiology

Surveys of patients diagnosed with MCS or food allergies have shown high rates of current and previous psychiatric disorders (especially mood and anxiety disorders) (see Table 22.5). Eating disorders (p. 1310) should be excluded in patients with food intolerances. Some patients, taking very low carbohydrate diets as putative treatments, may develop reactive hypoglycaemia after a high carbohydrate meal, which they then interpret as a food *allergy. It has* been shown that classical conditioning can produce

intolerances to foods and smells in healthy people and this may be a causative mechanism in some patients with intolerance. This study supports the existence of these intolerance conditions, but suggests they may be conditioned responses with attendant physiological consequences. This might explain why double-blinding abolishes the reaction to the stimulus.

Management.

The general principles in Box 22.7 apply. If one assumes a phobic or conditioned response is responsible, graded exposure (systematic desensitization) to the conditioned stimulus may be worthwhile. Preliminary studies do suggest that this approach may successfully treat such intolerances, in the context of cognitive behaviour therapy.

Premenstrual syndrome

The premenstrual syndrome (PMS) consists of **both** physical and psychological symptoms that regularly occur during the premenstrual phase and substantially diminish or disappear soon after the period starts. Physical symptoms include headache, fatigue, breast tenderness, abdominal distension and fluid retention. Psychological symptoms can include irritability, emotional lability or low mood, and tension. The *premenstrual dysphoric disorder* (PMDD) is a severe form of PMS with marked mood swings, irritability, depression and anxiety accompanying the physical symptoms. Women who generally suffer from mood disorders may be more prone to experience this disorder. The prevalence of PMS does not vary between cultures and is reported by the majority (75%) of women at some time in their lives. Severely disabling PMS (PMDD) occurs in about 3-8% of women. The cause of the premenstrual syndrome remain unclear, although exacerbating factors include some of those outlined in Table 22.5. Research suggests that abnormalities of reproductive hormone receptors may play a role.

Management

The general principles in Box 22.7 apply. Treatments with vitamin B_6 (p. 246), diuretics, progesterone, oral contraceptives, oil of evening primrose and oestrogen implants or patches (balanced by cyclical norethisterone) remain empirical. Psychotherapies aimed at enhancing the patient's coping skills can reduce disability. Two trials suggest that graded exercise therapy improves symptoms. Several studies have demonstrated that SSRIs (p. 1292) are effective treatments for the premenstrual dysphoric syndrome.

The menopause

The clinical features **and** management of **the** menopause are described on page 1052. A prospective study has shown that there is no increased incidence of depressive disorders at this time. Such a significant bodily change, sometimes occurring at the same time as children leaving home, is naturally accompanied by an emotional adjustment that does not normally amount to a pathological state.

SOMATOFORM DISORDERS

As explained in the section on functional disorders (p. 1281), the classification of somatoform disorders is unsatisfactory because of the uncertain nature and aetiology of these disorders. However, there are certain disorders, beyond those described in 'functional disorders', that present frequently and coherently enough to be usefully recognized.

Somatization **disorder**

One in ten patients presenting with a functional disorder will fulfil the criteria of a chronic somatization disorder, sometimes known as *Briquet's syndrome*. The condition is composed of multiple, recurrent, medically unexplained physical symptoms, usually starting early in adult life. Exhaustion, dizzy spells, headaches, hypersensitivity to light and noise, paraesthesiae, abdominal, neck and back pain, nausea, sexual symptoms, and abnormal skin sensations are among the most common complaints, but symptoms may be referred to almost any part or bodily system. The patient, usually female, has often had multiple medical opinions and repeated negative investigations. Medical reassurance that the symptoms do not have a demonstrable physical cause fails to reassure the patient, who will continue to 'doctor-shop'. The patient is usually reluctant to accept a psychological and/or social explanation for the symptoms even when such a link seems obvious. Abnormal illness behaviour is evident and patients can be attention-seeking and dependent on doctors. Yet they can complain about the medical care and attention they have previously received. The aetiology is unknown, but both mood and personality disorders are often also present. It is often associated with dependence upon or misuse *of prescribed* medication, usually sedatives and analgesics. There is

often a history of significant childhood traumas, or chronic ill-health in the child or parent, which may play an aetiological role (see Table 22.5). The condition is probably the somatic presentation of psychological distress, although iatrogenic damage (from postoperative and prescribed-drug-related problems) soon complicates the clinical picture. The course of the disorder is chronic and disabling, with long-standing family, marital and/or occupational problems.

Hypochondriasis

The conspicuous feature is a preoccupation with an assumed serious disease and its consequences. Patients commonly believe that they suffer from cancer or AIDS, or some other serious condition. Characteristically, such patients repeatedly request laboratory and other investigations to either prove they are ill or reassure themselves that they are well. Such reassurance rarely lasts long before another cycle of worry and requests begins. The symptom of hypochondriasis may be secondary to or associated with a variety of psychiatric disorders, particularly depressive and anxiety disorders. Occasionally the hypochondriasis is delusional, secondary to schizophrenia or a depressive psychosis. Hypochondriasis may coexist with physical disease but the diagnostic point is that the patient's concern is disproportionate and unjustified.

Management of somatoform disorders

The principles outlined in Box 22.7 also apply to these disorders. Patients very much appreciate a discussion and explanation of their symptoms. Further management consists of ceasing reassurance that no serious disease has been uncovered, since this simply reinforces dependence on the doctor. The doctor should sensitively explore possible psychological and social difficulties, if possible by demonstrating links between symptoms and stresses. Useful questions to ask include:

'When were you last completely well and happy?'

Such a patient may have trouble remembering such a time, which helps to support the diagnosis, and leads to a discussion as to why they have never been well or happy.

'What can't you do now because you are unwell?' 'What changes has your ill-health caused in your close relationships?'

These questions usually give information that can be used to formulate an agreed plan of management. Repeated laboratory investigations should be discouraged. It is vital that all members of staff and close family members adopt the same approach to the patient's problems. Such patients often consciously or unconsciously split both medical staff and family members into 'good' and 'bad' (or caring and uncaring) people, as a way of projecting their distress. Since these disorders have a poor prognosis, the aim is to minimize disability. A contract of mutually agreed care involving the appropriate professionals (general practitioner, and a choice of psychotherapist, health psychologist, complementary health professional, physician or psychiatrist), with agreed frequency of visits and a review date, can be helpful in managing the condition.

Cognitive behaviour therapy has been shown to provide effective rehabilitation in significant numbers of patients suffering from a somatoform disorder.

DISSOCIATIVE (CONVERSION) DISORDERS

Until recently these disorders were known as 'hysteria'; but because the word hysteria is sometimes used pejoratively to describe extravagant behaviour, the term is inappropriate.

A *dissociative disorder* is a condition in which there is a profound loss of awareness or cognitive ability without medical explanation. The term dissociative indicates the disintegration of different mental activities, and covers such phenomena as amnesia, fugues, and pseudoseizures (non-epileptic fits).

The term *conversion* was introduced by Freud to explain how an unresolved conflict could be converted into usually symbolic physical symptoms as a defence against it. Such symptoms commonly include paralysis, abnormal movements, sensory loss, aphonia, disorders of gait, and pseudocyesis (false pregnancy). The lifetime prevalence has been estimated at 3-6 per 1000 in women, with a lower prevalence in men. Most cases begin before the age of 35 years. Dissociation is unusual in the elderly.

Table 22.6 **Common dissociative/conversion symptoms**

Dissociative (mental)	**Conversion (physical)**
Amnesia	Paralysis
Fugue	Disorders of gait
Pseudodementia	Tremor
Dissociative identity disorder	Aphonia
Psychosis	Mutism
	Sensory symptoms
	Globus hystericus
	Hysterical fits
	Blindness

Clinical features

The various symptoms are usually divided into dissociative and conversion categories (Table 22.6). Dissociative disorders have the following four characteristics that are necessary in order to make the diagnosis:

- They occur in the absence of physical pathology that would explain the symptoms.

- They are produced unconsciously.
- The illness is always triggered by an unresolved conflict or life event.
- Symptoms are not caused by overactivity of the sympathetic nervous system.

Other characteristics include:

- Symptoms and signs often reflect a patient's ideas about illness.
- Patients may take up the symptoms of a relative/friend who has been ill.
- There is usually abnormal illness behaviour, with obvious exaggeration of disability.
- *Primary gain* is the immediate relief from the emotional conflict.
- *Secondary gain* refers to the social advantage gained by the patient by being ill and disabled (sympathy of family and friends, being off work, disability pension).
- There may be a curious lack of concern about the symptoms or disability ('belle indifference').
- Physical disease is not uncommonly present (e.g. pseudoseizures in someone with epilepsy).

Dissociative *amnesia* commences suddenly. Patients are unable to recall long periods of their lives and may even deny any knowledge of their previous life or personal identity. In a dissociative *fugue,* patients not only lose their memory but wander away from their usual surroundings, and, when found, deny all memory of their whereabouts during this wandering. The differential diagnosis of a fugue state includes post-ictal automatism, depressive illness and alcohol abuse.

Dissociative *pseudodementia* involves memory loss and behaviour that initially suggest severe and generalized dementia. A differential diagnosis is depressive pseudodementia (see p. 1289).

Multiple personality disorder is rare, but dramatic, and may be no more than the consequence of suggestion on the part of a psychotherapist. There are rapid alterations between two or more 'personalities' in the same person, each of which is repressed and dissociated from the other 'personalities'. A differential diagnosis is rapid cycling *manic depressive disorder* which would explain sudden apparent changes in personality.

Epidemic or *'mass hysteria'* usually occurs in institutions for girls or young women, in which the combined effects of suggestion and shared anxiety produce outbreaks of sickness or disturbed behaviour, often following sudden illnesses in leaders of the group at a time of threatened or actual social change.

Differential diagnosis

Dissociation is usually a stable and reliable diagnosis over time, although high rates of co-morbid mood and personality disorders are found in chronic sufferers. Particular care should be taken to make the diagnosis on positive grounds, and not simply on the basis of an absence of a medical diagnosis. Care should also be taken to exclude or treat co-morbid psychiatric disorders.

Aetiology

Preliminary research using functional brain scans where healthy controls feigning a motor abnormality were compared with patients with a similar conversion motor symptom suggests that dissociation involves different areas of the brain from stimulation. This supports the theory of unconscious mechanisms first suggested by Charcot (see Fig. 22.1). This research would suggest that there is a disinhibition of voluntary will at an unconscious level, so that the patient can no longer *will* the function to happen.

The psychoanalytical theory of dissociation is that it is the result of emotionally charged memories that are repressed into the unconscious at some point in the past. Symptoms are explained as the combined effects of repression and the symbolic conversion of this emotional energy into physical symptoms. This hypothesis is difficult to test, although there is some evidence that patients with dissociative disorders are more likely to have suffered childhood abuse, particularly when the abuse was both sexual and physical and started early in childhood. Caution should be taken with any such history obtained by therapies that 'recover' childhood memories that were previously completely unknown to the patient.

Patients with dissociative disorders, by definition adopt both the sick role and abnormal illness behaviour, with consequent secondary gains that help to maintain the illness.

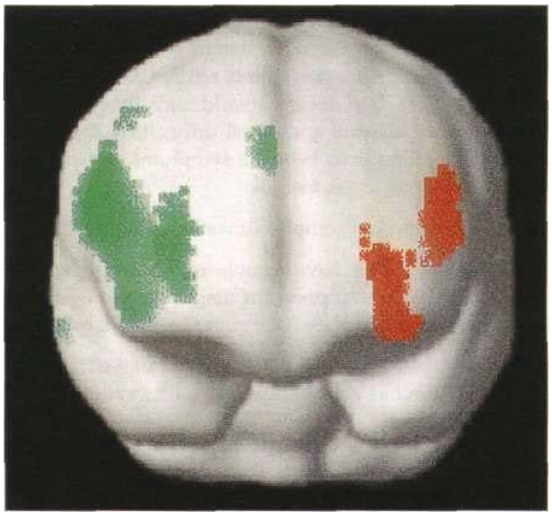

***Fig. 22.1* Statistical parametric maps superimposed on an MRI scan of the anterior surface of the brain, orientated as though looking at a person head on.** Red region shows hypofunction of patients with conversion motor symptoms. Green region shows hypofunction of healthy controls feigning the same motor abnormality. Reproduced from Spence SA, Crimlisk HL, Cope H, Ron MA, Grasby PM (2000) Discrete neurophysiological correlates in prefrontal cortex during hysterical and feigned disorders *of movement. Lancet* 355:1243-1244, © The Lancet Ltd. 2000, with permission.

Management

The treatment of dissociation is similar to the treatment of somatoform disorders in general, outlined above and in Box 22.7. The first task is to engage the patient and their family with a model of the illness that makes sense to them, is acceptable, and leads to the appropriate management. An invented example of a suitable explanation is given below:

You told me about the tremendous shock you felt when your mother suddenly died. This was particularly the case since you hadn't spoken to her for so long beforehand, after that big disagreement with her over your wedding to John. You weren't able to say good-bye before she died. Your brain was overloaded with grief, guilt and anger all at once. I wonder whether that is why you aren't able to speak now. I wonder whether it's difficult to think of anything to say that would make things right, particularly since you can't speak with your mother now.

Such an explanation would be modified by mutual discussion until an agreed understanding was achieved, which would serve as a working model for the illness. Provision of a rehabilitation programme that addresses both the physical and psychological needs and problems of the patient would then be planned. A graded and mutually agreed plan of a return to normal function can usually be led by the appropriate therapist (e.g. speech therapist for dysphonia, physiotherapist for paralysis). At the same time, a psychotherapeutic assessment should be made in order to determine the appropriate form of psychotherapy. For instance, couple therapy will address a significant relationship difficulty; individual psychotherapy could ease an unresolved conflict from childhood.

Abreaction brought about by *hypnosis* or by intravenous injections of small amounts of midazolam may produce a dramatic, if short-lived, recovery. In the abreactive state, the patient is encouraged to relive the stressful events that provoked the disorder and to express the accompanying emotions; i.e. to abreact. Such an approach has been useful in the treatment of acute dissociative states in wartime, but appears to be of much less value in civilian life. It should only be contemplated in the presence of an anaesthetist with suitable resuscitation equipment to hand.

Hypnotherapy is psychotherapy while the patient is in a hypnotic trance, the idea being that therapy is more possible because the patient is relaxed and not using repression. This may allow the therapist access to the previously unconscious emotional conflicts or memories. There are no published trials of this technique in dissociation, which Freud gave up as unsuccessful in order to found psychoanalysis, but some hypnotherapists claim good results. Care should be taken to avoid a catastrophic emotional reaction when the patient is suddenly faced with the previously repressed memories.

Prognosis

Most cases of recent onset recover quickly with treatment, which is why a positive diagnosis should be made early, rather than sending the patient on to the next medical specialist. Those cases that last longer than a year are likely to persist, with entrenched abnormal illness behaviour patterns that are hard to shift.

SLEEP DIFFICULTIES (p. 1227)

Sleep is divided into *rapid eye movement (REM)* and *non-REM* sleep. As drowsiness begins, the alpha rhythm on an EEG disappears and is replaced by deepening slow wave activity (non-REM). After 60-90 minutes, this slow wave pattern is replaced by low amplitude waves on which are superimposed rapid eye movements lasting a few minutes. This cycle is repeated during the duration of sleep, with the REM periods becoming longer. REM sleep is accompanied by dreaming and physiological arousal. Slow wave sleep is associated with release of anabolic hormones and cytokines, with an increased cellular mitotic rate. It helps to maintain host defences, metabolism and repair of cells. For this reason slow wave sleep is increased in those conditions where growth or conservation is required (e.g. adolescence, pregnancy, thyrotoxicosis).

Insomnia is difficulty in sleeping; a third of adults complain of insomnia and in a third of these it can be severe.

Primary sleep disorders include sleep apnoea (p. 1227), narcolepsy (see p. 1227), the *restless legs syndrome (Ekbom's)* (see p. 666) and its related *periodic leg movement disorder,* in which the legs (and sometimes the arms) jerk while asleep.

Delayed sleep phase syndrome occurs when the circadian pattern of sleep is delayed so that the patient sleeps from the early hours until mid-day or later. *Night terrors, sleep-walking* and *sleep-talking* are non-REM phenomena, most commonly found in children, which can recur in adults when under stress or suffering from a mood disorder.

Psychophysiological insomnia commonly occurs with functional, mood and substance misuse disorders, and when under stress (see Box 22.8). It can often be triggered by one of these factors, but then become a habit on its own, driven by anticipation of insomnia and day-time naps. Insomnia causes day-time sleepiness and fatigue, with consequences such as road traffic accidents. Assessment should pay particular attention to mood, life difficulties, and drug intake (especially alcohol, nicotine and caffeine). Initial insomnia (trouble getting off to sleep) is common in mania, anxiety, depressive disorders and substance misuse. Middle insomnia (waking up in the middle of the night) occurs with medical conditions, such as sleep apnoea and prostatism. Late insomnia (early morning waking) is caused by depressive illness and malnutrition (anorexia nervosa).

Habitual alcohol consumption should be carefully estimated since even a small excess can be a potent cause of insomnia, as well as recent withdrawal. *Caffeine* is perhaps the most commonly taken drug in the UK, and its effects are easily underestimated. Six cups (not mugs) *of*

I

***Box 22.8* Common causes of insomnia**

Psychiatric disorders
Mood disorders (mania, depressive and anxiety disorders) Delirium and dementia

Drug use or misuse
Addictive drug withdrawal (alcohol, benzodiazepines) Stimulant drugs (caffeine, amfetamines) Prescribed drugs (steroids, dopamine agonists)

Physical conditions
Pain (classically with carpal tunnel syndrome) Nocturia (e.g. from prostatism) Malnutrition

Primary sleep disorders
Sleep apnoea Restless legs syndrome

real coffee a day are likely to cause insomnia in the average healthy adult. Caffeine is not only found in tea and coffee, but is also found in chocolate, cola drinks and some analgesics. Prescription drugs that can either disturb sleep or cause vivid dreams include most appetite suppressants, glucocorticoids, dopamine agonists, lipid-soluble beta-blockers (e.g. propranolol) and certain psychotropic drugs (especially when first prescribed; e.g. fluoxetine, reboxetine, risperidone).

Hypersomnia is not uncommon in adolescents with depressive illness, occurs in narcolepsy, and may temporarily follow infections such as infectious mononucleosis.

Management of insomnia

This is particularly determined by diagnosis. Where none is immediately apparent, it is worth educating the patient about sleep hygiene. Simple measures such as decreasing alcohol intake, having supper earlier, exercising daily, having a bath prior to going to bed and establishing a routine of going to bed at the same time should be tried. Relaxation techniques and cognitive behaviour therapy have a role in those with intractable insomnia. Short half-life benzodiazepines can be useful for acute insomnia, but should not be used for more than 2 weeks continuously to avoid dependence. Non-benzodiazepine hypnotics (zaleplon, zopiclone, zolpidem) act at the benzodiazepine receptors and occasional dependence has been reported. Certain antihistamines (e.g. promethazine) and antidepressants (e.g. amitriptyline, trimipramine, trazodone mirtazapine) are not addictive and can be used as hypnotics in low dose, with the added advantage of improving slow wave sleep. The commonest side-effects are morning sedation and weight gain. . . ■ - ,

MOOD (AFFECTIVE) DISORDERS

Classification

The central and common feature of these disorders is an abnormality of mood. Mood is best considered in terms of a continuum ranging from severe depression at one extreme to severe mania at the other, with the normal, stable mood at the centre (Fig. 22.2). Mood disorders are divided into bipolar and unipolar affective disorders. In bipolar affective disorder (otherwise known as manic-depressive disorder) patients suffer bouts of both depression and mania. In unipolar affective disorder patients suffer from depressive mood swings alone, although they are commonly recurrent. Although mania can rarely occur by itself without depressive mood swings (thus being classified as unipolar) it is far more commonly found in association with depressive swings, even if sometimes it takes several years for the first depressive illness to appear. Hypomania is mild mania. Dysthymia is a chronic low-grade depressive illness.

DEPRESSIVE DISORDERS

Depressive disorders or 'episodes' are primarily classified as bipolar or unipolar and secondarily as mild, moderate or severe, with or without somatic symptoms. Severe depressive episodes are divided according to the presence or absence of psychotic symptoms. About 10% of patients with depressive illness are eventually found to have bipolar illnesses. ■.'■'■■-.■

Clinical features of depressive disorder

Whereas everyone will at some time or other feel cheesed off, fed up or down in the dumps, it is when such symptoms become qualitatively different, pervasive, or interfere with normal functioning that a depressive illness has occurred. Depressive disorder, clinical or 'major' depression is characterized by disturbances of mood, speech, energy and ideas (Table 22.7). Patients often describe their symptoms in physical terms. Marked fatigue and headache are the two most common physical symptoms in depressive illness and may be the first

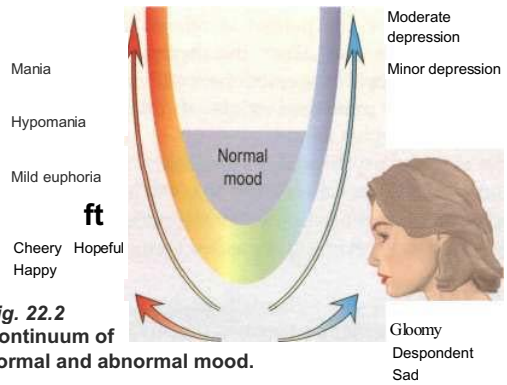

Fig. 22.2 **Continuum of normal and abnormal mood.**

^^^^^H *Table 22.7* **Clinical features of depression**

Characteristic	Clinical appearance
Mood	Depressed, miserable or irritable
Talk	Impoverished, slow, monotonous
Energy	Reduced, lethargic
Ideas	Feelings of futility, guilt, self-reproach, unworthiness, hypochondriacal preoccupations, worrying, suicidal thoughts, delusions of guilt, nihilism and persecution
Cognition	Impaired learning, pseudodementia in elderly patients
Physical	Early waking, poor appetite and weight loss, constipation, loss of libido, erectile dysfunction, fatigue, bodily aches and pains
Behaviour	Retardation or agitation, poverty of movement and expression
Hallucinations	Auditory - often hostile, critical

symptoms to appear. Patients describe the world as looking grey, themselves as lacking a zest for living and devoid of pleasure and interest in life (anhedonia). Anxiety and panic attacks are common; secondary obsessional and phobic symptoms may emerge. Symptoms should last for at least 2 weeks and should cause significant incapacity (e.g. trouble working or relating to others) to be considered an illness.

In the more severe forms, diurnal variation in mood can occur, feeling worse in the morning after waking in the early hours with apprehension. Suicidal ideas are more frequent, intrusive and prolonged. Delusions of guilt, persecution and bodily disease are not uncommon, along with second person auditory hallucinations insulting the patient or suggesting suicide. In severe depressive illness, particular in the elderly, concentration and memory can be so badly affected that the patient appears to have dementia (pseudodementia). Delusions of poverty and non-existence (nihilism) occur particularly in this age group. Suicide is a real risk, with the lifetime risk being approximately 5% in primary care patients, but 15% in those with depressive illness severe enough to warrant admission to hospital.

Epidemiology

About a third of the population will feel unhappy at any one time, but this is not the same as depressive illness. The point prevalence of depressive illness is 5% in the community, with a further 3% having dysthymia (see below). It is more common in women, but there is no increase with age, and no difference by ethnic group or socio-economic class (apart from an inverse relationship only with dysthymia). Married and never married people have similar prevalence rates, with separated and divorced people having two to three times the prevalence. Some studies have suggested that depressive illness is becoming more common.

Depressive illnesses are more common in the presence of:

- physical diseases, particularly if chronic, stigmatizing or painful
- excessive and chronic alcohol use (probably the most depressing drug humans use)
- social stresses, particularly loss events, such as separation, redundancy and bereavement
- interpersonal difficulties with those close to the patient, especially when socially humiliated
- lack of social support, with no confiding relationship.

Depressed patients with another physical disorder view themselves as more sick and visit their doctors almost four times as often as the non-depressed physically ill, stay in hospital longer, comply less with medical advice and medication, and undergo more medical and surgical procedures. Depressive illness may be associated with increased mortality (excluding suicide) in patients with physical illness, such as myocardial infarct.

Dysthymia

Dysthymia is a more mild depressive illness that lasts intermittently for 2 years or more and is characterized by tiredness and low mood, lack of pleasure, low self-esteem, and a feeling of discouragement. The mood relapses and remits, with several weeks of feeling well, soon followed by longer periods of being unwell. It can be punctuated by depressive episodes of more severity; so-called 'double depression'.

Seasonal affective disorder

Seasonal affective disorder is characterized by recurrent episodes of depressive illness occurring during the winter months in the northern hemisphere. Symptoms are similar to those found with *atypical depressive illness,* in that patients complain of hypersomnia, increased appetite (with carbohydrate craving) and weight gain, with profound fatigue. Such patients have a higher prevalence of bipolar affective disorder, and some doctors are uncertain whether the condition is different from normal depressive illness, with the accentuation of mood that naturally occurs by season. However, there is evidence that seasonal depressive illness can be successfully treated with bright light therapy given in the early morning, which causes a phase advance in the circadian rhythm of melatonin. In contrast, the same treatment given in the early evening, with consequent phase delay of melatonin secretion, is less antidepressant. Selective serotonin reuptake inhibitors (SSRIs) are alternative treatments.

Differential diagnosis

The differential diagnoses of depressive illness are shown in Table 22.8. Other psychiatric disorders are the most common misdiagnoses. Ninety per cent of patients presenting with a depressive illness, while misusing alcohol, will no longer be depressed 2 weeks after their last drink.

Pathological (abnormal) and normal grief are described on page 1300. Pathological grief is closely associated with depressive illness.

Table 22.8 **Common differential diagnoses of depressive illness**

Other psychiatric disorders
Alcohol misuse
Amfetamine (and derivatives) misuse and withdrawal
Borderline personality disorder
Dementia
Delirium
Schizophrenia
Normal and pathological grief

Organic (secondary) affective illness
Physical causes which are both necessary and sufficient as a cause
Cushing's syndrome Thyroid disease (although sometimes depression persists after treatment) Hyperparathyroidism Corticosteroid treatment Brain tumour (rarely without other neurological signs)

Investigations

A corroborative history can be valuable in helping to exclude differential diagnoses such as alcohol misuse and elucidating maintaining factors such as the relationship with a partner. Physical investigations should be guided by the history and examination. They will often include measurement of free T_4 and TSH (particularly in women), calcium, sodium, potassium, mean corpuscular volume, γ-glutamyl transpeptidase, haemoglobin, white cell count, ESR or plasma viscosity. Less commonly a chest X-ray, antinuclear antibody, morning and evening cortisols, electroencephalogram or a brain scan are indicated.

The aetiology of unipolar depressive disorders

The aetiology of unipolar depressive disorders is multifactorial and a mixture of genetic and environmental factors.

Genetic

Unipolar depression is probably polygenic, but no linkage has been firmly identified. The risk of unipolar depression in a first-degree relative of a patient is approximately three times the risk of the non-affected. The concordance of unipolar depression in monozygotic twins is between 30 and 60%, the concordance increasing with more recurrent illnesses. The issue is complicated by the genetic influence on sleep habits, 'neurotic' personality, and even life events, which are all involved in the genesis of depressive illness.

Biochemical

The monoamine theory of depressive illness is supported by the efficacy of monoamine reuptake inhibitors and the depressive effect of dietary tryptophan depletion. Neuroendocrine tests also suggest that the serotonin neurotransmitter system is downregulated. 5-HT_{1a} and 5-HT_2 receptor subtypes are thought most likely to be involved. Receptor-labelled functional brain scans suggest that dopamine underactivity is related to psychomotor retardation.

Hormonal

Cushing's syndrome is the most potent cause of 'organic' depressive illness, with 50-80% of patients with Cushing's suffering from a depressive illness. Corticosteroid treatment causes significant mood disturbance. Nearly half of patients with 'functional' depressive illness have raised cortisol levels, and this is associated with adrenal gland enlargement. Hypercortisolaemia can cause hippocampal damage, which has been found in chronic severe depressive illness. All these data suggest that cortisol may play a role in causing depressive illness.

In contrast *atypical depressive illness,* with prominent hypersomnia and weight gain, is associated with a downregulated hypothalamic-pituitary-adrenal axis, supporting the heterogeneity of depressive disorders.

Brain imaging

The use of magnetic resonance imaging (MRI) and positron emission tomography (PET) has revealed a number of abnormalities in the brains of patients with major depression. Increased brain ventricle volume, localized frontal lobe atrophy and reduced blood flow in specific brain areas have been reported, while more recent studies suggest that the hippocampus undergoes selective volume reduction in stress-related neuropsychiatric disorders such as recurrent depression. This may be related to hypercortisolaemia.

Sleep

A reduced time between onset of sleep and REM sleep (shortened REM latency) and reduced slow wave sleep both occur in depressive illness. These abnormalities are persistent in some patients when they are not depressed. Families with several sufferers of depressive illness can share these traits, suggesting that sleep patterns may be inherited and predispose to depression.

Psychological

Poor parenting and physical or sexual abuse in childhood all predispose adults to depressive illness, but the effect is non-specific. Both 'neurotic' (emotional) and perfectionist personality traits are risks for depressive illness, and these may be determined as much by genetic factors as early environment.

Social

Thirty per cent of women will develop a depressive illness after a severe life event or difficulty, such as a divorce, and this is compounded by low self-esteem and a lack of a confiding relationship. Unemployment is a significant risk factor in men.

An integrated model of aetiology

Stress is more likely to trigger depressive illness in a person predisposed by lack of social support and/or certain personality traits. Stress in turn triggers various brain changes in both stress hormones (such as the release

of corticotropin-releasing hormone) and neurotransmitters (e.g. serotonin) that are both known to be altered in depressive illness. We can thus start to glimpse the model of an integrated biopsychosocial model of depressive illness. This model challenges dualistic ideas that depressive illnesses are either psychological or physical; depressive illnesses involve both the mind and the body, which are themselves indivisible.

Puerperal affective disorders

Affective illnesses and distress are common in women soon after they have given birth. Such disturbances are usually divided into maternity blues, postpartum (puerperal) psychosis and postnatal depressive illness. *'Maternity blues'* describe the brief episodes of emotional lability, irritability and tearfulness that occur in about 50% of women 2-3 days postpartum and resolve spontaneously in a few days.

Postpartum psychosis occurs once in every 500-1000 births. Over 80% of cases are affective in type and the onset is usually within the first 2 weeks following delivery. In addition to the classical features of an affective psychosis, disorientation and confusion are often noted. Severely depressed patients may have delusional ideas that the child is deformed, evil or otherwise affected in some way, and such false ideas may lead to either attempts to kill the child or suicide. The response to speedy treatment is generally good. The recurrence rate for a psychosis in a subsequent puerperium is 20-30%.

Non-psychotic *postnatal depressive disorders* occur during the first postpartum year in 10% of mothers, especially in the first 3 months. Risk factors are first pregnancy, poor relationship with the partner, ambivalence about the pregnancy, and emotional personality traits. The Edinburgh Postnatal Depression Scale (EPDS) is a 10-item questionnaire and can be used as an effective screening tool. Depressive illness after childbirth is clinically similar to other depressive illnesses, but lack of emotional bonding with the baby is common.

Treatment of depressive illness

The patient needs to know the diagnosis to provide understanding and rationalization of the overwhelming distress inherent in depressive illness. Knowing that self-loathing, guilt and suicidal thoughts are caused by the illness can be 'antidepressant' on its own. The further treatment of depressive disorders involves physical, psychological and social interventions (Box 22.9). Patients who are actively suicidal, severely depressed or with psychotic symptoms should be admitted (necessary for perhaps 1 in 1000 patients with clinical depression in primary care). This provides the patient a break from self-care, and allows support, listening, observation, prevention of suicide, and close monitoring of treatments. Avoid the pitfall of not treating a depressive illness just because it seems an 'understandable' reaction to serious illness or difficult circumstances. This is particularly likely to happen if the patient is elderly, severely or even terminally ill.

Box 22.9 **Management of depressive illness**

Physical
Stop depressing drugs (alcohol, steroids)
Regular exercise (good for mild to moderate depression)
Antidepressants (choice determined by side-effects, co-morbid illnesses and interactions)
Adjunctive drugs (e.g. lithium; if no response to two different antidepressants)
Electroconvulsive therapy (ECT) (if life-threatening or non-responsive)

Psychological
Education and regular follow-up by same professional
Cognitive behaviour therapy (CBT) (most effective psychotherapy in clinical depression) Other indicated psychotherapies (couple, family, interpersonal therapies)

Social
Financial: eligible benefits, debt counselling
Employment: acquire or change the job or career
Housing: adequate, secure tenancy, safe, social neighbours Young children: child-care support

Treatments combined
The most effective treatment is a mixture of CBT and an antidepressant

Drugs used in the treatment of clinical depression

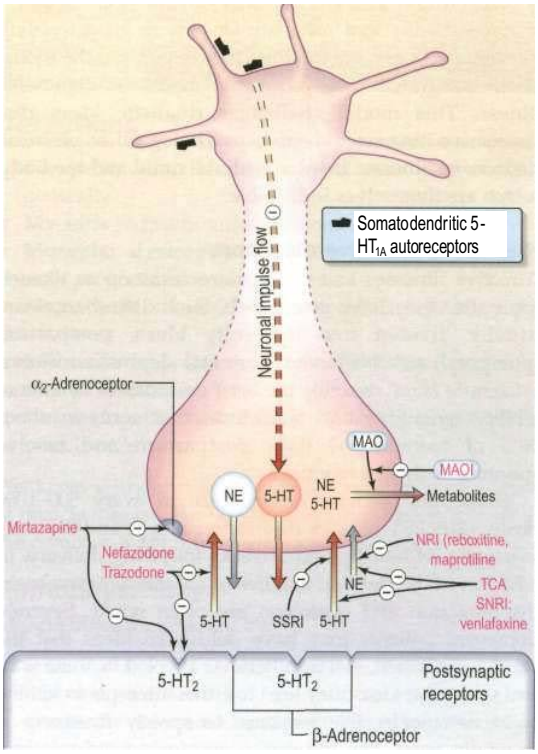
Recreational drugs such as alcohol should be stopped. Prescribed medicines suspected of exacerbating depression, such as corticosteroids, should be gradually stopped or reduced to a safe minimum.

The first course of antidepressant drugs is effective in relieving clinical depression in 60-70% of patients, if given in adequate doses for a sufficient time to the correctly diagnosed patient. Such treatment is more successful when accompanied by sufficient patient education and regular follow-up, particularly in the first 6 weeks of treatment. Dysthymia responds less well to antidepressants than does a depressive episode.

The commonest two pharmacological types of antidepressants are tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs). All antidepressants have similar efficacy and speed of onset. Choice depends on their side-effects, which can be used to positive effect (sedating drugs given at night to enhance sleep), and their safety. Patients should be warned about side-effects and that it will take 2 or more weeks before a positive benefit is apparent. Drugs should normally be started at a low dose and increased, depending on side-effects and efficacy. A course of antidepressants should be given until 4 months after recovery to prevent relapse. The two greatest problems with these drugs are persuading the patient to take them and compliance, since 80% of the UK public wrongly believe that they are addictive.

Psychotic depression needs either electroconvulsive therapy or a combination of an antidepressant and an antipsychotic drug.

\



Selective serotonin reuptake inhibitors (SSRIs)

SSRIs selectively inhibit the reuptake of the monoamine serotonin (5-HT) within the synapse, and are thus termed 'selective serotonin reuptake inhibitors' or SSRIs. Citalopram, and its laevo isomer, escitalopram, fluvoxamine, fluoxetine, paroxetine and sertraline have the advantage of causing less serious or disabling side-effects than tricyclics. For instance, SSRIs do not cause significant weight gain. Because of their long half-lives they can also be given just once a day, normally in the morning after breakfast. For these reasons patients comply more with treatment and therefore SSRIs are now first-line treatments for depressive disorders. Normal doses are between 20 and 60 mg, with sertraline and fluvoxamine needing higher doses. The most common side-effects resemble a 'hangover' and include nausea, vomiting, headache, diarrhoea and dry mouth. Insomnia and paradoxical agitation can occur when first starting the drugs. One in five patients also have sexual side-effects, such as impotence and loss of libido.

A toxic hyperserotonergic state *('serotonin'* syndrome) can be caused by the ingestion of two or more drugs that increase serotonin levels, e.g. an SSRI combined with a monoamine oxidase inhibitor (MAOI) or dopaminergic drugs (e.g. selegiline) or a tricyclic antidepressant. Symptoms include agitation, confusion, tremor, diarrhoea, tachycardia and hypertension; hyperthermia is characteristic. Treatment is supportive.

SSRIs have also been associated with a specific withdrawal syndrome *(discontinuity syndrome)*. This is characterized by shivering, anxiety, dizziness, headache and nausea. Patients should be warned not to leave out a dose and to gradually reduce SSRIs when stopping them.

Tricyclic antidepressants (TCAs)

Dosulepin (dothiepin), imipramine and amitriptyline are the three most commonly used in the UK, but many related compounds have been introduced, some having fewer autonomic and cardiotoxic effects (e.g. trazodone, lofepramine). These drugs potentiate the action of the monoamines, noradrenaline (norepinephrine) and serotonin, by inhibiting their reuptake into nerve terminals (Fig. 22.3(c)). Other tricyclics in common use include nortriptyline, doxepin and clomipramine. Depending on the particular drug, normal doses are between 75 and 150 mg. Having been available for more than 40 years, there is more evidence of the effectiveness of TCAs in depressive illness than for any other group of antidepressants. They are the drugs most commonly used in severe depressive illness.

TCAs have a number of side-effects (Table 22.9). In long-term treatment or prophylaxis, weight gain is most troublesome. Because of their toxicity in overdose, it is wisest NOT to prescribe them to potentially suicidal outpatients, without careful monitoring or giving the drugs to a reliable family member to look after.

SNaRIs, NaSSAs and NaRIs: antidepressants

The latest generation of antidepressants block a number of different neurotransmitter receptors both at the synapse

Fig. 22.3 **Sites of action of antidepressants with examples.** In a normal neurone, the stimulation of the somatodendritic 5-HT_{1A} autoreceptors inhibits the neuronal impulse flow down the axon, reducing 5-HT release. In depression, there is a reduction in amine neurotransmissions which results in upregulation of postsynaptic *and* somatodendritic receptors. Using 5-HT, as an example, the depletion of 5-HT results in upregulation of postsynaptic 5-HT_2 receptors and presynaptic (somatodendritic) 5-HT_{1A} receptors. The many antidepressants now available have different actions on serotonin and noradrenaline (norepinephrine) neuro-transmission. Classical antidepressants (TCA) have less effects on sedation and antimuscarinic and antihistaminergic activities. SSRI, selective serotonin reuptake inhibitors; SNRI, serotonin and noradrenaline (norepinephrine) reuptake inhibitors; NRI, noradrenaline (norepinephrine) reuptake inhibitor (selective); NE, noradrenaline (norepinephrine); MAO, monoamine oxidase; MAOI, monoamine oxidase inhibitor. From Waller DG, Renwick A, Hillier K (eds) (2001) *Medical Pharmacology and Therapeutics,* Edinburgh: Saunders, with permission from Elsevier.

***Table 22.9* Side-effects of tricyclic antidepressants**

Lowered seizure threshold

Other effects
Weight gain
Sedation Mania
(rarely)

and elsewhere. Their different receptor profiles cause different side-effects.

Venlafaxine is a potent *blocker* of both *serotonin* and *noradrenaline (norepinephrine) reuptake (SNaRI).* It has negligible affinity for other neurotransmitter receptor sites and so produces less sedation and fewer anti-muscarinic effects. It can be given in slow-release form with the advantage of once-daily dosage. Nausea is the commonest side-effect and high doses can occasionally cause hypertension. It does not cause weight gain.

Mirtazapine is a 5-HT_2 and 5-HT_3 receptor antagonist and a potent a_2-adrenergic blocker. The consequent effect is to *increase* both *noradrenaline {norepinephrine)* and *selective serotonin transmission:* an *NaSSA.* It can be given at night to aid sleep and rarely causes sexual side-effects. Mirtazapine can be sedating in low dose and can cause weight gain. An uncommon adverse effect is agranulocytosis.

Reboxetine is a *selective noradrenaline (norepinephrine) reuptake inhibitor (NaRI).* It is not sedating and may help reduced motivation and energy. Weight gain is not reported. Dry mouth, insomnia, constipation, urinary hesitancy and tachycardia are reported side-effects.

Monoamine oxidase inhibitors (MAOIs)

These act by irreversibly inhibiting the intracellular enzymes monoamine oxidase A and B, leading to an increase of norepinephrine (noradrenaline), dopamine and 5-hydroxytryptamine in the brain (see Fig. 22.3(b). Because of their side-effects and restrictions while taking them, they are rarely used by non-psychiatrists. Psychiatrists use them as a second-line treatment of depressive illnesses, particularly with atypical presentations (p. 1289). The most widely used is phenelzine, which is given in doses of 30-60 mg daily. Side-effects include increased appetite, weight gain, erectile dysfunction and insomnia. MAOIs also produce a severe and dangerous hypertensive reaction with foods containing tyramine or dopamine and therefore a restricted diet is prescribed. Tyramine is present in cheese, pickled herrings, yeast extracts, certain red wines, and any food, such as game, that has undergone partial decomposition. Dopamine is present in broad beans. MAOIs interact with drugs such as pethidine and can also occasionally cause liver damage. MAOIs should not normally be given within 2 weeks of a serotonin reuptake inhibitor, depending on half-lives.

Reversible inhibitors of monoamine A (RIMAs)

An example is moclobemide; usual dose 300 mg daily. These drugs appear to have fewer side-effects (insomnia and headache, but some sexual problems) and constitute a low risk in overdose. Patients prescribed such antidepressants should be told that they can eat a normal diet, but should be careful to avoid excessive amounts of food rich in tyramine (see above).

Antidepressant use in general medicine

In patients with cardiac disease, SSRIs, lofepramine and trazodone are preferred over more quinidine-like compounds. MAOIs and mirtazapine do not affect epileptic thresholds. SSRIs are metabolized by the cytochrome P450 system, unlike venlafaxine, mirtazapine and reboxetine; the latter therefore have fewer drug interactions. Care should be taken not to prescribe antidepressants while a patient is taking the herbal antidepressant St John's wort, which interacts with serotonergic drugs in particular. Doses of antidepressants should initially be halved in the elderly and in patients with renal or hepatic failure.

Antidepressants should be avoided if possible in pregnancy and breast-feeding. If other treatments are ineffective, the risks of drug therapy should be balanced against no treatment, which can affect fetal progress and the future mother-child bonding. Tricyclic antidepressants are generally believed to be safe in pregnancy, with no statistical increase in congenital malformations in fetuses exposed to them. However, occasionally their anti-muscarinic side-effects produce jitteriness, sucking problems and hyperexcitability in the new-born. Post-partum plasma levels of babies breast-fed by treated mothers are negligible. SSRIs do not seem to be teratogenic but manufacturers advise against their use in pregnancy until more data are available. MAOIs should be avoided during pregnancy because of the possibility of a hypertensive reaction in the mother.

Electroconvulsive therapy (ECT)

Although the use of ECT is declining in the UK, it is still the treatment of choice in severe life-threatening depressive illness, particularly when psychotic symptoms are present. It is sometimes essential treatment when the patient is dangerously suicidal or refusing to eat and drink. The treatment involves the passage of an electric current across two electrodes applied to the anterior temporal areas of the scalp, in order to induce an epileptic fit. The fit is the essential part of the treatment. Before the treatment is given, the patient is given a general anaesthetic and receives a muscle relaxant to prevent injury during the fit. Treatments are normally given twice a week for 3-6 weeks.

ECT is a controversial treatment, yet it is remarkably safe and free of serious side-effects. Post-ictal confusion and headache are not uncommon, but transient. Short-term retrograde amnesia and a temporary defect in new learning can occur during the weeks of treatment, but these are short-lived effects.

Uncommonly used treatments

Transcranial magnetic stimulation (TMS) is an experimental treatment, with promising early results. *Psychosurgery* is very occasionally considered in patients with severe intractable depressive illness, when all other treatments have failed (see p. 1302). A third improve remarkably, while a further third improve somewhat. *Vagus nerve stimulation* may represent a major advance in the management of chronic and treatment-refractory depressive disorders but definitive clinical trials are awaited.

Psychological treatments

Cognitive behaviour therapy (CBT)

Aaron Beck developed CBT in the 1960s to reverse the negative cognitive triad with which patients regarded

themselves, their situation and their futures. It involves the identification of the automatic dysfunctional thinking that maintains the negative perceptions that feed depression. They commonly include catastrophizing (e.g. making a 'mountain out of a mole-hill'), overgeneralizing (e.g. 'I failed an exam; therefore I am a failure as a person.'), categorical ('black or white') thinking (e.g. 'My work is either perfect or abysmal.'). CBT then involves identifying the links between these thoughts, consequent behaviour, and feeling low, and then testing their logic. This is done by considering the evidence either in the therapy sessions (e.g. Q: 'Did you pass the other exams you took?' A: 'Yes; I guess I did.') or by behavioural 'experiments' (e.g. showing the 'abysmal' work to a colleague and asking their opinion).

There is good evidence that CBT is as effective as antidepressant drugs for mild and moderate depressive illness. CBT is also effective in preventing a relapse of clinical depression. CBT is an effective treatment not only for depressive illness, but also for anxiety disorders and functional disorders (see pp. 1297 and 1281). It has even been shown to help reduce the severity of delusions in schizophrenia.

Interpersonal psychotherapy

This psychotherapy is probably as effective as antidepressants in mild and moderate clinical depression. The therapist focuses on a patient's interpersonal relationships involved in or affected by their illness (especially relationship changes or deficiencies), using problem-solving techniques to help the patient to find solutions.

Other psychotherapies

Couple therapy is particularly effective when a patient with clinical depression is in a relationship with problems (practical, emotional or sexual). Both the patient and partner attend therapy. *Family therapy* is effective not only in a family with problems, but also as a way of helping the family to help the patient get better. It may involve understanding one family member's 'depression' as a systemic 'solution' for a wider problem within the family.

Social treatments

Many patients with clinical depression have associated social problems (see Box 22.9). Assistance with social problems can make a significant contribution to clinical recovery. Other social interventions include the provision of group support, social clubs, occupational therapy and referral to a social worker. Educational programmes, self-help groups, and informed and supportive family members can help improve outcome.

Prognosis

The majority of patients have recovered by 6 months in primary care and 12 months in secondary care. About a quarter of patients attending hospital with depressive illnesses will have a recurrence within a year, and three-quarters will have a relapse within 10 years. Patients with recurrent depressive illnesses should be offered prevention. This may involve CBT that concentrates on relapse prevention, other forms of psychotherapy, or antidepressant medication. Full-dose antidepressants are the most effective prophylaxis in recurrent depressive disorders.

MANIA AND HYPOMANIA

The clinical features of mania reflect a marked elevation of mood, characterized by euphoria, overactivity and disinhibition (Table 22.10). Hypomania is the mild form of mania. Hypomania lasts a shorter time and is less severe, with no psychotic features and less disability. Hypomania can be distinguished from normal happiness by its persistence, non-reactivity (not provoked by good news and not affected by bad news) and social disability. Mania almost always occurs as part of a bipolar affective disorder. The social disability of mania can be severe, with disinhibited behaviour leading to significant debts (from overspending and over-generosity), lost relationships (from promiscuity), social ostracism and lost employment (from reckless or disinhibited behaviour).

Some patients have a *rapid cycling* illness, with frequent swings from one mood state to another. A *mixed affective state* occurs when features of mania and depressive illness are seen in the same episode. *Cyclothymia* is a personality trait with spontaneous swings in mood not sufficiently severe or persistent to warrant another diagnosis.

Table 22.10 **Clinical features of mania**

Characteristic	Clinical appearance
Mood	Elevated or irritable
Talk	Fast, pressurized, flight of ideas
Energy	Excessive
Ideas	Grandiose, self-confident, delusions of wealth, power, influence or of religious significance, sometimes persecutory
Cognition	Disturbance of registration of memories
Physical	Insomnia, mild to moderate weight loss, increased libido
Behaviour	Disinhibition, increased sexual activity, excessive drinking or spending
Hallucinations	Fleeting auditory or, more rarely, visual ^_

Differential diagnosis

Acute intoxication with recreational drugs, such as amfetamines, amfetamine derivatives (MDMA: Ecstasy), and cocaine can mimic mania. Long-term use of cannabis can also induce an illness with manic features. In one study a quarter of patients with Cushing's syndrome had a secondary manic illness during their illness. Similarly corticosteroids can induce mania less commonly than depressive illness. Dopamine agonists (e.g. bromocriptine) are also known to sometimes induce secondary mania. The excited phase of catatonic schizophrenia can sometimes be mistaken for mania.

Epidemiology

The lifetime prevalence of bipolar affective disorder is 1% across the world. Unlike unipolar depressive illness, it is equally common in men and women, supporting its different aetiology. There is no variation by socio-economic class or race. The mean age of onset is 21; earlier than unipolar depression. The higher prevalence found in divorced people is probably a consequence of the condition.

Aetiology

Genetic

There is strong evidence for a genetic aetiology in this disorder. There is a 60-80% concordance rate in monozygotic twins, compared to 15% in dizygotic twins, suggesting a high rate of heritability. Adoption studies show similar rates, so this high rate is probably genetic and not due to the family environment. Linkage studies have so far proved disappointing, with several suggestive chromosome linkages being found, suggesting there is no single gene with a large effect. Instead it is likely that the condition will prove to be caused by several genes acting together.

Biochemical

It is difficult to carry out research on patients with acute mania, so studies are few. Brain monoamines seem to be increased in mania. Dexamethasone tends not to suppress cortisol levels in patients with mania, suggesting a similar pattern of non-suppression to that seen in severe depressive illness.

Psychological

The effect of life events is much weaker in bipolar compared to unipolar illnesses, with most effect apparent at first onset. Similarly, personality does not seem to be a major influence, in contrast to unipolar depression, although there is some evidence of a link with the creativity and divergent thinking that is an advantage in the right occupation.

Treatment of mania

Acute mania

Acute mania is treated with lithium and/ or antipsychotic (neuroleptic) drugs. Lithium is the treatment of choice for acute mania in the absence of severe hyperactivity. The advantage of lithium is the lack of motor side-effects seen with neuroleptics (bipolar patients are particularly prone to tardive dyskinesia). The main disadvantage is slow speed of response (normally 2 weeks). The dose of lithium depends on whether the citrate or carbonate salt is used.

Haloperidol and the more sedating chlorpromazine are commonly used neuroleptics, given orally or intramuscularly. Doses are similar to those used in schizophrenia. The behavioural excitement and overactivity are usually reduced within days, but elation, grandiosity and associated delusions often take longer to respond. Severe mania is best treated with a combination of lithium and a neuroleptic, allowing the neuroleptic to be withdrawn after the first 2 or 3 weeks. First attacks of mania usually require treatment for up to 3 months. The anticonvulsants carbamazepine and sodium valproate are also helpful in hypomania or in rapidly cycling illnesses (see below). Recent work suggests it can be sometimes helpful to add to the regimen a benzodiazepine, such as clonazepam or lorazepam.

Prevention

Since bipolar illnesses tend to be relapsing and remitting, prevention of relapse is the major therapeutic challenge in the management of bipolar affective disorder. A patient who has experienced more than two episodes of affective disorder within a 5-year period is likely to benefit from preventative treatments.

Lithium

Lithium (carbonate or citrate) is the main agent used for prophylaxis in patients with repeated episodes of bipolar illness. It is rapidly absorbed into the gastrointestinal tract and more than 95% is excreted by the kidneys; small amounts are found in the saliva, sweat and breast milk. Renal clearance of lithium correlates with renal creatinine clearance. Lithium is a mood-stabilizing drug that prevents mania more than depression. It reduces the frequency and severity of relapses by half and significantly reduces the likelihood of suicide. Its mode of action is unknown, but lithium is known to act on the serotoninergic system. Poor responses to lithium are associated with a negative family history, an unstable premorbid personality, and a rapid cycling illness.

Patients should be screened for thyroid (free T_4, TSH and thyroid autoantibodies) and renal disease (serum urea and creatinine, 24-hour urinary volume) before starting on lithium. Lithium interferes with thyroid function and can produce frank hypothyroidism. The presence of thyroid autoantibodies increases the risk, so it is worthwhile measuring these before treatment. Long-term treatment with lithium causes two renal problems; nephrogenic diabetes insipidus (DI) and reduced creatinine clearance (see p. 609). The therapeutic range for prophylaxis is 0.5-1.0 mmol/L. Lithium levels should be checked every 3 months, along with regular thyroid (free T_4 and TSH) and renal function tests. The best screen for DI is to ask the patient about polyuria and polydipsia. Tests should include serum urea and creatinine, and 24-hour urinary volume if DI is suspected. A creatinine clearance should be carried out if glomerular disease is suspected. Patients

should carry a lithium card with them at all times.
Other side-effects of lithium include:

- nausea and diarrhoea
- a fine tremor (15%)
- polyuria and polydipsia (see above)
- weight gain, mainly through increased appetite.

Lithium toxidty begins to occur when the serum concentration exceeds 1.5 mmol/L. Symptoms include drowsiness, nausea, vomiting, blurred vision, a coarse tremor, ataxia and dysarthria. Toxicity is more likely when the patient is dehydrated or with a drug interaction increasing concentrations. Such symptoms progress to delirium and convulsions, and coma and death can occur. As a rule, lithium is not advised during pregnancy, particularly in the first trimester, because of an increased risk of fetal malformation (Ebstein's anomaly). Between 25-30% of women with a history of bipolar disorder relapse within 2 weeks of delivery. Restarting lithium within 24 hours of delivery (if the mother is prepared to forgo breast-feeding) markedly reduces the risk of relapse.

Anticonvulsant, mood-stabilizing drugs

Carbamazepine and *sodium valpwate* are used both in prophylaxis and treatment of manic states. Some patients who do not respond to lithium may respond to these anticonvulsants or a combination of both. Patients with rapid cycling illnesses show a better response to anticonvulsants than to lithium. For antimanic treatment, dosage in the initial stage of treatment will be 200 mg twice daily of carbamazepine, increasing to a normal dose of 800-1000 mg. Other drugs which appear to exercise a prophylactic mood-stabilizing effect include sodium valproate, olanzapine and risperidone. Both carbamazepine and valproate can be teratogenic (neural tube defects) and should be avoided in pregnancy. Other side-effects of these drugs are given on page 1224.

Prognosis

The average duration of a manic episode is 2 months, with 95% making a full recovery in time. Recurrence is the rule in bipolar disorders, with up to 90% relapsing within 10 years.

FURTHER READING

Daly I (1997) Mania. *Lancet* 349:1157-1160.

SUICIDE AND ATTEMPTED SUICIDE (DELIBERATE SELF-HARM) (see also p. 1002)

Suicide accounts for 2% of male and 1% of female deaths in England and Wales each year, equivalent to a rate of 8 per 100 000. The rate increases with age, peaking for women in their sixties and for men in their seventies. Suicide is the second most common cause of mortality in 15- to 34-year-olds. Approximately 15% of people who have suffered a severe depressive disorder (requiring admission) will eventually commit suicide, with 6% doing so in the 10 years after their first admission. Suicide rates in schizophrenia sufferers are likewise high, being 20-50 times the rate in the general population; 20^0% of people with schizophrenia make suicide attempts, and 9-13% are successful. A Finnish study suggests that the suicide rate is higher in women who have sustained a miscarriage or undergone an induced abortion, whereas it is significantly reduced in women who are pregnant. The highest rates of suicide have been reported in rural southern India (148 per 100 000 in young women and 58 per 100 000 in young men) and in Hungary (40 per 100 000), while the lowest are those of Spain (3.9 per 100 000) and Greece (2.8 per 100 000), but such variations may reflect differences in reporting, which may be related to religion, as much as genuine differences. Factors that increase the risk of suicide are indicated in Table 22.11.

A distinction must be drawn between those who attempt suicide - deliberate self-harm (DSH) - and those who succeed (suicides): .-■ -.> --

- The majority of cases of DSH occur in people under 35 years of age.
- The majority of suicides occur in people aged over 60.
- Suicides are more common in men, while DSH is more common in women.
- Suicides are more common in older men, although rates are falling. Rates in young men are rising fast throughout the UK and Western Europe.
- Suicides in women are slowly falling in the UK.
- Approximately 90% of cases of DSH involve self-poisoning.
- A formal psychiatric disorder is common retrospectively in suicide, but unusual in DSH.

There is, however, an overlap between DSH and suicide. Between 1-2% of people who attempt suicide will kill themselves in the year following DSH. The risk of suicide stays elevated in those with DSH, with 0.5% per annum committing suicide in the following 20 years. In the UK, over 100 000 suicide attempts are made each year, and the overwhelming majority of these are seen and treated within accident and emergency departments.

Table 22.11 **Factors that increase the risk of suicide**

Male sex
Older age
Living alone
Immigrant status
Recent bereavement, separation or divorce
Recent loss of a job or retirement
Living in a socially disorganized area
Family history of affective disorder, suicide or alcohol abuse
Previous history of affective disorder, alcohol or drug abuse
Previous suicide attempt
Addiction to alcohol or drugs
Severe depression or early dementia
Incapacitating painful physical illness

. The guidelines (Box 22.10) for the assessment of such patients will help ensure that the risk factors relating to suicide are covered. Indications for referral to a psychiatrist before discharge from hospital are also given.

In general, it is worth trying to interview a family member or close friend and check these points with them. Requests for immediate represcription on discharge should be denied, except in cases of essential medication (e.g. for epilepsy). In such cases, however, only 3 days' supply of medication should be given, and the patient should be requested to report to their general practitioner or to their psychiatric outpatient clinic for further supplies. Occasionally involuntary admission under the Mental Health Act (1983) will be required (p. 1314).

Box 22.10 **Guidelines for the assessment of patients who harm themselves**

Questions to ask: be concerned if positive answer

ft Was there a clear precipitant/cause for the attempt?
■ Was the act premeditated or impulsive?
m Did the patient leave a suicide note?
* Had the patient taken pains not to be discovered?
6 Did the patient make the attempt in strange surroundings (i.e. away from home)? ***i***
Would the patient do it again?

.*sOther relevant factors

■ Has the precipitant or crisis resolved?
K Is there continuing suicidal intent?
B Does the patient have any psychiatric symptoms?
m What is the patient's social support system?
* Has the patient inflicted self-harm before?
B Has anyone in the family ever taken their life?
B Does the patient have a physical illness?

Indications for referral to a psychiatrist

Absolute indications include:
Clinical depression
Psychotic illness of any kind - Clearly preplanned suicidal attempts which were not
intended to be discovered » Persistent suicidal intent (the more detailed the plans,
the more serious the risk)
[1] **i** A violent method used.

Other common indications include:
Alcohol and drug abuse » Patients over 45 years, especially if male, and young
adolescents
■ Those with a family history of suicide in first-degree relatives
K Those with serious (especially incurable) physical disease
m. Those living alone or otherwise unsupported ***t*** Those in whom there is a major unresolved crisis *ft* Persistent suicide attempts *B* Any patients who give you cause for concern.

THE ANXIETY DISORDERS

These are conditions in which anxiety dominates the clinical symptoms. They are classified according to whether the anxiety is persistent (general anxiety) or episodic, with the episodic conditions classified according to whether the episodes are regularly triggered by the same cue (phobia) or not (panic disorder). The differential diagnoses of anxiety disorders are given in Table 22.12.

General anxiety disorder

This occurs in 4% of the population and is more common in women. Symptoms are persistent and often chronic. General anxiety disorder (GAD) and its related panic disorder are differential diagnoses for medically unexplained symptoms, owing to the many physical symptoms that are caused by these conditions.

Clinical features

The physical and psychological symptoms are outlined in Table 22.13. The patient looks worried, has a tense posture, restless behaviour, a pale and sweaty skin. The

Table 22.12 **Anxiety disorders - the differential diagnosis**

Psychiatric disorder	Physical disorder
Depressive illness Obsessive compulsive disorder Presenile dementia Alcohol dependence Drug dependence Benzodiazepine withdrawal	Hyperthyroidism Hypoglycaemia Phaeochromocytoma

Respiratory Feeling of chest constriction Difficulty in inhaling Overbreathing	
Cardiovascular Palpitations Awareness of missed beats Feeling of pain over heart	
Genitourinary Increased *frequency* Failure of erection Lack of libido	

Box 22.11 **The hyperventilation syndrome**

Features
Panic attacks - fear, terror and impending doom - accompanied by some or all of the following:

dyspnoea (trouble getting a good breath in)
palpitations
chest pain or discomfort
* choking sensation
dizziness
paraesthesiae
* sweating
carpopedal spasms.

Cause
Overbreathing leading to a decrease in P_aco_2 and an increase in arterial pH.

Diagnosis
•*i»* A provocation test - voluntary overbreathing for 2-3 minutes - provokes similar symptoms; rebreathing from a large paper bag relieves them. Blood gases

Management
f Explanation and reassurance is given.
* The patient is trained in relaxation techniques and slow breathing.
[1] The patient is asked to breathe into a closed paper bag.

patient takes time to go to sleep, and when asleep wakes intermittently with worry dreams. Associated conditions include the hyperventilation syndrome, which is even more common in panic disorder (Box 22.11). The patient will sigh deeply, particularly when talking about the stresses in their life.

Mixed anxiety and depressive disorder

This disorder is probably the commonest mood disorder in primary care, in which there are equal elements of both anxiety and depression, showing how closely associated these two abnormal mood states are.

Panic disorder

Panic disorder is diagnosed when the patient has repeated sudden attacks of overwhelming anxiety, accompanied by severe physical symptoms, usually related to both hyperventilation (Box 22.11) and sympathetic nervous system activity. The prevalence is 1%. Patients with panic disorder often have catastrophic illness beliefs during the panic attack, such as convictions that they are about to die from a stroke or heart attack, or that they suffer from multiple sclerosis (MS). The fear of a stroke is related to dizziness and headache. Fear of a heart attack accompanies chest pain (atypical chest pain), and the fear of MS follows paraesthesiae.

Aetiology

General anxiety and panic disorder occurs four or more times as commonly in first-degree relatives of affected

Box 22.12 **Phobias**

A phobia is an abnormal fear and avoidance of an everyday object or situation. Phobias are common (8% prevalence), disabling, and treatable with behaviour therapy.

patients, suggesting a genetic influence. Sympathetic nervous system overactivity, increased muscle tension and hyperventilation are the common pathophysiological mechanisms. Psychodynamic theory suggests that anxiety is the emotional response to the threat of a loss, whereas depression is the response to the loss itself. There is some evidence that being bullied, with the explicit threats involved, leads to anxiety disorders in young people.

Phobic (anxiety) disorders

Phobias are common conditions in which intense fear is triggered by a single stimulus, or set of stimuli, that are predictable and normally cause no particular concern to others (e.g. agoraphobia, claustrophobia, social phobia). This leads to avoidance of the stimulus (see Box 22.12). The patient knows that the fear is irrational, but cannot control it. The prevalence of all phobias is 8%, with many patients having more than one. Many phobias of 'medical' stimuli exist (e.g. of doctors, dentists, hospitals, vomit, blood and injections) which affect the patient's ability to receive adequate healthcare.

Aetiology

Phobias may be caused by classical conditioning, in which a response (fear and avoidance) becomes conditioned to a previously benign stimulus (a lift) often after an initiating shock (being stuck in a lift). In children, phobias can arise through imagined threats (e.g. stories of ghosts told in the playground). Women have twice the prevalence of most phobias than men. Phobias aggregate in families, but genetic factors are probably weak.

Agoraphobia

Translated as 'fear of the market place', this common phobia (4% prevalence) presents as a fear of being away from home, with avoidance of travelling, walking down a road, and shops being common presentations. This can be a very disabling condition, since the patient can be too unwell to ever leave home, particularly by themselves. It is often associated with *claustrophobia*, a fear of enclosed spaces. ....

Social phobia

This is the fear and avoidance of social situations: crowds, strangers, parties and meetings. Public speaking would be the sufferer's worst nightmare. It is suffered by 2% of the population.

Simple phobias

The commonest is the phobia of spiders (arachnophobia), particularly in women. The prevalence of simple phobias

is 7% in the general population. Other common phobias include insects, moths, bats, dogs, snakes, heights, thunderstorms and the dark. Children are particularly phobic about the dark, ghosts and burglars, but the large majority grow out of these fears.

Treatment of anxiety disorders

Psychological treatments

For many people with brief episodes of an anxiety disorder, a discussion with a doctor concerning the nature of anxiety is usually sufficient.

- *Relaxation* techniques can be effective in mild/moderate anxiety. This can be achieved in many ways, including complementary techniques such as meditation and yoga. Conventional relaxation training involves slow breathing, muscle relaxation, and mental imagery.
- *Anxiety management training* involves two stages. In the first stage, verbal cues and mental imagery are used to arouse anxiety. In the second stage, the patient is trained to reduce this anxiety by relaxation, distraction and reassuring self-statements.
- *Biofeedback* is useful for showing patients that they are not relaxed, even when they fail to recognize it, having become so used to anxiety. Biofeedback involves feeding back to the patient a physiological measure that is abnormal in anxiety. These measures may include electrical resistance of the skin of the palm, heart rate, muscle electromyography, or breathing pattern.
- *Behaviour therapies* are treatments derived from experimental psychology that are intended to change behaviour and thus symptoms. The most common and successful behaviour therapy (with 80% success in some phobias) is *graded exposure,* otherwise known as *systematic desensitization.* This is the treatment of choice for a phobia. Firstly, the patient rates the phobia into a hierarchy or 'ladder' of worsening fears (e.g. in agoraphobia: walking to the front door with a coat on; walking out into the garden; walking to the end of the road). Secondly, the patient practises exposure to the least fearful stimulus until no fear is felt. The patient then moves 'up the ladder' of fears until they are cured.
- *Cognitive behaviour therapy* (CBT) (see p. 1293) is the treatment of choice for panic disorder and general anxiety disorder because the therapist and patient need to identify the mental cues (thoughts and memories) that may subtly provoke exacerbations of anxiety or panic attacks. CBT also allows identification and alteration of the patient's 'schema', or way of looking at themselves and their situation, that feeds anxiety.

Drug treatments

Drugs used in the treatment of anxiety can be divided into two groups: those that act primarily on the central nervous system, and those that block peripheral autonomic receptors.

Table 22.14 **Withdrawal syndrome with benzodiazepines**

Insomnia
Anxiety
Tremulousness
Muscle twitchings
Perceptual distortions
Hypersensitivities (light, sound, touch)
Convulsions

- *Benzodiazepines* are centrally acting anxiolytic drugs. They bind to specific receptors that stimulate release of the inhibitory transmitter y-aminobutyric acid (GABA). Diazepam (5 mg twice daily, up to 10 mg three times daily in severe cases) and chlordiazepoxide have relatively long half-lives (20^10 hours) and are used as anti-anxiety drugs in the short term. Side-effects include sedation and memory problems, and patients should be advised not to drive while on treatment. They can cause dependence and tolerance within 4-6 weeks, particularly in dependent personalities. The withdrawal syndrome (Table 22.14) can occur after just 3 weeks of continuous use and is particularly severe when high doses have been given for a longer time. Thus, if a benzodiazepine drug is prescribed for anxiety, it should be given in as low a dose as possible and for not more than 2 weeks continuously. A withdrawal programme from chronic use includes changing the drug to the long-acting diazepam, followed by a very gradual reduction in dosage.
- *Buspirone* (5-10 mg three times daily) is a 5-HT_{1A} partial agonist that is anxiolytic after 2 weeks of treatment. It is not yet established as a treatment in the UK. It does not seem to help panic disorder.
- Most SSRIs (e.g. paroxetine, sertraline, citalopram), venlafaxine, MAOIs (phenelzine) and moclobemide (a RIMA) are useful symptomatic treatments for general anxiety and panic disorders, as well as some phobias (social phobia). Imipramine is an established symptomatic treatment for panic disorder, and other tricyclics such as amitriptyline and clomipramine are probably equally effective. Treatment response is often delayed several weeks; a trial of treatment should last 3 months.
- Many of the symptoms of anxiety are due to an increased or sustained release of epinephrine (adrenaline) and norepinephrine (noradrenaline) from the adrenal medulla and sympathetic nerves. Thus, *beta-blockers* such as propranolol (20-40 mg two or three times daily) are effective in reducing peripheral symptoms such as palpitations, tremor and tachycardia, but do not help central symptoms such as anxiety.

Acute stress reactions and adjustment disorders

Acute stress *reaction*

This occurs in individuals without any other psychiatric disorder, in response to exceptional physical and/or

psychological stress. While severe, such a reaction usually subsides within hours or days. The stress may be an overwhelming traumatic experience (e.g. accident, battle, physical assault, rape) or a sudden change in the social circumstances of the individual, such as a bereavement. Individual vulnerability and coping capacity play a role in the occurrence and severity of an acute stress reaction, as evidenced by the fact that not all people exposed to exceptional stress develop symptoms. Symptoms usually include an initial state of feeling 'dazed' or numb, with inability to comprehend the situation. This state may be followed either by further withdrawal from the situation or by anxiety and overactivity. Autonomic signs of arousal, including tachycardia, sweating and hyperventilation, are commonly present. The symptoms usually appear within minutes of the stressor and disappear within 2-3 days.

Adjustment disorder

This disorder can follow an acute stress reaction and is common in the general hospital. This is a more prolonged (up to 6 months) emotional reaction to bad news or a significant life event, with low mood joining the initial shock and consequent anxiety, but not of sufficient severity to fulfil a diagnosis of a mood or anxiety disorder. Supportive counselling is usually a successful treatment, allowing facilitation of unexpressed feelings, elucidation of unspoken fears, and education about the likely future.

Pathological (abnormal) grief

This is a particular kind of adjustment disorder. It can be characterized as excessive and/or prolonged grief, or even absent grieving with abnormal denial of the bereavement. Usually the relative will be stuck in grief, with insomnia and repeated dreams of the dead person, anger at doctors or even the patient for dying, consequent guilt in equal measure, and an inability to 'say good-bye' to the loved person by dealing with their effects. *Guided mourning* uses cognitive and behavioural techniques to allow the relative to stop grieving and move on in life.

Normal grief immediately follows bereavement, is expressed openly, and allows a person to go through the social ceremonies and personal processes of bereavement. The three stages are firstly shock and disbelief, secondly the emotional phase (anger, guilt and sadness) and thirdly acceptance and resolution. This normal process of adjustment may take up to a year, with movement between all three stages occurring in a sometimes haphazard fashion.

Post-traumatic stress disorder (PTSD)

This arises as a delayed and/ or protracted response to a stressful event or situation of an exceptionally threatening nature, likely to cause pervasive distress in almost anyone. Causes include natural or human disasters, war, serious accidents, witnessing the violent death of others, being the victim of sexual abuse, rape, torture, terrorism or hostage-taking. Predisposing factors such as personality, previously unresolved traumas, or a history of psychiatric illness may prolong the course of the syndrome. These factors are neither necessary nor sufficient to explain its occurrence, which is most related to the intensity of the trauma, the proximity of the patient to the traumatic event, and how prolonged or repeated it was. Recent functional brain scan research suggests a possible neurophysiological relationship with OCD (p. 1301).

Clinical features

The typical symptoms of PTSD include:

- *'flashbacks'* - repeated vivid reliving of the trauma in the form of intrusive memories, often triggered by a reminder of the trauma
- *insomnia,* usually accompanied by nightmares, the nocturnal equivalent of flashbacks
- *emotional blunting,* emptiness or 'numbness', alternating with ...
- *intense anxiety* at exposure to events that resemble an aspect of the traumatic event, including anniversaries of the trauma
- *avoidance* of activities and situations reminiscent of the trauma
- *emotional detachment* from other people
- *hypervigilance* with autonomic hyperarousal and an enhanced startle reaction.

This clinical picture represents the severe end of a spectrum of emotional reactions to trauma, which might alternatively take the form of an adjustment or mood disorder. The course is often fluctuating but recovery can be expected in two-thirds of cases at the end of the first year. Complications include depressive illness and alcohol misuse. In a small proportion of cases the condition may show a chronic course over many years and a transition to an enduring personality change.

Treatment and prevention

Compulsory *psychological debriefing* immediately after a trauma does not prevent PTSD and may be harmful. Behaviourally based therapies should be offered for those with symptoms and CBT is often effective. It can be normalizing to have therapy in groups with other patients who have suffered similar trauma. Randomized controlled trials have now shown that *eye movement desensitization and reprocessing* (EMDR) is an effective treatment for PTSD. SSRIs, venlafaxine and nefazodone have a place in the management of chronic PTSD, but drop-out from pharmacotherapy is common.

The adult consequences of childhood sexual and physical abuse

Estimates of the prevalence of childhood sexual abuse (CSA) vary depending on definition but there is reasonable evidence that 20% of women and 10% of men suffered significant, coercive and inappropriate sexual activity in childhood. The abuser is usually a member of the family or known to the child, and preadolescent girls are at greatest risk. The likelihood of long-term consequences is determined by:

- an earlier age of onset
- the severity of the abuse
- the repeated nature and duration of the period of abuse
- the association with physical abuse.

Consequent adult psychiatric disorders include depressive illness, substance misuse, eating disorders, borderline personality disorder and deliberate self-harm. Other negative outcomes include a decline in socio-economic status, sexual problems, prostitution, and difficulties in trusting those closest to the patient.

Psychodynamic psychotherapy

Psychodynamic psychotherapy is derived from psychoanalysis and is based on a number of key analytical concepts. These include Freud's ideas about psychosexual development, defence mechanisms, free association as the method of recall, and the therapeutic techniques of interpretation, including that of transference, defences and dreams. Such therapy usually involves once-weekly 50-minute sessions, the length of treatment varying between 3 months and 2 years. The long-term aim of such therapy is twofold: symptom relief and personality change. Psychodynamic psychotherapy is classically indicated in the treatment of unresolved conflicts in early life, as might be found in non-psychotic and personality disorders, but to date there is a lack of convincing evidence concerning its superiority over other forms of treatment.

FURTHER READING

Fricchione G (2004) Generalized anxiety disorders. *New England Journal of Medicine* 351: 675-682.

Sher L (2004) Recognising post-traumatic stress disorder. *Quarterly Journal of Medicine* 97:1-5.

OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) is characterized by obsessional ruminations and compulsive rituals. It is particularly associated with and/or secondary to both depressive illness and *Gilles de la Tourette syndrome* (p. 1232). The prevalence is up to 2% in the general population, although it is probably undiagnosed. There is an equal distribution by gender, and the mean of onset ranges from 20-40 years.

Clinical features

The obsessions and compulsions are so persistent and intrusive that they greatly impede a patient's functioning and cause considerable distress. There is a constant need to check that things have been done correctly, and no amount of reassurance can remove the small amount of doubt that persists. Some rituals are derived from superstitions, such as actions repeated a fixed number of times, with the need to start again if interrupted. When severe and primary, OCD can last for many years and is resistant to treatment. However, obsessional symptoms commonly occur in other disorders, most notably general anxiety disorder, depressive illness and schizophrenia, and disappear with the resolution of the primary disorder. Minor degrees of obsessional symptoms and compulsive rituals or superstitions are common in people who are not ill or in need of treatment, particularly in times of stress. The mildest grade is that of obsessional personality traits such as over-conscientiousness, tidiness, punctuality and other attitudes and behaviours indicating a strong tendency towards conformity and inflexibility. Such individuals are *perfectionists* who are intolerant of shortcomings in themselves and others, and take pride in their high standards. When such traits are so marked that they dominate other aspects of the personality, in the absence of clear-cut OCD, the diagnosis is obsessional (anankastic) personality (see p. 1313).

Aetiology

Genetic

OCD is found in 5-7% of the first-degree relatives. Twin studies showed a 80-90% concordance in monozygotic twins and about 50% in dizygotic twins.

Basal ganglia dysfunction

OCD is associated with a number of neurological disorders involving dysfunction of the striatum, including Parkinson's disease, Sydenham's and Huntington's chorea. OCD can follow head trauma. Neuroimaging suggests that abnormalities exist in the frontal lobe and basal ganglia (Fig. 22.4). Hyperactivity of the orbitofrontal cortex has been a consistent finding in brain imaging research on OCD patients. The PET images shown here are from the initial report of this finding by a research group at the University of California at Los Angeles. Other work suggests the caudate nucleus is smaller than in healthy controls.

Serotonin

Serotonin function is probably abnormal in patients with OCD. Serotonin reuptake inhibitors are effective drugs. Postsynaptic serotonin receptor hypersensitivity may follow chronically low levels of synaptic serotonin.

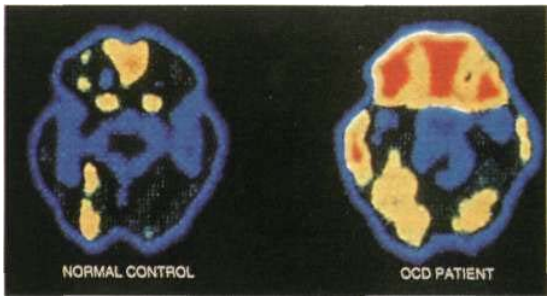

Fig. 22.4 **PET images of (left) a normal patient and (right) an obsessive-compulsive disorder (OCD) patient.** The right image shows the hyperactivity of the orbitofrontal cortex which is a consistent finding in this condition. Baxter R et al. *Archives of General Psychiatry* **44:** 211, with permission.

Conditioning

This suggests that compulsive rituals are classically conditioned avoidance responses, which therefore lend themselves to treatment with graded exposure therapy.

Treatment

Psychological treatments

A behaviour therapy that is particularly effective for rituals is *response prevention.* Patients are instructed not to carry out their rituals. There is an initial rise in distress but with persistence both the rituals and the distress diminish. Patients are encouraged to practise response prevention, while returning to situations that normally make them worse.

Modelling involves the therapist demonstrating to the patient what is required and encouraging the patient to follow this example. In the case of hand-washing rituals, this might involve holding an allegedly contaminated object and carrying out other activities without washing, the patient being encouraged to follow suit.

Thought stopping can reduce obsessional ruminations. The patient is taught to arrest the obsessional thought by arranging a sudden intrusion (e.g. snapping an elastic band, clicking the fingers).

Cognitive behaviour therapy involves exposure to the provocative stimulus plus cognitive therapy.

Physical treatment

Anxiolytic drugs provide short-term symptomatic relief for overwhelming anxiety on a short-term basis.

Selective *serotonin reuptake inhibitors* are the mainstay of drug treatment. Their efficacy is independent of their antidepressant action but the doses required are usually some 50-100% higher than those effective in depression. Three months' treatment with high doses may be necessary for a positive response. Positive correlations between reduced severity of OCD and decreased orbitofrontal and caudate metabolism following behavioural and SSRI treatments have been demonstrated in a number of studies. Clomipramine is the tricyclic most commonly used in the UK.

Psychosurgery

Psychosurgery is very occasionally recommended in cases of chronic and severe OCD that has not responded to other treatments. The development of stereotactic techniques has led to the replacement of the earlier, crude leucotomies with more precise surgical interventions such as subcaudate tractotomy and cingulotomy, with small yttrium radioactive implants, which induce lesions in the cingulate area or the ventromedial quadrant of the frontal lobe. Psychosurgery is performed only in a few specialist centres in the UK, and formal and detailed consent requirements are laid down in the appropriate mental health act.

Prognosis

Two-thirds of cases improve within a year. The remainder run a fluctuating or persistent course. The prognosis is worse when the personality is anankastic and the OCD is primary and severe. , ...

Jenike MA (2004) Obsessive—compulsive disorder. *New England Journal of Medicine* 350: 259-265.

ALCOHOL MISUSE AND DEPENDENCE

A wide range of physical, social and psychiatric problems are associated with excessive drinking. *Alcohol misuse* occurs when a patient is drinking in a way that regularly causes problems to the patient or others.

- The *problem drinker* is one who causes or experiences physical, psychological and/ or social harm as a consequence of drinking alcohol. Many problem drinkers, while heavy drinkers, are not physically addicted to alcohol.
- *Heavy drinkers* are those who drink significantly more in terms of quantity and/or frequency than is safe to do so long term.
- *Binge drinkers* are those who drink excessively in short bouts, usually 24-48 hours long, separated by often quite lengthy periods of abstinence. Their overall monthly or weekly alcohol intake may be relatively modest.
- *Alcohol dependence* is defined by a physical dependence on or addiction to alcohol. The term *'alcoholism'* is a confusing one with off-putting connotations of vagrancy, 'meths' drinking and social disintegration. It has been replaced by the term *'alcohol dependence syndrome'.*

Epidemiology of alcohol misuse

A survey of drinking in England and Wales found that 15% of men admitted drinking more than 35 units per week and 4% of women drank more than 25 units per week. In the survey, 4% of men and 2% of women reported alcohol withdrawal symptoms.

Approximately one in five male admissions to acute medical wards are directly or indirectly due to alcohol. Between 33^40% of accident and emergency attenders have blood alcohol concentrations above the present UK legal limit for driving. People with serious drinking problems have a two to three times increased risk of dying compared to members of the general population of the same age and sex.

Table 22.15 provides an approximate estimate of what can be expected in an average individual in the way of behavioural impairment resulting from a particular blood alcohol level. The usual drink (1 unit of alcohol: V_2 pint of ordinary beer (3.5%), a pub measure of wine) contains about 8 g of absolute alcohol and raises the blood alcohol concentration by about 15-20 mg/dL, the amount that is metabolized in 1 hour.

Detection

Alcohol misuse should be suspected in any patient presenting with one or more physical problems commonly associated with excessive drinking (see p. 263). Alcohol

Table 22.15 Approximate correlation between blood alcohol level and behavioural/motor impairment

Rising blood alcohol (mg/dL)	Expected effect
20-99	Impaired coordination, euphoria
100-199	Ataxia, poor judgement, labile mood
200-299	Marked ataxia and slurred speech; poor judgement, labile mood, nausea and vomiting
300-399	Stage 1 anaesthesia, memory lapse, labile mood
400+	Respiratory failure, coma, death

Table 22.16 Common alcohol-related psychological and social problems

Psychological	Social
Depression Anxiety and phobias Memory disturbances Personality disturbances Delirium tremens Attempted suicide Pathological jealousy	Marital and sexual difficulties Family problems Child abuse Employment problems Financial difficulties Accidents at home, on the roads, at work Delinquency and crime Homelessness

misuse may also be associated with a number of psychiatric symptoms/disorders and social problems (Table 22.16).

Guidelines

The patient's frequency of drinking and quantity drunk during a typical week should be established. Alcohol consumption can be assessed on the basis of units of alcohol.

- Drinking up to 21 units of alcohol a week for men and 14 units for women carries no long-term health risk.
- There is unlikely to be any long-term health damage with 21-35 units (men) and 14-25 units (women), provided the drinking is spread throughout the week.
- Beyond 36 units a week in men and 24 units a week in women, damage to health becomes increasingly likely.
- Drinking above 50 units a week in men (35 units in women) is a definitive health hazard. ....

Diagnostic markers of alcohol misuse

Laboratory parameters indicating alcohol misuse are often called markers of recent alcohol misuse. Elevated y-glutamyl transpeptidase (y-GT) and mean corpuscular volume (MCV) may indicate alcohol excess in the last few weeks. Blood or breath alcohol are useful tests in anyone suspected of very recent drinking.

Alcohol dependence *syndrome*

DSM-IV TR describes dependence as 'a pattern of repeated self-administration that usually results in tolerance, withdrawal and compulsive drug-taking behaviour', the essential element of which is the continued use of the substance despite significant substance-related problems. Figure 22.5 outlines the main characteristics of the syndrome but these do not necessarily present in any particular order. Symptoms of alcohol dependence in a typical order of occurrence are shown in Table 22.17. Diagnostic criteria for alcohol withdrawal syndrome are shown in Table 22.18.

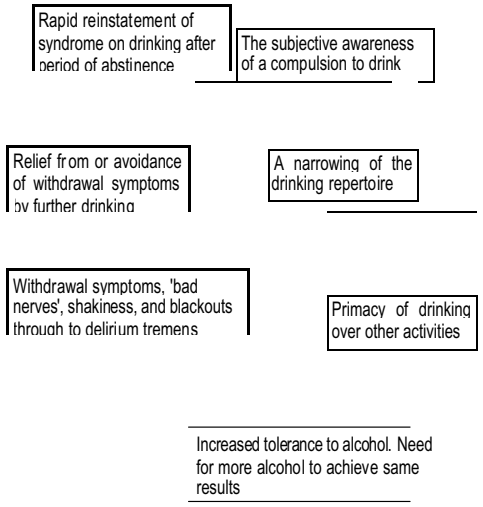

***Fig. 22.5* Elements of the alcohol-dependence syndrome.**

Table 22.17 Symptoms of alcohol dependence

Unable to keep a drink limit	Trembling after drinking the day before
Difficulty in avoiding getting drunk	Morning retching and vomiting
Spending a considerable time drinking	Sweating excessively at night
Missing meals	Withdrawal fits
Memory lapses, blackouts	Morning drinking
Restless without drink	Increased tolerance
Organizing day around drink	Hallucinations, frank delirium tremens

Table 22.18 Diagnostic criteria for alcohol withdrawal syndrome

Any three of the following:

Tremor of outstretched hands, tongue or eyelids
Sweating
Nausea, retching or vomiting
Tachycardia or hypertension
Anxiety
Psychomotor agitation
Headache
Insomnia
Malaise or weakness
Transient visual, tactile or auditory hallucinations or illusions
Grand mal convulsions

The course of the alcohol dependence syndrome

About 25% of all cases of alcohol misuse will lead to chronic alcohol dependence. This most commonly ends in social incapacity, death or abstinence. Alcohol dependence syndrome usually develops after 10 years of heavy drinking *(3-i* years in women). In some individuals who use alcohol to alter consciousness, obliterate conscience and defy social canons, dependence and apparent loss of control may appear in only a few months or years.

Delirium tremens (DTs)

Delirium tremens is the most serious withdrawal state and occurs 1-3 days after alcohol cessation, so is commonly seen a day or two after admission to hospital. Patients are disorientated, agitated, and have a marked tremor and visual hallucinations (e.g. insects or small animals coming menacingly towards them). Signs include sweating, tachycardia, tachypnoea and pyrexia. Complications include dehydration, infection, hepatic disease or the Wernicke-Korsakoff syndrome (p. 245).

Causes of alcohol dependence

Genetic factors. Sons of alcohol-dependent people who are adopted by other families are four times more likely to develop drinking problems than are the adopted sons of non-alcohol misusers. Genetic markers include dopamine-2 receptor allele Al, alcohol dehydrogenase subtypes and monoamine oxidase B activity, but they are not specific.

Environmental factors. A Boston follow-up study showed that one in ten boys who grew up in a household where neither parent misused alcohol subsequently became alcohol dependent, compared with one in four of those reared by alcohol-misusing fathers and one in three of those reared by alcohol-misusing mothers.

Biochemical factors. Several factors have been suggested, including abnormalities in alcohol dehydrogenase, neurotransmitter substances and brain amino acids, such as GABA. There is no conclusive evidence that these or other biochemical factors play a causal role.

Psychiatric illness. This is an uncommon cause of addictive drinking but it is a treatable one. Some depressed patients drink excessively in the hope of raising their mood. Patients with anxiety states or phobias are also at risk.

Excess consumption in society. The prevalence of alcohol dependence and problems correlates with the general level (per capita consumption) of alcohol use in a society. This, in turn, is determined by factors that may control overall consumption - including price, licensing laws, the number and nature of sales outlets, and the customs of society concerning the use and misuse of . alcohol.

Treatment

Psychological treatment of problem drinking

Successful identification at an early stage can be a helpful intervention in its own right. It should lead to:

- the provision of information concerning safe drinking levels
- a recommendation to cut down where indicated
- simple support and advice concerning associated problems.

Successful alcohol counselling involves *motivational enhancement {motivational therapy),* feedback, education about adverse effects of alcohol, and agreeing drinking goals. A motivational approach is based on five stages of change: precontemplation, contemplation, determination, action and maintenance. The therapist uses motivational interviewing and reflective listening to allow the patient to persuade himself along the five stages to change.

This technique, cognitive behaviour therapy and 12-step facilitation (as used by Alcoholics Anonymous (AA)) have all been shown to reduce harmful drinking. With addictive drinking, self-help group therapy, which involves the long-term support by fellow members of the group (e.g. AA), is helpful in maintaining abstinence. Family and marital therapy involving both the alcohol misuser and spouse may alsobe helpful. .■■';■ ■-.

Drug treatments of problem drinking

Alcohol withdrawal and DTs

Addicted drinkers often experience considerable difficulty when they attempt to reduce or stop their drinking. Withdrawal symptoms are a particular problem and delirium tremens needs urgent treatment (Box 22.13). In the absence of DTs, alcohol withdrawal can be treated on an outpatient basis, using one of the fixed schedules in Box 22.13, so long as the patient attends daily for medication and monitoring, and has good social support. Outpatient schedules are sometimes given over 5 days. Long-term treatment with benzodiazepines should not be prescribed in those patients who continue to misuse alcohol. Many alcohol misusers add dependence on diazepam or clomethiazole to their problems.

Drugs for prevention of alcohol dependence

Naltrexone, the opioid antagonist (50 mg per day), reduces the risk of relapse into heavy drinking and the frequency of drinking. *Acamprosate* (1-2 g per day) acts on several receptors including those for GABA, norepinephrine (noradrenaline) and serotonin. There is good evidence that it reduces drinking frequency. Neither drug seems particularly helpful in maintaining abstinence. Both drug effects are enhanced by combining them with counselling.

Drugs such as *disulfiram* react with alcohol to cause unpleasant acetaldehyde intoxication and histamine release. A daily maintenance dose means that the patient must wait until the disulfiram is eliminated from the body before drinking safely. There is mixed evidence of efficacy. ■

Box 22.13 **Management of delirium tremens (DTs)**

General measures

Admit the patient to a medical bed. Correct electrolyte abnormalities and dehydration. Treat any co-morbid disorder (e.g. infection). Give oral thiamine (200 mg daily) in the absence of Wernicke-Korsakoff (W-K) syndrome. Give parenteral thiamine in the presence of a W-K encephalopathy (NB: beware anaphylaxis). Give prophylactic phenytoin or carbamazepine, if previous history of withdrawal fits.

Specific drug treatment

One of the following orally:

- Diazepam 10-20 mg
- Chlordiazepoxide 30-60 mg
- Lorazepam 2-4 mg.

Repeat 1 hour after last dose depending on response.

Fixed-schedule regimens

- Diazepam 10 mg every 6 hours for 4 doses, then 5 mg 6-hourly for 8 doses OR
- Chlordiazepoxide 30 mg every 6 hours for 4 doses, then 15 mg 6-hourly for 8 doses OR
- Lorazepam 2 mg every 6 hours for 4 doses, then 1 mg 6-hourly for 8 doses. *Provide additional benzodiazepine when symptoms and signs are not controlled.*

One trial has suggested that fluoxetine is helpful in the treatment of patients who have both a depressive illness and alcohol dependence.

Outcome

Research suggests that 30-50% of alcohol-dependent drinkers are abstinent or drinking very much less up to 2 years following traditional intervention. It is too early to be certain of the long-term outcome of patients treated with the latest psychological and pharmacotherapies.

DRUG MISUSE AND DEPENDENCE

In addition to alcohol and nicotine, there are a number of psychotropic substances that are taken for their effects on mood and other mental functions (Table 22.19).

Table 22.19 **Commonly used drugs of misuse and dependence**

Stimulants	Narcotics
Methylphenidate	Morphine
Phenmetrazine	Heroin
Phencyclidine ('angel dust')	Codeine
Cocaine	Pethidine
Amfetamine derivates	Methadone
Ecstasy (MDMA)	
Hallucinogens	**Tranquillizers**
Cannabis preparations	Barbiturates
Solvents	Benzodiazepines
Lysergic acid diethylamide (LSD)	
Mescaline	

Causes of drug misuse

There is no single cause of drug misuse and/or dependence. Three factors appear commonly, in a similar way to alcohol problems:

- the availability of drugs
- a vulnerable personality
- social pressures, particularly from peers.

Once regular drug-taking is established, pharmacological factors determine dependence.

Solvents

One per cent of adolescents in the UK sniff solvents for their intoxicating effects. Tolerance develops over weeks or months. Intoxication is characterized by euphoria, excitement, a floating sensation, dizziness, slurred speech and ataxia. Acute intoxication can cause amnesia and visual hallucinations. About 300 teenagers die in the UK each year from asphyxiation or acute poisoning.

Amfetamines and related substances

These have temporary stimulant and euphoriant effects that are followed by fatigue and depression, with the latter sometimes prolonged for weeks. Psychological rather than true physical dependence is the rule with 'Speed'. In addition to a manic-like presentation, amfetamines can produce a paranoid psychosis indistinguishable from acute paranoid schizophrenia.

Ecstasy

'Ecstasy' (E, white burger, white dove) is the street name for 3,4-methylenedioxy-methamfetamine (MDMA), a psychoactive phenylisopropylamine, synthesized as an amfetamine derivative. It is a psychodelic drug which is often used as a 'dance' drug'. It has a brief duration of action (4-6 hours). There is evidence that repeated use of MDMA can cause permanent neurotransmittei cVianges in the brain. Deaths have been reported from malignant hyperpyrexia and dehydration. Acute renal and liver failure can occur.

Cocaine

Cocaine is a central nervous system stimulant (with similar effects to amfetamines) derived from *Erythroxylon coca* trees grown in the Andes. In purified form it may be taken by mouth, sniffed or injected. If cocaine hydrochloride is converted to its base ('crack') it can be smoked. This causes an intense stimulating effect and 'free-basing' is common. Compulsive use and dependence occur more frequently among users who are free-basing. Dependent users take large doses and alternate between the withdrawal phenomena of depression, tremor and muscle pains, and the hyperarousal produced by increasing doses. Prolonged use of high doses produces irritability, restlessness, paranoid ideation and occasionally convulsions. Persistent sniffing of the drug can cause perforation of the nasal septum. Overdoses cause death through myocardial infarction, hyperthermia and arrhythmias (p. 1011).

Hallucinogenic drugs

Hallucinogenic drugs, such as lysergic acid diethylamide (LSD) and mescaline, produce distortions and intensifications of sensory perceptions, as well as frank hallucinations in acute intoxication. Psychosis is a long-term complication. ■■

Cannabis

Cannabis (grass, pot, spliff, reefer) is a drug widely used in some subcultures. It is derived from the dried leaves and flowers of the plant *Cannabis sativa.* It can cause tolerance and dependence. Hashish is the dried resin from the flower tops whilst marijuana refers to any part of the plant. The drug, when smoked, seems to exaggerate the pre-existing mood, be it depression, euphoria or anxiety. It may have specific analgesic properties. An amotivational syndrome has been reported with chronic daily use. Cannabis may of itself sometimes cause psychosis in the right circumstances (see below).

Tranquillizers

Drugs causing dependence include barbiturates **and** benzodiazepines. Benzodiazepine dependence is common and may be iatrogenic, when the drugs are prescribed and not discontinued. Discontinuing treatment with benzodiazepines may cause withdrawal symptoms (see Table 22.14). For this reason, withdrawal should be supervised and gradual.

Opiates

Physical dependence occurs with morphine, heroin and codeine as well as with synthetic and semisynthetic opiates such as methadone and pethidine. These substances display cross-tolerance - the withdrawal effects of one are reduced by administration of one of the others. The psychological effect of such substances is of a calm, slightly euphoric mood associated with freedom from physical discomfort and a flattening of emotional response. This is believed to be due to the attachment of morphine and its analogues to receptor sites in the CNS normally occupied by endorphins. Tolerance to this group of drugs is rapidly developed and marked, but is rapidly lost following abstinence. *The opiate withdrawal syndrome* consists of a constellation of signs and symptoms (Table 22.20) that reaches peak intensity on the second or third day after the last dose of the opiate. These rapidly subside over the next 7 days. Withdrawal is dangerous in patients with heart disease or other chronic debilitating conditions.

Table 22.20 Opiate withdrawal syndrome

Yawning Rhinorrhoea Lacrimation Pupillary dilatation Sweating Piloerection Restlessness	■ 12-16 hours after last dose of opiate
Muscular twitches Aches and pains Abdominal cramps Vomiting Diarrhoea Hypertension Insomnia Anorexia Agitation Profuse sweating Weight loss	■ 24-72 hours after last dose of opiate

Opiate addicts have a relatively high mortality rate, owing to both the ease of accidental overdose and the blood-borne infections associated with shared needles. Heart disease (including infective endocarditis), tuberculosis and AIDS are common causes of death, while tetanus, malaria and the complications of hepatitis B and C are also common.

Treatment of chronic misuse

Blood and urine screening for drugs are required in circumstances where drug misuse is suspected (Table 22.21). When a patient with an opiate addiction is admitted to hospital for another health problem, advice should be sought from a psychiatrist or the patient's drug

Table 22.21 Length of time urine toxicology screens are likely to remain positive after abstinence

Substance	Usual time positive
Amfetamines	48 hours
Barbiturates	
Short-acting	24 hours
Long-acting	7+ days
Benzodiazepines	3+ days
Cannabinols	5+ days
Cocaine	3+ days
Codeine	48 hours
Morphine	48 hours

clinic regarding management of their addiction while an inpatient.

The treatment of chronic dependence is directed towards helping the patient to live without drugs. Patients need help and advice in order to avoid a withdrawal syndrome. Alternatively, patients can be helped to minimize harm to themselves and others. Some patients with opiate addiction who cannot manage such a regimen may be maintained on oral methadone. In the UK, only specially licensed doctors may legally prescribe heroin and cocaine to an addict for maintenance treatment of addiction. An overdose should be treated immediately with the opioid antagonist naloxone.

Drug psychoses

Drug-induced psychoses have been reported with amfetamine and its derivatives, cocaine, and hallucinogens. It can occur acutely after drug use, but is more usually associated with chronic misuse. Psychoses are characterized by vivid hallucinations (usually auditory, but often in more than one sensory modality), misidentifications, delusions and/or ideas of reference (often of a persecutory nature), psychomotor disturbances (excitement or stupor) and an abnormal affect. ICD-10 requires that the condition occurs within 2 weeks and usually within 48 hours of drug use and that it should persist for more than 48 hours but not more than 6 months.

Cannabis use can result in acute anxiety, depression or hallucinations. Manic-like psychoses occurring after long-term cannabis use have been described, but seem more likely to be related to the toxic effects of heavy ingestion. However, there are now five prospective studies which suggest, when taken together, that cannabis doubles the risk of schizophrenia, and that perhaps 8% of schizophrenia in the UK would be prevented if cannabis use ceased. This risk is higher in people taking cannabis early in their lives and heavily.

SCHIZOPHRENIA

The group of illnesses conventionally referred to as 'schizophrenia' is diverse in nature and covers a broad range of perceptual, cognitive and behavioural disturbances. The point prevalence of the condition is 0.5% throughout the world, with equal gender distribution. A physician primarily needs to know how to recognize schizophrenia, what problems it might present with in the general hospital, and how it is treated.

Table 22.22 **Genetic risk for schizophrenia**

General population	1%
Second-degree relative	2.5%
Parent	4%
Sibling	8%
Child of one affected parent	12%
Child of two affected parents	30-40%
Dizygotic twin	8-19%
Monozygotic twin	40-60%

Causes

No single cause has been identified. Schizophrenia is likely to be a disease of neural disconnection caused by an interaction of genetic and multiple environmental factors that affect brain development. It is likely that cannabis use is a risk factor. The genetic aetiology is likely to be polygenic and non-mendelian. Schizophrenia has a heritability of about 80%. The genetic risk in the general population and relatives of affected individuals is shown in Table 22.22. Brain scans and histology often show ventricular enlargement and disorganized cytoarchitecture in the hippocampus, supporting the neurodevelopmental theory of aetiology. Dopamine receptors are upregulated in the mesolimbic system, but the serotonin system may also be involved.

Clinical features

The illness can begin at any age but is rare before puberty. The peak age of onset is in the early twenties. The symptoms that have been considered as diagnostic of the condition have been termed *first rank symptoms* and were described by the German psychiatrist Kurt Schneider. They consist of:

- auditory hallucinations in the third person, and/ or voices commenting on their behaviour
- thought withdrawal, insertion and broadcast
- primary delusion
- delusional perception
- somatic passivity and feelings - patients believe that thoughts, feelings or acts are controlled by others.

The more of these symptoms a patient has the more likely the diagnosis is schizophrenia. Other symptoms of *acute* schizophrenia include behavioural disturbances, other hallucinations, secondary (usually persecutory) delusions and blunting of mood. Schizophrenia is sometimes divided into 'positive' (type 1) and 'negative' (type 2) types:

Positive schizophrenia is characterized by acute onset, prominent delusions and hallucinations, normal brain structure, a biochemical disorder involving dopaminergic transmission, good response to neuroleptics, and better outcome.

Negative schizophrenia is characterized by a slow, insidious onset, a relative *absence oi acute symptoms, the* presence of apathy, social withdrawal, lack of motivation, underlying brain structure abnormalities, and poor neuroleptic response.

Chronic schizophrenia

This is characterized by long duration and 'negative' symptoms of underactivity, lack of drive, social withdrawal and emotional emptiness.

Differential diagnosis

Schizophrenia should be distinguished from:

- organic mental disorders (e.g. partial complex epilepsy)
- mood (affective) disorders (e.g. mania)
- drug psychoses (e.g. amfetamine psychosis)
- personality disorders (schizotypal).

In older patients, any acute or chronic brain syndrome can present in a schizophrenia-like manner. A helpful diagnostic point is that clouding of consciousness and disturbances of memory do not occur in schizophrenia, and visual hallucinations are unusual.

A *schizoaffective psychosis* describes a clinical presentation in which clear-cut affective and schizophrenic symptoms coexist in the same episode.

Prognosis

The prognosis of schizophrenia is variable. A review of treatment studies suggests that 15-25% of people with schizophrenia recover completely, about 70% will have relapses and may develop mild to moderate negative symptoms, while about 10% will become seriously disabled.

Treatment

The best results are obtained by combining drug and social treatments.

Antipsychotic (neuroleptic) drugs

These act by blocking the D_1 and D_2 groups of dopamine receptors. Such drugs are most effective against acute, positive symptoms and are least effective in the management of chronic, negative symptoms. Complete control of positive symptoms can take up to 3 months, and premature discontinuation of treatment can result in relapse.

As antipsychotic drugs block both D_1 and D_2 dopamine receptors, they usually produce extrapyramidal side-effects. This limits their use in maintenance therapy of many patients. They also block adrenergic and muscarinic receptors and thereby cause a number of unwanted effects (Table 22.23).

An infrequent but potentially dangerous unwanted effect is the *neuroleptic malignant syndrome.* This occurs in 0.2% of patients on neuroleptic drugs, particularly the potent dopaminergic antagonists, e.g. haloperidol. Symptoms occur a few days to a few weeks after starting therapy and consist of hyperthermia, muscle rigidity, autonomic instability (tachycardia, labile BP, pallor) and a fluctuating level of consciousness. Investigations show a raised creatine phosphokinase, raised white cell count and abnormal liver biochemistry. Treatment consists of stopping the drug and general management, e.g. temperature reduction. Bromocriptine enhances dopaminergic activity and dantrolene will reduce muscle tone but no treatment has proven benefit. . . . .

Table 22.23 **Unwanted effects of neuroleptic drugs**

Common effects

Motor

Constipation Blurred vision Metabolic
Weight gain

Rare effects
Hypersensitivity Cholestatic jaundice
Leucopenia Skin reactions

Others
Precipitation of glaucoma Galactorrhoea
Amenorrhoea Cardiac arrhythmias
Seizures

Pregnancy. Data on the potential teratogenicity of antipsychotic (neuroleptic) medications are still limited. The disadvantages of not treating during pregnancy have to be balanced against possible developmental risks to the fetus. The butyrophenones (e.g. haloperidol) are probably safer than the phenothiazines. Subsequent management decisions on dosage will depend primarily on the ability to avoid side-effects, since the antiparkinsonian agents are still believed to be teratogenic and should be avoided.

Phenothiazines

Phenothiazines are the group of neuroleptics used most extensively. Chlorpromazine (100-1000 mg daily) is the drug of choice when a more sedating drug is required. Trifluoperazine is used when sedation is undesirable. Fluphenazine decanoate is used as a long-term prophylactic to prevent relapse, as a depot injection (25-100 mg i.m. every 1-4 weeks).

Butyrophenones

The butyrophenones (e.g. haloperidol 2-30 mg daily) are also powerful antipsychotics, used in the treatment of acute schizophrenia and mania. They are highly likely to cause a dystonia and/or extrapyramidal side-effects, but are much less sedating than the phenothiazines. A third of patients with acute schizophrenia will have a good response to haloperidol and a further third will make a partial response.

Atypical antipsychotics

These drugs are 'atypical' in that they block D_2 receptors less than D_a and thus cause fewer extrapyramidal side-effects and less tardive dyskinesia. They are now being used as first-line drugs for newly diagnosed schizophrenia.

Clozapine. Clozapine is also used in patients with intractable schizophrenia who have failed to respond to at least two conventiona] *antipsychotic drugs. This drug* is a dibenzodiazepine with a relative high affinity for D_1 compared with D_2 dopamine receptors, muscarinic and oc-adrenergic receptors. It also blocks 5-HT_2 and 5-HTj

receptors. Functional brain scans have shown that clozapine selectively blocks limbic dopamine receptors more than striatal ones, which is probably why it causes considerably fewer extrapyramidal side-effects.

Clozapine has been shown to exercise a dramatic therapeutic effect on both intractable positive and negative symptoms. However, clozapine is expensive and produces severe agranulocytosis in 1-2% of patients. Therefore it can only be prescribed in the UK to registered patients by doctors and pharmacists registered with the Clozaril patient-monitoring service. The starting dose is 25 mg per day with a maintenance dose of 150-300 mg daily. White cell counts should be monitored weekly for 18 weeks and then 2-weekly for the length of treatment. In addition to its antipsychotic actions, clozapine may also help reduce aggressive and hostile behaviour and the risk of suicide. It can cause considerable weight gain and sialorrhoea. There is an increased risk of diabetes mellitus.

Risperidone is a benzisoxazole derivative with combined dopamine D_2 receptor and 5-HT_{2A}-receptor blocking properties. Dosage ranges from 6-10 mg per day. The drug is not markedly sedative and the overall incidence and severity of extrapyramidal side-effects is lower than with more conventional antipsychotics.

Olanzapine has affinity for 5-HT_2, D_1, D_2, D_4, and muscarinic receptor sites. Clinical studies indicate it to have a lower incidence of extrapyramidal side-effects. The apparent better compliance with the drug may be related to its lower side-effect profile and its once-daily dosage of 5-10 mg. Weight gain is a problem with long-term treatment and there is an increased risk of diabetes mellitus.

Neither risperidone nor olanzapine seem as specific a treatment for intractable chronic schizophrenia as clozapine.

Other atypical antipsychotics include sulpiride, ziprasidone and quietiapine.

Psychological treatment

This consists of reassurance, support and a good doctor-patient relationship. Psychotherapy of an intensive or exploratory kind is contraindicated. In contrast, recent research shows that cognitive behaviour therapy can help reduce the intensity of delusions.

Social treatment

Social treatment involves attention being paid to the patient's environment and social functioning. Family education can help relatives and partners to provide the optimum amount of emotional and social stimulation, so that not too much emotion is expressed (a risk for relapse). Sheltered employment is usually necessary for the majority of sufferers if they are to work.

Medical presentations related to treatment

The motor side-effects of neuroleptics are the commonest reason for a patient with schizophrenia to present to a physician, followed by deliberate self-harm. *Acute dystonia* normally arises in patients newly started on neuroleptics, causing a *torticollis*. Extrapyramidal side-effects are common and present in the same way as Parkinson's disease. *Akathisia* is a motor restlessness, most commonly affecting the legs. It is similar to the restless legs syndrome (p. 666), but apparent during the day.

Amenorrhoea and galactorrhoea can be caused by dopamine antagonists. Postural hypotension can affect the elderly, and neuroleptics can be the cause of delirium in the elderly, if their antimuscarinic effects are prominent.

FURTHER READING

Freedman R (2003) Schizophrenia. *New England Journal of Medicine* **349:**1738-1749. Mueser KT, McGurk SR (2004) Schizophrenia. *Lancet* **363:** 2063-2072.

ORGANIC MENTAL DISORDERS

Organic brain disorders result from structural pathology, as in dementia (see p. 1254), or from disturbed central nervous system (CNS) function, as in fever-induced delirium. They do not include mental and behavioural disorders due to alcohol and misuse of drugs, which are classified separately.

Delirium

Delirium, also termed *toxic confusional state* and *acute organic reaction,* is an acute or subacute brain failure in which impairment of attention is accompanied by abnormalities of perception and mood. It is the most common psychosis seen in the general hospital. Ten to twenty per cent of older surgical and medical inpatients have delirium during their admission. Confusion is usually worse at night, with consequent sleep reversal, so that the patient is asleep in the day and awake all night. During the acute phase, thought and speech are incoherent, memory is impaired and misperceptions occur. Episodic visual hallucinations (or illusions) and persecutory delusions occur. As a consequence, the patient may be frightened, suspicious, restless and uncooperative.

A developing, deteriorating or damaged brain predisposes a patient to develop delirium (Table 22.24).

A large number of diseases may cause delirium, particularly in elderly patients. Some causes of delirium are listed in Table 22.25. Delirium tremens should be considered in the differential diagnosis (p. 1304) as well as Lewy body dementia (p. 1255). Diagnostic criteria are given in Box 22.14.

Management

History should be taken from a witness. Examination may reveal the cause. Investigation and treatment of the underlying physical disease should be undertaken (Table 22.25). The patient should be carefully nursed and rehydrated in a quiet single room with a window that does not allow exits. If a high fever is present, the

Table 22.24 Predisposing factors in delirium

Extremes of age (developing or deteriorating brain)

Postoperative states

***Box 22.14* Delirium - diagnostic criteria (derived from DSM-IV-TR)**

Disturbance of consciousness:
4 clarity of awareness of environment
i ability to focus, sustain or shift attention
Change in cognition:
memory deficit, disorientation,
language disturbance, perceptual disturbance
Disturbance develops over a short period (hours or days)
Fluctuation over course of day Disturbance is caused by the consequences of **a** general medical condition or medication

patient's temperature should be reduced. All current drug therapy should be reviewed and, where possible, stopped. Psychoactive drugs should be avoided if possible (because of their own risk of exacerbating delirium). In severe delirium, haloperidol is an effective choice, the daily dose usually ranging between 1.5 mg (in the elderly) to 30 mg per day. If necessary, the first dose can be administered intramuscularly. Olanzapine is an effective alternative, especially if given at night for insomnia. , … .,,.,, .,,. , ,..,.. .....

Prognosis of delirium

Delirium usually clears within a week or two, but brain recovery usually lags behind the recovery of the causative physical illness. The prognosis depends not only on the successful treatment of the causative disease, but also on the underlying state of the brain. Twenty-five per cent of the elderly with delirium will have an underlying dementia; 15% of patients do not survive their underlying illness; 40% are in institutional care at 6 months.

Nayeem K, O'Keefe ST (2003) Delirium. *Clinical Medicine* 3(5): 412-115.

EATING DISORDER

Obesity

This is the commonest eating disorder (see p. 252), which has become epidemic in some developed countries. It is usually caused by a combination of constitutional and social factors, but a binge eating disorder and psychological determinants of 'comfort eating' should be excluded.

Anorexia nervosa

The main clinical criteria for diagnosis are:

- a bodyweight more than 15% below the standard weight, or a body mass index (BMI) below 17.5 (ICD-10)
- weight loss is self-induced by avoidance of fattening foods, vomiting, purging, exercise, or appetite suppressants
- a distortion of body image so that the patient regards herself as fat when she is thin
- a morbid fear of fatness
- amenorrhoea in women.

Clinical features include:

- onset usually in adolescence
- a previous history of chubbiness or fatness
- the patient generally eats little
- amenorrhoea - an early symptom; in 20% it precedes weight loss
- binge eating
- usually a marked lack of sexual interest
- lanugo hair.

The physical consequences of anorexia include sensitivity to cold, constipation, hypotension and bradycardia. In most cases, amenorrhoea is secondary to the weight loss. Vomiting and abuse of purgatives may lead to hypokalaemia and alkalosis.

Prevalence

Case register data suggest an incidence rate of 19 per 100 000 females aged between 15 and 34 years. Surveys have suggested a prevalence rate of approximately 1% among schoolgirls and university students. However, many more young women have amenorrhoea

accompanied by less weight loss than the 15% required for the diagnosis. The condition is much less common among men (ratio of 1 : 10). The onset in women is usually at between 16-17 years of age and it seldom occurs after the age of 30 years.

Aetiology Biological factors

Genetic. Six to ten per cent of siblings of affected women suffer from anorexia nervosa. There is an increased concordance amongst monozygotic twins, suggesting a genetic predisposition.

Hormonal. The reductions in sex hormones and the hypothalamic-pituitary-adrenal axis are secondary to malnutrition and usually reversed by refeeding.

Psychological factors

Individual. Anorexia nervosa has often been seen as an escape from the emotional problems of adolescence and a regression into childhood. Patients will often have had dietary problems in early life. Perfectionism and low self-esteem are common antecedents. Studies suggest that survivors of childhood sexual abuse are at risk of developing an eating disorder, usually anorexia nervosa, in adolescence.

Family. Families of such patients are allegedly characterized by overprotection, inflexibility and lack of conflict resolution. Anorexia is alleged to prevent dissension in families. However, a case control study suggested that there is no more evidence of these factors in families of patients with anorexia nervosa than in control families with a child with an established physical disease.

Social and cultural factors

There is a higher prevalence in higher social classes, and a high rate in certain occupational groups (e.g. ballet dancers and nurses) and in societies where cultural value is placed on thinness.

Prognosis

The condition runs a fluctuating course, with exacerbations and partial remissions. Long-term follow-up suggests that about two-thirds of patients maintain normal weight and that the remaining one-third are split between those who are moderately underweight and those who are seriously underweight. Indicators of a poor outcome include:

a long initial illness
severe weight loss
older age at onset
bulimia (see below), vomiting or purging
personality difficulties
difficulties in relationships.

Suicide has been reported in 2-5% of patients with chronic anorexia nervosa. The mortality rate per year is 0.5% from all causes. More than one-third have recurrent affective illness, and various family, genetic and endocrine studies have found associations between eating disorders and depression. Fifty per cent of patients make a full recovery, 30% a partial recovery and 20% none.

Treatment

Treatment can be conducted on an outpatient basis unless the weight loss is severe and accompanied by marked physical symptoms, dizziness and weakness and/or electrolyte and vitamin disturbances. Hospital admission may then be unavoidable and may need to be on a medical ward initially. Rarely, the patient's weight loss may be so severe as to be life-threatening. If the patient cannot be persuaded to enter hospital, compulsory admission may have to be used. Inpatient treatment goals include:

- establishing a good relationship with the patient
- restoring the weight to a level between the ideal body-weight and the patient's ideal weight
- the provision of a balanced diet, building up to 12.6 MJ (3000 calories) in three to four meals per day
- the elimination of purgative and/or laxative use and vomiting.

Outpatient treatment can be conducted on cognitive behavioural or dynamic psychotherapeutic lines or on a combination of both. Setting up a therapeutic alliance is vital. Individual psychotherapy is better than family therapy if the patient has left home, and vice versa. Motivational enhancement techniques are being used with some success.

Drug treatment has met with limited success, except to symptomatically treat insomnia and depressive illness.

Bulimia nervosa

This refers to episodes of uncontrolled excessive eating, which are also termed 'binges'. There is a preoccupation with food and a habitual adoption of certain behaviours that can be understood as the patient's attempts to avoid the fattening effects of periodic binges. These behaviours include:

- self-induced vomiting
- laxative abuse
- misuse of drugs - diuretics, thyroid extract or anorectics.

Additional clinical features include:

- physical complications of vomiting:
  (a) cardiac arrhythmias
  (b) renal impairment - consequences of low K+
  (c) muscular paralysis
  (d) tetany - from hypokalaemic alkalosis
  (e) swollen salivary glands - from vomiting
  (f) eroded dental enamel
- associated psychiatric disorders:
  (a) depressive illness
  (b) alcohol misuse
- fluctuations in bodyweight within normal limits
- menstrual function - periods irregular but amenorrhoea rare
- personality - perfectionism and low self-esteem present premorbidly.

The prevalence of bulimia in community studies is high; it affects between 5% and 30% of girls attending high schools, colleges or universities in the USA. Bulimia is sometimes associated with anorexia nervosa. A premorbid history of dieting is common. The prognosis for bulimia nervosa is better than for anorexia nervosa.

Treatment

Cognitive behaviour therapy has been shown to be more effective than both interpersonal psychotherapy and drug treatments. SSRIs (e.g. fluoxetine) are also an effective treatment, even in the absence of a depressive illness.

Atypical eating disorders

These include eating disorders that do not conform clinically to the diagnostic criteria for anorexia nervosa or bulimia nervosa. Binge eating disorders consist of bulimia without the vomiting and other weight-reducing strategies.

SEXUAL DISORDERS

Sexual disorders can be divided into sexual dysfunctions, deviations, and gender role disorders (Table 22.26).

Sexual dysfunction

Sexual dysfunction in men refers to repeated inability to achieve normal sexual intercourse, whereas in women it refers to a repeatedly unsatisfactory quality of sexual satisfaction. Problems of sexual dysfunction can usefully be classified into those affecting sexual desire, arousal and orgasm. Among men presenting for treatment of sexual dysfunction, erectile dysfunction is the most frequent complaint. The prevalence of premature ejaculation is low, while ejaculatory failure is rare.

Sexual drive is affected by constitutional factors, ignorance of sexual technique, anxiety about sexual performance, medical and psychiatric conditions and certain drugs (Tables 22.27 and 22.28).

The treatment of sexual dysfunction involves careful assessment, the participation (where appropriate) of the patient's partner, and specific therapeutic techniques, including relaxation, behavioural therapy (Masters and Johnson) and psychotherapy. The introduction of phosphodiesterase type 5 inhibitors (e.g. sildenafil) has introduced an effective therapy for the treatment of erectile dysfunction (see p. 1055).

Sexual deviation

Sexual deviations are regarded as unusual forms of behaviour rather than as an illness. Doctors are only likely to be involved when the behaviour involves break-

ing the law (e.g. paedophilia or bestiality) and when there is a question of an associated mental or physical disorder. Homosexuality was formerly classified as an illness but it is now an accepted alternative sexual lifestyle. Men are more likely than women to have sexual deviations.

Gender role disorders

Transsexualism involves a disturbance in gender identity in which the patient is convinced that their body is the wrong gender. A person's gender identity refers to the individual's sense of masculinity or femininity as distinct from sex. It is thought to arise from a biological component (prenatal endocrine influences), psychological imprinting and social conditioning. Disturbances in these three areas have variously been blamed for the cause of transsexualism.

For males, treatment includes oestrogen administration and, if surgery is to be recommended, a period of living as a woman as a trial beforehand. In the case of female transsexuals, treatment involves surgery and the use of methyltestosterone.

PERSONALITY DISORDER

These disorders comprise deeply ingrained and enduring patterns of behaviour which manifest themselves as inflexible responses to a broad range of personal and social situations. Personality disorders are developmental conditions that appear in childhood or adolescence and continue into adult life. They are not secondary to another psychiatric disorder or brain disease, although they may precede or coexist with other disorders. In contrast, personality change is acquired, usually in adult life, following severe or prolonged stress, extreme environmental deprivation, serious psychiatric disorder or brain injury or disease.

Personality disorders are usually subdivided according to clusters of traits that correspond to the most frequent or obvious behavioural manifestations. The main categories of personality disorder are described below.

Borderline (emotionally unstable). Such people act impulsively and develop intense, but short-lived, emotional attachments to others. They describe chronic internal emptiness with frequent self-harm, self-abuse (eating disorders, substance misuse) and they may develop transient psychotic features of uncertain significance. There is often a strong family history of mood disorders.

Paranoid. A paranoid personality is characterized by extreme sensitiveness, suspiciousness, litigiousness, a tendency to excessive self-importance, and a preoccupation with unsubstantiated conspiratorial explanations of events.

Schizoid. A schizoid personality is characterized by emotional coldness and detachment, a limited capacity to express emotions, indifference to praise or criticism, an almost invariable preference for solitary activities, lack of close friendships, and a marked insensitivity to prevailing social norms and conventions.

Antisocial. An antisocial personality is characterized by a callous unconcern for the feelings of others, an incapacity to maintain enduring relationships, a very low tolerance of frustration, an incapacity to experience guilt and to profit from experience, and a marked proneness to rationalize and blame others.

Histrionic. A histrionic personality is characterized by self-dramatization, theatricality, suggestibility, shallow and labile emotions, a continual seeking for excitement and appreciation by others, and an inappropriate seductiveness in appearance or behaviour.

Anankastic (obsessive-compulsive). Such a personality is characterized by feelings of excessive doubt and caution, preoccupation with details, rules, lists, order, perfectionism, excessive conscientiousness, scrupulousness, excessive pedantry, rigidity and stubbornness, and intrusion of unwelcome thoughts or impulses.

Dependent. People with dependent personality encourage others to make their personal decisions, subordinate their needs to others on whom they are dependent, are unwilling to make demands on others, feel unable to care for themselves, are preoccupied with fears of being abandoned. Such patients have a limited capacity to make everyday decisions without an excessive amount of advice and reassurance from others.

Many individuals with disturbed personalities do not fit neatly into such categories, but manifest a mixture of features.

PSYCHIATRY AND THE LAW

The law in most developed countries provides for the compulsory admission and/or treatment of mentally disordered persons for their own protection and/or the protection of others and for mitigation in the case of mentally disordered individuals who commit a criminal offence (see also p. 6). In England and Wales the Act of Parliament that is crucially involved is the Mental Health Act 1983, although a new Act is about to go through parliament. The Mental Health (Scotland) Act 1984 and the Mental Health (Northern Ireland) Order 1986 contain clauses broadly similar to those in England and Wales.

Apart from one provision of the National Assistance Act 1948, the Mental Health Act 1983 is the only method whereby individuals can legally be deprived of their liberty without having committed a crime or being suspected of committing a crime. It is, therefore, necessary that doctors understand the seriousness of their responsibility and the details of the legislation.

There are three conditions that need to be met before an appropriate compulsory section form is signed. The patient must be:

- suffering from a defined mental disorder
- at risk to his/her and/or other people's health or safety
- unwilling to accept hospitalization voluntarily.

The reasons why there is no alternative approach to the treatment suggested for the patient should be outlined. Sexual deviance or alcohol/drug dependence are not defined mental disorders, but otherwise the definition of mental disorder is broad. Any registered medical practitioner may sign a medical recommendation under the Act, but the added signature of a specialist psychiatrist is needed for compulsory orders lasting for more than 72 hours. Unless the patient is already in hospital, the nearest relative or an approved mental health social worker is also required to sign the application form. Relevant sections of the Act are detailed in Table 22.29.

Physicians are likely to be involved in sections 5(2) and 2. It should be remembered that a section does not give a doctor the right to treat a physical disease, although it could be argued that a section would apply if the physical disease was causing the mental disorder (e.g. delirium). This has never been legally tested.

Although much of the process of detention against one's will is formalized, there is no liability for a doctor who acts in good faith with a patient's best interests at heart. Clearly written medical notes, accepted forms of treatment and common sense remain the basis of good practice.

Table 22.29 **Commonly used sections of the Mental Health Act 1983**

Section	Duration	Signatures required	Purpose
2 3	28 days 6		Assessment and treatment
4 5(2)	months	Two doctors (one approved) plus nearest relative or social worker Two doctors (one approved) plus nearest relative or	Treatment
5(4)	72 hours	social worker	Emergency admission
136	72 hours	One doctor plus relative or social worker Doctor in charge of patient's care	Emergency detention of a patient already in hospital Emergency detention of a patient already in hospital Psychiatric assessment of those in public places thought by police to be mentally ill and in need of a place of safety
	6 hours	Nurse (RMN) Police officer	
	72 hours

Skindisease 23

Introduction

Skin diseases have a high prevalence throughout the world. In developing countries infectious diseases such as tuberculosis, leprosy and onchocerciasis are common, whereas in developed countries inflammatory disorders such as eczema and acne are common. Skin disorders can be inherited, e.g. Ehlers-Danlos syndrome, a part of normal development, e.g. acne vulgaris, or may present as part of a systemic disorder, e.g. systemic lupus erythematosus (SLE).

Approximately 25% of the UK population will develop a skin problem and, although self-medication is common, skin disease still accounts for 10% of the workload of family doctors. The common reasons for this are itching or pain, which can interfere with people's ability to function normally or to sleep; rashes which cause anxiety, depression and lack of self-confidence and can lead to social isolation if obviously visible; and an inability to work, because certain dermatoses (such as allergic hand eczema in a builder or hairdresser) can interfere with or even prevent working.

Rarely skin disease can be fatal. Examples are malignant melanoma, toxic epidermal necrolysis and pemphigus. ■

STRUCTURE AND FUNCTION OF THE SK[1]"

The skin consists of four distinct layers: the epidermis, the basement membrane zone, the dermis and the subcutaneous layer (Fig. 23.1). The functions are summarized in Box 23.1.

The epidermis

The epidermis is a stratified epithelium of ectodermal origin that arises from dividing basal keratinocytes. The downward projections of the epidermis into the detmis are called the 'rete ridges'. The lower epidermal cells (basal layer) produce a variety of keratin filaments and desmosomal proteins (e.g. desmoglein and desmoplakin),

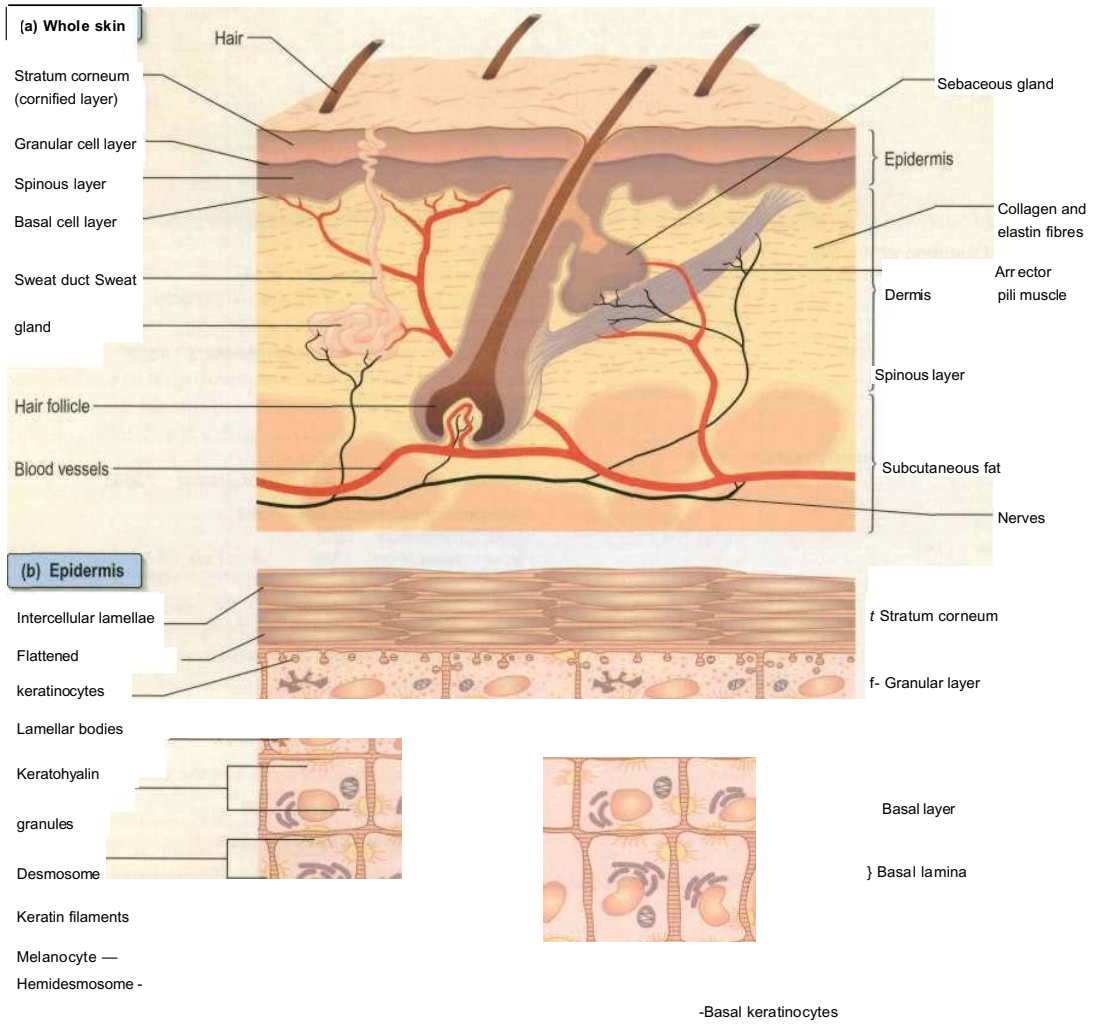

Fig. 23.1 **The structure of the skin.**

O

Box 23.1 **Functions of the skin**

Physical barrier against friction and shearing forces « Protection against infection (immune and innate), chemicals, ultraviolet irradiation *w* Prevention of excessive water loss or absorption
- Ultraviolet-induced synthesis of vitamin D
- Temperature regulation
- Sensation (pain, touch and temperature)

Si Antigen presentation/immunological reactions/wound healing

which make up the 'cytoskeleton'. This confers strength to the epidermis and prevents it shedding off. Higher up in the granular layer, complex lipids are secreted by the keratinocytes and these form into intercellular lipid bilayers which act as a semipermeable skin barrier. The upper cells (stratum corneum) lose their nuclei and become surrounded by a tough impermeable 'envelope' of various proteins (loricrin, involucrin, filaggrin and keratin). Changes in lipid metabolism and protein expression in the outer layers allow normal shedding of keratinocytes.

Keratinocytes can secrete a variety of cytokines (e.g. interleukins, gamma-interferon, tumour necrosis factor alpha) in response to tissue injury or in certain skin diseases. These play a role in specific immune function, cutaneous inflammation and tissue repair. There is a further layer of protection against microbial invasion, called the innate immune system of the skin. This includes neutrophils and macrophages as well as keratinocyte-produced antimicrobial peptides (called fi-defensins and cathelicidins). Expression of these peptides is both constitutive and induced by skin inflammation, and they are active against bacterial, viral and fungal pathogens. There is evidence to suggest a deficiency of these peptides may account for the susceptibility of patients with atopic eczema to skin infection.

Other cells in the epidermis

Melanoq/tes are found in the basal layer and secrete the pigment melanin. These protect against UV irradiation.

Racial differences are due to variation in melanin production not melanocyte numbers.

Merkel cells are also found in the basal layer and originate from either neural crest or epidermal keratinocytes. They are numerous on finger tips and in the oral cavity and play a role in sensation.

Langerhans' cells are dendritic cells found in the suprabasal layer. They derive from the bone-marrow and as they express the cytokine CCR6, they are guided to normal skin, which contains a CCR6 agonist called macrophage inflammatory protein 3a. Langerhans' cells endocytose extracellular antigens in the skin and then migrate to local lymph nodes for T cell presentation and thus act as antigen-presenting cells.

Basement membrane zone (see Fig. 23.27)

The basement membrane zone is a complex proteinaceous structure consisting of type IV and VII collagen, hemidesmosomal proteins, integrins and laminin. Collectively they hold the skin together keeping the epidermis firmly attached to the dermis. Inherited or autoimmune-induced deficiencies of these proteins can cause skin fragility and a variety of blistering diseases (see p. 1346).

The dermis

The dermis is of mesodermal origin and contains blood and lymphatic vessels, nerves, muscle, appendages (e.g. sweat glands, sebaceous glands and hair follicles) and a variety of immune cells such as mast cells and lymphocytes. It is a matrix of collagen and elastin in a ground substance.

The sweat glands

Eccrine sweat glands are found throughout the skin except the mucosal surfaces.

Apocrine sweat glands are found in the axillae, anogenital area and scalp and do not function until puberty.

The sweat glands and vasculature are involved in temperature control.

The sebaceous glands

These are inactive until puberty. They are responsible for secreting sebum or grease onto the skin surface (via the hair follicle) and are found in high number on the face and scalp.

Nerves

The skin is richly innervated. These fibres allow sensation of touch, pain, itch, vibration and change in temperature.

Hair

Hairs arise from a downgrowth of epidermal keratinocytes into the dermis. The hair shaft has an inner and outer root sheath, a cortex and sometimes a medulla. The lower portion of the hair follicle consists of an expanded bulb (which also contains melanocytes) surrounding a richly innervated and vascularized dermal papilla. The hair regrows from the bulb after shedding. There are three types of hair:

- *terminal* - medullated coarse hair, e.g. scalp, beard, pubic
- *vellus* - non-medullated fine downy hairs seen on the face of women and in prepubertal children
- *lanugo* - non-medullated soft hair on newborns (most marked in premature babies) and occasionally in people with anorexia nervosa.

All hair follicles follow a growth cycle: anagen (growth phase), catagen (involution phase), telogen (shedding phase). At any one time most hairs (> 90%) will be in the anagen phase, which is typically 3-5 years for scalp hair. Grey hair is due to decreased tyrosinase activity in the hair bulb melanocytes. White hair is due to total loss of these melanocytes.

Nails

Nails are tough plates of hardened keratin which arise from the nail matrix (just visible as the moon-shaped lunula) under the nail fold. It takes 6 months for a fingernail to grow out fully and 1 year for a toe-nail.

The subcutaneous layer

The subcutaneous layer consists predominantly of adipose tissue as well as blood vessels and nerves. This layer provides insulation and acts as a lipid store.

APPROACH TO THE PATIENT

The *history* should aim to elicit the following points:

time course of rash
distribution of lesions
symptoms (e.g. itch or pain)
family history (especially of atopy and psoriasis)
drug/allergy history
past medical history
provocating factors (e.g. sunlight or diet)
previous skin treatments.

Examination entails looking at and feeling a rash (for terminology, see Table 23.1). It should include an assessment of nails, hair, and mucosal surfaces, even if these are recorded as unaffected. The following terms are used to describe distribution: flexural, extensor, acral (hands and feet), symmetrical, localized, widespread, facial, unilateral, linear, centripetal (trunk more than limbs), annular and reticulate (lacy network or mesh like).

Investigation. With regard to investigation, clinical acumen remains the most useful tool in dermatology but a variety of tests are useful in confirming a diagnosis (Table 23.2).

Table 23.1 **Morphological description of skin lesions**

Atrophy	Thinning of the skin
Bulla	A large fluid-filled blister
Crusted	Dried serum or exudate on the skin
Ecchymosis	Large confluent area of purpura ('bruise')
Erosion	Denuded area of skin (partial epidermal loss)
Excoriation	Scratch mark
Fissure	Deep linear crack or crevice (often in thickened skin)
Lichenified	Thickened epidermis with prominent normal skin markings
Macule	Flat, circumscribed non-palpable lesion
Nodule	Large papule (> 0.5 cm)
Papule	Small palpable, circumscribed lesion (< 0.5 cm)
Petechia	Pinpoint-sized macule of blood in the skin
Plaque	Large flat-topped, elevated, palpable lesion
Purpura	Larger macule or papule of blood in the skin which does not blanch on pressure
Pustule	Yellowish white pus-filled lesion
Scaly	Visible flaking and shedding of surface skin
Telangiectasia	Abnormal visible dilatation of blood vessels
Ulcer	Deeper denuded area of skin (full epidermal and dermal loss)
Vesicle	A small fluid-filled blister
Weal	Itchy raised 'nettle rash'-like swelling due to dermal oedema

INFECTIONS

BACTERIAL INFECTIONS (see also P 62)

The skin's normal bacterial flora prevents colonization by pathogenic organisms. A break in epidermal integrity by trauma, leg ulcers, fungal infections (e.g. athlete's foot) or abnormal scaling of the skin (e.g. in eczema) can allow infection. If reinfection occurs this may be due to asymptomatic nasal carriage of bacteria or the presence of other infected close contacts.

Table 23.2 **Investigations used in skin disorders**

Test	Use	Clinical example
Skin swabs	Bacterial culture	Impetigo
Blister fluid	Electron microscopy and viral culture	Herpes simplex
Skin scrapes	Fungal culture	Tinea pedis
	Microscopy	Scabies
Nail sampling	Fungal culture	Onychomycosis
Wood's light	Fungal fluorescence	Scalp ringworm
		Erythrasma
Blood tests	Serology	Streptococcal cellulitis
	Autoantibodies	Discoid lupus erythematosus
	HLA typing	Dermatitis herpetiformis
	DNA analysis	Epidermolysis bullosa
Skin biopsy	Histology	General diagnosis
	Immunohistochemistry	Cutaneous lymphoma
	Immunofluorescence	Immunobullous disease
	Culture	Mycobacteria/ fungi
Patch tests	Allergic contact eczema	Hand eczema
Urine	Dipstick (glucose)	Diabetes mellitus
	Cytology (red cells)	Vasculitis
Dermatoscopy (direct microscopy of skin)	Assessment of pigmented lesions	Malignancy

Impetigo

Impetigo is a highly infectious skin disease most common in children (Fig. 23.2). It presents as weeping, exudative areas with a typical honey-coloured crust on the surface. It is spread by direct contact. The term 'scrum pox' is impetigo spread between rugby players. Group A (3 haemolytic streptococci and staphylococci are the causative agents: skin swabs should be taken. *Bullous impetigo* is caused by bacterial toxins (exfoliation A and B) from *Staphylococcus aureus.*

Treatment

Localized disease is treated with topical fucidic acid and mupirocin is used for MRS A (three times daily). The antiseptic povidone iodine is used to soften crusts and exudates for 1 week. Extensive disease is treated with oral antibiotics for 7-10 days (flucloxacillin 500 mg four times daily for *Staphylococcus;* penicillin V 500 mg four times daily for *Streptococcus).* Other close contacts should be examined, and children should avoid school for 1 week after starting therapy. If impetigo appears resistant to treatment or is

Fig. 23.2 Impetigo - crusted blistering lesions on the chin.

Fig. 23.3 Erythrasma of the axilla, showing pink fluorescence under a Wood's lamp.

recurrent, take nasal swabs and check other family members. Nasal mupirocin (three times daily for 1 week) is useful to eradicate nasal carriage in hospitals.

Cellulitis

Cellulitis presents as a hot, sometimes tender area of confluent erythema of the skin owing to infection of the deep subcutaneous layer. It often affects the lower leg, causing an upwards-spreading, hot erythema, and occasionally will blister, especially if oedema is prominent. It may also be seen affecting one side of the face. Patients are often unwell with a high temperature. It is usually caused by a streptococcus or a staphylococcus. In the immunosuppressed or diabetic patient, Gram-negative organisms or anaerobes should be suspected. There may be an obvious portal of entry for infection such as a recent abrasion or a venous leg ulcer. The web spaces of the toes should be examined for evidence of fungal infection. Skin swabs are usually unhelpful. Confirmation of infection is best done serologically by streptococcal litres (antistreptolysin O titre (ASOT) and ADB).

Erysipelas is the term used for a more superficial infection (often on the face) of the dermis and upper subcutaneous layer that clinically presents with a well-defined edge. However, both erysipelas and cellulitis overlap, so it is often impossible to make a meaningful distinction.

Necrotising fasciitis: (see p. 64).

Treatment

Treatment is with penicillin V (or erythromycin) and flucloxacillin (all 500 mg four times daily). If disease is advanced, treatment may need to be given intravenously for 3-5 days followed by 1-2 weeks of oral therapy. Treat any identifiable underlying cause. If cellulitis is recurrent, low-dose antibiotic prophylaxis (e.g. penicillin V 500 mg twice daily) should be given, as each episode will cause further lymphatic damage.

Ecthyma

Ecthyma is also an infection due to *Streptococcus* sp. or *Staphylococcus aureus* or occasionally both. It presents as chronic well-demarcated, deeply ulcerative lesions sometimes with an exudative crust. It is commoner in developing countries, being associated with poor nutrition and hygiene. It is rare in the UK but is seen more commonly in intravenous drug abusers and people with HIV.

Treatment is with penicillin V and flucloxacillin (both 500 mg four times daily) for 10-14 days.

Erythrasma

Erythrasma is caused by *Corynebacterium minutissimum.* It usually presents as an orange-brown flexural rash, and is often seen in the axillae or toe web spaces (Fig. 23.3). It is frequently misdiagnosed as a fungal infection. The rash shows a dramatic coral pink fluorescence under Wood's (ultraviolet) light.

Treatment is with topical fucidin three times daily for 7 days or oral erythromycin 500 mg four times daily for 7-10 days.

Folliculitis

Folliculitis is an inflammation of the hair follicle. It presents as itchy or tender papules and pustules. *Staphylococcus aureus* is frequently implicated. It is commoner in humid climates and when occlusive clothes are worn. A variant occurs in the beard area (called 'sycosis barbae') which is commoner in black Africans. This is probably caused by the ability of shaved hair to grow back into the skin, especially if the hair is naturally curly. Extensive, itchy folliculitis of the upper trunk and limbs should alert one to the possibility of underlying HIV infection. Folliculitis following exposure in hot tubs is due to pseudomonas ovale.

Treatment is with topical antiseptics, topical antibiotics (e.g. fucidin) or oral antibiotics (e.g. flucloxacillin 500 mg or erythromycin 500 mg both four times daily for 2-4 weeks).

Boils (furuncles)

Boils are a rather more deep-seated infection of the skin, often caused by *Staphylococcus.* These can cause painful red swellings. They are commoner in teenagers and often recurrent. Recurrent boils may rarely occur in diabetes mellitus or in immunosuppression. Large boils are sometimes called 'carbuncles'.

Treatment is with oral antibiotics (e.g. erythromycin 500 mg four times daily for 10-14 days) and occasionally by incision and drainage. Antiseptics such as povidone iodine, chlorhexidine (as soap) and a bath oil (e.g. Oilatum plus™) can be useful in prophylaxis.

Hidradenitis suppurativa

This is a rare condition characterized by a painful, discharging, chronic inflammation of the skin at sites rich in apocrine glands (axillae, groins, natal cleft). The cause is unknown but it is commoner in females, and within some families it appears to be inherited in an autosomal dominant fashion. Clinically it presents after puberty with papules, nodules and abscesses which often progress to cysts and sinus formation. With time, scarring may arise. The condition follows a chronic relapsing/remitting course and is often worse in obese individuals.

Treatment is very difficult but weight loss, antibiotics, oral retinoids and co-cyprindiol ('2 mg cyproterone acetate + 35 ug ethinylestradiol' in females only) have been tried. They should be used as for acne vulgaris (p. 1338). Severe recalcitrant cases have been treated occasionally with surgery and skin grafting and more recently intravenous infliximab, a monoclonal antibody (p. 498).

This is a superficial infection of the horny layer of the skin caused by a *Corynebacterium.* It frequently involves the sole of the forefoot and appears as numerous small punched-out circular lesions of a rather macerated skin (e.g. as seen after prolonged immersion). There may be an associated hyperhidrosis of the feet and a prominent odour.

Treatment. Topical antibiotics (e.g. fucidin or clindamycin, applied three times daily for *2-4* weeks) and topical anti-sweating lotions are effective therapies.

Erysipeloid

This is a very rare infection due to *Erysipelothnx insidiosa.* It is seen in people who handle raw meat (especially pork) and fish. The organism gains entry through breaks in the skin. It presents as a spreading well-demarcated purplish red lesion, usually on the fingers, hands or forearms. There are no systemic symptoms.

Treatment is with penicillin V or oxytetracycline (both 500 mg four times daily for 7-10 days).

MYCOBACTBRfAL INFECTIONS

Leprosy (Hansen's disease) (p. 80)

Leprosy usually involves the skin, and the clinical features depend on the body's immune response to the organism *Mycobacteriunt leprae.*

Indeterminate leprosy is the commonest clinical type, especially in children. This presents as hypopigmented or erythematous circular macules with occasional mild anaesthesia and scaling. This may resolve spontaneously or progress to one of the other types. Biopsy reveals a perineural granulomatous infiltrate and scant acid-fast bacilli.

Tuberculoid leprosy presents with a few hypopigmented or erythematous plaques with an active erythematous, raised rim. Lesions are usually markedly anaesthetic, dry and hairless reflecting the nerve damage. Nerves may be enlarged and palpable. Biopsy shows a granulomatous infiltrate centred on nerves, but no organisms.

Lepromatous leprosy presents with multiple inflammatory papules, plaques and nodules. Loss of the eyebrows ('madarosis') and nasal stuffiness are common. Skin thickening and severe disfigurement may follow. Anaesthesia is much less prominent. Biopsy shows numerous acid-fast bacilli.

Diagnosis and treatment are discussed on page 81.

Skin manifestations of tuberculosis

Tuberculosis can occasionally cause skin manifestations:

- *Lupus vulgaris* usually arises as a post-primary infection. It usually presents on the head or neck with red-brown nodules which look like apple jelly when pressed with a glass slide. They heal with scarring, and new lesions slowly spread out to form a chronic solitary erythematous plaque. Chronic lesions are at high risk of developing squamous cell carcinoma.
- *Tuberculosis verrucosa cutis* arises in people who are partially immune to tuberculosis but who suffer a further direct inoculation in the skin. It presents as warty lesions on a 'cold' erythematous base.
- *Scrofuloderma* arises when an infected lymph node spreads to the skin causing ulceration, scarring and discharge.
- *The tuberculides* are a group of rashes caused by an immune manifestation of tuberculosis rather than direct infection. Erythema nodosum is the commonest and is discussed on page 1341. Erythema induratum ('Bazin's disease') produces similar deep red nodules but these are usually found on the calves rather than the shins and they often ulcerate. .-.-.■-

Atypical mycobacteria

Atypical (non-tuberculous) mycobacteria can occasionally infect the skin. *Mycobacterium marinum* is found in fish tanks and occasionally swimming pools. It can gain access via a break in the skin and then causes deep granulomatous nodules, often in a linear fashion.

VIRAL INFECTIONS

Viral exanthem

This, probably the commonest type of virally induced rash, presents clinically as a widespread non-specific erythematous maculopapular rash. It probably arises because of circulating immune complexes of antibody and viral antigen localizing to dermal blood vessels. The rash can be caused by many different viruses (e.g. echo-, parvo-, human herpes virus-6, Epstein-Barr virus; see p. 47) and so is rarely diagnostic. The rash will resolve spontaneously in 7-10 days.

Slapped cheek syndrome (erythema infectiosum, fifth disease)

This affects children and is caused by parvovirus B19 (see p. 48). It is a mild viral illness which is followed by an intense erythema on the cheeks ('slapped cheeks') and a reticulate erythema on the proximal limbs.

Herpes simplex virus (see also p. 43)

Herpes simplex virus (HSV) occurs as two genomic subtypes. HSV type 1 is spread by direct contact and droplet infection. Most people are affected in early childhood but the infection is usually subclinical. Occasionally it can cause a self-limiting pyrexial primary illness with either clusters of painful blisters on the face or a painful gingivostomatitis. Once infected, cell-mediated immunity develops. In some individuals this response is poor and they may get recurrent attacks of HSV, often manifest as cold sores. Immunosuppression can also cause a recrudescence of HSV. HSV can also autoinnoculate into sites of trauma and present as painful blisters/pustules. For example they may be seen on the fingers of healthcare workers ('herpetic whitlow').

HSV type 2 infections occur mainly after puberty and usually affect the genital area. Infections are often symptomatic and transmitted sexually. However, HSV type 1 can also be found in the genital area due to orogenital contact.

Other rare complications of HSV infection include corneal ulceration, eczema herpeticum (p. 1327), chronic perianal ulceration in AIDS patients and erythema multiforme (p. 1342).

Treatment

Oral valaciclovir (500 mg twice daily for 5 days) is used for primary HSV and painful genital HSV. Recurrent cold sores are treated with aciclovir cream but this must be used early to be effective in shortening an attack. Attacks of genital herpes become less frequent with time. Intravenous aciclovir must be used in immunosuppressed patients.

Varicella zoster virus

Varicella zoster virus (VZV) causes the common childhood infection called chickenpox. It is discussed on page 45. It also causes herpes zoster.

Fig. 23.4 Herpes zoster in an African (courtesy of Dr P Matondo, Lusaka, Zambia).

Herpes zoster (shingles)

'Shingles' results from a reactivation of the VZV. It may be preceded by a prodromal phase of tingling or pain, which is then followed by a painful and tender blistering eruption in a dermatomal distribution (Fig. 23.4 and Fig. 2.15, p. 46). The blisters occur in crops, may become pustular and then crust over. The rash lasts *2-A* weeks and is usually more severe in the elderly. Occasionally more than one dermatome is involved.

Complications of shingles include severe, persistent pain (post-herpetic neuralgia), ocular disease (if ophthalmic nerve involved) and rarely motor neuropathy.

Treatment

Herpes zoster requires adequate analgesia and antibiotics (if secondary bacterial infection is present). Valaciclovir 1 g or famciclovir 500 mg three times daily for 7 days is used, or oral aciclovir 800 mg, five times daily for 7 days helps shorten the attack if given early in the illness. High-dose intravenous aciclovir is needed for immunosuppressed patients. It remains unclear how useful aciclovir therapy is in preventing prolonged post-herpetic neuralgia.

Human papilloma virus

Human papilloma virus (HPV) is responsible for the common cutaneous infection of 'viral warts'. There are more than 70 subtypes as detected by DNA hybridization. All can cause overgrowth of differentiated squamous epithelium.

Common warts are papular lesions with a coarse roughened surface, often seen on the hands and feet, but also on other sites. Small black dots (bleeding points) are often seen within the lesion (Fig. 23.5). Children and adolescents are usually affected. Spread is by direct contact and is also associated with trauma.

Plantar warts (verrucae) is the term used for lesions on the soles of the feet. They often appear flat ('inward

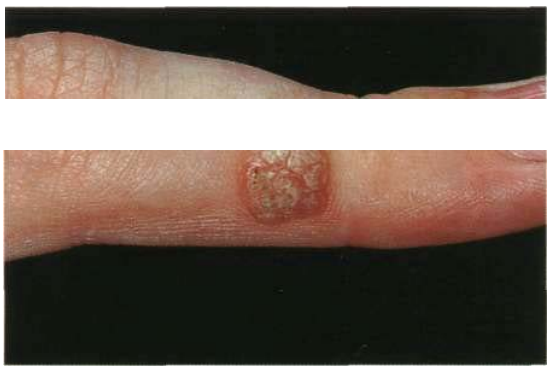

Fig. 23.5 **Viral wart.**

growing') although they have the same papillomatous surface change and black dots are often revealed if the skin is pared down (unlike callosities). Warts may be painful or tender if they are over pressure points or around nail folds.

Filiform warts occur on the face, at the nasal vestibule or around the mouth. They are elongated with a horny cap.

Plane warts are much less common and are caused by certain HPV subtypes. They are clinically different and appear as very small, flesh-coloured or pigmented, flat-topped lesions (best seen with side-on lighting) with little in the way of surface change and no black dots within them. They are usually multiple and are frequently found on the face or the backs of the hands.

Anogenital warts are usually seen in adults and are normally transmitted by sexual contact. They are rare in childhood and, whilst child sex abuse should always be considered, it should be remembered they may well have been transmitted through non-sexual contact. HPV subtypes 16 and 18 are potentially oncogenic and are associated with cervical and anal carcinomas.

Treatment

Common warts on the skin are surprisingly difficult to treat effectively but they almost always resolve spontaneously after months to years (with no scarring), presumably because of cell-mediated immune recognition. When they do resolve, they tend to do so rapidly within a few days.

Regular use of a topical keratolytic agent (e.g. 2-10% salicylic acid) over many months with weekly paring of the lesion helps speed up resolution in some patients and remains the mainstay of treatment. A course of cryotherapy (freezing) can also help. Cautery, surgery, carbon dioxide laser, alpha-interferon injection and bleomycin injection have all been used with variable success but are not recommended, as treatments may be very painful and can cause permanent scarring. Experimental usage of a complex of oc-lactalbumin and oleic acid (human cx-lactalbumin made lethal to tumour cells - HAMLET) is promising.

Genital warts (see p. 126) are usually treated with either cryotherapy, trichloracetic acid, 5% imiquimod cream or topical podophyllin. Patients with genital warts (and their sexual partners) must be screened for other sexually transmitted diseases.

Molluscum contagiosum ('water blisters')

Molluscum contagiosum is a common cutaneous infection of childhood caused by a pox virus. The virus can be seen in the fluid under EM. Clinically, lesions are multiple, small (1-3 mm) translucent papules which often look like fluid-filled vesicles but are in fact solid. Individual lesions may have a central depression called a punctum. They exhibit the Kobner phenomenon (p. 1332). They can occur at any body site including the genitalia. Transmission is by direct contact. Occasionally lesions may be up to 1 cm in diameter ('giant molluscum'). They are said to be more extensive in children with atopic eczema, which may just reflect that scratching aids their spread.

They usually continue to occur in crops over 6-12 months and rarely require treatment as they spontaneously resolve. Any form of localized trauma, including scratching, helps speed up resolution and cryotherapy may be considered in an older child. Molluscum in an adult, especially if giant, should raise the underlying possibility of immunosuppression, especially HIV infection.

Orf

Orf is a disease of sheep (and occasionally goats) due to a pox virus infection. It causes a vesicular and pustular rash around the mouths of young lambs. People who come into contact with the affected fluid may develop lesions on the hands. Clinically they appear as 1-2 cm reddish papules with a surrounding erythema which usually become pustular. The lesion(s) resolves spontaneously after 4-6 weeks and immunity lasts lifelong. Occasionally orf is complicated by erythema multiforme (p. 1342).

FUNGAL INFECTIONS

Fungi are primitive, saprophytic organisms found throughout our environment. Fungal skin disease (mycosis) has a high prevalence in humans, with 'thrush' and 'athlete's foot' being two of the commonest examples. In the immunosuppressed, mycoses can be widespread and life-threatening. There are three groups of pathogenic fungi that commonly affect the outer layer of skin or keratinizing epithelium: dermatophytes, *Candida albicans* and pityrosporum.

Dermatophyte infection

By definition, dermatophytes cause a 'ringworm' type of rash. The three main genera responsible are *Trichophyton, Microsporum* and *Epidermophyton.* These organisms are identified by microscopy and culture of skin, hair or nail samples. The clinical appearance of mycoses depends in

Fig. 23.6 Tinea cruris - ringworm of the groin.

part on the organism involved, the site affected and the host reaction. All are spread by direct contact from other humans or from infected animals. The use of communal showers and swimming baths and the sharing of towels or sportswear aids indirect fomite transmission.

Tinea corporis

Ringworm of the body usually presents with slightly itchy, asymmetrical, scaly patches which show central clearing and an advancing, scaly, raised edge. Occasionally vesicles or pustules may be seen in the edge. Central clearing is not a universal feature and it is recommended that all asymmetrical scaly lesions should be scraped for fungus. Ringworm of the face (tinea faciei) often arises after the use of topical steroids. It tends to be more erythematous and less scaly than trunk lesions and it may become itchy after sun exposure.

Tinea cruris

Ringworm of the groin is extremely common world-wide. Early on, the lesions appear as well-demarcated red plaques with an arc-like border extending down the upper thigh (Fig. 23.6). Central clearing may appear and a few pustules or vesicles may be seen if inflammation is intense. Satellite lesions, suggestive of *Candida,* are not present.

Tinea pedis

Athlete's foot may be confined to the toe clefts, where the skin looks white, macerated and fissured. It may also be more diffuse, usually causing a diffuse scaly erythema of the soles, spreading on to the sides of the foot. Annular lesions are rare and can be misdiagnosed. There may be an associated hyperhidrosis and fungal involvement of one or more toe-nails. In severe infection, a strong inflammatory reaction can occur causing pustules or blistering and this often leads to a misdiagnosis of pompholyx-type

Tinea manuum

Ringworm of the hands also presents with a diffuse erythematous scaling of the palms with variable skin peeling and skin thickening. Annular lesions are rare at this site.

Tinea capitis

The fungus is either within the hair shaft (endothrix) or spread out over the hair surface (ectothrix). The latter can cause fluorescence under a Wood's lamp (ultraviolet light). Scalp ringworm is spread by close contact (especially in schools and households) and may also be spread indirectly by hairdressers. The number of new cases has risen enormously in the large cities in developed countries. Increase in travel and immigration has allowed the spread of different pathogenic fungi (e.g. *Trichophyton tonsurans* from Central America, *Trichophyton violaceum* from India and Pakistan) into new countries where there is overcrowding and poor social conditions. The majority of UK cases are due to *T. tonsurans* (which does not show fluorescence).

Tinea capitis is much commoner in children, especially those of black African origin, whose scalp and hair seems more susceptible to fungal invasion. The clinical appearance of scalp ringworm is highly variable from a mild diffuse scaling with no hair loss (similar to dandruff) to the more typical appearance of circular scaly patches in the scalp with associated alopecia and broken hairs. As the hosts immune response increases, a few pustules may appear and an exudate may be present. At worst, a full-blown 'kerion' develops; a boggy swollen mass with copious quantities of discharging pus and exudate accompanied by severe alopecia. This is still poorly recognized and inappropriately treated with antibiotics and attempted surgical drainage.

Extensive infection is occasionally accompanied by a widespread papulopustular rash on the trunk. This is a so-called 'Id reaction' and probably relates to the host immune response to the fungus. It seems commoner in black African children. It resolves when the fungal infection is treated.

Tinea unguium

Ringworm of the nails is increasingly common with age and frequently ignored as it is often asymptomatic. Clinically this presents as asymmetrical whitening (or yellowish black discoloration) of one or more nails, which usually starts at the distal or lateral edge before spreading throughout the nail (Fig. 23.7). The nail plate appears

Fig. 23.7 Dermatophyte infection of the nail showing white crumbling dystrophy.

thickened. Crumbly white material appears under the nail plate and this is the best specimen to obtain for mycology sampling. The nail plate may become destroyed with advanced disease.

'Tinea incognito'

This is the term used to describe a fungal skin infection that has been modified by therapy with a topical steroid. The clinical appearance is variable but may show a non-specific erythema with little in the way of scaling or a few reddish nodules. The history of the rash improving with steroid treatment (owing to the suppression of inflammation) but worsening and spreading every time it is stopped is typical. Skin scrapings for mycology or even a biopsy should confirm the diagnosis.

Treatment

Localized ringworm of the body or flexures is treated with topical antifungal creams (clotrimazole, miconazole, terbinafine or amorolofine applied three times daily for 1-2 weeks). More widespread infection, including tinea pedis, tinea manuum and tinea capitis, requires oral antifungal therapy. Itraconazole (100 mg daily) and terbinafine (250 mg daily) are the most effective drugs used for periods of 1-2 months, but are not licensed for use in children. High-dose griseofulvin is still used in children for scalp ringworm (15-20 mg/kg per day for 8 weeks).

Tinea unguium of the toe-nails is the most resistant to treatment. Itraconazole (100 mg daily or 200 mg twice daily for 1 week per month 'pulsed therapy') or terbinafine (250 mg daily) given for 3 months will cure up to about 80% of cases.

Candida albicans (see also p. 91)

Candida albicans is a yeast that is sometimes found as part of the body's flora, especially in the gastrointestinal tract. It acts as an opportunist, taking hold in the skin when there is a suitable warm moist environment such as in nappy rash (p. 1362) or intertrigo in obese individuals (Fig. 23.8).

The flexural areas affected are red with a rather ragged peeling edge that may contain a few small pustules. Small circular areas of erythema or small papules and pustules may be seen in front of the advancing edge (satellite lesions). *Candida* may also affect the moist interdigital clefts of the toes and mimic tinea pedis. In people who have their hands immersed frequently in water (e.g. cleaners, nurses) *Candida* may cause infection in the macerated skin of the finger web spaces or the damaged skin around the nail folds ('chronic paronychia'). Nail infection may mimic tinea unguium. It can infect mucosal surfaces of the mouth or genital tract. This tends to occur in patients taking broad-spectrum antibiotics (due to suppression of protective bacterial flora) or in immunosuppressed patients. Clinically superficial white or creamy pseudomembranous plaques appear which can be scraped off leaving raw areas underneath.

Fig. 23.8 Intertrigo with satellite lesions typical of candidiasis.

Treatment

Treatment is aimed at removing any underlying predisposing factor and applying topical antifungal creams, e.g. clotrimazole or miconazole (or the equivalent as mouth lozenges/pessaries). *Candida* nail infections require systemic antifungal therapy with an imidazole such as itraconazole (100 mg daily for 3 months). Recurrent candidiasis is relatively common, especially in women. Diabetes mellitus should always be excluded. Repeated topical treatment or an oral imidazole may be needed.

Pityrosporum

This yeast occurs as part of the normal flora of human skin. Colonization is prominent in the scalp, flexures and upper trunk. There are two morphological variants called *Pityrosporum ovale* and *Pityrosporum orbiculare,* and the mycelial form of this yeast is called *Malassezia furfur. Pityrosporum* can overgrow in some individuals and has been implicated in three dermatoses:

- pityriasis versicolor
- seborrhoeic eczema (p. 1329)
- pityrosporum folliculitis.

Pityriasis versicolor

This is a relatively common condition of young adults caused by infection with *Pityrosporum.* In Caucasians it presents most commonly on the trunk with reddish brown scaly macules which are asymptomatic. In black-skinned individuals (or in whites who are sun-tanned) it more commonly presents as macular areas of hypopigmentation. Inappropriate use of topical steroids tends to spread the rash.

Diagnosis can be confirmed by skin scrapings or Wood's light examination (yellow fluorescence).

Treatment is with selenium sulphide shampoo (apply to body and remove after 30 minutes and repeat daily for 1 week) or a topical imidazole cream (twice daily for 10 days). Oral itraconazole (100 mg twice daily for 1 week) can be used for resistant cases. The pigmentation takes months to recover even after successful treatment. The condition may recur but can be retreated.

Pityrosporum folliculitis

This is common in young adult males and characterized by small itchy papules and pustules on the upper back which are centred on hair follicles. It is commoner in people with Down's syndrome. It responds well to ketoconazole shampoo or a topical imidazole cream (twice daily for 2 weeks).

JN^SWIONS _____ _____ _____

Scabies

Scabies is an intensely itchy rash caused by the mite *Sarcoptes scabiei*. It can affect all races and people of any social class. It is most common in children and young adults but can affect any age group. There are 300 million cases of scabies in the world each year. It is commoner in poorer countries with social overcrowding.

Scabies is spread by prolonged close contact such as within households or institutions, and by sexual contact. It presents clinically with itchy red papules (or occasionally vesicles and pustules), which can occur anywhere in the skin but rarely on the face, except in neonates. The distribution of lesions is often suggestive of the diagnosis (Fig. 23.9). Sites of predilection are between the web spaces of the fingers and toes, on the palms and soles, around the wrists and axillae, on the male genitalia, and around the nipples and umbilicus.

Fig. 23.9 Scabies - itchy papules and pustules centred on the web spaces of the hand.

The pathognomonic sign is of linear or curved skin burrows but these are not always present. The pruritus is normally worse at night. Excoriations and secondary bacterial infection may complicate the rash. Scabies can be confirmed by taking skin scrapings of a lesion and examining a potassium hydroxide preparation for the mite and/or its eggs by microscopy.

Treatment

This involves application of a topical scabicide (e.g. 5% permethrin or malathion). For the treatment to be successful the following factors should be noted:

- All the skin below the neck should be treated, including the genitalia, palms and soles, and under the nails. Treat the head and neck regions in infants (up to age 2 years).
- All close contacts should be treated at the same time even if asymptomatic.
- Reapply scabicide to the hands if they are washed during the treatment period.
- Patients should be warned that the pruritus may persist for up to 4 weeks after successful treatment. Adjunct treatment with crotamiton cream, an emollient or a mild topical steroid is helpful.
- A patient information leaflet about therapy helps improve compliance.

Benzyl benzoate is still used occasionally but it can be very irritant. Lindane is a cheap therapy which is still used in many countries but there are concerns about resistance to this drug and possible neurotoxic side-effects.

Crusted scabies (Norwegian scabies)

Crusted scabies is a clinical variant that occurs in immunosuppressed individuals where huge numbers of mites are carried in the skin. Patients are not always itchy but they are extremely infectious after relatively minimal contact, which is unfortunate as the diagnosis is often delayed. Clinically this presents as hyperkeratotic crusted lesions, especially on the hands and feet. Lesions may progress such that the patient has a widespread erythema with irregular crusted plaques. It can therefore mimic infected eczema or psoriasis. .: - . , . . .

Treatment is with careful barrier nursing, repeated applications of a scabicide and, in resistant cases, oral ivermectin (100-200 (ig/kg - two doses 1 week apart) may be given but this is an unlicensed use. ■. ■ ■-. . -:,

Lice infection

Lice are blood-sucking ectoparasites that can affect man in three ways.

Head lice (pediculosis capitis)

Head lice is a common infection world-wide, afferiing predominantly children and being commoner in females. Spread is by direct contact and encouraged by overcrowding. It usually presents with itch or scalp

excoriations. Occasionally, erythematous papules on the neck may be seen.

Diagnosis can be confirmed by the presence of eggs ('nits') seen tightly bound to the hair shaft. Adult lice may be seen rarely in heavy infection. School nurses and parents are usually adept at this.

Treatment. Eradication is difficult because of non-compliance as well as resistance patterns. Malathion, carbaryl or permethrin applications (two applications 7 days apart) are the most commonly used. Nit combing of wet hair is not as effective as chemical treatment. District policies of rotating insecticides are outmoded. If one treatment fails, a different insecticide is used for the next course in an individual. Treatment is usually repeated after 7 days and metal nit combs may help remove the eggs. Some areas in the UK have given up with specific anti-lice treatments but have a policy of treating schools and family members with regular nit-combing, shampooing and conditioning of the hair. However, a recent study showed that chemical therapies are more effective than physical treatments, but more studies are needed.

Body lice (pediculosis corporis)

Body lice is a disease of poverty and neglect. It is rarely seen in developed countries except in homeless individuals and vagrants. It is spread by direct contact or sharing infested clothing. The lice and eggs are rarely seen on the patient but are commonly found on the clothing. It presents with itch, excoriations and sometimes post-inflammatory hyperpigmentation of the skin.

Treatment consists of malathion or permethrin for the patient and high-temperature washing and drying of clothing.

Pubic lice (crabs, phthiriasis pubis)

Pubic lice are transmitted by direct contact, usually sexual. It presents with itching, especially at night. Lice can be seen near the base of the hair with eggs somewhat further up the shaft. Occasionally eyebrows, eyelashes and the beard area are affected.

Treatment is as for head lice but all sexual contacts should be treated and other sexually transmitted diseases should be screened for. Pubic lice of the eyelashes is treated with white soft paraffin three times daily for 1-2 weeks.

Arthropod-borne diseases ('insect bites' or papular urticaria)

These depend on contact with an animal (e.g. dog, cat, bird) that is infected with fleas *('Ctenocephalides')* or on bites from flying insects (e.g. midges, mosquitoes). In the case of flea bites the animal itself may be itchy with scaly and thickened skin. These fleas can also live in soft furnishings (e.g. carpets and beds) even after the animal has been removed. Bites present as itchy urticated lesions which are often grouped in clusters. The legs are most commonly affected. It is not unusual for an individual to react badly to bites when other family members seem unaffected. Anti-flea treatment of the animal **and** furnishings is required. Insect repellents and appropriate clothing help reduce bites from flying insects.

PAPULO-SQUAMOUS/ INFLAMMATORY RASHES

ECZEMA

The term 'eczema' derives from **the** Greek word **for** 'boiling', which reflects that the skin can become so acutely inflamed that fluid weeps out or vesicles appear. It is synonymous with the term dermatitis and the two words are interchangeable. In the developed world eczema accounts for a large proportion of skin disease, both in hospital and community-based populations. It is estimated that 10% of people have some form of eczema at any one time, and up to 40% of the population will have an episode of eczema during their lifetime.

All eczemas (see Table 23.3) have some features in common and there is a spectrum of clinical presentation from acute through to chronic. Vesicles or bullae may appear in the acute stage if inflammation is intense. In subacute eczema the skin can be erythematous, dry and flaky, oedematous, and crusted (especially if secondarily infected). Chronic persistent eczema is characterized by thickened or lichenified skin. Eczema is nearly always itchy. Histologically 'eczematous change' refers to a col-

Table 23.3 **Classification of eczema**

Endogenous	Exogenous
Atopic eczema Discoid eczema Hand eczema Seborrhoeic eczema Venous ('gravitational') eczema Asteatotic eczema	Contact eczema - irritant Contact eczema - allergic Photosensitive eczema Lichen simplex/nodular prurigo

lection of fluid in the epidermis between the keratinocytes ('spongiosis') and an upper dermal perivascular infiltrate of lymphohistiocytic cells. In more chronic disease there is marked thickening of the epidermis ('acanthosis').

Atopic eczema

This type of eczema (often called 'endogenous eczema') occurs in individuals who are 'atopic' (p. 912). It is common, occurring in up to 5% of the UK population. It is commoner in early life, occurring at some stage during childhood in up to 10-20% of all children.

Aetiology

The exact pathophysiology is not fully understood but there is a selective activation of Th2-type CD4 lymphocytes in the skin which drives the inflammatory process. In at least 90% of cases there is a raised serum total IgE level. Atopic eczema is a genetically complex, familial disease with a strong maternal influence. A positive family history of atopic disease is often present: there is a 90% concordance in monozygotic twins but only 20% in dizygotic twins. If one parent has atopic disease the risk for a child of developing eczema is about 20-30%, and 50% if both parents are affected. Genetic studies in atopy have so far shown linkage to several different loci where pathologically relevant candidate genes exist: e.g. the (i-subunit of the high-affinity IgE receptor (Ilql3); Th2 cytokine genes (5q31-33); the a-subunit of IL-4 (16ql2); and RANTES (17qll). Both eczema and psoriasis have been linked to chromosome Iq21 and 17q25, suggesting common candidate genes controlling skin inflammation. Genetic heterogeneity is likely and it may be that certain genes are more involved in developing eczema rather than asthma, and other genes may be significant in determining severity of the disorder or age of onset. The disease is also significantly influenced by environmental factors.

Exacerbating factors

Infection either in the skin or systemically can lead to an exacerbation, possibly by a superantigen effect. Paradoxically, lack of infection (in infancy) may cause the immune system to follow a Th-2 pathway and allow eczema to develop (the so-called 'hygiene hypothesis'). Strong detergents, chemicals and even woollen clothes can be irritant and exacerbate eczema. Teething is another factor in young children. Severe anxiety or stress appear to exacerbate eczema in some individuals. Cat and dog fur can certainly make eczema worse, possibly by both allergic and irritant mechanisms. The role of house dust mite and diet is less clear cut. There is some evidence that food allergens may play a role in triggering atopic eczema and that dairy products may exacerbate eczema in a few selected infants under 12 months of age.

Clinical features

Atopic eczema can present as a number of distinct morphological variants. The commonest presentation is of itchy erythematous scaly patches, especially in the flexures such as in front of the elbows and ankles, behind the knees (Fig. 23.10) and around the neck. In infants eczema often starts on the face before spreading to the body. Very acute lesions may weep or exude and can show small vesicles. Scratching can produce excoriations, and repeated rubbing produces skin thickening (lichenification) with exaggerated skin markings.

Fig. 23.10 Atopic eczema behind the knees.

In patients with pigmented skin, eczema often shows a reverse pattern of extensor involvement. Also, the eczema may be papular or follicular in nature and lichenification is common. A final problem in pigmented skin is of post-inflammatory hyper- or hypopigmentation which is often very slow to fade after control of the eczema.

Associated features

Involvement of the nail bed may produce pitting and ridging of the nails. In some atopic individuals the skin of the upper arms and thighs may feel roughened because of follicular hyperkeratosis ('keratosis pilaris'). The palms may show very prominent skin creases ('hyperlinear palms'). There may be an associated dry 'fish-like' scaling of the skin which is non-inflammatory and often prominent on the lower legs ('ichthyosis vulgaris').

Complications

Broken skin commonly becomes secondarily infected by bacteria. This is usually due to *Staphylococcus aureus* although streptococci can colonize eczema, especially in macerated flexural areas such as the neck and groin. Clinically this infection may appear as crusted, weeping impetigo-like lesions. Occasionally *Pseudomonas* can be grown from skin swabs but this rarely causes a clinical problem. Cutaneous viral infections (e.g. viral warts and molluscum) are often widespread in atopic eczema and are probably spread by scratching. HSV can cause a widespread eruption called eczema herpeticum (Kaposi's varicelliform eruption). This can occasionally be a very severe infection and rarely can be fatal. This appears as multiple small blisters or punched-out crusted lesions associated with malaise and pyrexia, and needs rapid treatment with oral (or intravenous if severe) aciclovir. Ocular complications of atopic eczema include conjunctival

irritation and less commonly keratoconjunctivitis and cataract. Retarded growth may be seen in children with chronic severe eczema; it is due to the disease itself and not the use of topical steroids.

Investigations

The diagnosis of atopic eczema is normally clinical. Atopy is characterized by high serum IgE levels or high specific IgE levels to certain ingested or inhaled antigens. The latter can be tested by radio-immunoabsorbent assay (RAST tests) of blood, or indirectly by skin prick testing (p. 918). A peripheral blood eosinophilia may also be

Prognosis

The majority (90%) of children with early-onset atopic eczema will spontaneously improve and 'clear' before the teenage years, 50% being clear by the age of 6. A few will get a recurrence as adults, even if just as hand eczema. However, if the onset of eczema is late in childhood or in adulthood, the disorder follows a more chronic remitting/relapsing course.

Treatment (Box 23.2)

General measures

These include avoiding known irritants (especially soaps or furry animals), wearing cotton clothes, and not getting too hot. Manipulating the diet (e.g. dairy-free diet) is rarely beneficial except in children under 12 months with a hereditary risk of eczema. Any change in diet should be done under supervision, especially with growing children who may need supplements such as calcium.

Topical therapies

Topical therapies (p. 1364) are sufficient to control atopic eczema in most people. The 'triple' combination of topical steroid, frequent emollients (see Table 23.16) and bath oil and soap substitute (e.g. aqueous cream) helps.

Written information or a practical demonstration of how to apply these treatments improves compliance.

Use of topical Steroids. Unjustified fear about the dangers of topical steroids has often led to under-treatment of eczema. Providing appropriate-strength steroid preparations are used for the right body site, these compounds can be used quite safely on a long-term intermittent basis. Topical steroids can be divided into five groups depending on their potency (Table 23.4).

Table 23.4 **Classification of topical steroids by potency**

Very potent	0.05% clobetasol propionate 0.3% diflucortolone valerate 0.1%
Potent	betamethasone valerate 0.025% fluocinolone acetonide 0.025%
Diluted potent	betamethasone valerate 0.00625% fluocinolone acetonide 0.05%
Moderately potent	clobetasone butyrate 0.05% alclometasone dipropionate 2.5%
Mild	hydrocortisone 1 % hydrocortisone

The following guidelines should be followed to allow their safe use in common chronic inflammatory skin conditions.

- The face should be treated with mild steroids.
- In adults the body should be treated with either mild, moderately potent or diluted potent steroids.
- In young children the body should be treated with mild and moderately potent steroids.
- Potent steroids may be used for short courses (7-10 days).
- Treatment of the palms and soles (but not the dorsal surfaces) may require potent or very potent steroids as the skin is much thicker.
- Regular use of emollients may lessen the need for steroid use.
- Only use steroids on inflamed skin. Do not use as an emollient.
- 'Apply sparingly' means use sufficient to leave a glistening surface to the skin after application.
- Use weaker steroid preparations in flexures (e.g. the groin, and under breasts) as apposition of the skin at these sites tends to occlude the treatment and increase absorption.

Topical immunomodulators

Tacrolimus ointment (0.1% and 0.03%) and the less potent pimecrolimus (a skin-selective inflammatory cytokine inhibitor) cream have recently been licensed for atopic eczema in patients over 2 years old. They have the advantage over potent steroids of not causing atrophy and are thus very useful for treating sensitive areas such as the face and eyelids. They can be very irritant when first used (although this settles with continued use) and 9% of patients develop flushing after alcohol. The long-term side-effects remain unknown. They do not work so well on lichenified eczema, probably because of poor absorption. Current advice is to avoid vaccinations and sun exposure when using these agents. The milder potency steroid creams should still be considered as first-line therapy but tacrolimus is a useful alternative to excessive use of potent steroids.

Box 23.2 **Management of atopic eczema**

Education and explanation
Avoidance of irritants/allergens
Emollients
Bath oils/soap substitutes
Topical therapies:
- steroids
- immunomodulators

Adjunct therapies:
- oral antibiotics
- sedating antih/stamines
- bandaging

Phototherapy/systemic therapy (for severe cases)

Antibiotics

These are needed for bacterial infection and are usually given orally for 7-10 days. Flucloxacillin (500 mg four times daily) is effective against *Staphylococcus,* and penicillin V (500 mg four times daily) acts against *Streptococcus.* Erythromicin (500 mg four times daily) is useful if there is allergy to penicillin. Topical antiseptics may be useful in cases of recurrent infection but they can be irritant. They are usually added to the bath water rather than directly onto the skin. Combination topical steroid/antibiotic creams are used for short periods but there is little evidence that they are better than topical steroids alone.

Sedating antihistamines

These (e.g. oral hydroxyzine 25 mg) are useful at night-time. They help by their sedative properties, not by their antihistamine activity.

Bandaging

Paste bandaging can be useful for resistant or lichenified eczema of the limbs. It helps absorption of treatment and acts as a barrier to prevent scratching. Wet tubular gauze bandages are useful for inpatient therapy but are difficult and time-consuming to use at home.

Second-line agents

These may be considered in severe non-responsive cases, especially if the eczema is significantly interfering with an individual's life (e.g. growth, sleeping, schoolwork or job). Ultraviolet phototherapy (see p. 1339), prednisolone (initial doses up to 30 mg daily), ciclosporin (3-5 mg/kg daily) and azathioprine (1-2 mg/kg daily) (p. 1347) can all be effective treatments. However, they all have side-effects and the risk/benefit ratio must be openly discussed with the patient before they are used.

Use *of ciclosporin.* Ciclosporin is a selective immunosuppressant that inhibits interleukin-2 production by T lymphocytes. A large number of other drugs interact with ciclosporin (e.g. erythromycin, NSAIDs) and should be avoided. Renal damage and hypertension are the two most serious side-effects so blood pressure and serum creatinine should be measured every 6-12 weeks. Creatinine clearance should be measured yearly in people on long-term therapy. Renal damage becomes increasingly common with time and tends to be dose-dependent but is mostly reversible. Hypertrichosis, paraesthesia and nausea are less serious side-effects. Pregnancy should be avoided.

Discoid eczema (nummular eczema)

Discoid eczema is a morphological variant of eczema, characterized by well-demarcated scaly patches especially on the limbs, and this can be confused sometimes with psoriasis. It is commoner in adults and can occur in both atopic and non-atopic individuals. It tends to follow an acute/subacute course rather than a chronic pattern. There is often an infective component *(Staphylococcus aureus).*

Fig. 23.11 **Pompholyx eczema** (courtesy of Dr A Bewley, London).

Hand eczema

Eczema may be confined to the hands (and feet). It can present with:

- itchy vesicles or blisters of the palm and along the sides of the fingers (also called 'pompholyx') (Fig. 23.11)
- a diffuse erythematous scaling and hyperkeratosis of the palms
- a scaling and peeling most marked at the finger tips.

Hand eczema is not unusual in atopies but more frequently occurs in non-atopic individuals, and a cause is not always found. A history of contact with irritants (e.g. detergents, chemicals) and an occupational history should be sought, especially in finger-tip eczema. Patch testing for specific allergic or contact eczema should always be considered, as up to 10% of individuals with hand eczema will show a positive test. Finally look for evidence of fungal infection, as this can occasionally induce a secondary pompholyx of the hands or feet (a so-called 'Id reaction').

Seborrhoeic eczema

Aetiology

Overgrowth of *Pityrosporum ovale* (also called *Malassezia furfur* in its hyphal form) together with a strong cutaneous immune response to this yeast produces the characteristic inflammation and scaling of seborrhoeic eczema. The condition is more common in parkinsonism as well as in HIV disease.

Clinical features

Seborrhoeic eczema affects body sites rich in sebaceous glands, although these do not appear to be involved in its cause. Three age groups are affected:

- *In childhood* it is common and presents in the first few months of life as 'cradle cap' in most babies. This may in part be due to the effect of maternal androgens on infant sebaceous glands. Yellowish, greasy, thick crusts are seen on the scalp. A more widespread erythematous, scaly rash can be seen over the trunk,

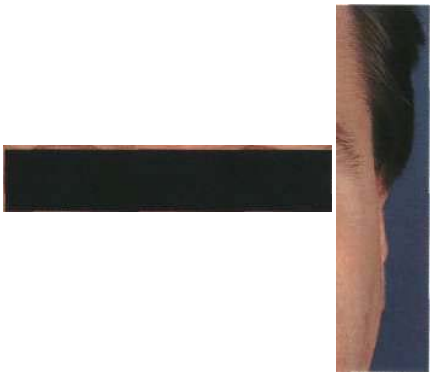

Fig. 23.12 Seborrhoeic eczema affecting the sides of the nose.

especially affecting the nappy area. Unlike with atopic eczema, the child is normally unbothered as there is little associated pruritus. The rash normally improves spontaneously after a few weeks.

- *In young adults* (especially males) it occurs in 1-3% of the population. The rash is more persistent and presents as an erythematous scaling along the sides of the nose (Fig. 23.12), in the eyebrows, around the eyes and extending into the scalp (which shows marked dandruff). It affects the skin over the sternum, axillae and groins, and the glans penis. A blepharitis may also be present.
- *In elderly people* seborrhoeic eczema can be more severe and progress to involve large areas of the body and even cause erythroderma.

Treatment

This is suppressive rather than curative. A combination of a mild steroid ointment (e.g. 1% hydrocortisone applied twice daily) and a topical antifungal cream (e.g. miconazole cream applied twice daily) will help to control the eruption. Two per cent sulphur or 2% salicylic acid can be added to help control resistant cases. Recent studies have shown 0.1% tacrolimus ointment to be very effective. Ketoconazole shampoo and arachis oil are useful for the scalp. Emollients and a soap substitute are useful adjuncts.

Venous eczema (varicose eczema, gravitational eczema)

This type of eczema occurs on the lower legs because of chronic venous hypertension (usually of more than 2 years' duration) (see p. 1353). The exact cause remains unknown but it has been suggested that venous hypertension causes endothelial hyperplasia and extravasation of red and white blood cells, which in turn causes inflammation, purpura and pigmentation.

Clinical features

Venous eczema tends to occur in older people, especially women. It usually appears on the lower legs around the ankles. There may be a past history of venous thrombosis or previous surgery for varicose veins. Brownish pigmentation (haemosiderin) is seen in the skin and a venous leg ulcer or varicose veins may be present.

Superimposed contact eczema is common in venous eczema patients, especially when there have been chronic venous leg ulcers. This is usually due to an allergic reaction to topical therapies or skin dressings. Patch testing is useful in treatment-resistant cases.

Treatment

This should include emollients and a moderately potent topical steroid. Support stockings or compression bandages, together with leg elevation, help reverse the underlying venous hypertension (p. 1353).

Asteatotic eczema (winter eczema, eczema craquele, senile eczema)

This is a dry plate-like cracking of the skin with a red, eczematous component which occurs in elderly people. It occurs predominantly on the lower legs and the backs of the hands, especially in winter. The exact cause is unknown but the repeated use of soaps in the elderly may be causal. The loss of the stratum corneum lipids with age may also be of some relevance. Rarely, asteatotic eczema can be the presenting sign of myxoedema or can follow the commencement of diuretic therapy.

Treatment

Avoiding soaps, and the regular use of emollients and bath oils should be encouraged. Humidifying centrally heated rooms may help. If the skin is very inflamed, a mild topical steroid can be used.

Contact and irritant eczema

These types of eczema can be caused by many environmental agents (exogenous eczema); they are often in an unusual or localized distribution (Fig. 23.13). There is no personal or family history of atopic disease. A history of an exacerbation of eczema at the workplace is also

Fig. 23.13 Contact eczema secondary to perfume allergy.

suggestive. This can happen by two mechanisms: direct irritation or an allergic reaction (type IV delayed hypersensitivity, p. 226). A detailed history of occupation, hobbies, cosmetic products, clothing and contact with chemicals is necessary.

Allergic contact eczema occurs after repeated exposure to a chemical substance but only in those people who are susceptible to develop an allergic reaction. It is common, occurring in up to 4% of some populations. Many substances can cause this type of reaction but the commoner culprits are nickel (in costume jewellery and buckles), chromate (in cement), latex (in surgical gloves), perfume (in cosmetics and air fresheners), and plants (such as primula or compositae). A good history is necessary and if suspicious, patch testing should be arranged to prove any allergy.

Irritant contact eczema can occur in any individual. It often occurs on the hands after repeated exposures to irritants such as detergents, soaps or bleach. It is therefore common in housewives, cleaners, hairdressers, mechanics and nurses.

Treatment

Treatment is as for atopic eczema as well as strict avoidance of any causative agent. This may also involve the wearing of protective clothing such as gloves, or in extreme cases (such as with chromate sensitivity in builders) even changing occupation or hobbies.

Photosensitive eczema

This is discussed on page 1340.

Lichen simplex/nodular prurigo (neurodermatitis)

These two terms are applied to a pattern of cutaneous response to scratching or rubbing in the absence of an underlying dermatosis. They are more common in Asians and also in black African and Oriental patients.

Lichen simplex appears as thickened, scaly and hyperpigmented areas of lichenification (Fig. 23.14). It starts with intense itching that becomes tender with increased rubbing or scratching. It is rare before adolescence and is commoner in females. Common sites are the nape of the neck, the lateral calves, the upper thighs, the upper back and the scrotum or vulva but any accessible site can be affected.

Fig. 23.14 Lichen simplex from chronic rubbing.

Nodular prurigo is a different pattern of cutaneous response to scratching, rubbing or picking. Individual, itchy papules and domed nodules appear especially on the upper trunk and the extensor surfaces of the limbs. They show significant surface damage from scratching. This is a chronic unremitting condition which is often resistant to treatment

These two conditions overlap, with some patients showing mixed features. Atopic individuals seem predisposed to develop these conditions (in the absence of obviously active eczema). However, they can occur in non-atopies. Emotional stress appears to be a contributory factor in many of these patients.

The diagnosis is made by exclusion of other pathologies and may require a skin biopsy. General medical causes of pruritus should be excluded (p. 1344). In the elderly, nodular prurigo may be an early sign of bullous pemphigoid, before the more typical blistering phase has appeared.

Treatment

Treatment is often difficult as symptoms can be intractable. Very potent topical steroids (e.g. 0.05% clobetasol propionate) with occlusive tar bandaging sometimes help. Intralesional steroids can also be useful but there is a risk of atrophy. For resistant cases (especially of prurigo lesions), phototherapy (p. 1339) and even ciclosporin (3-5 mg/kg/day) can be used but the risk/benefit ratio must be discussed with the patient as these therapies are potentially toxic.

PSORIASIS

Psoriasis is a common papulo-squamous disorder affecting 2% of the population and is characterized by well-demarcated, red scaly plaques. The skin becomes inflamed and hyperproliferates to about 10 times the normal rate. It affects males and females equally and can affect all races. The age of onset occurs in two peaks. Early onset (age 16-22) is commoner and is often associated with a positive family history. Late-onset disease peaks at age 55-60 years.

Aetiology

The condition appears to be polygenic but is also dependent on certain environmental triggers. Twin studies show 73% concordance in monozygotic twins compared with 20% of dizygotic pairs. Five genetic regions (on chromosomes 6-21p, 17q, 4q, lq and 3q) have been linked to psoriasis but as yet no genes have been identified. Infection (group A *Streptococcus),* drugs (e.g. lithium), *ultraviolet light, alcohol abuse and possibly* stress may trigger or exacerbate disease in certain individuals. The exact aetiology is unknown but it is likely that psoriasis is a T-lymphocyte driven disorder to

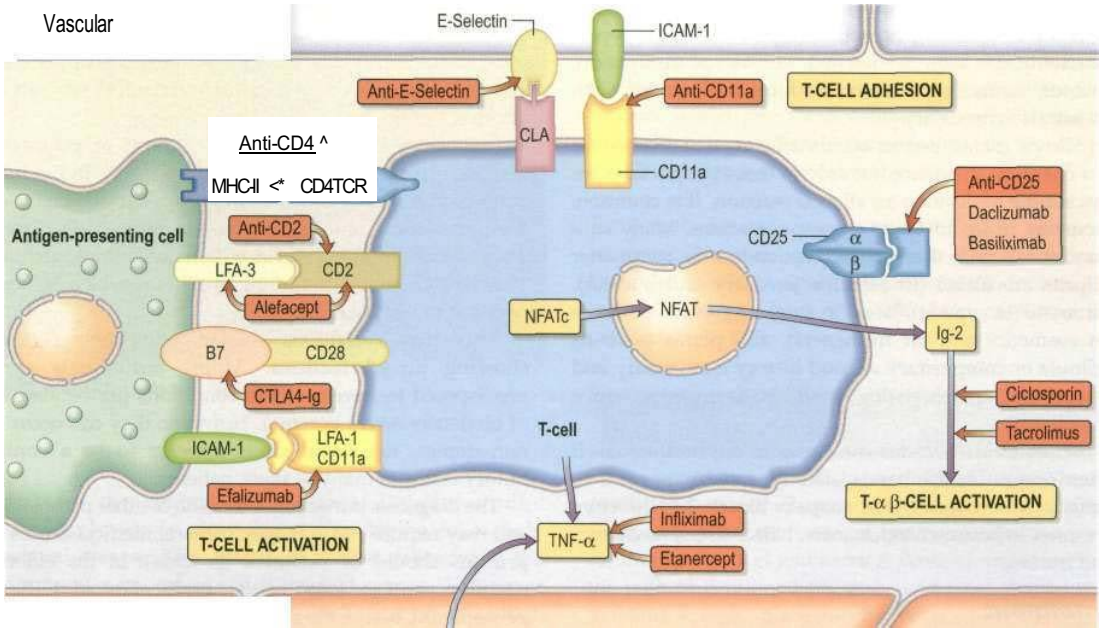

Fig. 23.15 **Psoriasis - pathogenesis.** The figure shows the interaction of T cells with antigen-presenting cells and keratinocytes. Novel T-cell-targeted therapies are shown (red). NFAT, nuclear factor of activated T cells; ICAM, intracellular adhesion molecule; LFA, lymphocyte function-associated antigen; MHC, major histocompatibility complex; TNF, tumour necrosis factor; IL, interleukin; CLA, cutaneous lymphocyte antigen; B7 = CD80.

an unidentified antigen(s) with a possible altered response from the keratinocyte (Fig. 23.15). The initial T cell activation requires a complex interaction between T lymphocyte and antigen-presenting cell and this has provided a number of potential 'targets' for the newly developed biological therapies. This activation results in upregulation of Thl-type T cell cytokines, e.g. gamma-interferon (INF-y), interleukins (IL-1, -2, -8), growth factors (TGF-a and TNF-a) and adhesion molecules (ICAM-1) and these are all potential therapeutic targets. The cytokine TNF-a is also produced by keratinocytes and this may be involved in both initiation and maintenance of psoriatic lesions. TNF-a blockade seems to be the most promising of the new biological agents (see Fig. 23.15).

Pathology

Skin biopsy shows acanthosis and parakeratosis, reflecting the increase in skin turnover. The granular layer is often absent. Polymorphonuclear abscesses may be seen in the upper epidermis. The epidermal rete ridges appear elongated and clubbed as they fold down into the dermis. Dermal changes include capillary dilatation surrounded by a mixed neutrophilic and lymphohistiocytic peri vascular infiltrate.

Clinical features

Psoriasis can present in different clinical patterns but there is an overlap between the different forms. Certain drugs can make psoriasis worse - notably lithium, antimalarials and rarely beta-blockers.

Chronic plaque psoriasis

This is the 'common' type of psoriasis. It is characterized by pinkish red scaly plaques, especially on extensor surfaces such as knees (Fig. 23.16a) and elbows. The lower back, ears and scalp are also commonly involved. New plaques of psoriasis occur at sites of skin trauma - the so-called Kobner phenomenon. The lesions can become itchy or sore.

Flexural psoriasis

This tends to occur in later life. It is characterized by well-demarcated, red glazed plaques confined to flexures such as the groin, natal cleft and sub-mammary area. As these sites are apposed there is rarely any scaling. In the absence of psoriasis elsewhere the rash is often mis-diagnosed as Candida intertrigo but the latter will normally show satellite lesions.

Guttate psoriasis

'Raindrop-like' psoriasis is a variant most commonly seen in children and young adults (Fig. 23.16b). An explosive eruption of very small circular or oval plaques appears over the trunk about 2 weeks after a streptococcal sore throat.

Erythrodermic and pustular psoriasis

These are the most severe types oi psoriasis *reflecting 3* widespread intense inflammation of the skin. They can occur together ('Von Zumbusch' psoriasis) and may be associated with malaise, pyrexia and circulatory disturb-

Fig. 23.16 **(a) Psoriasis of the knees. (b) Guttate psoriasis in an African** (courtesy of Dr P Matondo, Lusaka, Zambia).

ance. This form can be life-threatening. The pustules are not infected but are sterile collections of inflammatory cells. There is also a more localized variant of pustular psoriasis that confines itself to the hands and feet (palmo-plantar psoriasis) but is not associated with severe systemic symptoms. This latter type is more common in heavy cigarette smokers.

Associated features

Nails. Up to 50% of individuals with psoriasis develop nail changes (Fig. 23.17) and, rarely, these can precede the onset of skin disease. There are five types of nail change: (a) pitting of the nail plate; (b) distal separation of the nail plate (onycholysis); (c) yellow-brown discoloration; (d) subungual hyperkeratosis; (e) rarely, a damaged nail matrix and lost nail plate. Treatment of nail dystrophy is very difficult.

Arthritis. From 5-10% of individuals develop psoriatic arthritis and most of these will have nail changes.

Treatment

This is concerned with control rather than cure. It should

Fig. 23.17 **Psoriasis of the nail** - yellowish brown discoloration and distal nail plate separation (onycholysis).

be tailored to the patient's wishes and not just to the doctor's assessment of disease severity. Treatments include topical agents (dithranol, tar, calcipotriol, tazarotene and corticosteroids), UVB and PUVA therapy (p. 1340) and systemic immunosuppressive/immuno-modulating agents. Severe cases may require inpatient treatment.

Chronic plaque psoriasis: emollients should always be used to hydrate the skin. Mild to moderate topical steroids, synthetic vitamin D_3 analogues (e.g. calcipotriol, calcitriol, tacalcitol), 0.05% tazarotene (a vitamin A antagonist, i.e. a retinoid) and purified coal tar are the most popular specific therapies. Salicylic acid can be a useful adjunct. All should be applied once to twice daily to palpable lesions. Once lesions have flattened, therapy can be discontinued. Dithranol can also be helpful but it causes staining of the skin and clothing and it may prove difficult to use at home on a regular basis. It is normally applied for 20-60 minutes and then washed off. It must be applied carefully to the lesions as it causes irritation to normal skin. Dithranol is more likely to induce remission than other topical therapies. Tazarotene and calcipotriol can be very irritant (calcitriol somewhat less so) so they are often used in combination with steroid creams. Vitamin D analogues should be used with caution in erythrodermic or pustular psoriasis because of hypercalcaemia.

Topical therapies are sometimes used in combination with UVB or PUVA. The 'Goeckerman regimen' consists of tar and UVB; the 'Ingram's regimen' consists of dithranol and UVB. The latter has similar results to oral PUVA in terms of clearance rates and lengths of remission - approximately 75% in 6 weeks.

Flexural psoriasis is usually treated with mild steroid and/or tar topical creams. Calcitriol and 0.1% tacrolimus ointment are also useful for treating flexural (facial and genital) psoriasis where irritation can be a problem.

Guttate psoriasis is usually treated with topical therapies and/or UVB phototherapy.

Palmo-plantar psoriasis is treated with very potent topical steroids, coal tar paste or local hand and foot PUVA.

Systemic therapy (such as methotrexate, acitretin, mycophenolate, ciclosporin or hydroxycarbamide (hydroxyurea)) are used for resistant cases.

Erythrodermic psoriasis also requires systemic therapy (but not phototherapy) as well as general supportive measures (p. 1341).

All systemic treatments must be monitored for toxicity.

Use *Of methotrexate.* Methotrexate is normally given once weekly. Some patients experience severe nausea on the day they take it, which can be lessened by folic acid therapy. Both males and females should avoid conception during and for 3 months after therapy. Some patients are allergic to methotrexate and develop a pyrexia and mouth ulceration. Regular blood tests need to be done to monitor for bone marrow suppression and liver damage. Alcohol must be avoided as this increases the risk of hepatotoxicity. NSAIDs should also be avoided as these inhibit renal excretion. Lower doses should be used in the elderly. Long-term users will need either a liver biopsy every 2-3 years to monitor for hepatic damage or, if available, regular monitoring of their serum procollagen III peptide. Patients with concomitant psoriatic arthritis are more likely to develop pulmonary fibrosis.

Biological agents (see Fig. 23.15)

A large number of specific biological agents are being developed but only one is licensed in the UK for use in cutaneous psoriasis. They show variable efficacy and all need to be given by injection. All are prohibitively expensive.

The *TNF-a blockers* infliximab, adalimumab and etanercept (p. 563) seem to be the most effective with almost 60-80% of patients having at least a 75% improvement within 12 weeks. Many of the other agents show a disappointing lower efficacy with only 30-50% of patients showing such improvement, i.e. less than with phototherapy or methotrexate. Alefacept (a fusion protein of LFA-3 and IgG which binds to CD2) was the first biological agent to be licensed for cutaneous psoriasis, but so far only in the USA. Efalizumab is now licensed in Europe.

Long-term side-effects of these new biological agents are unknown. Infection (especially reactivation of tuberculosis) and increased malignant disease (such as skin cancer and lymphoma) remain real concerns. It seems sensible to restrict these new therapies to those patients who have failed to respond to (or cannot tolerate because of toxicity) all the conventional systemic treatments.

Prognosis

Most individuals who develop chronic plaque psoriasis will have the condition lifelong but 80% will get a remission at times. It fluctuates in severity and there are no available tests to predict outcome. Guttate psoriasis resolves spontaneously over 1—2 months and in up to a third of individuals does not recur. However, two-thirds will go on to get recurrent guttate attacks or will progress to chronic plaque psoriasis.

Fig. 23.18 Urticaria.

URTICARIA

Urticaria (hives, 'nettle rash') is a common skin condition characterized by the acute development of itchy weals or swellings in the skin because of leaky dermal vessels (Fig. 23.18). Urticaria is described as 'acute' if it lasts less than 6 weeks and 'chronic' if it persists beyond this.

Aetiology

The final event in pathogenesis involves degranulation of cutaneous mast cells, which releases a number of inflammatory mediators (including histamine) that in turn make the dermal capillaries leaky. In most cases the underlying cause is unknown. Occasionally urticaria is secondary to viral or parasitic infection, drug reactions (e.g. aspirin or penicillin allergy), food allergy (e.g. to strawberries, food colourings or seafood), or rarely systemic lupus erythematosus. There is evidence for an autoimmune aetiology in some of the 'idiopathic' cases as certain individuals develop autoantibodies against the high-affinity IgE receptor a-subunit of the mast cell. Urticaria is commoner in atopic individuals and usually presents in children and young adults.

Clinical features

The history is of cutaneous swellings or weals developing acutely over a few minutes. They can occur anywhere on the skin and last between minutes and hours before resolving spontaneously. Lesions are intensely itchy and show no surface change or scaling. Lesions are normally erythematous but if very acutely swollen, they may appear flesh-coloured or whitish and people often mistake them for blisters. Severe urticaria with subcutaneous involvement can present as soft tissue swelling (angio-oedema) especially around the eyes, the lips and the hands. This can be very alarming to the patient. It can also be dangerous if mucosal areas such as the mouth and larynx are involved but fortunately this is very rare.

Physical urticarias

Occasionally urticaria can be caused by physical stimuli such as cold (cold urticaria), deep pressure (delayed pressure urticaria), stress or heat (cholinergic urticaria),

sunlight (solar urticaria, p. 1340), water (aquagenic urticaria) or chemicals such as latex (contact urticaria).

Cholinergic urticaria is one of the commonest physical urticarias and has rather different clinical lesions from the other forms. Small itchy papules rather than weals appear on the upper trunk and arms after exercise or anxiety.

Pressure can cause two types of urticaria. More superficial pressure can cause *dermographism,* which is relatively common. This presents as urticated weals occurring a few minutes after application of light pressure. Even scratching or rubbing will bring up linear weals in dermographic individuals. *Delayed pressure urticaria* is rare and occurs as deep swellings some hours after pressure is removed (e.g. on the soles of the feet or under a tight belt).

Investigations

The history is often the best guide to determining the cause of urticaria. Investigation is probably not justified unless the history suggests one of the underlying causes listed above. The physical urticarias should be reproducible by applying the relevant stimulus.

Treatment

Any identifiable underlying cause should be treated. Patients should avoid salicylates and opiates as they can degranulate mast cells. Oral antihistamines (H_1 blockers) are the most useful in treating idiopathic cases. Therapy should be started with regular use of a non-sedating antihistamine (e.g. cetirizine 10 mg daily or loratadine 10 mg daily). If control proves difficult, addition of a sedating antihistamine or an H_2 blocker may be helpful. Dietary manipulation (e.g. additive and colouring free diets) helps a small proportion of patients with chronic urticaria but it is generally unrewarding. Angio-oedema of the mouth and throat may require urgent treatment with intramuscular epinephrine (adrenaline) and intravenous steroids (see Emergency box 16.1).

Prognosis

Most cases of 'idiopathic' urticaria last a few weeks to months before disappearing spontaneously. A small percentage of people go on to develop chronic urticaria which can last for several months or years. The physical urticarias (especially cholinergic urticaria) are more persistent, often lasting for years, and they are often resistant to therapy.

Urticarial vasculitis

This is a variant of urticaria and should be suspected if individual urticarial lesions last longer than 24 hours and leave bruising behind after resolution. There is often an associated arthralgia or myalgia and a small proportion may go on to develop a connective tissue disease. The diagnosis is confirmed by skin biopsy. A full vasculitis screen should be carried out for an underlying cause (p. 581).

Treatment is with antihistamines, oral dapsone (50-100 mg daily) or immunosuppressants.

Hereditary angio-oedema. This is an extremely rare autosomal dominant condition due to an inherited deficiency of C1-esterase inhibitor, a component of the complement system. The defect may be due to either reduced function or reduced absolute levels. Serum C2 and C4 levels are normally low but C1 and C3 are normal. Rarely this condition is acquired and associated with lymphoma or SLE. These types show low C1 esterase inhibitor levels but also low C1 levels.

Clinical features

It presents with attacks of non-itchy cutaneous angio-oedema (but no urticaria) which may last up to 72 hours. It may also present with recurrent abdominal pain (due to intestinal oedema) and there may be a family history of sudden death (due to laryngeal involvement). A non-specific erythematous rash may precede an attack of angio-oedema but urticaria is not a feature.

Treatment

In the acute setting treatment is with C1 esterase inhibitor concentrates and fresh frozen plasma. Epinephrine (adrenaline) and steroids are often ineffective. Maintenance treatment with the anabolic steroid stanozolol (or danazol) stimulates an increase in hepatic synthesis of C1 esterase inhibitor but this should not be used in children. Family members should be screened.

PITYRIASIS ROSEA

Pityriasis rosea is a self-limiting rash seen in adolescents and young adults. The cause is unknown but it is thought to be viral or post-viral. There is an increased incidence in spring and autumn and outbreaks may occur in institutions.

Clinical features

The rash consists of circular or oval pink macules with a collarette of scale and is more prominent on the trunk than on the limbs. The long axis of the oval lesions tends to run along dermatomal lines giving a 'Christmas tree' pattern on the back. The rash may be preceded by a large solitary patch with peripheral scaling ('herald patch') and this is most commonly found on the trunk. The rash is usually asymptomatic and spontaneously resolves over 4-8 weeks.

Treatment

Treatment is not normally required but 1% menthol in aqueous cream helps relieve any itch. In persistent cases UVB may be helpful.

LICHEN PLANUS

Lichen planus is a pruritic inflammatory dermatosis that is commonly associated with mucosal involvement and rarely with nail dystrophy and scarrii\s* alopecia.

The cause is unknown but a T-cell driven immune mechanism is postulated, as an almost identical rash can be caused by certain drugs (e.g. gold, levamisole,

Fig. 23.19 Lichen planus.

penicillamine or antimalarials) or by graft-versus-host disease.

Pathology

A mixed lymphohistiocytic infiltrate is seen at the dermoepidermal junction, which becomes ragged and saw-toothed. The basal layer shows liquefactive degeneration with the production of colloid bodies in the upper dermis. There may be acanthosis and a hyperkeratosis of the epidermis.

Clinical features

The rash is characterized by small, purple flat-topped, polygonal papules that are intensely pruritic (Fig. 23.19). It is common on the flexors of the wrists and the lower legs but can occur anywhere. There may be a fine lacy white pattern on the surface of lesions (Wickham's striae). Lesions may fuse into plaques, especially on the lower legs and in black Africans. Hyperpigmentation is common after resolution of lesions, especially in patients with pigmented skin. Atrophic, hypertrophic and annular variants can occur. Lichen planus lesions often localize to scratch marks. If lesions occur in the scalp they may cause a scarring alopecia.

Mucosal involvement is common. The mouth is the most commonly affected but the oesophagus and the anogenital region can be involved. It can present as lacy white streaks, white plaques or as ulceration. The prominent mucosal symptom is of severe pain rather than itch. Nails may be dystrophic and can be lost altogether (with scarring and 'wing' formation) in severe disease.

Prognosis

The condition often clears by 18 months but can recur at intervals. The hypertrophic and atrophic variants and mucosal disease are more persistent, lasting years. Ulcerative mucosal disease is premalignant.

Treatment

This requires the use of potent topical steroids (0.05% clobetasol propionate) and occasionally oral prednisolone (30 mg daily for *2-4* weeks). Occlusion of topical treatments can be helpful. Resistant cases may respond to PUVA, oral retinoids (0.5 mg/kg/day) or azathioprine (1-2 mg/kg daily). Topical 0.1% tacrolimus ointment has proved a very useful off-license therapy for painful mucosal disease.

GRANULOMA ANNULARE

Granuloma annulare is a dermatosis predominantly of children and young adults. It is characterized by clusters of small dermal papules (with no surface change) that often form into rings or part of a ring. They are common on the dorsal surface of the hands and feet. They are flesh coloured or slightly erythematous and are usually asymptomatic. As they heal the centre becomes dusky and altered in texture. A deep form, which is tender, exists in children. Diffuse granuloma annulare may be associated with diabetes mellitus. The pathology shows a granulomatous dermal infiltrate with foci of degeneration of collagen (necrobiosis). Spontaneous resolution often occurs but cryotherapy or triamcinolone injection may help localized disease.

LICHEN SCLEROSUS ET ATROPHICUS

Lichen sclerosus et atrophicus is a common inflammatory dermatosis that occurs in all age groups and particularly affects the anogenital region. It is more common in females. It presents with atrophic ivory-white macules with a well-defined edge, on the vulva, glans penis, foreskin or perianal skin. Telangiectasia is seen over the surface. Occasionally lesions involve the shaft of the penis and the urethral meatus. Lesions are often itchy but are sore at times. Long-standing vulval lesions are associated with fissuring and a marked loss of architecture, especially of the clitoral hood and the labium minora, which may become fused. Early lesions in young girls present as haemorrhagic blisters and these are occasionally mistaken as signs of sexual abuse. Involvement of the foreskin can cause phimosis, and urethral disease may interfere with micturition. Perianal lesions can fissure and cause constipation.

Rarely lichen sclerosus can affect non-genital skin. It is most common in females and shows rather more hyperkeratosis and follicular plugging than is seen in the anogenital region.

If the clinical picture is unclear, diagnosis may require biopsy to exclude genital lichen planus and extramammary Paget's disease. Vulval scarring can also occur with cicatricial pemphigoid (p. 1348), so occasionally immunofluorescence studies are needed.

The underlying cause is unknown but HLA associations and recent studies showing antibodies to extracellular matrix protein-1 suggest an autoimmune aetiology.

Treatment with very potent topical steroids helps control the symptoms. Hydroxychloroquine (200 mg twice daily) is used in resistant cases. The condition can burn itself out after many years, especially in children. There is a risk of developing squamous cell carcinoma in long-standing lesions. Male patients may require circumcision if phimosis does not respond to medical therapy.

FACIAL RASHES

Facial rashes often cause diagnostic confusion but a close examination of the clinical signs should help differentiate the underlying cause (Table 23.5). All facial rashes, by virtue of their visibility, can cause significant distress to the patient and this should never be underestimated.

Acne vulgaris

Acne is a common facial rash occurring in adolescence and rarely in early and mid-adult life. The cause is multifactorial but the blockage of pilosebaceous units with surrounding inflammation is the main pathological process and this can be due to a number of different factors (Fig. 23.20a).

Clinical features

Acne presents in areas rich in sebaceous glands such as the face, back and sternal area. The three cardinal features are:

Table 23.5 **Causes of facial rashes**

Acne vulgaris	Perioral dermatitis
Rosacea	Photosensitivity
Seborrhoeic eczema	Sarcoidosis
Atopic eczema	Chronic discoid lupus erythematosus
Contact eczema	Systemic lupus erythematosus Subacute
Dermatomyositis	lupus erythematosus

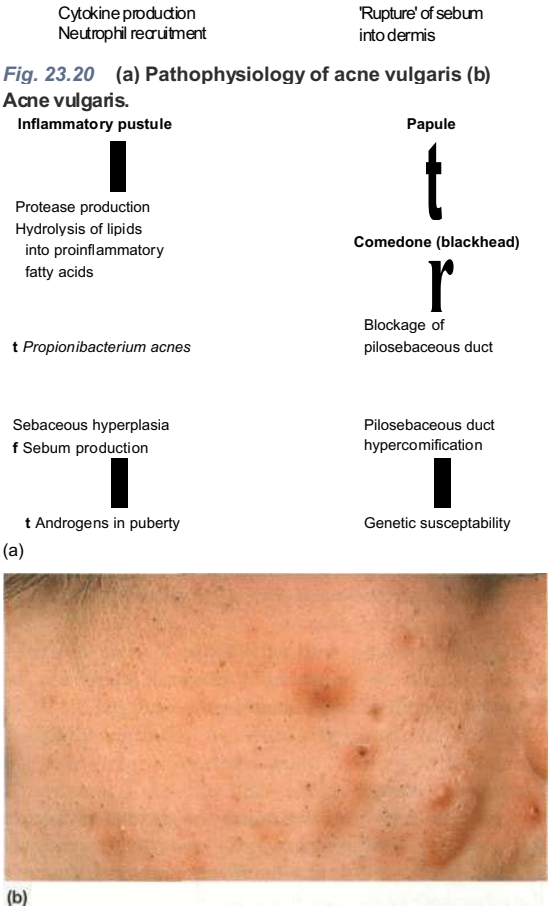

Fig. 23.20 **(a) Pathophysiology of acne vulgaris (b) Acne vulgaris.**

- open comedones (blackheads) or closed comedones (whiteheads)
- inflammatory papules
- pustules (Fig. 23.20b).

The skin may be very greasy (seborrhoea). Rupture of the inflamed lesions may lead to deep-seated dermal inflammation and nodulocystic lesions, which are more likely to cause facial scarring. A premenstrual exacerbation of acne is sometimes noticed. There is a tendency for spontaneous improvement over a number of years but acne can persist unabated into adult life.

A number of clinical variants exist:

- *Infantile acne.* Facial acne is occasionally seen in infants and is sometimes cystic. It is thought to be due to the influence of maternal androgens and resolves spontaneously.
- *Steroid acne.* Acne may occur secondary to corticosteroid therapy or Cushing's syndrome. Comedones and cysts are rare in this variant but involvement of the back and sriouftfers (rather *than (he* race/ is> common. Clinically the rash often appears as a pustular folliculitis.

- *Oil acne.* This is an industrial disease seen in workers who have prolonged contact with oils or other hydrocarbons and is common on the legs and other exposure sites.
- *Acne fulminans.* This is a rare variant seen most commonly in young male adolescents. Severe necrotic and crusted acne lesions appear, associated with malaise, pyrexia, arthralgia and bone pain (due to sterile bone cysts). It requires urgent treatment with oral prednisolone (30^0 mg daily) and analgesics followed by a course of oral isotretinoin (see below).
- *'Follicular occlusion triad'.* This is a rare disorder most commonly seen in black Africans. It is characterized by the presence of severe nodulocystic acne, dissecting cellulitis of the scalp (p. 1361) and hidradenitis suppurativa (p. 1320). It has been suggested that this is caused by a problem of follicular occlusion rather than having an infective aetiology.

Treatment

Treatment is aimed at decreasing sebum production, decreasing bacteria, normalizing duct keratinization or decreasing inflammation.

Regular washing with acne soaps to remove excess grease should be encouraged (normal soaps can be comedogenic). 'Picking' should be discouraged.

First-line therapy

Topical agents are used for mild acne such as antibiotics (tetracycline, clindamycin) and keratolytics (benzoyl peroxide); these are similar in efficacy and the latter have the advantage of not causing antibiotic resistance. Topical retinoids (tretinoin) or retinoid-like agents (adapalene) are also used. If these fail, second-line agents should be added.

Second-line therapy

m *Low-dose oral antibiotic therapy* often helps but must be given for at least 3-4 months. Oxytetracycline 500 mg twice daily is often used first. Minocycline 100 mg daily, erythromycin 500 mg twice daily or trimethoprim 100 mg twice daily is also used.

- An extra treatment 'cyproterone acetate 2 mg/ethinylestradiol 35 |ig' (co-cyprindolj is of value in females if there is no contraindication to oral contraception. This acts as a normal combined contraceptive but has antiandrogen activity. It may take 6-8 months to have its maximum effect.
- *UVB phototherapy* can be helpful but is rarely used now owing to the development of retinoid drugs.

Third-line therapy

Third-line treatment with a retinoid drug (isotretinoin) should be given if:

- the above measures fail
- there is nodulocystic acne with scarring
- there is severe psychological disturbance.

Use *of retinoids (isotretinoin or acitretin).* Retinoids are synthetic vitamin A analogues that affect cell growth and differentiation. They are very teratogenic.

Isotretinoin is a 'hospital-only drug' in most countries because of its teratogenicity and is restricted to the use of dermatologists. A pregnancy test and contraceptive advice are mandatory prior to its use in fertile women, and new UK regulations demand that this is done monthly during treatment. It is given as a 4-month course at a dose of 0.5-1 mg/kg/day. Over 90% of individuals will respond to this therapy and 65% of people will obtain a long-term 'cure'.

Patients must avoid pregnancy during therapy and for 1 month after stopping isotretinoin (but for 2 years after stopping acitretin as it is very lipophilic). Both drugs cause drying of the skin, especially of the lips and nasal mucosa. Hair thinning and exercise-induced myalgia are not uncommon. Blood count, liver function and fasting lipids need to be monitored during therapy. In a few individuals retinoids may cause depression but it should also be remembered that acne itself has been a cause of suicide.

Potential new treatment

A single study has shown pulsed-dye laser therapy to have some benefit in mild to moderate acne but was not curative. Further work is needed to establish its effectiveness, the optimum 'dosing' schedule and long-term safety.

Rosacea

Rosacea (Fig. 23.21) is a common inflammatory rash predominantly affecting the face. The onset is usually in middle age and it is commoner in women. It often causes significant psychological distress.

The cause is unknown. Theories have suggested an underlying problem in vasomotor stability of blood vessels or a role of the skin mite *Demodex* but there is little evidence to confirm these speculations.

Fig. 23.21 Rosacea. Papules and pustules on a background erythema. There are no comedones.

Clinical features

The cardinal features are of facial flushing, inflammatory papules and pustules affecting the nose forehead and cheeks. The flushing may precede the other signs by some years. There are no comedones. Additional features may include dilated blood vessels (telangiectasia), inflammation of the eyelid margins (blepharitis), keratitis and sebaceous gland hypertrophy especially of the nose. The latter is commoner in men and can cause a disfiguring enlargement of the nose called rhinophyma. The flushing may be exacerbated by alcohol, hot drinks, sunlight and changes in ambient temperature. Prolonged use of topical steroids can exacerbate or trigger the condition. As the disease progresses the flushing may be replaced by a permanent erythema.

Treatment

This is suppressive rather than curative. Long-term use of topical 0.075% metronidazole may help. Avoid topical steroids. A 3-month course of oral tetracycline (500 mg twice daily) is also helpful. Oral metronidazole (400 mg twice daily) or oral isotretinoin (0.5-1 mg/kg/day) is occasionally given in resistant cases (p. 1338). The papules and pustules tend to respond best to therapy but repeat courses may be necessary. The flushing and erythema are often resistant to treatment but cosmetic camouflage can be helpful for these features. Intense pulse light or pulsed-dye laser therapy can help the erythema and telangiectasia but often needs to be repeated as they tend to recur. Rhinophyma can be treated with plastic surgery or by carbon dioxide laser.

Perioral dermatitis

Perioral dermatitis is a common rash found around the mouth, especially in young females. The exact cause is unknown but it often has an iatrogenic component as topical steroids often exacerbate the condition in the long term.

Clinical features

It presents with erythema, scaling, papules and occasionally pustules around the mouth. It usually spares a halo of skin immediately adjacent to the lips.

Treatment

Treatment involves stopping topical steroids, although they may have to be withdrawn slowly to prevent too severe a rebound after withdrawal. The mainstay of treatment is with a 3- to 4-month course of low-dose oxytetracycline or erythromycin (both 500 mg twice daily) and topical metronidazole.

PHOTODERMATOLOGY

Sunlight - light in the ultraviolet (UV) part of the spectrum - combines short, medium and long wavelengths (UVC, UVB, and UVA respectively). Both UVB and UVA can penetrate the atmosphere and reach the skin. This light energy is potentially mutagenic and carcinogenic but it can also suppress cutaneous inflammation. Thus UV irradiation can both *cause* skin disease and be used to *treat* it.

Photosensitive rashes usually appear on sites exposed to the sun's rays, such as the face, the anterior 'V of the chest, the ears and the backs of the hands. Certain 'protected' areas are characteristically spared such as under the chin or the upper eyelid and between the finger webs. Porphyria, drug sensitivity and lupus erythematosus should be excluded in all photosensitive patients.

Photosensitive rashes may be divided into photoexacerbated/provoked rashes and the idiopathic photodermatoses (Table 23.6). The former are discussed on pages 574 (SLE), 245 (pellagra) and 1148 (porphyria).

Phototherapy and photoprotection

Phototherapy

UVB and UVA are both used in the treatment of inflammatory dermatoses. They have a suppressive effect on cutaneous inflammation and there is evidence that they can suppress systemic immunoreactivity to some degree. However, both types can cause skin ageing and predispose to skin malignancy if excessive doses are used. This is more of a problem in white-skinned

Table 23.6 **Differential diagnosis of photosensitive rashes**

Photoexacerbated/provoked rashes	
Systemic disease	SLE, CDLE, SCLE (p. 574)
Metabolic disease	Porphyrias (pp. 1148 and 1346), pellagra (p. 245)
Drugs	Thiazides, phenothiazines, tetracyclines, amiodarone
Plant phototoxins	Phytophotodermatitis (photosensitivity induced by contact of the skin with certain plants, e.g. celery, hogweed, rue)
Skin disease	Rosacea
	Rarely atopic eczema, psoriasis, lichen planus (these normally improve in sunlight)
Idiopathic photodermatoses	
Polymorphic light eruption	
Chronic actinic dermatitis	
Solar urticaria	

CDLE, chronic discoid lupus erythematosus SCLE, subacute cutaneous lupus erythematosus

individuals. Unaffected regions of skin or high-risk areas like the scrotum can be screened during phototherapy.

UVB is less carcinogenic than UVA. *Narrow-band UVB* (311 nanometre) is used more than broad-band UVB because it is much more effective and less likely to burn. It is used in the treatment of eczema and psoriasis (especially in children) and is given three times per week for 6-10 weeks. Eye protection needs to be worn during therapy.

UVA is relatively ineffective on its own so is used in conjunction with a photosensitizer ('psoralen') hence the term 'PUVA'. The psoralen can be given by mouth or applied to the skin in bath water. PUVA is given twice per week and eye protection must been worn *for the whole of the treatment day* as the psoralen sensitizes the retina. It is more effective than narrow-band UVB but is limited by its carcinogenic potential, especially squamous cancer. A maximum dose is given over a lifetime depending on skin type (1000 joules or 200 sessions approximately). It is used for many conditions including psoriasis, eczema, cutaneous T cell lymphoma, some photosensitive dermatoses and vitiligo.

Sunbeds are used for tanning and consist of predominantly UVA light; they are therefore rarely effective in treating skin disease. If used frequently there is an increased risk of skin cancer and premature ageing.

Photoprotection

There are two broad classes of sunblock cream: they either absorb UV light (e.g. aminobenzoic acid or methoxycinnamate) or reflect it (e.g. titanium dioxide). Most modern creams protect against UVA and UVB to varying degrees. UVB protection is graded by the 'sun protection factor' (SPF): an SPF of 15 implies you can spend 15 times as long in the sun before burning providing it is applied correctly. SPFs above 15 confer little extra protection. There is no standardized way of assessing efficiency against UVA. Some sunscreens (especially aminobenzoates) may rarely cause photosensitization. This can be proven by photopatch testing.

IDIOPATHIC PHOTODERMATOSES

Polymorphic light eruption (PLE)

This is the most common photosensitive eruption in temperate regions, affecting up to 10-20% of the population. It is most common in young women. In many it is mild and often goes undiagnosed. An itchy rash appears some hours after sun exposure which is strictly confined to the exposed sites. Lesions may be papules, vesicles or plaques. They can last for several hours or several days. The condition starts in spring and often improves during the summer because of skin 'hardening'.

Treatment

Avoidance of sunlight and the use of sunblocks are helpful in mild cases. Topical steroids help treat an attack. In those individuals who only get PLE after very intense sun exposure (e.g. on sunny holidays) a short course of oral prednisolone (30 mg daily for 7-10 days) will often prevent or treat an attack. For resistant cases 'desensitization' with low-dose PUVA (or narrow-band UVB) in the springtime may be required but patients will need to 'top up' their sun exposure from natural sunlight during the summer to keep their skin desensitized.

Chronic actinic dermatitis (photosensitive eczema, actinic reticuloid)

This is a relatively rare type of eczema occurring in a photosensitive distribution over the face, neck and hands. It typically affects middle-aged or elderly males. There may be a pre-existing eczema, so the subsequent development of photosensitivity is often missed. This is further confounded by the fact that the eczema usually will spread to affect skin not exposed to sunlight, and in fact the patient can become erythrodermic. The skin has typical features of eczema but there is often marked skin thickening. Histology is often atypical and can look almost lymphoma-like. The diagnosis can be confirmed by specialist monochromator light-testing. The most severe cases can be exacerbated by even artificial lighting, as these patients can become exquisitely photosensitive.

Treatment

This consists of strict avoidance of sunlight, including high-factor sunblocks and screening of house and car windows. Topical steroids and emollients are useful in milder cases. Oral prednisolone may be needed and azathioprine (1-2 mg/kg daily) should be considered for long-term suppression. Low-dose PUVA under steroid cover may help with 'desensitization'.

Solar urticaria

This is extremely rare. Itchy urticarial lesions occur within minutes of sun exposure and characteristically settle within 1-2 hours. Sun avoidance, sunblocks, H, antihistamines and low-dose PUVA are all used in treatment.

ERYTHRODERMA

Erythroderma, meaning 'red skin', refers to the clinical state of inflammation or redness of all (or nearly all) of the skin. It is sometimes called *exfoliative dermatitis,* but dermatitis is not always present.

Aetiology

There are a number of underlying causes (Table 23.7); previous skin disease and drugs are the most common.

Table 23.7 Causes of erythroderma

Common
Atopic eczema
Psoriasis
Drugs (e.g. sulphonamides, gold, sulphonylureas, penicillin, allopurinol, captopril)
Seborrhoeic eczema
Idiopathic
Rare
Chronic actinic dermatitis
Cutaneous T-cell lymphoma (Sezary syndrome) (p. 1353)
Malignancy (especially leukaemias)
Pemphigus foliaceus
Pityriasis rubra pilaris (a hereditary disorder of keratinization) HIV infection
Toxic shock syndrome (p. 64)

Clinical features

It is commoner in males and later in life. Patients often complain of their skin feeling 'tight' as well as itchy. Long-standing erythroderma is often associated with hair loss, ectropion of the eyelids and even nail shedding. Systemic symptoms are common such as malaise, pyrexia, widespread lymphadenopathy and other complications (see below). Erythroderma can occasionally lead to death so it should be regarded as a medical 'emergency'.

Examination should specifically look for pustules and nail changes suggestive of psoriasis.

A skin biopsy may elucidate the cause, especially of cutaneous lymphoma. Techniques such as T-cell receptor gene rearrangement studies (looking for evidence of clonal T cell expansion in the skin and blood) are also useful in the diagnosis of lymphoma.

A number of cases defy an exact diagnosis and a lymph node biopsy is required. If there is no malignancy, lymph nodes normally show non-specific, reactive (dermatopathic) changes.

Complications

The skin is one of the largest organs of the body; perhaps it is no surprise that inflammation of the whole organ can cause metabolic and haemodynamic problems including:

- high-output cardiac failure from increased blood flow
- hypothermia from heat loss
- fluid loss by transpiration
- hypoalbuminaemia
- increased basal metabolic rate
- 'capillary leak syndrome'.

Capillary leak syndrome is the most severe complication and has been responsible for a fatal outcome in some cases of psoriasis, although this is extremely rare. It is thought that the inflamed skin releases large quantities of cytokines that cause a generalized vascular leakage. This can cause cutaneous oedema and leaky vessels in the lungs, resulting in acute lung injury (p. 986).

Treatment

Treatment of erythroderma is best initiated in hospital. Patients must be kept very warm (with space blankets and heaters), with fluid-balance charts. Their vital signs should be monitored regularly. Changes in electrolytes, albumin and circulatory status should be monitored regularly. Swabs should be taken to detect any secondary skin infection.

The skin condition is treated with bed rest and either a bland emollient or a mild topical steroid. All non-essential drugs should be stopped. Where known, the underlying cause should be treated. The blanket use of systemic steroid therapy for erythroderma remains controversial in view of possible side-effects.

Advanced capillary leak syndrome will require specialized haemodynamic management in an intensive care unit.

Rothe MJ et al. (2000) Erythroderma. *Dermatologic Clinics* 18: 405-415.

CUTANEOUS SIGNS OF SYSTEMIC DISEASE

Some dermatoses are associated with a variety of underlying systemic diseases. Furthermore some medical conditions may present with cutaneous features.

Erythema nodosum

Erythema nodosum has a number of underlying causes (Table 23.8). It presents as painful or tender dusky blue-red nodules, commonly over the shins or lower limbs, which fade over 2-3 weeks leaving a bruised appearance (see Fig. 23.39). It is most common in young adults, especially females. It may be associated with arthralgia, malaise and fever. The inflammation involves the dermis and the subcutaneous layer (panniculitis).

Treatment

Symptomatic therapy with non-steroidal anti-inflammatory drugs (avoid in pregnancy), light compression bandaging and bed rest are all that are necessary as the condition resolves spontaneously. The underlying cause

Table 23.8 Causes of erythema nodosum

Streptococcal infection*
Drugs* (e.g. sulphonamides, oral contraceptive)
Sarcoidosis*
Idiopathic*
Yersinia infection
Fungal infection (histoplasmosis, blastomycosis)
Tuberculosis
Leprosy
Inflammatory bowel disease
Chlamydia infection

*Common causes in the UK

should be treated. In very persistent cases dapsone (100 mg daily), colchicine (500 |ig twice daily) or prednisolone (up to 30 mg daily) can be useful.

Erythema multiforme

Erythema multiforme (EM) is a hypersensitivity rash of acute onset frequently caused by infection or drugs. A cell-mediated T lymphocytic response is seen in the skin, which causes epidermal cell death.

In 50% of cases, the cause is not found but the following should be considered:

- herpes simplex virus (the most common identifiable cause)
- other viral infections (e.g. EBV, orf disease)
- drugs (e.g. sulphonamide, anticonvulsants)
- mycoplasma infection
- connective tissue disease (e.g. SLE, polyarteritis nodosa)
- HIV infection
- Wegener's granulomatosis
- carcinoma, lymphoma.

Clinically the lesions can be erythematous, polycyclic, annular or show concentric rings called 'target lesions' (Fig. 23.22). Frank blistering is not uncommon. The rash tends to be symmetrical and commonly affects the limbs, especially the hands and feet where palms and soles may be involved. Occasionally there is severe mucosal involvement leading to necrotic ulcers of the mouth and genitalia, and a conjunctivitis ('EM major' - previously called Stevens-Johnson syndrome - see Box 23.3). The term 'EM minor' may be used for cases without mucosal involvement.

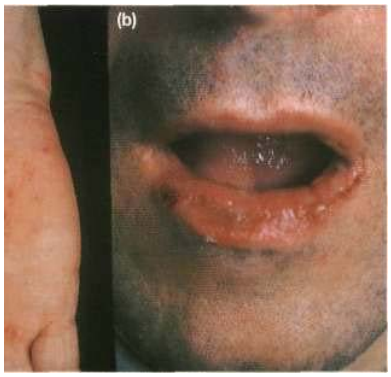

Fig. 23.22 **Erythema multiforme major** - target lesions of (a) the palm and (b) with mucosal involvement around the mouth.

Erythema multiforme usually resolves in 2-4 weeks. Rarely, recurrent erythema multiforme can occur and this is triggered by herpes simplex infection in 80% of

Sox *23.3* Stevens-Johnson syndrome

This term is now used for a mild form of toxic epidermal necrolysis (p. 1359) which shares similar mucosal lesions to 'erythema multiforme major' but does not show typical target lesions. Both Stevens-Johnson syndrome and toxic epidermal necrolysis are more likely to be drug induced.

Treatment

This is symptomatic and involves treating the underlying cause. Some advocate the use of oral steroids in severe disease but this remains controversial.

Recurrent erythema multiforme can be treated with prophylactic oral aciclovir (200 mg twice daily) even if no cause has been found, as 80% appear to be driven by herpes simplex virus. In resistant cases, azathioprine (1-2 mg/kg daily) is used.

Pyodermagangrenosum

Pyoderma gangrenosum is of unknown aetiology and presents with erythematous nodules or pustules which frequently ulcerate (Fig. 23.23). The ulcers can be large and grow at an alarming speed. The ulcer has a typical bluish black ('gangrenous') undermined edge and a purulent surface ('pyoderma'). There may be an associated pyrexia and malaise. Biopsy through the ulcer edge shows an intense neutrophilic infiltrate and occasionally a vasculitis but the diagnosis depends mostly on the clinical appearance. The main causes are:

- inflammatory bowel disease
- rheumatoid arthritis
- myeloma, leukaemia, lymphoma
- liver disease (primary biliary cirrhosis)
- idiopathic (> 20% in some series).

Treatment

This is with very potent topical steroids or 0.1% tacrolimus ointment. High-dose oral steroids may be needed to prevent rapidly progressive ulceration. Oral dapsone and minocycline may help. Other immunosuppressants, such as ciclosporin, are useful in resistant cases. The underlying cause should be treated.

Fig. 23.23 **Pyoderma gangrenosum.**

Fig. 23.24 **Acanthosis nigricans.**

Acanthosis nigricans

Acanthosis nigricans presents as thickened, hyperpigmented skin predominantly of the flexures (Fig. 23.24). It can appear warty or velvety when advanced. In early life it is seen in obese individuals who have very high levels of insulin owing to insulin resistance (and this is sometimes termed 'pseudo-acanthosis nigricans'). In older people it normally reflects an underlying malignancy (especially gastrointestinal tumours). Rarely it is associated with hyperandrogenism in females.

Treatment

Topical or oral retinoids (0.5 mg/kg/day) may help (p. 1338) and weight loss is advised in the obese. Any underlying malignancy should be treated.

permatomyositis (see also p. 579)

The rash is distinctive. Facial erythema and a magenta-coloured rash around the eyes with associated oedema are often present. Bluish red nodules or plaques may be present over the knuckles and extensor surfaces. The nail folds are frequently ragged with dilated capillaries. The diagnosis is made from the clinical appearance, muscle biopsy, EMG and a serum creatine phosphokinase. Skin biopsy is not diagnostic.

There is a childhood form which usually occurs before the age of 10 and which eventually resolves. This type is often associated with calcinosis in the skin and can cause significant long-term functional problems with weak muscles and contractures. Life-threatening bowel infarction can also occur in the childhood form. The adult form usually occurs after the age of 40. Some cases are associated with an underlying malignancy, whereas others appear to reflect a 'connective tissue disease'. This latter group may overlap with scleroderma and lupus erythematosus.

Treatment

Skin disease may respond to hydroxychloroquine (200 mg twice daily) as well as immunosuppressants, e.g. azathioprine or ciclosporin.

Scleroderma (see also p. 577)

The term scleroderma refers to a thickening or hardening of the skin owing to abnormal dermal collagen. It is not a diagnostic entity in itself. Systemic sclerosis and morphoea both show sclerodermatous changes but are separate conditions.

Systemic sclerosis (often called scleroderma) has cutaneous and systemic features and is discussed fully on page 577.

Morphoea is confined to the skin and usually presents in children or young adults. It is commoner in females and the cause is unknown. Lesions are usually on the trunk and appear as bluish red plaques which progress to induration and then central white atrophy. A linear variant exists in childhood which is more severe as it can cause atrophy of underlying deep tissues and thus can cause unequal limb growth or scarring alopecia.

Rarely, sclerodermatous skin changes may be seen in chronic Lyme disease (acrodermatitis chronica atrophicans), chronic graft-versus-host disease, polyvinyl chloride disease, eosinophilic myalgia syndrome (due to tryptophan therapy) and bleomycin therapy.

Lupus erythematosus (LE)

There are three clinical variants to this disease but some patients may show features of more than one type.

- chronic discoid lupus erythematosus (CDLE)
- subacute lupus erythematosus (SCLE)
- systemic lupus erythematosus (SLE).

The aetiology is unknown but is due to abnormality in immune function as variable autoantibodies may be found in all types. Very rarely it can be induced by certain drugs such as phenothiazines, hydralazine, methyldopa, isoniazid, tetracycline, mesalazine and penicillin.

Chronic discoid lupus erythematosus (CDLE)

CDLE is the most common type of LE seen by dermatologists and more frequently affects females. Clinically it presents with fixed erythematous, scaly, atrophic plaques with telangiectasia, especially on the face or other sun-exposed sites (Fig. 23.25). Hypopigmentation is common and follicular plugging occurs. Scalp involvement leads to a scarring alopecia. Oral involvement (erythematous patches or ulceration) occurs in 25% of cases.

CDLE can be triggered and exacerbated by UV exposure. A few patients also suffer with Raynaud's phenomenon or unusual chilblain-like lesions (chilblain lupus). Only 5% of cases will go on to develop SLE but this is more common in children. Serum antinuclear antibody (ANA) is positive in 30% of cases.

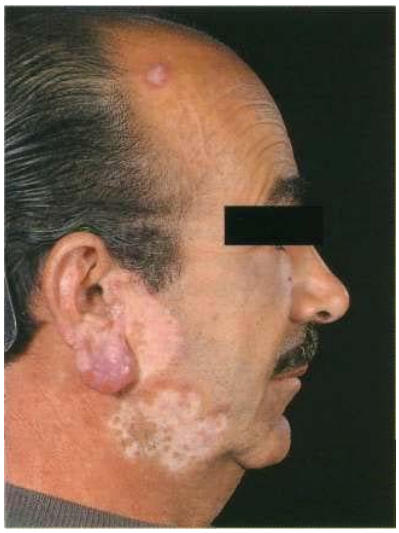

Fig. 23.25 Chronic discoid lupus erythematosus, showing scaling, atrophy and hypopigmentation.

Fig. 23.26 Systemic lupus erythematosus - showing the structural sites of damage in bullous disorders. LAD, linear IgA disease; EB, epidermolysis bullosa.

Skin biopsy shows a dense patchy, dermal lympho-histiocytic infiltrate which often is centred on appendages. Epidermal basal layer damage, follicular plugging and hyperkeratosis may be present. Direct immunofluorescence studies of lesional skin may show the presence of IgM and C3 at the dermoepidermal junction ('lupus band').

Treatment

First-line therapy is with sunscreens and potent topical steroids. Certain oral antimalarials (hydroxychloroquine 100-200 mg twice daily and mepacrine 100 mg daily) can prove very useful and are generally safe for long-term intermittent use. Oral prednisolone is beneficial but its use is limited by its side-effect profile. Azathioprine, retinoids, ciclosporin and thalidomide can be useful in resistant cases.

Prognosis

The disease is usually chronic, although it may fluctuate in severity. CDLE remains confined to the skin in most patients and it will eventually go into remission in up to 50% of cases (after many years).

Subacute lupus erythematosus (SCLE)

SCLE is a rare cutaneous variant of LE. It presents with widespread indurated, sometimes urticated, erythematous lesions, often on the upper trunk. The lesions can also be annular. Photosensitivity is often a prominent feature. Complications, such as arthralgia and mouth ulceration, •are seen but significant organ involvement is rare. ANF and extractable nuclear antibodies (anti-Ro and anti-La) are usually positive (see p. 534).

Treatment is with oral dapsone, antimalarials or systemic immunosuppression (prednisolone and ciclosporin).

Systemic lupus erythematosus (SLE)

(see also p. 574)

The cutaneous involvement of SLE is one of the minor problems of the disease but it may be the presenting feature.

Features include macular erythema over the cheeks, nose and forehead ('butterfly rash', Fig. 23.26). Palmar erythema, dilated nail fold capillaries, splinter haemorrhages and digital infarcts of the finger tips may also be seen but are not always noticed by the patient. Joint swellings, Iivedo reticularis and purpura are occasionally seen. Rarely SLE can be complicated by an atypical erythema multiforme-like rash ('Rowell's syndrome'). Treatment (p. 576) is usually managed by a rheumatologist.

Pruritus

The pathophysiology of pruritus is poorly understood but is due to peripheral mechanisms (e.g. skin disease), central or neuropathic mechanisms (e.g. multiple sclerosis), neurogenic (e.g. cholestasis/u.-opioid receptor stimulation, p. 386) or psychogenic mechanisms (e.g. parasitophobia). Evidence suggests that low stimulation of unmyelinated C-fibres in the skin is associated with the sensation of itch (high stimulation produces pain). Histamine, tachykinins (e.g. substance P) and cytokines (e.g. interleukin-2) may also play a role peripherally in the skin. The major nerve pathways for itch and the influence of the central nervous system are not well characterized but opioid ^-receptor-dependent processes can regulate the perception and intensity of itch.

Pruritus (see lichen simplex, nodular prurigo/ neurodermatitis) in the absence of a demonstrable rash can be caused by a number of different medical problems (Table23.9).

Table 23.9 Medical conditions associated with pruritus
Iron deficiency anaemia
Internal malignancy (especially lymphoma)
Diabetes mellitus
Chronic renal failure
Chronic liver disease (especially primary biliary cirrhosis)
Thyroid disease
HIV infection
Polycythaemia vera

Asteatotic eczema and cholinergic urticaria are common causes of pruritus where the rash is often missed. The term idiopathic pruritus or 'senile' pruritus probably overlaps with asteatotic eczema and this is common in the elderly.

Treatment involves avoiding soaps and using symptomatic measures (as for asteatotic eczema). Phototherapy may help intractable cases. Oral opiate antagonists, which act centrally, are under assessment. Underlying medical problems should be treated.

Sarcoidosis (see also p. 934)

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology. It can present as reddish brown dermal papules and nodules, especially around the eyelid margins and the rim of the nostrils. More polymorphic lesions (papules nodules and plaques) may appear on the body. It is most common in black Africans where it is often accompanied by hypo- or hyperpigmentation. Rarely it can present with a bluish red infiltrate or swelling, especially of the nose or ears, called lupus pernio. Both these types of lesion can be seen anywhere on the body but are common on the face. Erythema nodosum (p. 1341) of the shins is sometimes seen in acute-onset sarcoidosis. Erythema nodosum is an immunological reaction and not due to sarcoid tissue infiltration. Swollen fingers from a dactylitis occur. Whilst sarcoidosis may be confined to the skin, all patients should be investigated for evidence of systemic disease (p. 934).

Treatment of cutaneous lesions includes very potent topical steroids (0.05% clobetasol propionate), intralesional steroids, oral steroids and occasionally methotrexate or antimalarials.

Neurofibromatosis type 1 (von Recklinghausen's disease) (see also p. 1257 and Table 3.4)

Type 1 neurofibromatosis is an autosomal dominant condition with complete penetrance. It often presents in childhood with a variety of cutaneous features. Many cases are new mutations in the *NF1* gene. Early signs include *cafe-au-Mt* spots (brown macules, greater than 2.5 cm in diameter and more than five lesions) and axillary freckling. Lisch nodules (hyperpigmented iris hamartomas) may be seen in the eyes by slit lamp examination. Later on, fleshy skin tags and deeper soft tumours (neurofibromas) appear and they may progress to completely cover the skin causing significant cosmetic disability. Learning difficulties and skeletal dysplasias occur. A number of endocrine disorders may be rarely associated including phaeochromocytoma, acromegaly and Addison's disease.

Tuberous sclerosis (epiloia)

Tuberous sclerosis is also an autosomal dominant condition of variable severity which may not present until later childhood. It is characterized by a variety of hamartomatous growths. The three cardinal features are (a) mental retardation, (b) epilepsy, and (c) cutaneous abnormalities - but not all have to be present. The skin signs include:

- adenoma sebaceum (reddish papules/fibromas around the nose)
- periungual fibroma (nodules arising from the nail bed)
- shagreen patches (firm, flesh-coloured plaques on the trunk)
- ash-leaf hypopigmentation (pale macules best seen with UV light)
- forehead plaque (indurated flesh-coloured patch)
- *cafe-au-lait* patches
- pitting of dental enamel.

Internal hamartomas can arise in the heart, kidney, retina and CNS. Parents of a suspected case should be carefully examined (under UV light) as they may have a forme fruste of the condition which can manifest just as hypopigmented patches. This would have genetic implications for future offspring.

Diabetes mellitus (see also p. U3i)

Diabetes mellitus can have a number of cutaneous features. Complications of diabetes itself include:

fungal infection (e.g. candidiasis)
bacterial infections (e.g. recurrent boils)
xanthomas
arterial disease (ulcers, gangrene)
neuropathic ulcers.

Specific dermatoses of diabetes include:

- necrobiosis lipoidica (a patch of spreading erythema over the shin which becomes yellowish and atrophic in the centre and may ulcerate)
- diffuse granuloma annulare (p. 1336)
- diabetic dermopathy (red-brown flat-topped papules)
- blisters (usually on the feet or hands)
- diabetic stiff skin (tight waxy skin over the fingers with limitation of joint movement owing to thickened collagen - also called cheiroarthropathy).

Chronic liver disease (see also p. 357)

Chronic liver disease may present with jaundice, palmar erythema, spider naevi, white nails, hyperpigmentation and pruritus.

Porphyria cutanea tarda (PCT, p. 1149) is a rare genetic disorder associated with liver disease usually due to hepatic damage from excessive alcohol consumption or hepatitis C infection: 75% of cases are sporadic, 25% familial. Overall, 20% of cases have underlying hereditary haemochromatosis (p. 386). It presents clinically on exposed skin with sun-induced blisters, skin fragility, scarring, milia and hypertrichosis. Treatment of the cutaneous features is with repeated venesection and/ or very low-dose chloroquine plus an avoidance of alcohol. There is anecdotal evidence that specific treatment of hepatitis C (p. 373) will also help the skin, presumably through improving liver function. All forms of PCT are at risk of hepatic carcinoma.

CJhromcrejnalfailure (see also p. 668)

Chronic renal failure is commonly associated with intractable pruritus. Pallor, hyperpigmentation and ecchymoses are commonly seen. Rarely it is associated with non-inflammatory blisters, pseudo-porphyria cutanea tarda and cutaneous calcification. Long-standing renal transplant patients often suffer with recurrent viral warts and squamous cell carcinomas due to the immunosuppression.

Thyroid disease (see also p. 1069)

Hypothyroidism may cause dry firm gelatinous (myxoedematous) skin with diffuse hair thinning and a loss of the outer third of the eyebrows. Hyperthyroidism may be associated with warm sweaty skin and a diffuse alopecia. Graves' disease is rarely associated with thyroid acropachy ('clubbing' with underlying bone changes) and pretibial myxoedema (a red-brown mucinous infiltration of the shins which can become lumpy and tender).

Cushing's syndrome (see also p. 1085)

Cushing's syndrome may cause hirsutism, a moon face, a buffalo hump, stretch marks (striae) and a pustular folliculitis (often called steroid acne) of the skin.

Hyperlipidaemias (see also p. 1138)

Hyperlipidaemias can present with xanthomas, which are abnormal collections of lipid in the skin. All patients with xanthomas should be investigated for hyperlipidaemia although the most common type called xanthelasma (yellow plaques around the eyes) are usually associated with normal lipids. There are a number of other clinical variants of xanthomas such as (i) tuberous xanthoma (firm orange-yellow nodules and plaques on extensor surfaces), (ii) tendon xanthoma (firm subcutaneous swellings attached to tendons), (iii) plane xanthoma (orange-yellow macules often affecting palmar creases), (iv) eruptive xanthoma (numerous small yellowish papules commonly on the buttocks).

Table 23.10 **Non-metastatic cutaneous manifestations of underlying malignancy**

Dermatosis	Tumour
Dermatomyositis	Acanthosis Lung, GI tract, GU tract
nigricans	Paget's disease (localized GI tract, lung, liver
patch of eczema around the nipple)	Erythroderma Ductal breast carcinoma
Tylosis (thickened palms/soles)	Lymphoma/leukaemia
Ichthyosis (dry flaking of skin)	Oesophageal carcinoma
Erythema gyratum repens (concentric rings of erythema which change rapidly)	Necrolytic Lymphoma Lung, breast
migratory erythema (burning, geographic and spreading annular areas of erythema)	Glucagonoma

Cutaneous amyloid

Cutaneous amyloid can be confined to the skin or be part of systemic disease (p. 1148). Macular amyloid is a common, purely cutaneous variant seen in Asians. It is characterized by itchy brown rippled macules on the upper back.

Systemic amyloid may be associated with reddish brown papules, nodules or plaques, especially around the eyes, the flexural areas and mucosal surfaces. Distinctive periorbital bruising and macroglossia may also be present.

Systemic malignant disease

Certain rashes may be a non-metastatic manifestation of an underlying malignancy (Table 23.10). Rarely tumours can metastasize to the skin where they normally present as papules or nodules which may proceed to ulceration.

BULLOUS DISEASE

Primary blistering diseases of the skin are rare. A variety of skin proteins hold the skin together. Inherited abnormalities or immune damage of these proteins causes abnormal cell separation, inflammation, fluid accumulation

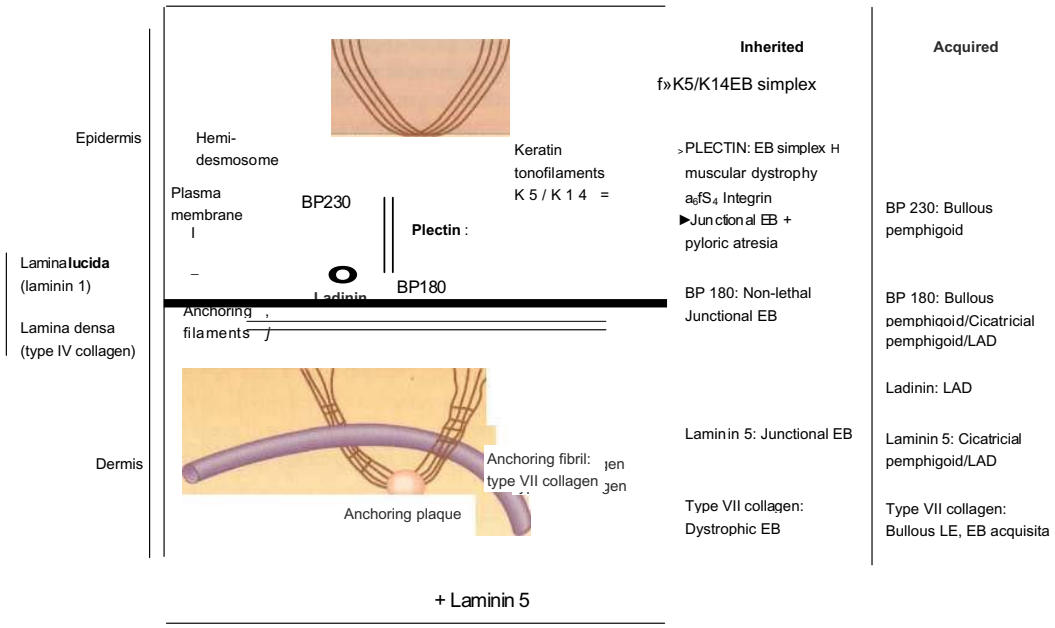

Fig. 23.27 Section of the basemet membrane zone, showing the structural sites of damage in bullous disorders. LAD, linear IgA disease; EB, epidermolysis bullosa.

and blistering (Fig. 23.27). The level of blistering determines the clinical picture as well as the prognosis. Therefore skin biopsy for light and electron microscopy together with immunofluorescence (IMF) studies is paramount in diagnosis. However, remember that the commonest causes of skin blistering are chickenpox, herpes, impetigo, pompholyx eczema and insect bite reactions, although these are often localized.

IMMUNOBULLOUS DISEASE

Pemphigus vulgaris

Pemphigus vulgaris is a potentially fatal blistering disease occurring in all races but commoner in Ashkenazi Jews and possibly in people from the Indian subcontinent. Onset is usually in middle age and both sexes are affected equally. Prior to the development of oral steroids this condition was frequently fatal. The development of autoantibodies against the desmosomal protein, desmoglein 3, is pathogenic in this disease and they can be measured experimentally as markers of disease activity. Rarely the disease can be drug induced (e.g. penicillamine or captopril).

Skin biopsy shows a superficial intraepidermal split just above the basal layer with acantholysis (separation of individual cells). In the rarer variant, pemphigus foliaceous (characterized by anti-desmoglein 1 autoantibodies), the split is higher in the upper epidermis. Both direct IMF of skin (perilesional) and indirect IMF using patients' serum show intercellular staining of IgG within the epidermis.

Clinical features

Mucosal involvement (especially oral ulceration) is common and is the presenting sign in up to 50% of cases. This is followed by the appearance of flaccid blisters, particularly involving the trunk. They tend to be sore rather than itchy. Blistering usually becomes widespread but they rapidly denude; thus pemphigus often presents with erythematous, weeping erosions. Blisters can be extended with gentle sliding pressure (Nikolsky's sign). Flexural lesions often have a vegetative appearance. In *pemphigus foliaceous* the blisters and erosions often start in a seborrhoeic distribution (scalp, face and upper chest) before becoming more widespread.

Treatment

This is with very high-dose oral prednisolone (60-100 mg daily) or pulsed methylprednisolone, and this may need to be lifelong. Other immunosuppressants such as azathioprine, or mycophenolate mofetil (or occasionally cyclophosphamide or ciclosporin) are used as steroid-sparing agents but they often take many weeks to be effective. Intravenous immunoglobulin infusions may help gain quick control whilst waiting for these other drugs to work. Anti-CD20 monoclonal antibody (rituximab) has recently been reported to help multidrug-resistant cases.

Whilst treatment is normally effective, perhaps up to 10% of patients may die, either because of complications of the disease or more commonly from side-effects of the treatment.

Use of azathioprine. Azathioprine can cause bone marrow suppression and an allergic hepatitis. Therefore blood count and liver function tests should be regularly monitored during therapy (every 6 weeks). Long-term use with other immunosuppressants causes a slightly increased risk of malignancy, especially of the skin.

Fig. 23.28 Bullous pemphigoid.

Bullous pemphigoid

Bullous pemphigoid is more common than pemphigus. It presents in later life (usually over 60 years old) and mucosal involvement is rarer. Autoantibodies against a 230 kDa or 180 kDa hemidesmosomal protein ('bullous pemphigoid antigens 1 and 2') play an aetiological role.

Skin biopsy shows a deeper blister (than in pemphigus) owing to a subepidermal split through the basement membrane. Direct and indirect IMF studies show linear staining of IgG along the basement membrane.

Clinical features

Large tense bullae appear anywhere on the skin (Fig. 23.28) but often involve limbs, hands and feet. They may be centred on an erythematous or urticated background and they can be haemorrhagic. Pemphigoid can be very itchy. Mucosal ulceration is uncommon but a variant of pemphigoid exists which predominantly affects mucosal surfaces with scarring (cicatricial pemphigoid).

Treatment

This is with high-dose oral prednisolone (30-60 mg daily) and steroid-sparing agents such as azathioprine or mycophenolate mofetil. Weekly methotrexate is also occasionally used. In general disease control is easier than with pemphigus. Treatment can often be withdrawn after 2-3 years. Pemphigoid treatment frequently causes side-effects, especially as most patients are elderly. Occasionally localized or mild disease can be controlled with superpotent topical steroids, oral dapsone or high-dose oral minocycline.

Dermatitis herpetiformis (see also p. 303)

Dermatitis herpetiformis (DH) is a rare blistering disorder associated with gluten-sensitive enteropathy (coeliac disease). DH and celiac disease are associated with other organ-specific autoimmune disorders.

Skin biopsy shows a subepidermal blister with neutrophil microabscesses in the dermal papillae. Direct IMF studies of uninvolved skin show IgA in the dermal papillae and patchy granular IgA along the basement membrane. The jejunal mucosa usually shows a partial villous atrophy.

Clinical features

Dermatitis herpetiformis is commoner in males and can present at any age but is most likely to appear for the first time in young adult life. It presents with intensely itchy, small blisters of the skin. The lesions have a predilection for the elbows, extensor forearms, scalp and buttocks. The tops of the blisters are usually scratched off; thus crusted erosions are often seen at presentation. Remissions and exacerbations are common.

Treatment

This should always be with a gluten-free diet (GFD). Control of the skin disease can be obtained with oral dapsone (50-200 mg daily) or sulphonamides. If a strict GFD is adhered to, oral medication can often be withdrawn after 2 years. The GFD will need to be lifelong. It protects against the rare complication of small bowel lymphoma.

Use of dapsone. Dapsone frequently causes a mild, dose-related haemolytic anaemia but the haemolysis can be devastating if there is G6PD deficiency. Liver damage, peripheral neuropathy and aplastic anaemia can also rarely occur, so regular monitoring of a blood count and liver function is needed.

Linear IgA disease (chronic bullous dermatosis of childhood)

Linear IgA disease is a subepidermal blistering disorder of adults and children. Pathogenic IgA autoantibodies can bind to a variety of basement membrane proteins including ladinin, BP 180 antigen and laminin 5 (see Fig. 23.27). It is the most common immunobullous disease seen in children. Rarely it is drug induced by vancomycin.

Clinical features

Linear IgA disease can present with circular clusters of large blisters, a pemphigoid type of blistering or a dermatitis herpetiformis picture. Mucosal involvement of the mouth, vulva and eyes is not uncommon and can cause scarring. Direct IMF studies of skin show linear IgA deposition along the basement membrane.

Treatment

This is with oral dapsone (50-200 mg daily) or sulphonamides. Occasionally immunosuppression is needed. Many patients show spontaneous resolution after 3-6 years.

MECHANOBULLOUS DISEASE (EPIDERMOLYSIS BULLOSA, 'EB')

These are due to inherited abnormalities in structural skin proteins which lead to 'skin fragility'. The resultant blistering tends to arise secondary to trauma and often appears at or shortly after birth. These conditions can be a mild inconvenience, severely disabling or fatal but fortunately are very rare. There are three groups of disorders in which the fundamental gene/ protein abnor-

malities have been characterized. This enables prenatal amniocentesis diagnosis.

Epidermolysis bullosa simplex

This is a group of autosomal dominant genodermatoses characterized by 'superficial' blistering owing to mutations of cytoskeleton proteins within the basal layer of the epidermis, e.g. keratin 5 (chromosome 12q) or keratin 14 (chromosome 17q). Most forms of EB simplex show mild disease with intermittent blistering of the hands and feet, especially in hot weather. The teeth and nails are normal and scarring is absent.

Epidermolysis bullosa dystrophica

This group of genodermatoses is characterized by 'deeper' blistering associated with scarring and milia formation. The level of split is deep within the basement membrane and is due to a mutation in the *COL-7A1* gene (locus at chromosome 3p21.1) which causes a loss of collagen VII in the anchoring fibrils. Nails, mucosae and even the larynx are often involved. The autosomal dominant variety is milder but the autosomal recessive type produces severe disease with disabling scarring, fusion of digits, joint contractures and dysphagia. Life expectancy is significantly reduced. Repeated scarring results in the development of multiple squamous cell carcinomas and most die from this complication in early adult life. The average life expectancy after the appearance of the first squamous cell carcinoma is 5 years.

Junctional epidermolysis bullosa

This, the most severe form, is characterized by a split in the lamina lucida of the basement membrane and is due to mutations in various proteins, mainly laminin 5 but also $\alpha_6\beta_4$ integrin or the 180 kDa bullous pemphigoid-2 antigen. It presents at birth with widespread blistering and areas of absent skin. Erosions of the central face and hoarseness from laryngeal involvement are common. Nail and teeth abnormalities are also common. Both a lethal and a rarer non-lethal form of junctional EB exist and they show an autosomal recessive inheritance. The lethal form causes death in infancy or early childhood.

Investigation and treatment

Investigation and treatment of EB should be carried out in a specialist centre. Diagnosis at birth on clinical grounds is difficult and should be avoided. Exact diagnosis depends on ultrastructural analysis of induced blisters in the skin and immunohistochemistry. Only then can prognosis and genetic counselling be given accurately to parents. Prenatal diagnosis is available for the more severe forms of EB.

SKIN TUMOU

BENIGN CUTANEOUS TUMOURS

Melanocytic naevi (moles)

Moles are a benign overgrowth of melanocytes that are common in white-skinned people. They appear in childhood and increase in number and size during adolescence and early adult life. They often start as flat brown macules with proliferation of melanocytes at the dermoepidermal junction (junctional naevi). The melanocytes continue to proliferate and grow down into the dermis (compound naevi), which causes an elevation of the mole above the skin surface. The pigmentation is usually even and the border regular. They eventually mature into a dermal naevus (cellular naevus) often with a loss of pigment.

Blue naevus is an acquired asymptomatic blue-looking mole. It is due to a proliferation of melanocytes deep in the mid-dermis.

Basal cell papilloma (seborrhoeic wart)

This is a common benign overgrowth of the basal cell layer of the epidermis. The lesion can be flesh coloured, brown or even black and often has a greasy appearance. The surface is irregular and warty and the lesions appear very superficial as though stuck on to the skin (Fig. 23.29).

Fig. 23.29 **Seborrhoeic warts** (basal cell papillomas).

Tiny keratin cysts may be seen on the surface. They can be treated with cryotherapy or curettage.

Dermatofibroma (histiocytoma)

Dermatofibromas appear as firm, elevated pigmented nodules which may feel like a button in the skin. A peripheral ring of pigmentation is sometimes seen. They are often found on the leg and are commoner in females. There may be a preceding history of trauma or insect bite. The lesion consists of histiocytes, blood vessels and varying degrees of fibrosis. If symptomatic, excision is required.

Epidermoid cyst (previously 'sebaceous cyst')

Epidermoid cysts present as cystic swellings of the skin with a central punctum. They contain 'cheesy' keratin rather than sebum; thus the old term 'sebaceous cyst' should be avoided. These cysts occasionally rupture causing significant dermal inflammation which is not infected.

Pilar cyst (trichilemmal cyst)

Pilar cysts are smooth cysts without a punctum, usually found on the scalp. They may be multiple and familial.

Keratoacanthoma

Keratoacanthomas are rapidly growing epidermal tumours which develop central necrosis and ulceration (Fig. 23.30). They occur on sun-exposed skin in later life and can grow up to 2-3 cm across. Whilst they may resolve spontaneously over a few months, they are best excised, both to exclude a squamous cell carcinoma (which they can mimic) and to improve the cosmetic outcome.

Pyogenic granuloma (granuloma telangiectaticum)

Pyogenic granulomas are a benign overgrowth of blood vessels. They present as rapidly growing pinkish red nodules which are friable and readily bleed. They may follow trauma and are often found on the fingers and lips. They are best excised to exclude an amelanotic malignant melanoma.

Fig. 23.30 **Keratoacanthoma.**

Cherry angioma (Campbell de Morgan spots)

They are benign angiokeratomas that appear as tiny pinpoint red papules, especially on the trunk, and increase with age. No treatment is required.

POTENTIALLY PRE-MALIGNANT CUTANEOUS TUMOURS

Solar keratoses (actinic keratoses)

These frequently develop later in life in white-skinned people who have had significant sun exposure. They appear on exposed skin as erythematous silver-scaly papules or patches with a conical surface and a red base (Fig. 23.31). The background skin is often inelastic, wrinkled and may show flat brown macules (Tiver spots' or solar lentigos) reflecting diffuse solar damage. A small proportion of these keratoses can transform into squamous cell carcinoma but only after many years.

Treatment of lesions is with cryotherapy, topical 5-fluorouracil cream or 5% imiquimod cream.

Bowen's disease

This is a form of intraepidermal carcinoma-in-situ which rarely can become invasive. It presents on exposed skin as an isolated scaly red patch or plaque, looking rather like psoriasis, although it has a rather irregular edge. The lesions do not clear but slowly increase in size with time. A variant which can show partial or full-thickness dysplasia can involve the epidermis of the mucosa or neighbouring skin - this can affect the vulva, the glans penis and perianal skin. It is termed vulval- (penile-, or anal-) intraepithelial dysplasia. Clinically it can present as non-specific erythema or as a warty thickening. These diseases have a stronger link with HPV and probably have a higher premalignant potential than Bowen's disease. They are commoner in immunosuppressed individuals. The anal form is increasingly reported in HIV-positive patients and extension into the rectum has been reported.

Fig. 23.31 Solar keratoses with background actinic damage.

Treatment is with topical 5-fluorouracil, 5% imiquimod cream, cryotherapy, curettage, photodynamic therapy or a tissue-destructive laser.

Atypical mole syndrome (dysplastic naevus syndrome)

This is often familial. A large number of melanocytic naevi begin to appear in childhood, even on unexposed sites. Individual lesions may be large with irregular pigmentation and border, and histologically they may show cytological and architectural atypia but no frank malignant change. Individuals with this condition have an increased risk of developing malignant melanoma. They should have their moles photographed and be regularly reviewed. Suspicious lesions should be excised.

Giant congenital melanocytic naevi

These are very large moles present at birth. They show an increased risk of developing malignant melanoma. Approximately 10% of lesions larger than 20 cm across will develop a malignant melanoma in childhood. Excision should be undertaken if possible.

Lentigo maligna

This is a slow-growing macular area of pigmentation seen in elderly people, commonly on the face. The border and pigmentation are often irregular. Some people regard this lesion as a melanoma-in-situ. There is an increased risk of developing invasive malignant melanoma. Treatment is by excision if possible but 5% imiquimod cream is currently under assessment in the very large lesions where surgery would be so disfiguring.

MALIGNANT CUTANEOUS TUMOURS

Basal cell carcinoma (rodent ulcer)

Basal cell carcinomas are the most common malignant skin tumour and most relate to excessive sun exposure. They are common later in life on exposed sites although rare on the ear. They present as a slow-growing papule or nodule (or rarely be cystic) which may go on to ulcerate (Fig. 23.32). Telangiectasia over the tumour or a skin-coloured jelly-like 'pearly edge' may be seen. A flat, diffuse superficial form exists and an ill-defined 'morphoeic' variant. Basal cell carcinomas will slowly grow and erode structures if untreated but these tumours almost never metastasize. . . . t

Treatment

Treatment is usually with surgical excision with a 3-5 mm border. Radiotherapy, photodynamic therapy, cryotherapy or 5% imiquimod cream can be useful for large superficial forms but follow-up for recurrence is required. Curettage is occasionally used in older patients, although not for central facial lesions as they often recur. Recurrent tumour or morphoeic basal cell carcinoma is best treated with Mohs' micrographic surgery to ensure adequate clearance.

Fig. 23.32 Ulcerating basal cell carcinoma.

Squamous cell carcinoma

Squamous cell carcinoma is a more aggressive tumour than basal cell carcinoma as it can metastasize if left untreated. Most relate to sun exposure and daily application of sun cream has been shown to reduce the incidence in Australia. They can arise in pre-existing solar keratoses or Bowen's disease or be due to chronic inflammation such as in lupus vulgaris. Rarely multiple tumours arise because of arsenic ingestion in early life. Multiple tumours occur in people who have had prolonged periods of immunosuppression, such as renal transplant patients where certain human papilloma virus subtypes may be involved in malignant transformation.

Clinically the lesions are often keratotic, rather ill-defined nodules which may ulcerate (Fig. 23.33). They can grow very rapidly. Examination of regional lymph

Fig. 23.33 Squamous cell carcinoma.

nodes is essential. They are most common on sun-exposed sites in later life. One should have a high index of suspicion for ulcerated lesions on the lower lip or ear.

Treatment is with excision or occasionally radiotherapy. Curettage should be avoided.

Malignant melanoma

Malignant melanoma is the most serious form of skin cancer as metastases can occur early and it causes a number of deaths even in young people. As with other types of skin cancer the incidence is continuing to increase, probably because of excessive exposure to sunlight. The history of childhood sun exposure and intermittent sun exposure appears to play a role in the development of malignant melanoma. Other risk factors include atypical mole syndrome, giant congenital melanocytic naevi, lentigo maligna and a positive family history of malignant melanoma. Malignant melanoma is commoner in later life; young adults are also affected. The tumour suppressor gene *pl6* (on chromosome 9p) is frequently mutated or deleted in melanoma cell lines and its role in atypical mole syndrome/familial melanoma is currently under investigation.

Diagnosis of melanoma is not always easy but the clinical signs listed in Table 23.11 help distinguish malignant from benign moles. Examination with a dermatoscope can further help in detecting malignant lesions.

Four clinical types exist:

- *Lentigo maligna melanoma* is where a patch of lentigo maligna develops a papule or nodule signalling invasive tumour.
- *Superficial spreading malignant melanoma* is a large flat irregularly pigmented lesion which grows laterally before vertical invasion develops.
- *Nodular malignant melanoma* (Fig. 23.34) is the most aggressive type. It presents as a rapidly growing pigmented nodule which bleeds or ulcerates. Rarely they are amelanotic (non-pigmented) and can mimic pyogenic granuloma.

Fig. 23.34 Nodular malignant melanoma.

- *Acral lentiginous malignant melanoma* arises as pigmented lesions on the palm, sole or under the nail and it usually presents late.

Treatment

This consists of urgent wide excision (2 cm margin) of the lesion. Histological analysis will determine the depth of invasion ('Clark's level') and the thickness of the tumour ('Breslow thickness'). These two factors are significant in predicting prognosis and 5-year survival rates: 96% for local lesions, 60% for regional spread and 14% for distant metastases. For localized melanomas the thickness and presence or absence of ulceration are the strongest independent predictors of outcome. Excision and histology interpretation should only be done by experts to ensure optimum treatment and assessment of prognosis. Sentinel node biopsy for patients with thicker lesions is required for predicting prognosis: 15% will be positive without clinical lymphadenopathy. Metastatic disease is best managed by an oncologist with a multidisciplinary team and can involve surgery to lymph nodes, radiotherapy, immunotherapy and chemotherapy. Initial optimism for high-dose alpha-interferon therapy in advanced disease has recently been challenged with a systematic review suggesting no clear benefit.

The role of governments and medical personnel in public health education to discourage sunbathing and to use sunscreens is of the utmost importance in skin cancer prevention.

Cutaneous T-cell lymphoma (mycosis fungoides)

This is a rare type of skin tumour which often follows a relatively benign course. It presents insidiously with scaly patches and plaques which can look eczematous or psoriasiform. Lesions often appear initially on the buttocks. These lesions may come and go or remain persistent over many years. Patients may well die of unrelated causes. Skin biopsy confirms the diagnnsis. showing invasion by atypical lymphocytes. T-cell receptor gene rearrangement studies show that the there is often a monoclonal expansion of lymphocytes in the skin.

Occasionally the disease can progress to a cutaneous nodular or tumour stage which may be accompanied by systemic organ involvement. In elderly males the disease may progress rarely to an erythrodermic variant accompanied by lymphadenopathy and peripheral blood involvement ('Sezary syndrome').

All patients should be staged at the time of diagnosis to assess for any systemic involvement.

Treatment

Early cutaneous disease can be left untreated or treated with topical steroids or PUVA. More advanced disease of the skin, or systemic involvement, may require radiotherapy, chemotherapy, immunotherapy or electron beam **therapy.** Bexarotene, an agonist at the retinoid X receptor, can cause regression.

Kaposj's sarcoma

This is a tumour of vascular and lymphatic endothelium that presents as purplish nodules and plaques. There are three types:

- *The 'classic' or 'sporadic' form* (as described by Kaposi) occurs in elderly males, especially Jews from Eastern Europe. It presents as slow-growing purple tumours in the foot and lower leg **which** rarely cause any significant problem.
- *The 'endemic' form* occurs in males from central Africa and shows more widespread cutaneous involvement as well as lymph node (or occasionally systemic) involvement. Oedema is a prominent feature.
- *The immunosuppression-related form* is more severe and is most common in homosexual patients with HIV (p. 142). Lesions are widespread and often affect the skin, bowel, oral cavity and lungs.

All three types have a strong association with herpes virus type 8 but other factors must be involved as herpes type 8 seroprevalence in the general population is up to 10% in the USA and 50% in some African countries. HAART (p. 143) has significantly reduced the incidence of Kaposi's sarcoma in HIV.

Treatment

Treatment of advanced Kaposi's sarcoma is with radiotherapy, immunotherapy or chemotherapy.

DISORDERS OF BLOOD VESSELS/LYMPHATir ~

LEG ULCERS

Venous ulcers

Leg ulcers are common in western societies and can have many causes (Table 23.12). Venous ulcers are the most common type in developed countries.

Venous ulcers are the result of sustained venous hypertension in the superficial veins, owing to incompetent valves in the deep or perforating veins or to previous deep vein thrombosis. The increased pressure causes extravasation of fibrinogen through the capillary walls, giving rise to perivascular fibrin deposition, which leads to poor oxygenation of the surrounding skin.

Venous ulcers are common in later life and cause a significant drain on healthcare budgets as they are often chronic and recurrent; they affect 1% of the population over the age of 70 years. They are most commonly found on the lower leg in a triangle above the ankles (Fig. 23.35), and are associated with:

- venous eczema (p. 1330)
- brown pigmentation from haemosiderin
- varicose veins
- lipodermatosclerosis (the combination of induration, reddish brown pigmentation and inflammation)
- scarring white atrophy with telangiectasia (atrophie blanche).

Treatment

High-compression bandaging (e.g. Unna boot or four-layer bandaging) and leg elevation are used to try to

Table 23.12 Causes of leg ulceration

Venous hypertension
Arterial disease (e.g. atherosclerosis)
Neuropathic (e.g. diabetes, leprosy)
Neoplastic (e.g. squamous or basal cell carcinoma)
Vasculitis (e.g. rheumatoid arthritis, SLE, pyoderma gangrenosum)
Infection (e.g. ecthyma, tuberculosis, deep mycoses, tropical ulcer, syphilis, yaws)
Haematofogicaf (e.g. *sickle cell* disease, sprrerucyfosisj'
Drug (e.g. hydroxycarbamide (hydroxyurea))
Other (e.g. necrobiosis lipoidica, trauma, artefact)

Fig. 23.35 Venous leg ulcer.

decrease the venous hypertension. Doppler studies should always be done before bandaging to exclude arterial disease. This treatment is best delivered in the community by appropriately trained nurses. 'Four-layer bandaging' is increasingly popular as this provides high levels of graduated compression (with pressures decreasing up the leg). The choice of ulcer dressing is less critical but one should be chosen to keep the ulcer moist and free of slough and exudate. Up to 80% of ulcers can be healed within 26 weeks. Slower healing rates occur in patients with decreased mobility and if the ulcers are very large, present for longer than 6 months or are bilateral. Diuretics are sometimes helpful to reduce the oedema. Antibiotics are necessary only for overt bacterial infection. Unusual fungal infection ('tinea incognito') is increasingly reported under compression bandaging.

Venous leg ulcers can be very painful so adequate analgesia should be given, including opiates if required. Underlying venous disease is best investigated with duplex ultrasound or plethysmography. Split-thickness skin grafting is used in resistant cases. Life-long support stockings (individually fitted) should be worn after healing as this lessens recurrence.

Surgery for purely superficial venous disease can occasionally be useful for ulcer healing but, in general, venous surgery is unhelpful.

Arterial ulcers

Arterial ulcers may present as punched-out, painful ulcers higher up the leg or on the feet. There may be a history of claudication, hypertension, angina or smoking. Clinically the leg may be cold and show pallor. Absent peripheral pulses, arterial bruits and loss of hair may be present. Doppler ultrasound studies will confirm arterial disease (p. 866) and digital subtraction angiography will further delineate the extent and site of the disease.

Treatment depends on keeping the ulcer clean and covered, adequate analgesia and vascular reconstruction if appropriate.

Neuropathic ulcers

Neuropathic ulcers tend to be seen over pressure areas of the feet, such as the metatarsal heads, owing to repeated trauma. These are most commonly seen in diabetics because of peripheral neuropathy. In developing countries leprosy is a common cause.

Treatment depends on keeping the ulcer clean and removing pressure or trauma from the affected area. Diabetics should pay particular attention to foot care and correctly fitting shoes with the help of a specialist podiatrist (p. 1130).

PRESSURE SORES (DECUBITUS ULCERS, BEDSORES)

These occur in the elderly, immobile, unconscious or paralysed patients. They are due to skin ischaemia from sustained pressure over a bony prominence, most commonly the heel and sacrum. Normal individuals feel the pain of continued pressure, and even during sleep, movement takes place to change position continually. Pressure sores may be graded:

- Stage I: non-blanchable erythema of intact skin
- Stage II: partial-thickness skin loss of epidermis/ dermis (blister or shallow ulcer)
- Stage III: full-thickness skin loss involving subcutaneous tissue but not fascia
- Stage IV: full-thickness skin loss with involvement of muscle/bone/ tendon/joint capsule.

There are numerous risk factors for development of pressure sores (Table 23.13).

The majority of pressure sores occur in hospital. Seventy per cent appear in the first 2 weeks of hospitalization, and 70% are in orthopaedic patients, especially those on traction. Between 20% and 30% of pressure sores occur in the community.

Table 23.13 **Risk factors for the development of pressure sores**

Prolonged immobility:
paraplegia
arthritis
severe physical disease
apathy
operation and postoperative states
plaster casts
intensive care
Decreased sensation:
coma, neurological disease, diabetes mellitus
drug-induced sleep
Vascular disease:
atherosclerosis, diabetes mellitus, scleroderma, vasculitis
Poor nutrition:
anaemia
hypoalbuminaemia
vitamin C or zinc deficiency

Eighty per cent of patients with deep ulcers involving the subcutaneous tissue die in the first 4 months.

The early sign of red/blue discoloration of the skin can lead rapidly to ulcers in 1-2 hours. Leaving patients on hard emergency room trolleys, or sitting them in chairs for prolonged periods, must be avoided.

Management

Prevention

Prevention is better than cure. Specialist 'tissue-viability nurses' help identify at-risk patients and train other medical staff. Several risk-assessment tools have been devised for the immobile patient based on the known risk factors. The 'Norton scale' and Waterlow Pressure Sore Risk Assessment (Box 23.4) are two such validated systems which produce a numerical score, enabling staff to identify those at most risk.

Treatment

- Bed rest with pillows and fleeces to keep pressure off bony areas (e.g. sacrum and heels) and prevent friction.
- Air-filled cushions for patients in wheelchairs.
- Special pressure-relieving mattresses and beds.
- Regular turning but avoid pressure on hips.
- Ensure adequate nutrition.
- Non-irritant occlusive moist dressings (e.g. hydrocolloid).
- Adequate analgesia (may need opiates).
- Plastic surgery (debridement and grafting in selected cases).
- Treatment of underlying condition.

VASCULITIS (see also p. 581)

Vasculitis is the term applied to an inflammatory disorder of blood vessels which causes endothelial damage. Cutaneous vasculitis (confirmed by skin biopsy) may be an isolated problem but occasionally is associated with vasculitis in other organs. The most commonly used classification is based on the size of blood vessel involved (see Tables 10.18 and 10.19).

The cutaneous features are of haemorrhagic papules, pustules, nodules or plaques which may erode and ulcerate. These purpuric lesions do not blanche with pressure. Occasionally a fixed livedo reticularis pattern may appear which does not disappear on warming. Pyrexia and arthralgia are common associations even in the absence of significant systemic involvement. Other clinical features depend on the underlying cause.

The most common cutaneous vasculitis affects small vessels and is called leucocytoclastic vasculitis (LCV) or angiitis. This usually appears on the lower legs as a symmetrical palpable purpura. It is rarely associated with systemic involvement. This can be caused by drugs (15%), infection (15%), inflammatory disease (10%), malignant disease (< 5%) but often no cause is found (55-60%). Extensive investigations are probably best reserved for

Box 23.4 **Pressure sore risk-assessment tools Norton Scale for Pressure Sores**

		Clammy	1	Doubly incontinent	3	Inert/traction	65-75			
							75-80			
							81+			

Special risk factors	Assessment value	
1. Poor nutrition; e.g. terminal cachexia	At risk	10
2. Sensory deprivation, e.g. diabetes, paraplegia, cerebrovascular accident	High risk	15
3. High-dose anti-inflammatory or steroids in use	Very *high risk*	*20*
4. Smoking 10+ per day		
5. Orthopaedic surgery/fracture below waist		

those with persistent lesions or associated signs and symptoms. Whilst LCV often settles spontaneously, treatment with analgesia, support stockings, dapsone or prednisolone may be needed to control the pain and to heal up any ulceration. Urticarial vasculitis is discussed on page 1335.

LYMPHATICS

Lymphoedema

Lymphoedema refers to a chronic non-pitting oedema due to lymphatic insufficiency. It is most commonly seen affecting the legs and tends to progress with age. The legs can become enormous and prevent wearing of normal shoes. Chronic disease may cause a secondary 'cobblestone' thickening of the skin. Lymphoedema can be primary (and present early in life) owing to an inherited deficiency of lymphatic vessels (e.g. Milroy's disease) or can be secondary because of obstruction of lymphatic vessels (e.g. filarial infection or malignant disease).

Treatment is with compression stockings and physical massage. If there is recurrent cellulitis, long-term antibiotics are advisable as each episode of cellulitis will further damage the lymph vessels. Surgery should be avoided.

Lymphangioma circumscriptum

Lymphangioma circumscriptum is a rare hamartoma of lymphatic tissue. It usually presents in childhood with multiple small vesicles in the skin which weep lymphatic fluid and sometimes blood. They reflect deeper vessel involvement so surgery should be avoided. Cryotherapy or CO_2 laser treatment may help the superficial lesions.

DISORDERS OF COLLAGEN AND ELASTIC TISSUE

Ehlers-Danlos syndrome (see also p. 602)

Ehlers-Danlos syndrome can be subdivided into at least 10 variants. They are all inherited disorders causing abnormalities in collagen of the skin, joints and blood vessels. Clinically this causes increased elasticity of the skin, hypermobile joints and fragile blood vessels causing easy bruising or in some cases internal haemorrhage. The skin is hyperextensible but recoils normally after stretching. It is easily injured and heals slowly with scarring like tissue paper. Pseudotumours may occur at the sites of scarring (such as elbows and knees) consisting mainly of fat, but calcification can occur.

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum is a rare group of disorders characterized by abnormalities in collagen and elastic tissue affecting the skin, eye and blood vessels. The skin may be loose, lax and wrinkled. It can look yellowish and papular ('plucked chicken skin') and tends to lose its elastic recoil when stretched. Skin changes are best seen in the flexures especially the sides of the neck. Non-cutaneous features are not always present but they include recurrent gastrointestinal bleeding, early myocardial infarction, claudication and angioid streaks on the retina reflecting disruption of vascular elastic tissue.

Marfan's syndrome (see also p. 839)

Marfan's syndrome, an autosomal dominant disorder of connective tissue, is described on page 839. The syndrome is characterized by tall stature and long thin digits (arachnodactyly) (Fig. 13.98). The arm span can exceed the height of the patient and a high arched palate may be present. Lax ligaments result in frequent dislocation of joints. Inguinal and femoral hernias are common. Scoliosis and flat feet may be present. Pulmonary changes include emphysema, diaphragmatic hernia and spontaneous pneumothorax. Dislocation of the ocular lens is common. Skin changes are usually absent but striae may develop. Patients with homocystinuria (see p. 602), type III and VI Ehlers-Danlos syndrome (EDS) and 'marfanoid phenotype' have some similar features but often do not develop the life-threatening complications of Marfan's syndrome, so accurate diagnosis by an expert is essential.

Treatment

Patients should be reviewed by an ophthalmologist, an orthopaedic surgeon and a cardiologist to screen for and deal with the above complications. Genetic counselling should be offered to families.

Striae

Striae are visible linear scars due to dermal collagen damage and stretching. Histologically a thinned epidermis overlies parallel bundles of fine collagen. They occur commonly over the abdomen and breasts in pregnancy but also occur on the thighs and trunk in rapidly growing adolescents as well as in some obese individuals. They are also seen in Cushing's syndrome and corticosteroid therapy. Striae are initially reddish blue but fade

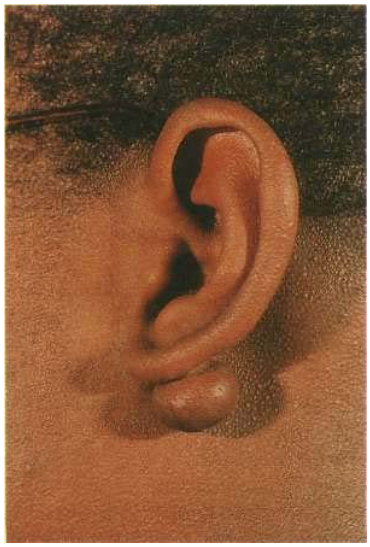

Fig. 23.36 Keloid scar of the lobe of the ear.

to white atrophic marks. Puberty-related striae normally disappear completely.

Keloid scars

Keloid scars are characterized by smooth hard nodules (Fig. 23.36) due to excessive collagen production. They may occur spontaneously or follow skin trauma/surgery, and they are often itchy. They tend to affect young adults and are much commoner in black Africans. Sites of predilection include the shoulders, upper back and chest, ear lobes and the chin. Unlike hypertrophic scars (which fade within 12 months) keloids are persistent and may fade with time.

Treatment is with triamcinolone injection, compression with silica gels or surgery but the latter must be followed by steroid injection or superficial radiotherapy or it may make the problem worse.

DISORDERS OF PIGMENTATION

HYPOPIGMENTATION ^

Vitiligo

Vitiligo is a common disorder of depigmentation which probably has an autoimmune aetiology. Sufferers often have relatives with other organ-specific autoimmune disorders. It presents in childhood or early adult life with well-demarcated macules of complete pigment loss. There is no history of preceding inflammation. Patients are very susceptible to sunburn. Lesions are often symmetrical and frequently involve the face, hands (Fig. 23.37) and genitalia. The hair can also depigment. Trauma may induce new lesions. Spontaneous repigmentation can occur and often starts around hair follicles, giving a speckled appearance. However, repigmentation is rare if a lesion has persisted for more than 1 year or if the hair is depigmented. The psychological consequences of vitiligo can be devastating especially in Asian or black African people.

Fig. 23.37 Vitiligo of the hands showing areas of depigmentation.

Treatment is very unsatisfactory and has no impact on the long-term outcome. Sunblocks should be used to prevent burning. Potent topical steroids or phototherapy help some individuals. Treatment with 0.1% tacrolimus ointment is currently under assessment, with conflicting early results. If vitiligo is almost universal and fixed, depigmentation with monobenzone may be considered. Finally, referral to a specialist camouflage clinic is often the most helpful 'treatment'.

Post-inflammatory hypopigmentation

This is one of the most common causes of pale skin. It is much more common in people with pigmented skin. It is seen as a consequence of eczema, acne or psoriasis and may even be the reason for individuals presenting to a doctor. Providing the skin disease is controlled, the pigmentation will recover slowly after many months. Post-inflammatory hyperpigmentation can also occur.

Oculocutaneous albinism

This is a group of rare autosomal recessive disorders affecting the pigmentation of skin, hair and eyes. It can affect all races. Melanocytes are in normal number but have abnormal function. Clinically it presents with universal pale skin, white or yellow hair and a pinkish iris. Photophobia, nystagmus and a squint are also present in most cases.

Treatment involves obsessive protection against sunlight to avoid sunburning and development of skin cancer.

Idiopathic guttate hypomelanosis

This occurs most commonly in black African people and is of unknown aetiology. It presents with small *(2-A* mm) asymptomatic porcelain-white macules, often on skin exposed to sunlight. The borders are often sharply defined and angular. There is no effective treatment.

Leprosy (see also p. 80)

Both tuberculoid leprosy and indeterminate leprosy can present with anaesthetic patches of depigmentation and should always be considered in people from endemic regions. Loss of hair and decreased sweating may also be present in the lesions.

HYPERPIGMENTATION

Freckles (ephelides)

These appear in childhood as small brown macules after sun exposure. They fade in the winter months.

Lentigos

These are a more permanent macule of pigmentation similar to freckles but they tend to persist in the winter. Solar lentigos (also called 'liver spots') occur in older people on exposed skin because of actinic damage.

Chloasma

These are brown macules often seen symmetrically over the cheeks and forehead and are most common in women. They can occur spontaneously but are also associated with pregnancy and the oral contraceptive pill.

Metabolic/endocrine effects

A generalized skin darkening can occur with chronic liver disease, especially haemochromatosis. It also is seen sometimes in Cushing's syndrome, Addison's disease (more marked in palmar creases and buccal mucosa) and Nelson's syndrome.

Peutz-Jeghers syndrome (p. 309) This is an autosomal dominant genetic condition. It presents with brown macules of the lips and perioral region. It is associated with gastrointestinal polyposis which occasionally become malignant.

Urticaria pigmentosa (cutaneous mastocytosis)

This presents most commonly with multiple pigmented macules in children. These lesions tend to become red, itchy and urticated if they are rubbed (Darier's sign). Occasionally lesions may blister and in the rare congenital, diffuse form of the disease the skin can become thickened and leathery.

Occasionally, systemic symptoms are present, such as wheeze, flushing, syncope or diarrhoea, reflecting extensive mast cell degranulation from the skin. Anaphylaxis occurs very rarely and may be precipitated by mast cell degranulators such as aspirin or opiates. The condition spontaneously resolves after some years in children but is persistent in adults.

Skin biopsy shows an excess of mast cells in the skin. Recently a mutation in the proto-oncogene *c-kit* has been demonstrated, resulting in mast cell proliferation and mast cell apoptosis. Monoclonal antibodies against mast cell markers (tryptase and CD117) on immunohistochemistry confirm the diagnosis.

Treatment of the skin, if required, is with antihistamines or PUVA.

Rarely there may be infiltration of internal organs with mast cells *(systemic mastocytosis),* especially in adult disease or neonatal disease. This can involve any organ but especially the bone (where it can cause severe pain), gastrointestinal tract, liver and spleen. There is a small risk of developing leukaemia if the bone marrow is heavily infiltrated.

Other conditions with pigmentation

Cafe-au-lait macules are seen in neurofibromatosis types 1 and 2. They also occur in a wide variety of disorders including tuberous sclerosis, ataxia, telangiectasia, Fanconi's anaemia, multiple endocrine neoplasia type 1, McCune—Albright syndrome.

Multiple lentigines: apart from in Peutz-Jeghers syndrome these are also seen in xeroderma pigmentosum.

Acquired melanocytic naevi are seen in Turner's syndrome (p. 1064) and familial atypical mole-melanoma syndrome (dysplastic naevi, p. 1351).

FURTHER READING

Tharp MD et al. (2003) Mastocytosis. *Advances in Dermatology* 19: 207-236.

DRUG-INDUCED RASHES

Drugs can be toxic and teratogenic but they can also cause problems through allergic reactions. This frequently presents in the skin where just about any type of skin rash can arise (Table 23.14) although a widespread symmetrical maculopapular rash is the most common type (Fig. 23.38). 'Fixed drug eruptions' may occur where a rash evolves and resolves at a specific site. The rash is reproduced at exactly the same site after a repeated exposure.

A thorough history is of great value and always think of a drug cause for any skin condition. The use of prick-testing and patch-testing is rarely helpful and not without risk. Drug allergy can only be proven by rechallenging but this is rarely justified as it carries some risks. Rechallenging is occasionally justified for anti-tuberculosis drugs or antiretroviral drugs but this should be carried out as an inpatient as there is a risk of anaphylaxis. Certain individuals (e.g. those with HIV infections) are more susceptible to drug rashes (Fig. 23.39).

Most rashes will settle spontaneously once the offending agent is removed. The commonest culprits in a hospital setting are antibiotics and chemotherapy agents.

Table 23.14 Morphological types of drug rashes and some common causes

Maculopapular	Penicillin/amoxicillin Penicillin, aspirin
Urticaria	Gold, hydralazine Phenolphthalein in laxatives,
Vasculitis Fixed drug rash	tetracyclines, paracetamol
Pigmentation	Minocycline (black), amiodarone (slate grey)
Lupus erythematosus	Penicillamine, isoniazid
Photosensitivity	Thiazides, chlopromazine, sulphonamide, amiodarone
Pustular Erythema nodosum	Carbamazepine Sulphonamide, oral contraceptive Barbiturates
Erythema multiforme	Corticosteroids Chloroquine, thiazides, gold, allopurinol Methyldopa, gold,
Acneiform	lithium, beta-
Lichenoid	blockers Penicillin, co-trimoxazole,
Psoriasiform	carbamazepine, NSAIDs
Toxic epidermal necrolysi	Penicillamine, ACE inhibitors Gold, sulphonylureas, allopurinol
Pemphigus	
Erythroderma	

Morbilliform drug rash due to penicillin allergy.

Fig. 23.38

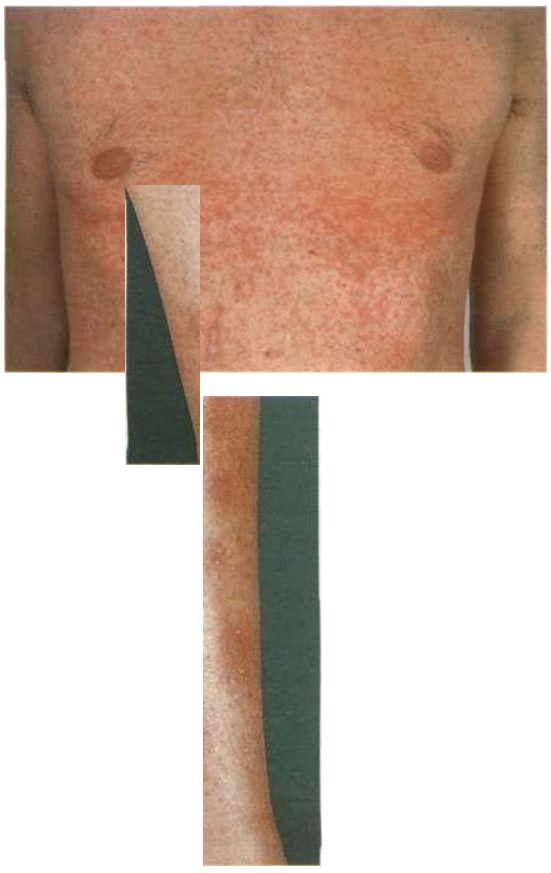

Fig. 23.39 **Erythema nodosum in a patient with HIV on co-trimoxazole.**

The three most serious types of drug rashes are:

- erythroderma (p. 1340)
- toxic epidermal necrolysis
- anticonvulsant hypersensitivity syndrome.

Toxic epidermal necrolysis is characterized by a widespread subepidermal blistering and sloughing of most of the skin. The skin may be itchy but typically takes on a burning quality. Fever and mucosal involvement are common. The internal epithelial surfaces (lung, bladder, gastrointestinal tract) are also involved. Multiorgan failure and sepsis often occur. Toxic epidermal necrolysis can be fatal even after drug withdrawal and intensive care support. Patients should be managed in intensive care or a specialized burns unit. Occlusive cutaneous dressings significantly reduce the pain. Ophthalmological assessment and oral hygiene are necessary. Specific medical treatment with steroids or ciclosporin is controversial. Intravenous immunoglobulin may be beneficial if given early in the disease.

A variant exists called *Stevens-Johnson syndrome* where the damage is restricted to the mucosal surfaces with milder bullous involvement of the skin.

Anticonvulsant hypersensitivity syndrome is characterized by a generalized mucocutaneous rash, fever and lymphadenopathy with variable arthralgia, pharyngitis, periorbital oedema and hepatosplenomegaly. Rarely pustulation of the skin and conjunctivitis are present. The blood may show a peripheral eosinophilia, lymphocytosis with atypical lymphocytes, and a hepatitic picture. It can progress to multiorgan failure. This reaction occurs typically 3-4 weeks into therapy. It can occur with any of the aromatic anticonvulsants (carbamazepine, phenytoin, phenobarbital, primidone and clonazepam). As they often cross-react, all these drugs must be avoided in the future. Sodium valproate is a suitable alternative. There is also potential for cross-reaction with the newer anticonvulsants vigabatrin and lamotrigine.

DISORDERS OF NAILS

Psoriasis *and iunga) nati infection are the* causes of nail dystrophy and are discussed on pages 1333 and 1323.

- *Nail pitting* can be caused by psoriasis, alopecia areata and atopic eczema. A few pits can be present because of trauma.
- i *Onycholysis* (distal nail plate separation) is caused by psoriasis, thyrotoxicosis, following trauma and rarely due to a photosensitive reaction to drugs such as tetracyclines.
- *Koilonychia* (thin spoon-shaped nails) can be caused by iron deficiency anaemia or rarely is congenital.
- *Leuconychia* (white nails) is seen in hypoalbuminaemia. A striate congenital leuconychia exists.
- *Beau's lines* (transverse lines) appear as solitary depressions which grow out slowly over many months. They arise due to a severe illness or shock which causes a temporary arrest in nail growth.
- *Yellow-nail syndrome* is a rare disorder of lymphatic drainage. It presents with thickened, slow-growing, yellow nails with associated pleural effusions, bronchiectasis and lymphoedema of the legs.
- *Onychogryphosis* is a gross thickening of the nail which is seen in later life especially in the big toe-nail. There is often a history of preceding trauma. Both psoriasis and fungal infection can also cause nail thickening.
- *Nail—patella syndrome* is an autosomal dominant condition which presents with triangular rather than half-moon-shaped lunulae, especially of the thumb and forefingers. The nail plates may be small or dystrophic. The patellae are hypoplastic or absent. Other skeletal anomalies can be present and renal impairment (glomerulonephritis) occurs in up to 30% of individuals.
- *Melanonychia* (longitudinal brown streaks) are seen as a normal variant in black-skinned patients. In a white patient it may reflect an underlying subungual melanoma, especially if the pigmentation progresses proximally onto the nail fold ('Hutchinson's sign').
- *Clubbing* is discussed on page 884.

DISORDERS OF HAIR

HAIR LOSS

Hair loss can be due to a disorder of the hair follicle in which the scalp skin looks normal (non-scarring alopecia) or due to a disorder within the scalp skin that causes permanent loss of the follicle (scarring or cicatricial alopecia). This latter form causes shiny atrophic bald areas in the scalp which are devoid of follicular openings. There are many causes of alopecia (Table 23.15).

Androgenic alopecia

Androgenic alopecia (male pattern baldness) is the most common type of non-scarring hair loss and depends on genetic factors and an abnormal sensitivity to androgens. It presents in young men with frontal receding followed by thinning of the crown and there is often a positive family history. It also occurs in females but tends to occur at a later age, be milder and show little in the way of frontal recession. If acne and menstrual disturbance are also present, polycystic ovary syndrome and other endocrine disorders of androgens can be present.

Table 23.15 **Causes of alopecia**

Scarring alopecia	Non-scarring alopecia
Discoid lupus erythematosus Kerion (tinea capitis) Lichen planus Dissecting cellulitis X-irradiation Idiopathic fpseudopelade')	Androgenic alopecia Telogen effluvium Alopecia areata Trichotillomania (self-induced hair-pulling) Tinea capitis Traction alopecia Metabolic (iron deficiency, hypothyroidism) Drug (e.g. heparin, isotretinoin, chemotherapy)

Treatment. This may not be required. Topical 5% minoxidil lotion or oral finasteride (1 mg daily) can help arrest progression and may cause a small amount of regrowth, providing it is used early in disease but the treatment needs to be continued possibly lifelong. Approximately one-third of patients will not respond to either therapy. Finasteride is a selective inhibitor of 5a-reductase type II and it can cause side-effects in 1% of patients such as loss of libido. It should not be used in females as it can affect the sexual development of a male fetus. However, antiandrogen therapy (e.g. cyproterone acetate or spironolactone) helps some women.

Alopecia areata

Alopecia areata is an immune-mediated type of hair loss. It is associated with other organ-specific autoimmune diseases. It presents in childhood or young adults with patches of baldness. These may regrow to be followed by new patches of hair loss. The presence of broken exclamation mark hairs (narrow at the scalp/wider and more pigmented at the tip) at the edge of a bald area is diagnostic. Regrowth may initially be with white hairs and often occurs slowly over months. Occasionally all of the scalp hair is lost (alopecia totalis) and rarely all body hair is lost (alopecia universalis). The nails may be pitted or roughened.

Treatment has no effect on the long-term progression. Potent topical or injected steroids are of limited use. Topical immunotherapy with diphencyprone, PUVA or topical 5% minoxidil are occasionally tried but often do

not help. Wigs can be provided for severe cases and patient support groups are often beneficial.

Traction alopecia

This refers to the 'mechanical damage' type of hair loss that arises from pulling the hair back into a bun or tight plaiting. It is more common in black Africans.

Telogen effluvium

Telogen effluvium refers to the pattern of diffuse hair loss that occurs some 3 months after pregnancy or a severe illness. It occurs because 'stress' puts all the hairs into the telogen phase of hair shedding at the same time. The hair fully recovers and the normal staggered hair growth/hair shedding cycle resumes within a few months.

Dissecting cellulitis

This is a chronic folliculitis affecting predominantly young black males. It presents with papules and pustules over the occipital region of the scalp with hair loss. If severe, the back of the scalp becomes a boggy swelling (discharging pus) with areas of scarring alopecia. It can be complicated by keloid scar formation ('acne keloidalis nuchae').

Treatment is difficult but prolonged courses of low-dose antibiotics are worth trying in early disease. Prolonged courses of isotretinoin can help a few individuals and deep surgical excision can be used in recalcitrant cases.

INCREASED HAIR GROWTH

Hirsutism (p. 1058)

Hirsutism refers to the male pattern of hair growth seen in females. The racial variation in hair growth must be considered. Certain races (e.g. Mediterranean and Asian) have more male pattern hair growth than northern European females. This is not due to excess androgens but may reflect a genetically determined altered sensitivity to them. If virilizing features (deep voice, clitoromegaly, dysmenorrhoea, acne) are present, one should carry out a full endocrine assessment. Hirsutism can cause severe psychological distress to some individuals.

Treatment involves physical methods such as bleaching, waxing, electrolysis and laser therapy. Antiandrogen therapy is occasionally helpful.

Hypertrichosis

Hypertrichosis refers to the state of excessive hair growth at any site and occurs in both sexes. It can be seen in anorexia nervosa, porphyria cutanea tarda, and underlying malignancy and is caused by certain drugs (e.g. ciclosporin, minoxidil).

BIRTH MARKS/NEONATAL RASHES

Strawberry naevus (cavernous haemangioma)

Strawberry naevus affects up to 1% of infants. It presents at, or shortly after, birth as a single red lumpy nodule (Fig. 23.40) that grows rapidly for the first few months. Multiple lesions can be present. They will spontaneously resolve with good cosmesis but this may take up to 7 years for complete resolution. Occasionally plastic surgery is needed after resolution to remove residual slack skin. Reassurance of parents is usually all that is required.

Treatment is indicated if:

- the lesion interferes with feeding or vision
- the lesion ulcerates or bleeds frequently
- the lesion is associated with high-output cardiac failure from shunting of large volumes of blood
- the lesion consumes platelets and/or clotting factors causing potentially life-threatening haemorrhage ('Kasabach-Merritt syndrome').

The latter two complications are very rare and only tend to occur in large lesions with significant deep vessel involvement.

Treatment modalities include intralesional or oral corticosteroids, surgery (for selected lesions), and tunable

Fig. 23.40 **Strawberry naevus** (cavernous haemangioma).

dye laser (for treating ulceration). Alpha-interferon injections, vincristine or embolization is only used for life-threatening events.

Port-wine stain (naevus flammeus)

Port-wine stain is also called a capillary haemangioma but strictly speaking it is not a haemangioma but is just an abnormal dilatation of dermal capillaries. It presents at birth as a flat red macular area and is commonly found on the face. It does not improve spontaneously and it may become thickened with time. If the lesion is found in the distribution of the first division of the trigeminal nerve it may be associated with ipsilateral meningeal vascular anomalies which can cause epilepsy and even hemiplegia (Sturge-Weber syndrome, p. 1257). If a port-wine stain involves the skin near the eye, glaucoma is a risk and ophthalmic assessment is mandatory.

Treatment of port-wine stains is ideally carried out with the tunable dye laser.

Milia

'Milk spots' are small follicular epidermal cysts. They are small pinhead white papules commonly found on the face of infants. They resolve spontaneously.

Mongolian blue spot

This appears in infants as a deep blue-grey bruise-like area, usually over the sacrum or back, and is occasionally mistaken as a sign of child abuse. It is due to deep dermal melanocytes. It is very common in Oriental children, less common in black Africans and rare in Caucasians. It has usually disappeared by the age of 7 years.

Toxic erythema of the newborn (erythema neonatorum)

Toxic erythema of the newborn is a term used to describe a common transient blotchy maculopapular rash in newborns. The rash is occasionally pustular but the child is not toxic or unwell. It disappears within a few days, spontaneously.

Nappy rash ('diaper dermatitis')

This is an irritant eczema caused by occlusion of faeces and urine against the skin. It is almost universal in babies. The flexures are usually spared, which is a useful differentiating feature from seborrhoeic and atopic eczema. If satellite lesions are present around the edge, it may indicate a superimposed *Candida* infection. This rash can also occur in the elderly incontinent.

Treatment involves frequent changing of the nappy and regular application of a barrier cream.

Acrodermatitis enteropathica (p. 249)

This is due to a rare inherited deficiency of zinc absorption. It presents 4-6 weeks after weaning, or earlier in bottle-fed babies. There is an erythematous, sometimes blistering, rash around the perineum, mouth, hands and feet. It may be associated with photophobia, diarrhoea and alopecia.

Treatment is with lifelong oral zinc, which seems to override the poor absorption. The response is rapid.

HUMAN IMMUNODEFICIENCY VIRUS AND THE SKIN (p 34)

HTV infection commonly causes significant dermatological problems. A rash may even be the presenting feature of underlying HIV infection. It is estimated that 90% of HIV-positive patients will suffer with a mucocutaneous disorder during the illness. It is also estimated that up to 30% of people with AIDS will suffer from three different dermatoses. These rashes can often be clinically atypical and difficult to diagnose. One must have a low threshold for skin biopsy and skin culture. On top of this many of the skin problems are resistant to standard treatments. Most of these dermatoses have become less prevalent since the advent of HAART (p. 144).

Cutaneous infection and opportunistic infection

Not surprisingly, infections are increased because of the HIV-induced immune deficiency. Molluscum contagiosum are particularly common especially on the face. They are often multiple and of a 'giant' size measuring over 1 cm across. Molluscum are rarely seen in adults and they can be the presenting feature of HIV. Other viral infections such as extensive ulcerative herpes or widespread viral warts may be seen. Bacterial infections (e.g. staphylococcal boils) and fungal infections (e.g. ringworm and *Candida)* are also common. Recalcitrant and recurrent oropharyngeal candidiasis is a particular problem.

Opportunistic infections such as cutaneous cytomegalovirus (pustules or necrotic ulcers), sporotrichosis (linear nodules) or cryptococcus (red papules, psoriasiform or molluscum-like lesions) can pose diagnostic difficulties, stressing the need for skin biopsy and culture.

Inflammatory *dermatoses*

Inflammatory dermatoses show an increased incidence with HIV infection, probably due to an immune dys-

function or imbalance rather than as a consequence of immune suppression. Severe, extensive seborrhoeic eczema is very common and may be a presenting sign of HIV. Other types of eczema, psoriasis, ichthyosis (dry scaly skin), nodular prurigo and pruritus are all common in HIV infection and can be very severe. Granuloma annulare and lichen planus are probably increased in incidence. The treatment of these conditions is difficult as oral immunosuppressive therapies (e.g. prednisolone, ciclosporin) are best avoided in patients with low CD4 counts. Topical therapies and phototherapy seem relatively safe. Oral retinoids are useful in the management of psoriasis.

'Autoimmune dermatoses'

Bullous pemphigoid, thrombocytopenic purpura, and vitiligo seem to be increased in incidence. The polyclonal stimulation of B lymphocytes by HIV and the resulting abnormal antibody production may be involved in their aetiology. Erythroderma is sometimes seen in HIV disease where skin biopsy suggests a 'graft-versus-host disease' mechanism. This presumably reflects a severe underlying immune dysfunction of T lymphocyte control.

Drug rashes

Adverse drug rashes are much commoner in HIV patients. Reactions to co-trimoxazole, dapsone and antiretroviral drugs appear particularly common. Drug rashes may be severe (especially with nevirapine) resulting in erythroderma or toxic epidermal necrolysis. Other unusual rashes include a striking nail/mucosal pigmentation from zidovudine, paronychia from indinavir and facial lipodystrophy mostly from protease inhibitors.

Cutaneous tumours

Kaposi's sarcoma (p. 142) is much commoner in homosexuals with HIV than in other groups. Basal and squamous cell carcinomas and benign melanocytic naevi are also a little increased in incidence, presumably reflecting a loss of immune surveillance.

'Specific' HIV dermatoses

'Itchy folliculitis' of HIV (also called papular pruritic eruption)

Itchy follicular eruptions are common in HIV as CD4 counts decline. The previously described staphylococcal folliculitis, eosinophilic folliculitis, pityrosporum folliculitis, and demodex mite folliculitis are probably all part of a spectrum and the term itchy folliculitis is useful to encompass these. It presents with intensely itchy papules centred on hair follicles and occurring most commonly over the upper trunk and upper arms. The face is more commonly involved in black patients. Individual lesions frequently have the top scratched off, leaving a crateriform appearance. The aetiology is unknown but may reflect a hypersensitivity reaction as high IgE and eosinophil counts may be present.

Treatment with oral minocycline, potent topical steroids and emollients may help. Phototherapy or oral isotretinoin is useful in resistant cases.

Oral hairy leucoplakia

This is characterized by white plaques with vertical ridging on the sides of the tongue. Unlike with oral *Candida,* the lesions cannot be peeled off to leave raw areas underneath. It was first recognized in HIV disease but can rarely occur in other forms of immunosuppression. It is thought to be due to co-infection with Epstein-Barr virus.

Treatment with aciclovir, ganciclovir or foscarnet may help.

DERMATOSES OF PREGNANCY

There are a number of minor skin changes during pregnancy. There is an increase in spider naevi, melanocytic naevi, skin tags and chloasma. The abdomen shows midline pigmentation (linea nigra) and striae (stretch marks). There are four less common skin problems associated with pregnancy.

Polymorphic eruption of pregnancy (PEP)

This rash tends to appear in the last trimester of a first pregnancy in 1 in 160 cases. It is of unknown aetiology and recurs only rarely in subsequent pregnancies. It presents with very itchy urticated papules and plaques and occasionally small vesicles. Lesions usually start on the abdomen and striae but may spread to the upper arms and thighs. The umbilicus may be spared. PEP is commoner in twin pregnancies. The rash is not associated with any maternal or fetal risk. PEP has been shown to be associated with low maternal serum cortisol levels.

Treatment is with reassurance, bland emollients and mild topical steroids. The rash disappears after childbirth.

Prurigo of pregnancy

This affects 1 in 300 pregnancies. It usually starts on the abdomen in the third trimester but may persist for some months after delivery. Clustered excoriated papules

(prurigo-like lesions) occur on the abdomen and extensor surfaces of the limbs. The cause is unknown but pregnancy-related itch (pruritus gravidarum) may be due to cholestasis (p. 393). Rarely liver function tests are abnormal and urinary HCG levels may be elevated. It can recur in subsequent pregnancies. Some authors believe the condition is associated with an increase in fetal mortality but this remains controversial.

Treatment is with topical steroids and oral antihistamines.

Pruritic folliculitis of pregnancy

This occurs in the second or third trimester of pregnancy and is characterized by an itchy folliculitis which looks similar to steroid-induced 'acne'. It is not associated with any increased maternal or fetal risk.

Treatment with topical benzoyl peroxide and hydrocortisone cream help relieve symptoms.

Pemphigoid gestationis (herpes gestationis)

This is the rarest of the pregnancy-related rashes (1 in 60 000). The immune changes of pregnancy appear to set off bullous pemphigoid. It is characterized by an itchy blistering urticated eruption starting on the abdomen but may become widespread. Large bullae may be present. Unlike PEP it can occur early, starting in the second or even first trimester of pregnancy, and the umbilicus is often involved. It tends to recur in subsequent pregnancies and at an earlier stage. Diagnosis is confirmed by immunofluorescence studies.

A transient bullous eruption occurs in 5% of infants, presumably owing to transplacental passage of the offending antibody. There is no increase in fetal mortality but there is an increased incidence of prematurity and low birth weight, which is probably due to the autoantibody causing placental insufficiency. Therefore, it seems sensible to keep such pregnancies closely monitored and to advise on hospital rather than home delivery.

Treatment of mild cases may be with potent topical steroids but most cases will require oral corticosteroids. The steroid dose may need to be increased after delivery as there is often a postpartum flare-up of the disease. The rash can be set off again by the oral contraceptive pill and this should be avoided.

PRINCIPLES OF TOPICAL THERAPY

Dermatology is unique in having such direct accessibility to the affected organ. This allows the use of topical treatments, which can avoid certain systemic side-effects. A topical therapy consists of an *active ingredient,* an appropriate *vehicle* or *base* to deliver this, and often a *preservative* or *stabilizer* to maintain the product's shelf-life. Cosmetically acceptable products need to be found and patients should be instructed about their correct usage. Without this, compliance tends to be poor. Perfumed or scented products should be avoided.

Bases and their uses

Creams

These are a semisolid mixture of oil and water held together by an emulsifying agent. They need to have added preservatives such as parabens. They are 'lighter' and rub in more easily than ointments. They have a high cosmetic acceptability and are useful for topical treatments of the face and hands. Aqueous cream is particularly useful as a soap substitute.

Ointments

These are semisolid and contain no water, being based usually on oils or greases such as polyethylene glycol (water soluble) or paraffin (fatty). They feel greasy or sticky to the touch. They are the best treatment for dry, flaky skin disorders as they are good at hydrating the stratum corneum and they deliver an active ingredient (e.g. a steroid) more effectively.

If patients dislike the greasy nature of ointments, a cream is better than no treatment at all, but creams are less effective and do have to be used more frequently. A compromise may be to use a cream on the face and an ointment elsewhere (Table 23.16).

Lotions

These are based on a liquid vehicle such as water or alcohol. They are usually volatile and rapid evaporation promotes a cooling effect on the skin. They are useful for weeping skin conditions and are ideal for use on hairy skin (e.g. the scalp). The cooling effect can be a useful antipruritic. Alcohol-based lotions should be avoided on broken skin as they cause stinging.

Gels

These are semisolid preparations of high molecular weight polymers. They are non-greasy and liquefy on contact with the skin. They are useful for treating hairy skin (e.g. the scalp).

Table 23.16 **Emollients commonly used in the UK**

Greasy emollients	Lighter creams
Diprobase ointment* Oily cream	E45 cream*
Unguentum Merck* 50 : 50 white soft paraffin/liquid *paraffin*	Diprobase cream*
	Aveeno cream*
	Aqueous cream

'Trade names

Pastes

Pates contain a high percentage (> 40%) of powder in an ointment base. They are thick and stiff and difficult to remove from the skin. They are useful when a treatment needs to be applied precisely to a skin lesion without it smearing on to surrounding normal skin. An example would be dithranol in Lassar's paste (used on plaques of psoriasis) as dithranol will burn the surrounding normal skin.

Safety of topical steroids

Providing that preparations of appropriate strength are used ***for the body*** *site being treated,* **these compounds can be used** safely on a long-term intermittent basis (p. 1328). If potent steroids are misused they will cause skin atrophy manifest as striae, wrinkling, fragility and telangiectasia.

Problems with topical therapies

- *Systemic absorption* may occur but only if very large areas of inflamed skin are treated topically and especially if the treatment is occluded with bandages or polyurethane films. Neonates are particularly susceptible to this owing to the relative increase in body surface area to volume.

Contact allergy to topical preparations is not uncommon and may be suspected by unusually resistant disease or by apparent worsening of a condition after application of a substance. It is more common with creams as it often the result of allergy to the preservative or emulsifying agent. Allergy can also be due to the active ingredient itself (e.g. neomycin or hydrocortisone).

Folliculitis can occur because of blockage of hair follicles. Creams and ointments should be applied to the skin in the same direction as hair growth to try to prevent this blockage. It is a particular problem with the use of ointments in hot weather (especially if under occlusive bandages) and a lighter cream may be more appropriate at this time.
