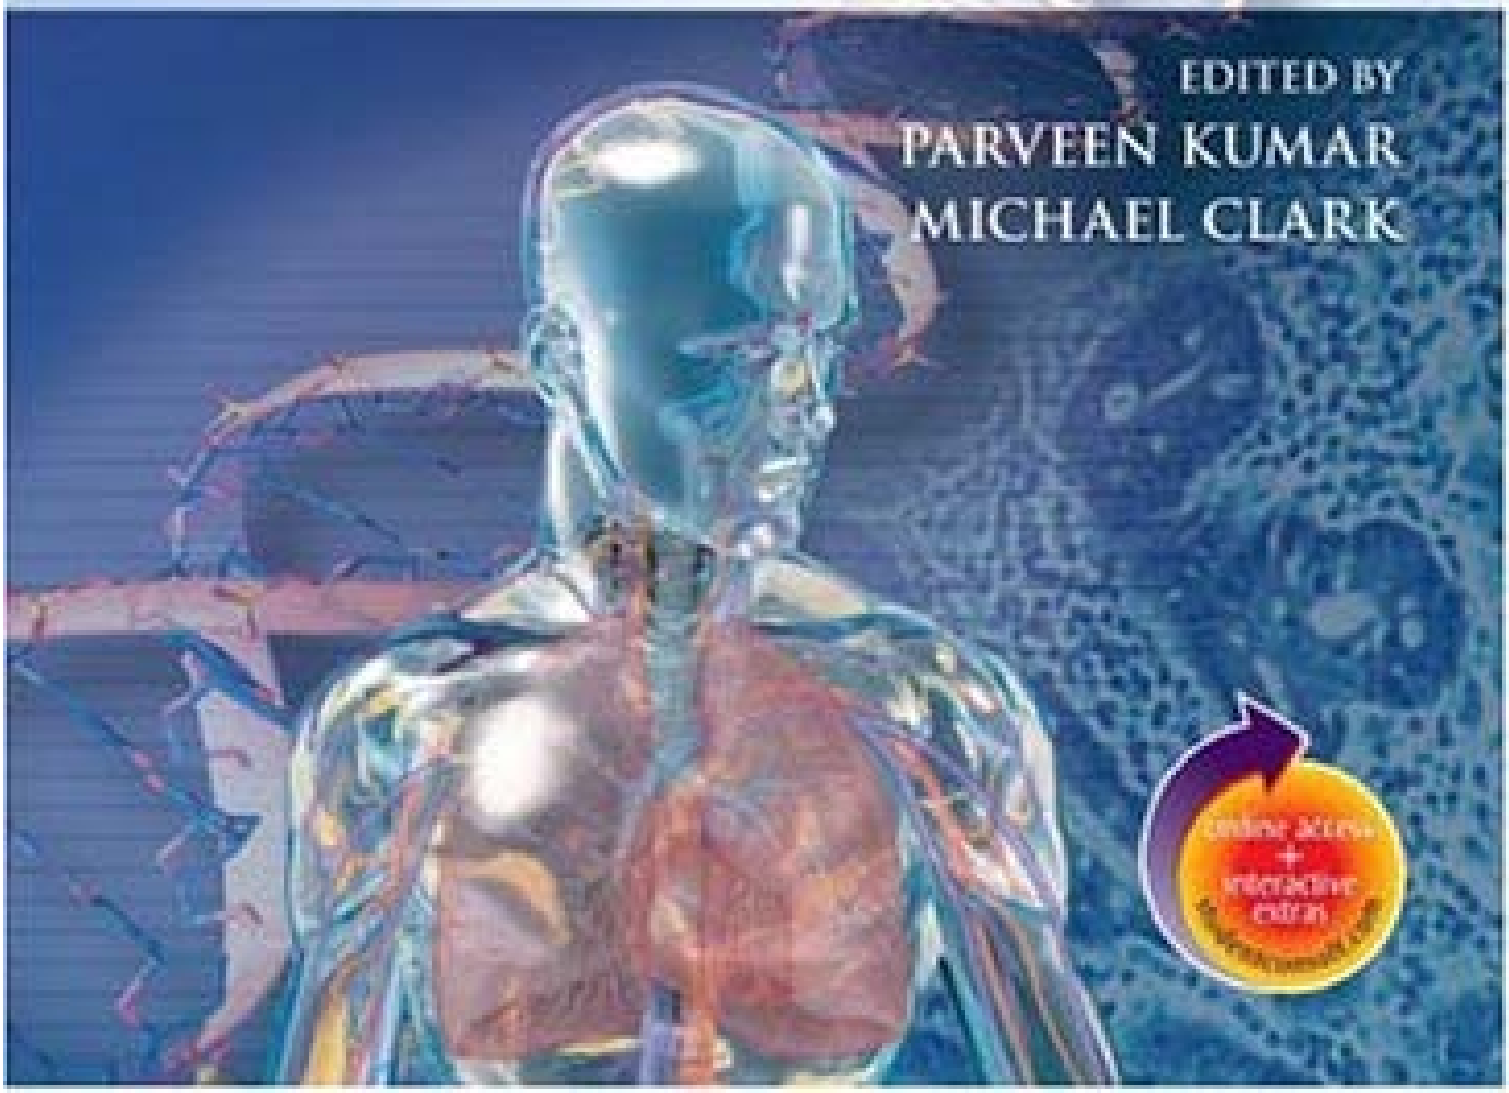
CLINICAL MEDICINE

SIXTH EDITION



EDITED BY
PARVEEN KUMAR
MICHAEL CLARK

Reviews

I have seen this book mature over the editions and the latest incarnation does the lineage proud. This is one of a select few books that deserves to be in most doctors' personal possession and it's as simple as that. Clinical medicine impacts on every aspect of medicine and so most doctors in most specialties should have one general medical textbook in their possession and this one certainly fits the bill. This is primarily a British textbook with a wide range of contributors. However there is also an international advisory panel which gives this book global appeal and it is good to see a British textbook still slugging it out with the big guns. This is a big book and is over 1500 pages and despite being a paperback, it can survive the ravages of regular use. The depth of coverage is superb and will certainly help the majority of users from general clinicians to all the specialties. It will make a superb reference source as well. There is extensive use of colour, boxes, tables and pictures whilst the text is eminently readable, understandable and up to date. Over several months usage, I found it comprehensive, accessible and answered the majority of my clinical medical questions with common and unusual topics covered in sensible detail. Dermatology and special senses are also covered as well as all the usual suspects. The book alone is worth the money but you get more than this when you purchase it. You get free on line access to the full text through http://www.studentconsult.com/ and this is marvellous. This facility can be accessed through any Internet enabled computer and is dead easy to use. Navigation is easy as is searching and the whole book is there. Also thrown are animations of practical procedures, a drug database, cardiac and breathing sounds. These are nice little extras but it is having the book online and freely accessible (being built into the purchase price) is the big boon. The beauty of this book lies in its wide appeal which includes students and post graduates, GPs and Consultants and those in the training grades. Having an online twin to accompany the book as standard is truly fantastic. Throw in a competitive price and this makes the book a worthwhile purchase. Dr. Harry Brown, www.univadis.co.uk

Ethics and communication

ETHICS

WHY STUDY ETHICS AND LAW APPLIED TO MEDICINE?

Professional concern about ethics and law

Many clinical choices created by advances in medical technology are essentially ethical rather than scientific. Doctors may be expert in understanding and applying clinical science, yet this expertise does not in itself answer many ethical questions about the circumstances in which such science should and should not be applied. For example, they may know a great deal technically about advanced life-support systems or the termination of pregnancy. Their knowledge, however, will not tell them whether or not it is ethical to withdraw ventilatory support from a severely brain-damaged patient who will not otherwise die or to perform a termination on a 13-year-old girl who does not want her parents to know that she is pregnant. Answers to these questions derive from moral beliefs and arguments.

Patients are increasingly aware of what they believe to be their human rights and expect doctors to respect them.

- Rights are claims for specific types of goods or services that individuals are believed to be entitled to make on others (e.g. free speech, access to primary and secondary education, access to an acceptable standard of medical care).
- In the UK, if patients believe their rights have been ignored by doctors, they may formally complain to the General Medical Council (GMC) or seek legal redress.
- As it pertains to medicine, the law establishes boundaries for what government and the courts - through statute and common law - have deemed to be acceptable professional practice. The GMC - the UK regulatory body - sets boundaries for acceptable standards of conduct and care through its guidance documents and decisions in cases heard by its Professional Conduct and Performance Committees. ■ Whether or not legal actions or formal complaints against doctors are successful, they contribute toward bringing the medical profession into disrepute.

The three duties of clinical care

The rights of patients may be summarized by three corresponding duties of care which apply to all patients for whom doctors have clinical responsibility.

1. **Protect life and health.** Clinicians should practise medicine to a high standard, taking care not to cause unnecessary harm or suffering. Patients should only be given treatments which they need. Treatments should not be prescribed, for example, just because patients request them.
2. **Respect autonomy.** Humans have autonomy - the ability to reason, plan and make choices about the future. Respect for these attributes goes hand in hand with respect for human dignity. Doctors should respect the autonomy, and thus the dignity, of their patients. This respect for the autonomy of patients leads to two further rights - informed consent and confidentiality. Competent adult patients should be able to choose to accept proposed treatments and to control personal information which they divulge concerning such treatments. Denying patients such choice and control robs them of their human dignity.
3. **Protect life and health and respect autonomy with fairness and justice.** In the conduct of public and professional life, it is generally thought that people

have the right to expect to be treated equally. Medicine is no exception and doctors have a duty to practise accordingly. The access to, and quality of, clinical care should be based only on the dictates of need rather than arbitrary prejudice or favouritism.

Why should doctors take the duties of care seriously?

Professional regulation

Within the UK, the practice of medicine is regulated by the General Medical Council (GMC). It is responsible for the registration of doctors, setting and monitoring the quality of their education and disciplining for unprofessional conduct. Doctors have no professional choice but to conform to the standards laid down by the GMC, which are based on the three duties of care (Box 1.1). These same duties are confirmed by other professional bodies like the Royal College of Physicians, the Royal College of Surgeons, the British Medical Association and the Medical Research Council.

National practices differ but all countries have similar regulatory bodies.

The law

The three duties of care are also enshrined in statute and common law, which also regulate medical practice. Doctors may be sued in civil law for financial compensation for any harm that they may cause while failing in their professional duties. If it can be shown that this failure is intentional, or reckless causing extreme harm or death, doctors may face prosecution in the criminal courts and, if found guilty, imprisonment.

Box 1.1 **General Medical Council (UK), Good Medical Practice: 2-4**

The importance of protecting life and health:

- » 'an adequate assessment of the patient's condition ... (and) ... if necessary, an appropriate examination'
- « 'providing or arranging investigations or treatments where necessary'
- ft 'competence when making diagnoses and when giving or arranging treatment'

The importance of respect for autonomy:

- «; 'listen to patients and respect their views and beliefs'
- * 'giving patients the information they ask for or need about their condition, its treatment and prognosis' 'respecting patients' privacy and dignity'

The importance of fairness and justice:

- " '... (not allowing)... views about a patient's lifestyle, culture, beliefs, race, colour, gender, sexuality, disability, age or social or economic status, to prejudice ... treatments'
- * '... (not refusing or delaying) treatment because you believe that patients' actions have contributed to their condition, or because you may be putting yourself at risk'

Similar statements are made by a variety of professional bodies in many countries.

Box 1.2 **European Convention on Human Rights**

Substantive rights which apply to evaluating good medical practice

Right to life (Article 2)
Prohibition of torture, inhuman or degrading treatment or punishment (Article 3)
Prohibition of slavery and forced labour (Article 4)
Right to liberty and security (Article 5)
Right to a fair trial (Article 6)
No punishment without law (Article 7)
Right to respect for private and family life (Article 8)
Freedom of thought, conscience and religion (Article 9)
Freedom of expression (Article 10)
Right to marry (Article 12)
Prohibition of discrimination (Article 14)

f

«

UK law includes the Human Rights Act 1998. This law incorporates the European Convention on Human Rights, making it legally binding in the UK (Box 1.2). The provisions of the Act impose duties on doctors to ensure that their clinical practice is not in violation of these rights - the same duties that all other doctors in Europe must observe. The Act also thus helps to ensure that what constitutes legal practice in the UK is judged by broader, trans-national moral standards.

Rational self-interest

The most rational way for doctors to ensure that their own medical treatment (as well as the treatment of those for whom they have deep personal feelings) meets high standards of care is to support, through the usual professional and legal channels, the right of all patients to the same high standards of care.

The clinical importance of trust

Patients will not trust doctors whom they suspect may ignore their human rights. Without trust, patients will not cooperate in their diagnosis and treatment, undermining the prospect for clinical success. Lack of trust also engenders a defensive and impersonal approach to medicine by both clinicians and patients, potentially spoiling the quality of patient care and professional life.

The doctor/patient relationship

Doctors are expected to treat patients, and their carers where appropriate, as active partners in the healing process.

THE NATURE OF MEDICAL MISTAKES

Doctors have a duty to protect the life and health of patients to an acceptable professional standard. What does this mean in practice and what are the penalties for not doing so?

Clinical negligence

If clinicians are suspected not to have provided an acceptable standard of clinical care, they may be sued for negligence - a breach of their professional duty. To win a legal action and financial damages for negligence, patients/claimants must provide convincing evidence to a judge that:

- they were harmed
- the harm was caused by the accused doctor
- the action which caused the harm was a breach of professional duty.

However, in practice, demonstrating that these three things have occurred may be more difficult. For example, the alleged harm may have occurred against the background of a complex medical condition or course of treatment, making it difficult to establish the actual cause.

When has a breach of professional duty occurred?

In the UK, whether or not a doctor has acted inconsistently with the duty to protect life and health to an acceptable standard, is ordinarily decided in civil cases by a judge on the basis of testimony from expert witnesses.

- Such experts are selected to represent a responsible body of professional opinion. The testimony of these experienced clinicians will be used to help the court determine a professional standard which doctors working in their specializations should meet in clinical practice of the kind under dispute. Both the patient/ claimant and defendant/doctor will try to produce experts to support their case.
- There will be clinical conduct so unreasonable that its negligence speaks for itself (e.g. a dramatic and harmful mistake about drug dosage).
- If expert witnesses are found for the doctor/ defendant who will state that under similar circumstances, they would have clinically responded in the same way as the doctor then the patient/claimant will probably lose. Provided that their testimony is logically consistent and compatible with other widely accepted professional beliefs about good clinical practice, it is likely that the doctor's actions will be found to be reasonable. This will be so irrespective of how representative the clinical opinions given in court are of other doctors practising in the same field. Experts can differ about what is and is not clinically acceptable.
- Because only a minority opinion is required for doctors to defend claims of negligence against them, the professional standard employed in deciding such claims can make it difficult for patients/claimants to win damages. . ■

Inexperience is irrelevant

Lack of experience is not taken into account in legal determinations of negligence or the GMC's formal hearings. All doctors are expected to work to a professional standard of expertise based on similar clinical work of experienced clinicians. This does not mean that doctors have to be experts in everything. In the face of doubts about their ability or training to provide treatment to a reasonable standard, doctors should seek appropriate supervision and refuse to proceed otherwise.

Mistakes are not necessarily to be feared

Poor professional practice - for example, clinical care which is overly defensive - can result from unfounded fears of patients' readiness to make formal complaints or take legal action.

- All doctors make clinical mistakes in their professional careers. Yet it should be clear that a clinical error is not necessarily a negligent error. Responsible and experienced clinicians may testify that the erroneous action was and is unavoidable in that type of clinical practice. Under similar circumstances, they too some times make - or might make - the same error.
- Just because doctors can make professionally defensible mistakes does not mean that they should in any way relax their professional standards.
- Professional bodies within medicine, and the defence associations which insure doctors against negligence, recommend that doctors should be honest and apologetic about their mistakes, remembering that to do so is not necessarily an admission of negligence. As a result of such honesty and humility, there is mount ing evidence that patients will feel that they have been respected and are less likely to take legal action or to make formal complaints. ■•-■■•

For all of these reasons, there is less to fear legally from patients than doctors sometimes believe. The law offers wide protection for clinicians provided that they do their best to act reasonably and responsibly in protecting the lives and health of their patients.

RESPECT FOR AUTONOMY

Legally valid consent

Obtaining the consent of patients to treatment is just as fundamentally a part of good medical care as is proper clinical diagnosis and good therapeutic management. Doctors seeking consent for a particular procedure must be competent in the knowledge of how the procedure is performed and its problems.

For agreement to treatment to be legally acceptable it must meet three conditions:

- Consent must be informed to an adequate standard.
- Patients must be competent to consent to treatment.
- Patients must not be coerced into accepting treatment against their wishes.

Patients need to weigh up the pros and cons of proposed treatments with other objective interests in their personal lives. They cannot do so without the basic ability to reason about information concerning what is wrong with them, what their doctors propose to do about it, and with what potential benefits and risks. If patients are coerced into making choices about treatment, the ethical and legal right to exercise control over their personal life is ignored. In these circumstances, such choices become more those of clinicians who unduly pressure patients rather than of patients themselves.

Battery

It is an unlawful battery intentionally to touch a competent person without their consent.

- For competent adult patients to be touched lawfully, they must be given information in broad terms about the proposed treatment - what it is and why it is being suggested. Thus a clinician will commit a battery if such a patient is given an injection without permission, irrespective of the need for it.
- Treatment can be given legally to adult patients without consent if they are temporarily or permanently incompetent to provide it and the treatment is *necessary* to save their life, or to prevent them from incurring serious and permanent injury. Otherwise, consent must be obtained, however inconvenient this may be for the patient or clinician.

Negligence: information about risks

Clinicians may also be in breach of their professional duty to obtain adequate consent through not providing a reasonable amount of information about the *risks* of proposed treatment. Here the legal claim of a patient/claimant would be for negligence.

The reasonable doctor standard of disclosure:

- Success will depend on the court being convinced that the patient/claimant had been harmed by the treatment and would not have agreed to it if they had been given more information about its risks.
- The patient/claimant must also show the amount of information provided about risks was unreasonable. If the clinician/defendant can find expert witnesses deemed to constitute a reasonable body of medical opinion who will say that they too (at that point in time) would have provided no more information about risks, the patient/plaintiff will probably lose, just as we saw in the case of litigation for clinical negligence.
- This 'professional standard' of disclosure of information about risks is open to dispute.

The reasonable patient standard of disclosure.

Patients may disagree with clinicians about how much information they require to protect their personal interests. Indeed, in deciding what information to disclose to patients about risks, clinicians may know little about how they perceive their interests. Since it is the health and lives of patients that are potentially at risk, the moral focus of such disclosure should be on what is acceptable to them rather than the medical profession.

- It is increasingly argued that clinicians obtaining consent to treatment should ask what sort of information about risks a 'reasonable person' in the position of the patient would want before agreeing to treatment. To do otherwise constitutes an unacceptable threat to the moral rights and dignity of patients and entails a potential loss of trust in the medical profession.
- Practically, clinicians should interpret this standard of disclosure of the reasonable person as meaning that they should ask what sort of information someone in the position of the patient needs, in order to make an informed choice. When in doubt, clinicians should also ask what sort of information they would want for themselves, their families and friends. They should also remember that the graver the risk, the more important it is to disclose information about it, even when the chance of it occurring is small.

Express vs implied consent

Consent to treatment may be obtained in two ways:

- Express consent may be verbal or written, usually through the patient signing a consent form. Here consent is given explicitly in relation to specific information about the proposed treatment. Consent to surgical treatment is usually express and written. Consent to lesser forms of physical intervention (e.g. venepuncture) is ordinarily express and verbal. Clinicians should always remember that a signed consent form is not legal or professional proof that proper express consent has been obtained. Informed consent should be viewed as an educational process. Signed consent forms are symbols of the completion rather than the success of this process.
- Consent may also be implied by the fact that the patient accepts treatment without question, protest or any other physical sign that might be associated with rejection. Implied consent is ordinarily given against the background of an express consent to a specific treatment which has already been obtained. For example, once patients have given their express consent for being connected to a drip, there is no need for them to given further consent whenever its contents are replenished.
- Patients have not given their implied consent to a specific treatment simply because they have presented themselves for care in a hospital. They must be given appropriate information about the proposed care and provide express consent to it. <

Medical students or their supervisors should always obtain the explicit consent of patients to provide case histories or to be examined for purely educational purposes. Students should always make it clear to patients that they are not qualified doctors.

Confidentiality

If clinicians violate the confidentiality of their patients, they risk causing harm rather than protecting patients from it. Through violating the right of patients to control information which they divulge as part of their medical care, such clinicians disrespect autonomy, undermine trust and call the medical profession into disrepute. These rights are protected by common and statute law. Doctors who breach the confidentiality of patients face severe professional and legal sanctions.

Respecting confidentiality in practice

Patients should be informed of the ways in which information about them will need to be shared with other clinicians and healthcare workers involved in their treatment. On the basis of this information, unless patients state the contrary, they give their implied consent for this information to be shared. Where patients object to particular information being shared, their wish should be respected unless this interferes with the successful execution of their treatment. Information should be sought from patients as early as possible about who, if anyone, they wish to be given information about their condition and treatment. A note should be made of their wishes in the clinical record. Clinicians or healthcare workers not involved in the care of a patient have no right of access to related information without the patient's consent, simply because such information is considered useful for other purposes. In almost all clinical circumstances, therefore, the confidentiality of patients must be respected.

When confidentiality must or may be breached

The principle of confidentiality in medicine is not absolute. Sometimes, the law dictates that clinicians must reveal private information about patients to others in contexts that they may or do object to. At other times, they have the discretion to do so, in accordance with good professional practice. Both circumstances highlight the difficult ethical tension which can be posed between the rights of individual patients and the interests of the public. The right to privacy does not entail the right to harm others in exercising it.

Therefore, clinicians must breach confidentiality when (among others):

- patients have infectious diseases which must be notified, through informing the relevant local authority officer
- police request information about patients who have been involved in a traffic accident
- patients are suspected of engaging in terrorist activity in the UK
- they are presented with a court order by a judge or asked to do so by a judge in judicial proceedings.

Clinicians have the discretion to breach confidentiality when they become aware of, for example:

- past or potential criminal and violent behaviour that has resulted, or is likely to result, in serious harm to the patient or others, such as child abuse - note that in these circumstances, the ordinary expectation would be in favour of discretion
- refusal of patients to comply with their own legal obligations to provide information about their medical condition to the relevant authority (e.g. to the Driver and Vehicle Licensing Agency); again, it would usually be expected for this discretion to be exercised
- infectious patients who pose a threat to specific individuals through undisclosed risks
- infectious patients who pose a potential threat to unknown members of the public through undisclosed risks.

In all these circumstances, patients should be informed of any intent to breach their confidentiality, unless doing so may place the clinician or others at risk of serious harm. Clinicians should always remember that they are professionally accountable for discretionary breaches and may be asked to justify in court, or by the GMC in the UK, their decision either to disclose or not to disclose.

Respect for autonomy in the treatment of vulnerable patients

We have seen that for consent to treatment to be valid, patients must be competent to give it.

What is competence?

Competence should be understood as task-oriented. People may be competent to do some things but incompetent to do others. This means that they should not be judged to be either competent or incompetent in absolute terms. Legally, if patients are competent they must be able to:

- understand information about their condition and treatment
- remember this information
- deliberate about the therapeutic choices posed by the information
- believe that the information applies to them and is not, for example, being made up for other reasons.

Competence to consent to treatment may be compromised by many things - age, mental illness, congenital disease, accident and injury (among others).

Children

In the UK, the legal age of presumed competence to consent to treatment is 16. Below this age, those with parental responsibility are the legal proxies of their children and usually consent to treatment on their behalf. Yet:

- The age of 16 is somewhat arbitrary and many children below this age clearly possess the abilities associated with competence. For example, they may be mature

enough to understand and reason about information given to them about their condition and treatment.

- Clinicians should ordinarily respect the dignity of such children through asking them if they agree to the proposed treatment, even when the consent of parents is also obtained.
- If such children wish to have clinical consultations and clinically indicated care without the knowledge of their parents then this - along with their confidentiality - should be respected.
- Young children may be incompetent to make important decisions about their medical care, although they may have developed some degree of autonomy in this regard. They should be consulted about their care and due consideration given to their wishes.
- In England, unlike Scotland, young people do not acquire the right to refuse medical treatment thought to be in their best interest until the age of 18. In practice, the legal ability to force treatment on mature children against their wishes should only be contemplated in circumstances where life is at risk or there is a risk of serious and permanent injury. Doing otherwise is not in the best interests of young people because of the potentially dangerous alienation that it may create toward doctors and medicine.

Those with parental responsibility have questionable legal authority to direct clinicians to administer or withdraw treatments deemed necessary to protect children from death or serious harm. The court should be consulted about such disagreements, unless an emergency dictates otherwise.

Psychiatric illness

The vast majority of patients being treated for psychiatric illness are competent to consent and to refuse treatment. There is no difference between their rights and those of other competent patients. Because of the danger of stigma associated with mental illness, great care should be taken to protect their confidentiality. If patients with severe psychiatric illness are incompetent to understand the nature and consequences of their illness, they will be unable to provide valid consent to treatment. Here, the ethical duty of care shifts from respect for autonomy of such patients to protecting them.

The 1983 Mental Health Act (England and Wales). Mental illness may so compromise the autonomy of patients that they become a danger to themselves and/ or to others. Provided that their illness is treatable, such patients may be detained under the 1983 Mental Health Act for further examination and treatment. Because of the terrible risks and ethical significance of denying someone their ordinary civil liberties, the conditions of detainment under the Act are highly specific: the longer the period of detainment, the more safeguards there are to ensure the clinical need for it (see Table 22.29, p. 1314).

Psychiatric treatment without consent. Under certain circumstances, detained patients may be given psychiatric treatment without their consent. However, attempts should be made to obtain consent, if possible. Unless their mental illness has made them incompetent to do so, such patients must still give their consent to proposed treatments for physical disorders. Again, incompetence in one respect does not entail incompetence in all respects. However, if patients are unable competently to consent because of the severity of their psychiatric condition - and treatment is required to save their life or to prevent serious and permanent disability - they can be given necessary care without it. If treatment can wait, without seriously compromising their interests, then patients should be asked to consent to it when they become competent to do so.

Other forms of incompetence to provide consent to treatment

Patients may also be incompetent because of congenital, developmental or accidental brain damage. With children, those with parental responsibility consent to treatment on their behalf. With adults, there is no provision in English law for adults to act as legal proxies for other adults, although this is not so in other legal jurisdictions (e.g. Scotland). The moral argument for this being so is that some people might not be motivated by protecting the best interests of their family members. Therefore, relatives should not have the final say over treatment decisions. However, relatives should be asked their views about the wishes or concerns of the patient and consulted about medically relevant information which might be used to optimize the success of the patient's care. They should not be given the impression as a result of such consultation that it is they who are determining treatment decisions. Within the jurisdiction of English law, doctors and no one else must decide what is and is not in the best clinical interests of patients. All forms of treatment can be administered to permanently incompetent adults on this basis. Of course, the moral coherence of these arguments depends on the assumption that clinicians are best placed to protect the interest of vulnerable patients and this, in turn, rests on consistently high standards of clinical care and reflection about ethics and law.

ETHICAL AND LEGAL BOUNDARIES OF THE DUTY TO PROTECT LIFE AND HEALTH

Generally speaking, clinicians are professionally obligated to intervene to save the lives of patients for whom they have clinical responsibility. However, there are a range of circumstances where the duty of care to provide life-

sustaining treatment is superseded by other ethical and legal responsibilities.

Competent refusal

The right of competent refusal supersedes the ordinary duty clinicians have to try to save the lives of such patients, along with any preferences others might have that they should be forced to accept treatment (Box 1.3). Patients may refuse life-sustaining treatment explicitly when it is offered or they may formulate an 'advance directive' which stipulates the circumstances under which they refuse it, should they become incompetent to do so in the future. Competent refusals of life-sustaining treatment (e.g. refusal of blood transfusion by Jehovah's Witnesses) must be made on the basis of clear information about the consequences of refusal. Equally, decisions not to attempt to sustain life medically should also only be made with the consent of competent patients (e.g. a decision not to provide cardiopulmonary resuscitation). Such patients may have arrangements which they need to make that their clinicians will know nothing about and it would be ethically wrong to pre-empt this.

The best interests of the incompetent

There will be some situations where the provision of life-sustaining treatment will not be regarded as being in the best interests of permanently incompetent patients, even though not providing it will lead to their death occurring before it otherwise would. This is when prolongation of patients' lives will be of no benefit to them, against the background of their dire clinical circumstances. For example, it is acceptable not to use medical means to prolong the lives of patients when:

- it is believed on good evidence that further treatment will not save life
- patients are already imminently and irreversibly close to death
- patients are so permanently or irreversibly brain damaged that they are incapable of any future self-directed activity or intentional social interaction.

One ethical justification for the latter two provisions is that such patients have no further need for medical treatment because they have no further objective interest in continuing to live. Because of their clinical condition, they can no longer do or achieve anything in life. However, because of potential differences in moral and religious belief, decisions not to provide or continue life-sustaining treatment should always be made with as much consensus as possible among the clinical team responsible for the patient's care and people close to the patient who are consulted about their care. Where there is unsolvable conflict, especially in relation to children and their parents, the court should be consulted. In emergencies, judges are always available in the appropriate court, usually the Family Law Division.

Clinicians may decide not to prolong the lives of imminently dying and/or extremely brain-damaged patients for the legally acceptable reason that they are acting in the best interests of their patients to attempt to minimize their suffering rather than intending to kill them. To do the latter would be murder. Clearly, when contemplating not providing or withdrawing life-sustaining treatments, doctors should do their best to act within the law. However, it should also not be forgotten that much debate continues about whether or not there is a much closer ethical link between clinical decisions not to save life and decisions actively to end it. The law concerning such matters may change at some point in the future.

Box 1.3 Competent refusal

Prima facie every adult has the right and capacity to decide whether or not he will accept medical treatment, even if a refusal may risk permanent injury to his health or even lead to premature death. Furthermore, it matters not whether the reasons for the refusal were rational or irrational, unknown or even non-existent. This is so notwithstanding the very strong public interest in preserving the life and health of all citizens.

Re 7 (adult: refusal of medical treatment) [1992]

The duty as a **doctor to** be fair and just

The principle of equality of persons should dominate the way in which the duties of care are discharged in clinical practice. Clinicians may show technical mastery of treatment options and great ability and sensitivity in obtaining informed consent to treatment and maintaining confidentiality. However, if in the process of doing so, they actively discriminate against individual or groups of patients, they are still acting unprofessionally and should be penalized accordingly. For example, discrimination on the basis of race, age, social worth, class, intelligence or occupation should not be tolerated (Box 1.4).

Scarce resources

As a matter of right in the UK, the National Health Service (NHS) provides *equal* access to appropriate medical care on the basis of need alone. This right is mitigated by scarce resources and the courts have made it clear that they will not force health authorities or trusts to provide treatments which are beyond their means. However, the courts also demand that decisions about such means must be made on reasonable grounds and that patients have a clear right to expect this. Thus on both ethical and legal grounds, prejudice or favouritism is not acceptable in the allocation of scarce resources. If

Box 1.4 The duty as a doctor to be fair and just

Injustice can occur in medicine through treating patients unequally according to (among others):

- race
- age
- fitness
- social worth
- class
- intelligence
- physical attractiveness
- profession
- parenthood.

rationing healthcare is inevitable in the NHS, as many believe to be the case, then ways must be found to do so which are fair and just. In practice this means that scarce resources should be allocated to patients on the basis of the similarity and extremity of their need (e.g. triage) and the time at which they presented themselves for treatment (e.g. the randomness imposed by the 'lottery of nature'). To the degree that this procedure of allocation is followed, all patients will be said to have had an equal opportunity to be treated on the basis of equal need. It is respect by clinicians and healthcare teams for these principles of equality - equal need and equal chance - that guarantees fairness and justice in the delivery of healthcare. In the UK, the National Institute for Clinical Excellence (NICE) is a body set up to evaluate treatments on a clinical and cost-effective basis, and to ensure equal access to care across the country. In circumstances of scarcity, waste and inefficiency are clearly matters of great ethical concern.

More specifically, any well-run A&E department within the United Kingdom will follow precisely these moral principles in the way in which decisions are made about who to treat first and with what. The treatments on offer will be those that have been shown to deliver optimal results for minimal expense. Patients who are in the most need - as determined by the triage nurse - will be seen first. Everyone else will receive treatment in relation to the assessment of the urgency of their need and when they initially register for treatment. In this way a waiting list will be constructed for each clinical session. So long as no one attempts to jump the queue, patients traditionally respect these rules - sometimes to a point of waiting for long periods to be seen without complaint. Waiting lists in other clinical settings should be similarly constructed, although here other variables will come into play (e.g. the accuracy with which general practitioners communicate the urgency of need to hospital consultants). What is unacceptable in any aspect of the allocation of scarce healthcare resources is for prejudice or favouritism - treating equals unequally - to influence their construction.

Lifestyle

Patients should not be denied potentially beneficial treatments on the grounds that their lifestyles have been more unhealthy than others with whom they compete for the same treatments. Decisions to do so are almost always prejudicial. For example, why single out smokers or the obese for blame as opposed to those who engage in dangerous sports? Patients are not equal in their abilities to lead healthy lives and to make correct healthcare choices for themselves. Some are better educated and informed, more emotionally confident and more supported by their social environment. To ignore this, to regard all patients as equal competitors and to reward the already better off is unjust and unfair. In this situation it is incorrect to treat unequals equally.

COMMUNICATION

COMMUNICATION IN HEALTHCARE

During the last 50 years, the subject of communication in healthcare has become a serious study. At the beginning of the 21st century it is now established in the curriculum of every training institute for healthcare professionals at every level. Evidence is that healthcare fails without a conscious informed effort of communication which is the personal and professional responsibility of everyone concerned with the care of the sick: healthcare professionals including nurses, doctors, therapists and pharmacists as well as ancillary staff and managers. It is a major issue in the strategies of all health organizations representing providers, consumers, managers or governmental departments.

Healthcare is seldom a simple matter of 'find it and fix it', in spite of the unquestionable advances of biomedical science. Rather it is a complicated interaction of at least four elements: physical care - surgical or medical; cognitive care to provide clear information for patients to help themselves and to adhere to advice; behavioural care whereby patients can modify their habits and lives; psychological care, either of coincident primary psychological factors or those secondary to physical illness.

It is the aim and mission of the modern healthcare professional to provide care that is evidence-based, unconditionally patient centred and shared in a collaborative partnership. Effective communication is an absolute necessity at every stage in each and every clinical interview. It cannot be delegated.

Communication, good or bad, affects in opposite ways every one of the four aspects of care above and it has an

immense potential for influencing the use of healthcare resources and finances on a grand scale.

Health outcomes

Effect of communication on biomedical care and its outcome

The best biomedical outcome obviously depends upon accurate diagnosis and appropriate treatment. Communication styles that are 'patient centred' provide a more complete clinical picture upon which diagnosis and treatment can be based and lead to improvement in health outcomes (Box 1.5). Patients describe several consistent failures of communication (Box 1.6) which lead to an incomplete history and a poor professional relationship.

Adherence to treatment

Health outcomes also depend on the extent to which patients adhere to their clinical advice. Patients do not do so for many reasons. The correctable factors are all matters of communication: letting patients know why their treatment is being given and what benefits they stand to gain, what the pros and cons may be, what options exist, and doing so in a way which builds trust and collaboration (Box 1.7). The annual economic cost of non-adherence to advice runs into many millions of pounds in the UK.

Social outcomes

Patient satisfaction is the result of their:

- knowing that they are getting the best appropriate biomedical healthcare

Sox *1.5* Communication improves health outcomes

Outcome improved with better communication

Symptom resolution Psychological distress reduced Health and functional status improved Blood pressure control improved Pain control improved Patient anxiety reduced

From Stewart M (1995). Effective physician-patient communication and health outcomes: a review. *Canadian Medical Association Journal* **152:** 1423-1433.

Box *1.6* Failures of communication

Patients reported the following problems in interviews:

54% of their complaints were not elicited ■ 45% of their concerns were not elicited , 50% of psychological problems were not elicited i. In 50% of visits, patients and doctors disagreed on main presenting problem K In 50% of cases, their history was blocked by interruption within 24 seconds.

Simpson M et al. (1991) The Toronto Consensus Statement. *British Medical Journal* **303:** 1385-1387.

***jf* *Box 1.7* Factors in communication which improve patients' adherence to clinical advice**

Clinician understands the patient
Clinician's tone of voice
Clinician elicits all the patient's health concerns
Patient is comfortable asking questions
Patient perceives that sufficient time is spent with the clinician

Stewart M et al. (1999) Evidence on patient communication. *Cancer Prevention and Control* 3(i): 25-30.

- knowing that they are being treated as individuals and not items on a conveyor belt
- being treated in a humane manner.

These are all strongly related to good communication.

Satisfaction also affects psychological well-being and adherence to treatment, both of which have a knock-on effect on physical health outcomes.

Discord between patients and clinicians

Modern healthcare is carried out in a climate of consumerism and critical participation. With this has come an increasing number of complaints and lawsuits from what is nevertheless a small proportion of patients. The majority of complaints are not based on failures of biomedical practice but on poor communication (Box 1.8). In contrast, Box 1.9 shows the qualities that patients describe in interviews with primary care physicians who have never been sued.

Complaints and lawsuits, however, represent the tip of an iceberg. There is widespread failure of even the most basic communication in hospital and general practice, at least in the UK. Box 1.8 shows the results of a very large study of what patients experience rather than their opinion of it. A very large proportion of patients were not provided with even basic civility let alone simple information about their future care.

The monetary costs of these failures of communication is enormous.

Clinician satisfaction

While staffing shortages and inadequate resources and facilities for biomedical care are commonly cited as causes of discontent amongst clinicians of all kinds, it is the quality of their relationships with their patients

***Box 1.8* Factors leading to poor relationships with clinicians**

Factors cited by 75% of complaining patients as the cause of their complaint against their clinician:

Feeling deserted
Feeling devalued t
Information poorly delivered *
Lack of understanding. V

Stewart M et al. (2000) The impact of patient-centred care on outcomes. *Journal of Family Practice* 49: 796-804.

Box *1.9* Qualities leading to good relationships

Primary care physicians (who have never been sued):

orientated patients to the process of the visit, e.g. introductory comments: 'We are going to do this first and then go on to that'
used facilitative comments
asked patients their opinion
used active listening
used humour and laughter
conducted slightly longer visits (18 versus 15 minutes).

Stewart M et al. (2000) The impact of patient-centred care on outcomes. *Journal of Family Practice* 49: 796-804.

and colleagues which is the most reliable global indicator of clinician satisfaction and happiness. Healthcare professionals have a very high incidence of occupational morbidity, a major source of which is seen to be due to difficulties with personal relationships including clinician-patient relationships. The health of clinicians as well as their patients is closely connected with the development of skill, knowledge and above all attitude to communication.

The cost of loss of work, early retirement, healthcare for clinicians and poor performance is a further heavy burden on any health service.

POOR COMMUNICATION BETWEEN DOCTORS AND PATIENTS

HP*-

Difficulties clinicians have in communicating with patients

Lack of knowledge

Clinicians usually concentrate on the biomedical model of clinical medicine rather than the psychosocial model, as they are often ignorant of the qualitative research on the latter. This can lead to major diagnostic and therapeutic errors, for example:

- numerous illnesses have physical symptoms without an organic basis
- physical illnesses are prolonged by psychological factors (p. 1280)
- 20% of medical patients have psychiatric disease (p. 1280).

Many clinicians 'know' that patients never remember what they are told so think it is a waste of time giving them more than reassurance. The evidence is that patients' memory for even complicated matters is good if they are informed skilfully, as outlined on page 13.

Attitude

Clinicians who take an authoritarian role and have a negative attitude to shared care and multiprofessional teamwork tend to reveal themselves in their questioning styles and are unlikely to be self-critical of their communication skills even when they are shown the evidence of their poor performance.

Lack of skill

m Time. It takes coaching and practice to acquire the skill to integrate good communication into every interview and to make patients feel that they have had enough time devoted to them. Clinicians often see communication as desirable but too time-consuming. However, time skimped at a critical moment deprives the patient and involves someone else in more time later.

- *Uncomfortable topics and patients*. Lack of skill also leaves clinicians uneasy in certain difficult interviews, and Box 1.10 shows the different strategies patients notice clinicians use to avoid uncomfortable topics or 'difficult patients'. These strategies are largely the result of clinicians' fears and inadequate training. It is necessary for clinicians to find their own ways of managing patients who are widely found to be difficult.

Failure of empathy

One of the things which distinguishes the healthcare professions from others is that patients expect humanity from their doctors as well as competence. Clinicians provide this by demonstrating empathy (p. 12). This may require an effort from doctors who have never been ill themselves. It takes commitment as well as skill to demonstrate empathy to a large number of similar patients in a morning.

Personal failures

Like anyone else, clinicians can be unhappy, short-tempered, rushed and interrupted, ignorant on some subjects, or charmless. But this is not the patients' problem and it is a professional obligation not to allow doctors' problems to affect a patient's experience or care.

Sox *1.10* Strategies which patients find their doctors use to distance themselves from their patients

Strategy	Example
Selective attention to cues	Chooses biomedical topics, avoids others 'Everyone feels that. Forget it.' 'I am sure everything will be.OK.'
Normalizing Premature reassurance	'Everything is OK.' 'A headache? Tell me about your feet.' 'Nurse will tell you all about that.' 'Worse things happen at sea.' Waving but not stopping
False reassurance	
Switching the topic	
Passing the buck Jollying along Physical avoidance	

Maguire P (2000) *Communication Skills for Doctors*. London: Arnold.

Difficulties for patients in communicating with doctors

Inferiority

Patients commonly feel themselves to be in the weaker position in a medical interview. This may be exacerbated by their own problems or by their clinicians. The aim of shared care is to overcome this inequality.

Anxiety and its consequences

Most patients are anxious to some extent and often try to hide it. Anxiety can make patients seem to regress in behaviour, mental power and memory. Free-floating anxiety may cause ideas which are worse than reality and contribute to complex misconceptions.

Misconceptions

Anxiety and medical ignorance commonly create misconceptions in patients' minds about their illnesses which in turn profoundly affect their symptoms and the ability to recover. Such misconceptions need detecting and uprooting, without which correct information will not register. Simple reassurance will not supplant a misconception.

Conflicting information

Apart from friends, family and the media, patients get varied information from many different healthcare professionals. Clinicians seldom record what they tell patients. Conflicting information can lie long undetected whilst it contributes to misconceptions.

Forgetfulness

Patients, like most of us who are provided with numerous new and alarming facts, tend to forget all but a few, unless care is taken to aid their memory. This is compounded if they are told information in words they do not understand. However, if information is given carefully, 70-80% of the facts will be remembered by a patient after 6 weeks, or even indefinitely. An exception is evident in well-informed surgical patients who often forget most of what they were told within weeks of their operation.

Disinclination to disclose their concerns

Patients may not disclose all their concerns if they feel nothing can be done, or they are wasting the doctors' time, or fear being thought neurotic with non-physical problems. They are less likely to be forthcoming if their first questions are blocked or answered incomprehensibly, if they fear their effective treatment may be withdrawn, if they are distracted or distressed, or if they do not like or trust their doctor.

Impaired faculties of communication

Patients with impaired hearing or speech or vision or mental function or whose clinician does not speak their language all experience substandard healthcare as a direct result of their inability to communicate.

One in five medical patients have psychiatric illnesses, diagnosed or otherwise, which may affect their ability or inclination to communicate.

THE MEDICAL INTERVIE'

Clinicians conduct about 200 000 interviews during their careers. Such interviews often provide more critical information than do clinical tests and they also form the basis of the relationship which leads to collaborative partnership with their patients.

There is no single prescription for a medical interview because each patient is different, but well-researched guiding principles and well-coached skills will allow clinicians to use their time to the greatest benefit of their patients.

The overriding principle is to find out not only the medical facts in detail, but what patients have experienced and what impact this experience has had upon them. This information is essential to expand the diagnosis and recommend appropriate action and also to gain the confidence, the trust and the compliance of the patient.

The example below is in the context of a first medical interview in a consulting room. Obviously this is different from a follow-up interview, or an emergency.

It is helpful to regard the interview in three phases (Box1.11).

Opening

The start of the interview will be helped by well-organized arrangements for appointments, reception and punctuality. If possible, the clinician should come out of the room to greet each patient. Otherwise it is polite to rise, look at the patient, establish eye contact and shake hands if appropriate. Greet them and find out the way the patient prefers to be addressed. The patient sits beside the clinician, not on the far side of a desk. The clinician sits in a posture which conveys attention and friendliness.

Box 1.11 The three phases of an interview

Opening Exploring and focusing Closing	During which the clinician will	Engage Empathize Educate Enlist

Clinicians should introduce themselves indicating a name badge and their status and responsibility to the patient. On no account should the patient be undressed before the first meeting.

First impressions are critical. The patients' non-verbal cues indicate their emotional state, and the main influences on the emotional tone of the interview are the clinicians' own non-verbal messages, facial expression, body language and unspoken attitudes.

Start by discovering what the patient expects from the interview and indicate how long it will last.

Exploring and focusing

Taking a full history

The components of a complete history are shown in Table 1.1. A clear factual account of the biomedical details is, of course, essential, but is not enough. The order of taking a history is not prescribed, for example many experienced clinicians begin with the social history: 'To start with, can you tell me something about yourself?'

Listening skills and questioning styles

Questioning style determines whether the clinician or the patient talks more. Clinicians will obtain more information by starting with open questions, letting the patients speak more than they do, then guiding the history by using closed questions for further detail, rather than asking closed questions of their own (Box 1.12). The aim is to obtain all the patients' concerns, remembering that they usually have at least three (range 1-12). Only then can the agenda be prioritized, balancing the patients' concerns with the clinician's main points of interest.

It is a failure on the part of the clinician if a serious point is raised only as the patient has a hand on the door knob, preparing to leave.

Facilitating the patient

If the clinician sits in complete silence, the patient will flounder and lose confidence. The patient will be helped by some eye contact, a grunt even or a smile to show that the clinician is listening attentively. Reflecting questions (see Box 1.12) guide the history, allowing the clinician to take up unexpected points as they arise or expand topics, without interrupting the patient. As the history unfolds, detail can be brought into focus by using screening and closed questions.

Table 1.1 **Components of a medical interview**

The nature of the key problems
Clarification of these problems
Date and time of onset
Development over time
Precipitating factors
Help given to-date
Impact of the problem on patient's life
Availability of support
Patient's ideas and fears
Patient's attitude to similar problems in others
Screening question

Box 1.12 **Questioning style**

Question	Example
Open question	'What has brought you to see me today?'
Open screening question	'Is there anything else you want to tell me?'
Open directive question	'How did the treatment for your headache go?'
Reflecting question	'Could you tell me a bit more about that?'
Closed question	'What date exactly did the headache start?'
Rhetorical leading question	'The headache has got better on my treatment hasn't it?'

Leading questions may be helpful but they should not end in the rhetorical 'isn't it?', 'wouldn't it?' challenge which makes the questions difficult for the patient to discuss even when they are completely wrong.

Ideas and fears and their validation

While the clinician may be mainly interested in the biomedical explanation, patients seek help because of their own interpretation of their condition. They need to know that their ideas have been heard and acknowledged and are henceforth incorporated in their clinician's interpretation of their complaints. Otherwise the patient may tend to believe that the clinician has not got things right, which increases the risk of the patient not adhering to the recommendations that follow. So hearing these ideas and then acknowledging them, i.e. *validating* them, is an essential step in engaging a patient's trust, and beginning to 'treat the whole patient'.

If clinicians habitually summarize their biomedical and psychosocial notes at each interview, such misunderstandings can be avoided and their interview is immediately well founded.

Empathizing

Empathy has been described as 'imagination for others'. An empathic response is one which demonstrates a genuine interest in patients' experiences. This is a key skill in building the patient-clinician relationship and is highly therapeutic. Like other communication skills, it can be taught and learnt but it cannot be counterfeited by a repertoire of routine mannerisms.

Techniques which demonstrate empathy are:

- seeing, hearing and accepting patients as they are - illustrated in Box 1.13
- reflecting what the patients are feeling as they talk and what the patient sees as important and what the patient may be thinking
- using the patient's own words and ideas
- letting the patient correct any misunderstanding that arises
- using appropriate self-disclosure without capping the patient's story.

Box 1.13 **Demonstrating empathy by showing the patient that their experiences are recognized and accepted**

Demonstration	Questioning style
The patient experiences being seen	'That last point made you look worried. Is there something more serious about that point you would like to tell me?'
The patient experiences being heard	'I notice that you have talked about the death of your mother but could I ask you to tell me something about how your brother died?'
The patient experiences being accepted	'I can tell you that most people in your circumstances get angry at some point, even with the people who have helped them.'
The clinician shows self-disclosure	'I'm a bit like you. Whenever I get heartburn I think it's a heart attack.'

Giving information - educating the patient

When information is given skilfully, patients are able to understand what is said, to remember it and to find it helpful. Patients are more likely to adhere to clinical advice if they get comprehensible information, if it makes sense of their problems and if they can get easy access to more if they need it. The whole point of giving information is to allow patients to understand their problem and use their information to help themselves. This aspect of patient partnership is a keystone of modern medical practice.

One study of junior doctors showed that they gave information poorly because they lacked both clear objectives and a systematic technique of giving information.

There is a large amount of research to show that:

- Information must be related not only to the biomedical facts, but to the patients' ideas about their condition.
- While most patients are voracious for information, this is not invariably the case, particularly when the information is sensitive or threatening. The pacing of information is discussed further in 'Breaking bad news' on page 14.
- Most patients will understand and recall 70-80% of even the most unfamiliar, complex or alarming information if it is provided along the following guidelines:
  (a) Use a logical sequence to explain the cause and effect of the condition in the context of the patient's symptoms. (Be proactive about explaining causes; patients always want to know.)
  (b) Talk about one thing at a time and check that the patient understands before you move on to the next.

Box 1.14 **Possible aids to giving information**

Method	Example
Write it down	As you go - make a copy for your records With a patient's paragraph
Use a diagram	as a routine Desk-top recorder
Send the patient a copy of your report	£20; tapes 50p each Leaflets, audio
Make an audio tape	or video BACUP for cancer patients
Use prepared information	NHS Direct for help of all kinds. Tel: 0845 4647 Patient
Provide address of support organization	UK:
Provide a website reference	http://www.patient.co.uk

  (c) Use simple language; translate any unavoidable medical terms and write them down.
  (d) Make your information and instructions direct, detailed and concrete.
  (e) At the outset show patients that you will write down the key words, use a simple diagram, and can offer them other aids to memory as shown in Box 1.14. Otherwise patients may be alarmed to find that they are forgetting half of what you say, perhaps distracted by some of the earlier information. Write out the risks of operations for patients, which tend to be rapidly forgotten after operations, however well understood before.
  (f) For the numerous patients who need more information than you can provide in the time, give them prepared information, or a source of it.
  (g) Do not be exasperated when patients refer to the Internet; have a useful website reference ready and written out (see Box 1.14).

Negotiating the next steps - enlisting the patient's collaboration

To achieve optimum adherence, the clinician's suggestions about diagnosis or treatment must be negotiated with the patient. This requires an explanation of the benefits and disadvantages and the risks of these suggestions and any alternatives, all with the aim of enlisting patients to take an active part in their own care.

Patients adhere best to suggestions about investigation and treatment when they are thus enlisted as partners as a result of:

- a frank exchange of information
- a negotiation of options
- involving the patient in decisions.

Summarizing

Misunderstanding can be greatly reduced if clinicians make a brief summary first of the patient's agenda and then their own. This may include matters which have to be postponed to a further interview, and certainly should include the arrangements for any such interview or the commitment to informing other healthcare professionals involved with the patient. It is good, but still rare, practice

to make a note together of what the patient has been told and what has been understood.

Closing

Any human contact ends with an appropriate farewell, not forgetting some words of encouragement.

INTERVIEWS IN WHICH DIFFICULTIES IN COMMUNICATION CAN BE EXPECTED

Some interviews are bound to be difficult for patients or clinicians or both. Usually this is because they have a high emotional content - frightening, painful or embarrassing - and there is no straightforward medical solution. So clinicians have to rely on their personal qualities to an extent which their training may not have prepared them for and can rely less, if at all, on biomedical knowledge.

The three commonest subjects requested on communication courses for doctors reflect problems commonly reported by patients:

- breaking bad news
- complaints and lawsuits
- cultural differences.

These are discussed below.

Other popular topics are: hostility and anger, 'difficult' patients and colleagues, taking a sexual history, and eliciting a psychiatric history, which is discussed in detail on page 1274.

These are all interviews in which, patients find, many clinicians exhibit the distancing strategies listed in Box 1.10. Every clinician has a professional responsibility to recognize interviews they find difficult. Otherwise they will make difficult matters even worse than they need be for their patients and themselves.

The basic principles of the medical interviews described above hold good for all of the above examples but certain details become more prominent.

Breaking bad news

Bad news is any information which is likely to alter drastically a patient's view of the future. It is one of the most potent causes of distress and psychological morbidity and of complaints and lawsuits.

Those interviews may be difficult because:

- bad news commonly means that biomedical measures are of little or no help; so the clinician's familiar basis of experience and authority is discounted
- the patient can be expected to be upset, behave unpredictably and require emotional support which may be beyond what the clinician can give
- the clinician is upset as well
- the patient may blame the clinician, and indeed there may be an element of medical mishap to complicate matters
- the clinician may have had little experience in such interviews (being ushered out during training) or have had bad previous experiences and no help subsequently.

Breaking bad news is a professional skill which is acquired by practice under supervision. It should give a clinician confidence and satisfaction rather than alarm, although it can never be painless.

The way that bad news is broken has a major psychological and physical effect upon patients. For example, the main predictive factor for patients developing full-blown psychiatric disorders on learning of the diagnosis of cancer depends upon the way their bad news is broken. Likewise the memories and well-being of the relatives now and later depends on the way that the subject is introduced; for example, the rehabilitation of patients after acute coronary events depends, damage for damage, on the way in which the news is broken and patients' ideas about it are educated.

Relatives may ask that bad news is withheld from the patient. The information belongs to the patient not to relatives; moreover the evidence is clear that patients:

- usually know more than anyone has guessed
- may imagine things to be worse than they are
- welcome clear information even about the worst news
- welcome the liberty to speak as they wish about their illness and their future rather than join in a charade of deception decided by others
- differ in how much they can take at a time.

The interview

The basic clinical interview described above requires particular attention to certain points:

Opening

- The patient is seen as soon as possible once the current information has been gathered.
- If possible, the patient should have someone with them.
- The interview should take place with everyone introduced, sitting in a quiet place.
- Clinicians must indicate their status and the extent of their responsibility toward the patient and the amount of time available.

Exploring and focusing

- The clinician should find out if anything new has happened since the last encounter.
- What does the patient know and how does the patient react to it? In detail.
- The clinician should then introduce a warning that the news is bad: 'I'm afraid it looks more serious than we hoped.' Then the details.

- At this point the clinician should pause and allow the patient to think, and only continue when the patient gives some lead to follow. This pause may be a long one while thoughts go round in the patient's head, and is often accompanied by shutdown which makes patients unable to hear anything further until these thoughts settle down and allow them to re-emerge.

Only then should the clinician:

- Discover how much the patient is likely to be able to take in at this point - methods for finding this out are shown in Table 1.2.
- Give the information without fudging, in small chunks and make sure that the patient understands each one before moving on.
- Be prepared for the patient to have disorderly emotional responses of some kind and acknowledge them early on as being what you expect and under stand and wait for them to settle before continuing. The clinician must learn to judge which patients wish to be touched and which do not. You can always reach out and touch their chair.
- Watch out for shutdown; when it occurs, just wait. When the patient emerges it is best to deal with what they then say, and only after that take up the running.
- Keep pausing to allow the patient to think.
- Stop the interview if necessary and arrange to resume later.

Focusing on planning and support

m The clinician can emphasize that some things are fixable and others are not. A broad time frame can be given for the fixable aspects of care.

Table 1.2 Two ways to find out how much a patient in an oncology clinic wants to know

Buckman (Canada)	An open screening question: 'If this condition turns out to be something serious are you the type of person who likes to know exactly what is going on?'
Sanson-Fisher (Australia)	Explicit categorization by direct questions in succession: 'If you would like to know, I will tell you ... 1. What the diagnosis is' 2. What the treatment will be' 3. What sort of symptoms you will have' 4. What examinations and tests will be necessary' 5. What can be done for any physical discomfort or pain you may have' 6. What the outcome might be.'

Buckman R (1994) *How* to *Break Bad News.* London: Papermac.
Reynolds PM, Sanson-Fisher RW et al. (1981) Cancer and Communication. *British Medical Journal* 282: 1449-1451.

- No time frame is ever accurate for the unfixable, but the clinician must be prepared for the question: 'How long have I got?' and avoid the trap of providing a figure which is bound to be inaccurate. Rather stress the importance of ensuring that the quality of life is made as good as possible from day to day.
- The patient must be provided with some positive information and hope tempered with realism.

Closing

The clinician must be sure that:

- the patient has understood what has been discussed so far and that crucial information has been written down for the patient
- the patient knows how to contact the appropriate team member and thus has a safety net in place
- the next interview date - preferably soon - has been agreed, for what purpose and with whom
- other members of the family have been invited to meet the clinicians as the patient wishes
- written material and further sources of information are readily available
- everyone is bid goodbye, starting with the patient.

After the bad news is broken

Patients who are facing the loss of life, limb or liberty can be expected to have many questions that are difficult to answer and to exhibit their own pattern of the disorderly emotions summarized in Table 1.3. The way questions are answered and emotions are empathically treated has a major long-term effecton patients and clinicians alike.

Patients want to know if they are going to die and if so when? Will they be able to stay at home? Will they be in pain? Must they eat if they don't want to? Patients facing the end of life have different priorities from the clinicians, and need clear information about their pain and symptom control, the extent to which they can influence this and how long active treatment will continue. Settling family matters and completing unfinished business come high on their agenda, and must be reconciled with attempts at palliation or treatment, particularly if these are of uncertain benefit. It is the clinician's responsibility to mediate between the patient, other medical staff and the patients' relatives.

Even if there is no medical solution, the clinician has a valuable role at this stage as an empathic experienced professional who can help the patient in many ways.

Table 1.3 Emotional responses to the fact or threat of loss: some or all of these can be expected but in no particular pattern

Despair
Denial
Anger
Bargaining
Depression
Acceptance

DEALING WITH ADVERSITY

Complaints and lawsuits

The enormous increase in complaints and medicolegal lawsuits is one indication of the importance of communication in healthcare in these consumerist times.

Unfortunately adversity is as unavoidable in healthcare as it is in life. However, hardworking clinicians doing their best do not always respond appropriately to adverse criticism of any kind. They tend not to deal effectively with grumbles and complaints at the appropriate time, which is as soon as they are made, but use avoiding strategies as for other forms of difficulty (see Box 1.10).

In a national commission on patients' complaints, the two main recommendations were that all healthcare professionals should have training in communication and should be aware of their responsibility for dealing promptly with complaints made by patients in their care and not dump them automatically on managers or complaints officers - especially when patients have suffered the results of a mistake or a mishap.

Complaints

The majority of complaints come from the exasperation of patients who:

- have not been able to get clear information
- feel that they are owed an apology
- are concerned that other patients will go through what they have.

Many complaints are resolved satisfactorily once these points are satisfied, and the sooner the better. In these consumerist times, clinicians should not take criticism as a personal affront but respond professionally by providing the information that patients need, not just by a defence or a medical account but in answer to the patient's specific questions. A personal apology, as medical defence organizations emphasize, is not an expression of guilt; it is a common courtesy. Nor should it be wrapped up so cautiously as to become a worthless token.

Clinicians should work in a professional culture which regards complaints as a valuable source of feedback which deserve to be noted, collected systematically and acted upon if need be. The constructive use of complaints is built into the concept of patient involvement in achieving quality in healthcare.

When clinicians learn of a complaint they should:

be objective, not resentful or defensive - remember that there is a duty of care to the patient in this as every way
remember that the complainant is still a patient
allow all the facts to speak through a clear account, verbal or written
explain the reasons and circumstances behind the facts
express regret
explain how things will improve
leave the medical records strictly unaltered.

Lawsuits

Lawsuits, the extreme form of complaint, are commonly rooted in poor communication arising from:

- delay in providing information to complainants
- misinformation which comes from unclear language and medical jargon
- different words being used by the large number of different healthcare professionals that many patients see
- no clear explanation being given to patients as situations change or when they are discharged
- misunderstanding of the medical records
- failure to provide adequate information during consent procedures.

The difficulty of unravelling these issues is usually complicated by the absence of any record of what the patient was told.

The communication styles that distinguish clinicians who have never been sued (shown in Box 1.9) can help to prevent these frustrations.

A lawsuit is the ultimately wasteful and damaging way of resolving these failures of communication. As in complaints procedures, many patients abandon a lawsuit when they get a clear exposition of the facts which they can see explains their circumstances; something which could usually have been provided long before and should not have arisen in the first place.

Reports

Certain points should be borne in mind when writing in response to a complaint or a court.

The report is for the use of the tribunal (the judge) and not just for representatives of one side. It should be the same regardless of whether the clinician is instructed by the plaintive or the defence.

Writing a legal report is complex and requires the clear separation of the recorded facts from the evidence-based opinions of the experts. It must be comprehensible to the lay members (nearly all) of the tribunal. The clinician who takes on the work of expert witness would be well advised to seek training in the preparation of reports, court procedure and cross-examination. Training is best provided by the firms of solicitors which specialize in this work. Without preparation, the clinician risks failing the court and having an unforgettably bruising experience.

PATIENTS WITH IMPAIRED FACULTIES FOR COMMUNICATION

All healthcare professionals need to exert particular patience and ingenuity, and acquire some special knowledge, when communicating with certain patients with impaired faculties for communication.

Patients with limited understanding or speech. With certain patients, for example with organic brain disease or severe mental disease, clinicians require energy and

Table 1.4 **Dos and don'ts of communicating with people who are deaf or hard of hearing (from RAD - Royal Association in Aid of Deaf People)**

Smile and use eye contact
If you are stuck write it down
Speak normally, don't mouth slowly
Put your face in a good light
Stay still and don't put things in your mouth
Trim moustaches and beards, avoid sunglasses, big earrings or background activity
Never say 'forget it'

imagination to make the best of the limited lines of communication. Open questions are often impossible for them; open directive questions have to be adjusted to the ability of each patient together with every non-verbal gesture, mime or murmur that can help. Just as much ingenuity may be called upon to confirm the meaning of the responses. Third parties involved in the care of the patient can help. Much can be learnt by watching a specialized speech therapist at work.

Patients with impaired hearing. Patients with severely impaired hearing may be accompanied by a signer in one of the two sign languages. Deaf patients who do not use signing are helped by several factors shown in Table 1.4, many of which would not occur to the uninformed.

It is a help for deaf patients to have access to a Minicom - a telephone adapted for the deaf.

Patients whose doctors do not share their cultural background. Patients who do not have the language of their host country or their doctor suffer poor healthcare relative to their socio-economic status, sometimes shamefully so. When such patients depend upon a third party in the form of an interpreter, clinicians must remember to talk to the patient, and not to the interpreter or other third party, to avoid marginalizing the patient and missing what non-verbal communication occurs. Clinicians should also be aware of certain taboos concerning shaking hands, eye contact or topics that cannot be discussed, for example with unmarried women. It is difficult to produce prepared written material for every ethnic group, particularly when these change rapidly. However, members of the patient's community may be able to find appropriate material on the Internet or acquire it otherwise. Another source of help would be a fellow healthcare professional from the same cultural background.

The role Of third parties. It has been suggested that all patients are in need of a third party 'advocate' to help them through the foreign language and culture of healthcare. 'I speak perfect English, but I don't speak Biology.'

Patients in all of the above groups often depend on third parties either for their care or as interpreters, as do very many other patients, particularly at the extremes of life.

With the best of intentions third parties may take over the patients in their care, reading their minds and taking responsibility for them. Whether the patient is with a carer, a relative, another doctor or an interpreter, the clinician should if possible speak to the patient and not to the third party, and make a distinction between what is a straight translation and what the third party is contributing. However, third parties also deserve respect; paediatricians have often been found to communicate more considerately with children than with parents, and the army of carers who look after the disabled are often disregarded by the professionals and family members who may know their charges much less well.

IMPROVING COMMUNICATION

In the UK, improving communication is a stated objective in the policy statement of every national, governmental, professional and academic body concerned with healthcare, particularly in respect of increasing the extent to which patients take part in their own healthcare and its management and reducing the wastage of resources from complaints and non-adherence to treatment.

Most UK institutions which offer undergraduate, postgraduate and continuing education diplomas to healthcare professionals now teach and examine the communication skills of the candidates.

The challenge to the professional bodies and to healthcare management equally is:

- to provide facilities, time, resources and trained personnel to develop and support good communication practice in every healthcare professional
- at the same time to motivate healthcare professionals in communication
- to provide patients with accurate accessible information
- to organize systematic regular feedback from patients and the community and respond to the evidence therefrom.

This requires consistent and persistent strategic initiative, money, an effective programme for change management, and the capacity to provide the individual coaching that is needed to change the performance of individuals. In this sort of strategy it is the peer pressure of senior and influential professionals which has the greatest influence.

Improving communication In individuals

There are certain basic factors which contribute to improving communication skills:

- Having clear objectives about the work, the nature of communication and medical interviews and how the basic interview can be adapted to all others.

Teaching in small groups of learners who get to know each other, all of whom go through the same process. This allows each member to reveal difficulties and weaknesses and to discuss and improve them comfortably.

- Experiential methods are needed; learning by doing it, not by reading the manual.
- Role-play is one cornerstone of learning communi cation skill - role-play with experienced actors as simulated patients rather than amateur role-players selected from the group.
- Discussion of each simulated consultation is carried out along pre-decided rules of feedback, designed to explore what has happened; working from the strengths of the learner towards weaknesses; among friendly, discreet and equally vulnerable colleagues. Learning from feedback can be enhanced by using a video-recording of the process.
- A few hours' work can only raise awareness. A new skill needs to be practised at least three times and often more before it will stick. Improvement in performance requires coaching until the skill is established, and like any other human activity communication skills need to be exercised regularly.

Teaching the teachers

Widespread improvement in communication will require a lot more teachers and well-motivated learners. All teachers should be taught to teach and supported adequately.

Research

One reason that many clinicians do not know the results of research on communication is that the qualitative and meta-analytic methods used are unfamiliar and are dispersed in non-clinical literature.

Qualitative research seeks to ask broad questions concerning social phenomena in a natural rather than an experimental setting - questions about the meaning, the experience, the views and values of healthcare issues to all participants.

The methods used - observation, in-depth interviews, focus groups and detailed case studies - are complementary rather than antithetical to quantitative research. They are designed to answer the questions that quantitative research cannot reach. For example, while quantitative research demonstrates the dangers of smoking, qualitative research examines what makes people stop or continue doing it.

Research into the effect of communication on health is complicated because in the same patient at the same time, good or bad communication influences every one of the four categories of healthcare issues above. Separating the effects of these variables under research conditions requires meticulous techniques of qualitative care, achieved in certain studies hitherto, but only with great difficulty.

Many questions on communication issues remain to be answered:

- What are the most effective methods of practice and teaching?
- How can clinicians become more self-aware and why do they resist learning communication skills?
- How can clinicians get fast personal feedback?
- To what extent does improved communicationinfluence outcome?
- How can cost-benefit calculations be made in com munication practice and how can these best be explained to hard-pressed managers?

Infectiousdiseases, tropicalmedicineand sexuallytransmitted diseases

2

INFECTION AND INFECTIOUS DISEASE

Infection remains the main cause of morbidity and mortality in man, particularly in underdeveloped areas where it is associated with poverty and overcrowding. In the developed world increasing prosperity, universal immunization and antibiotics have reduced the prevalence of infectious disease. However, antibiotic-resistant strains of microorganisms and diseases such as human immunodeficiency virus (HIV) infection, variant Creutzfeldt-Jakob disease (vCJD), and severe acute respiratory syndrome (SARS) have emerged. There is increased global mobility, both enforced (as a result of war, civil unrest, and natural disaster), and voluntary (for tourism and economic benefit). This has aided the spread of infectious disease and allowed previously localized pathogens such as SARS and West Nile virus to establish themselves world-wide. An increase in the movement of livestock and animals has enabled the spread of zoonotic diseases like monkeypox, while changes in farming and food-processing methods have contributed to an increase in the incidence of food and water-borne diseases. Deteriorating social conditions in the inner city areas of our major conurbations have facilitated the resurgence of tuberculosis and other infections. Prisons and refugee camps, where large numbers of people are forced to live in close proximity, often under poor conditions, are providing a breeding ground for devastating epidemics of infectious disease. There are new concerns about the deliberate release of infectious agents such as smallpox or anthrax by terrorist groups or national governments.

In the developing world successes such as the eradication of smallpox have been balanced or outweighed by the new plagues. Infectious diseases cause nearly 25% of all human deaths (Table 2.1). Two billion people - one-third of the world's population - are infected with tuberculosis, 500 million people catch malaria every year, and 200 million are infected with schistosomiasis. Infections are often multiple, and there is synergy both between different infections, and between infection and other factors such as malnutrition. Many of the infectious diseases affecting developing countries are preventable or treatable, but continue to thrive owing to lack of money and political will.

The climate also has consequences on diseases. The El Nino Southern Oscillation (ENSO) is a climatic event originating in the Pacific Ocean that affects the weather world-wide, causing droughts and floods. ENSO affects, for example, the cholera risk and malaria epidemics.

Table 2.1 World-wide mortality from infectious diseases

Disease	Estimated deaths (in 2002/2003)
HIV/AIDS	5 million
Acute lower respiratory infection	3.8 million
Tuberculosis	2.5 million
Diarrhoeal disease	1.8 million
Malaria	1.2 million
Measles	760 000
Tetanus	292 000
Whooping cough	301 000
Meningitis	175 000
Leishmaniasis	51 000
Trypanosomiasis	48 000

Infectious agents

The causative agents of infectious diseases can be divided into four groups.

Prions are the most recently recognized and the simplest infectious agents, consisting of a single protein molecule. They contain no nucleic acid and therefore no genetic information: their ability to propagate within a host relies on inducing the conversion of endogenous prion protein PrPc into a protease resistant isoform PrPres.

Viruses contain both protein and nucleic acid, and so carry the genetic information for their own reproduction. However, they lack the apparatus to replicate autonomously, relying instead on 'hijacking' the cellular machinery of the host. They are small (usually less than 200 nanometres in diameter) and each virus possesses only one species of nucleic acid (either RNA or DNA).

Bacteria are usually, though not always, larger than viruses. Unlike the latter they have both DNA and RNA, with the genome encoded by DNA. They are enclosed by a cell membrane, and even bacteria which have adopted an intracellular existence remain enclosed within their own cell wall. Bacteria are capable of fully autonomous reproduction, and the majority are not dependent on host cells.

Eukaryotes are the most sophisticated infectious organisms, displaying subcellular compartmentalization. Different cellular functions are restricted to specific organelles, e.g. photosynthesis takes place in the chloroplasts, DNA transcription in the nucleus and respiration in the mitochondria. Eukaryotic pathogens include unicellular protozoa, fungi (which can be unicellular or filamentous), and multicellular parasitic worms.

Other higher classes, notably the insects and the arachnids, also contain species which can parasitize man and cause disease: these are discussed in more detail on page 117.

Host-organisminteractions

Each of us is colonized with huge numbers of microorganisms (10^{14} bacteria, plus viruses, fungi, protozoa, and worms) with which we coexist. The relationship with some of these organisms is symbiotic, in which both partners benefit, while others are commensals, living on the host without causing harm. Infection and illness may be due to these normally harmless commensals and symbiotes evading the body's defences and penetrating into abnormal sites. Alternatively, disease may be caused by exposure to exogenous pathogenic organisms which are not part of our normal flora.

The symptoms and signs of infection are a result of the interaction between host and pathogen. In some cases, such as the early stages of influenza, symptoms are almost entirely due to killing of host cells by the invading organism. Usually, however, the harmful effects of infection are due to a combination of direct microbial pathogenicity, and the body's response to infection. In meningococcal septicaemia, for example, much of the tissue damage is caused by cytokines released in an attempt to fight the bacteria. In a few instances, such as chronic South American trypanosomiasis (Chagas' disease), morbidity is almost entirely immunological, with the parasite itself having little effect once the inflammatory process has been triggered. The molecular mechanisms underlying host-pathogen interactions are discussed in more detail on page 199.

Sources of infection

The endogenous skin and bowel commensals can cause disease in the host, either because they have been transferred to an inappropriate site (e.g. bowel coliforms causing urinary tract infection), or because host immunity has been attenuated (e.g. candidiasis in an immunocompromised host). Many infections are acquired from other people, who may be symptomatic themselves or be asymptomatic carriers. Some bacteria, like the meningococcus, are common transient commensals, but cause invasive disease in a small minority of those colonized. Infection with other organisms, such as the hepatitis B virus, can be followed in some cases by an asymptomatic but potentially infectious carrier state.

Zoonoses are infections that can be transmitted from wild or domestic animals to man. Infection can be acquired in a number of ways: direct contact with the animal, ingestion of meat or animal products, contact with animal urine or faeces, aerosol inhalation, via an arthropod vector, or by inoculation of saliva in a bite wound. Many zoonoses can also be transmitted from person to person. Some zoonoses are listed in Table 2.2.

Most microorganisms do not have a vertebrate or arthropod host but are free-living in the environment. The vast majority of these environmental organisms are non-pathogenic, but a few can cause human disease (Table 2.3). Person-to-person transmission of these infections is rare. Some parasites may have a stage of their life cycle which is environmental (for example the free-living

Table 2.2 **Zoonotic infections**

Disease	Pathogen	Animal reservoir	Mode of transmission
Prions			
vCJD	Priori protein	Cattle	Ingestion (CNS tissue)
Viral			
Lassa fever Japanese	Arenavirus	Multimammate rat	Direct contact
encephalitis Rabies	Flavivirus	Pigs	Mosquito bite
Yellow fever Monkey	Rhabdovirus	Dog and other mammals	Saliva, faeces (bats)
pox SARS	Flavivirus	Primates	Mosquito bite
	Orthopox virus	Rodents, small mammals	Uncertain Droplet
	Coronavirus	Civet cats and small mammals	
Bacterial			
Gastroenteritis	*Escherichia coli* 0157	Cattle, chickens	Ingestion (meat)
	Salmonella enteritidis and others	Chickens, cattle	Ingestion (meat, eggs)
	Campylobacter jejuni	Various, e.g. chicken	Ingestion (meat, milk, water)
Leptospirosis	*Leptospira interrogans*	Rodents	Ingestion (urine)
Brucellosis	*Brucella abortus*	Cattle |	Contact; ingestion of
	Brucella melitensis	Sheep, goats J	milk/cheese
Anthrax	*Bacillus anthracis*	Cattle, sheep	Contact; ingestion
Lyme disease	*Borrelia burgdorferi*	Deer	Tick bite
Cat scratch fever	*Bartonella henselae*	Cats	Flea bite
Plague	*Yersinia pestis*	Rodents	Flea bite
Typhus	Various *Rickettsia* spp.	Various	Arthropod bite
Psittacosis (ornithosis)	*Chlamydia psittaci*	Psittacine and other birds	Aerosol
Others			
Toxoplasmosis	*Toxoplasma gondii*	Cats and other mammals	Ingestion (meat, faeces)
Cryptosporidiosis	*Cryptosporidium parvum*	Cattle	Ingestion (faeces)
Hydatid disease	*Echinococcus granulosus*	Dogs	Ingestion (faeces)
Trichinosis	*Thchinella spiralis*	Pigs, beans	Ingestion (meat)
Toxocariasis	*Toxocara canis*	Dogs	Ingestion
Cutaneous larva migrans	*Ancylostoma caninum*	Dogs	Penetration of skin by larvae
Leishmaniasis	*Leishmania* spp.	Dogs	Ingestion

vCJD, variant Creutzfeldt-Jakob disease; SARS, severe acute respiratory syndrome

larval stage of *Strongyloides stercomlis* and the hookworms) even though the adult worm requires a vertebrate host. Other pathogens can survive for periods in water or soil and may be transmitted from host to host via this route (see below): these should not be confused with true environmental organisms.

Routes of transmission

Endogenous infection

The body's own endogenous flora can cause infection if the organism gains access to an inappropriate area of the body. This can happen by simple mechanical transfer, for example colonic bacteria entering the female urinary tract. The non-specific host defences may be breached, for example by cutting or scratching the skin and allowing surface commensals to gain access to deeper tissues; this is frequently the aetiology of cellulitis. There may be more serious defects in host immunity owing to disease or chemotherapy, allowing normally harmless skin and bowel flora to produce invasive disease.

Airborne spread

Many respiratory tract pathogens are spread from person to person by aerosol or droplet transmission. Secretions containing the infectious agent are coughed, sneezed, or breathed out, and are then inhaled by a new victim. Some enteric viral infections may also be spread by aerosols of faeces or vomit. Environmental pathogens such as *Legionella pneumophila,* and zoonoses such as psittacosis, are also acquired by aerosol inhalation, while rabies virus may be inhaled in the dust from bat droppings.

Faeco-oral spread

Transmission of organisms by the faeco-oral route can occur by direct transfer (usually in small children), by contamination of clothing or household items (usually in institutions or conditions of poor hygiene), or most commonly via contaminated food or water. Human and animal faecal pathogens can get into the food supply at any stage. Raw sewage is used as fertilizer in many parts of the world, contaminating growing vegetables and fruit. Poor personal hygiene can result in contamination during production, packaging, preparation or serving of foodstuffs. In the western world, the centralization of food supply and increased processing of food has allowed the potential for relatively minor episodes of contamination to cause widely disseminated outbreaks of food-borne infection.

Table 2.3 **Environmental organisms which can cause human infection**

Organism	Disease (most common presentations)
Bacteria	
Burkholderia pseudomallei	Melioidosis
Burkholderia cepacia	Lung infection in cystic fibrosis
Pseudomonas spp.	Various
Legionella pneumophila	Legionnaires' disease (pneumonia)
Bacillus cereus Listeria monocytogenes	Gastroenteritis
Clostridium tetani	Various Tetanus
Clostridium perfringens	Gangrene, septicaemia
	Pulmonary infections
Fungi	
Candida sp.	Local and disseminated infection
Cryptococcus neoformans	Meningitis, pulmonary infection
Histoplasma capsulatum	Pulmonary infection Pulmonary infection Mucormycosis (rhinocerebral, cutaneous)
Coccidioides immitis	
Mucor spp.	
Sporothrix schenkii	Lymphocutaneous sporotrichosis
Blastomyces dermatitidis	Pulmonary infection
Aspergillus fumigatus	Pulmonary infections

Table 2.4 **Infections transmitted by arthropod vectors**

Disease	Infective organism	Vector
Dengue Yellow fever West Nile fever J Scrub typhus Rickettsial spotted fevers Tick-borne relapsing fever Louse-borne relapsing fever	Flavivirus	Mosquito
	Orientiae tsutsugamushi	Mite
	Rickettsia sp.	Hard tick
	Borrelia duttoni Borrelia recurrentis	Soft tick Body louse
Carrion's disease	*Bartonella bacilliformis*	Sandfly
Lyme disease	*Borrelia burgdorferi Yersinia pestis Plasmodium* sp.	Hard tick
Plague Malaria		Flea
Lymphatic filariasis	*Wuchereria bancrofti Brugia malayi Onchocerca volvulus*	Mosquito Mosquito
Onchocerciasis		
Leishmaniasis	*Leishmania* sp. *Trypanosoma brucei*	Mosquito Blackfly
African trypanosomiasis		Sandfly
South American trypanosomiasis	*Trypanosoma cruzi*	Tsetse fly Reduviid bug

Water-borne faeco-oral spread is usually the result of inadequate access to clean water and safe sewage disposal, and is common throughout the developing world. Global coverage for access to clean drinking water is 83% of the world population but global sanitation coverage is currently 58%.

Vector-borne disease

Many tropical infections, including malaria, are spread from person to person or from animal to person by an arthropod vector. Vector-borne diseases are also found in temperate climates, but are relatively uncommon. In most cases part of the parasite life cycle takes place within the body of the arthropod, and each parasite species requires a specific vector. Simple mechanical transfer of infective organisms from one host to another can occur, but is rare. Some vector-borne diseases are shown in Table 2.4.

Direct person-to-person spread

Organisms can be passed on directly in a number of ways. Sexually transmitted infections are dealt with on page 117. Skin infections such as ringworm, and ectoparasites such as scabies and head lice, can be spread by simple skin-to-skin contact. Other organisms are passed on by blood- (or occasionally other body fluid) to-blood transmission. In some cases such as HIV and hepatitis B virus this is the only route: in others such as malaria and Chagas' disease it is an unusual alternative to the normal arthropod vector. Blood-to-blood transmission can occur during sexual contact, from mother to infant peripartum, between intravenous drug users sharing any part of their injecting equipment, when infected medical equipment is reused, if contaminated blood or blood products are transfused, or in any sporting or accidental contact when blood is spilled.

Direct inoculation

Infection can occur when pathogenic organisms breach the normal mechanical defences by direct inoculation. Some of the circumstances in which this can occur are covered under endogenous infection and blood-to-blood transmission above. Some environmental organisms may be inoculated by accident: this is a common mode of transmission of tetanus and certain fungal infections. Rabies virus may be inoculated by the bite of an infected animal.

Consumption of infected material

Although many food-related zoonotic infections are due to contamination of food with animal faeces (and are thus, strictly speaking, faeco-oral), several diseases are transmitted directly in animal products. These include some strains of salmonella (eggs, chicken meat), brucellosis (unpasteurized milk), and the prion diseases kuru and vCJD (neural tissue).

Prevention and control

Methods of preventing infection depend upon the source and route of transmission, as described above.

- *Eradication of reservoir.* In a few diseases, for which man is the only natural reservoir of infection, it may be possible to eliminate disease by an intensive programme of case finding, treatment and immunization. This has been achieved in the case of smallpox. If there is an animal or environmental reservoir complete

eradication is unlikely, but local control methods may decrease the risk of human infection (for example killing of rodents to control plague, leptospirosis, and other diseases).

- *For arthropod-vector-borne infections:*
  - destroying vector species (which may be practical in certain circumstances)
  - taking measures to avoid being bitten (e.g. insect repellent sprays, bed nets).
- *For food-borne infections.* Improvements in food handling and preparation result in less contamination during processing, transport or preparation. Organisms intrinsically present in food can be killed by appropriate preparation and cooking. Improved surveillance and regulation of the food industry, as well as better health education for the public is necessary.
- *For faeco-oral infections.* Thirty per cent of the world's population do not have access to adequate safe drinking water, and over half do not have adequate sanitation. Improvements in water supply could dramatically decrease the prevalence of faeco-oral infections.
- *For blood-borne infections.* Prevention of blood transfer, e.g. in blood transfusions and contaminated medical equipment. Donated blood is routinely tested for infection in most developed countries.
- *For infections spread by airborne and direct contact.* Some airborne-transmitted respiratory infections, and some infections spread by direct contact, can be controlled by isolating patients. This is often difficult, but isolation is useful in patients with severe immunodeficiency to protect them from infection.
- *Immunization* (p. 42).

Cases of some infectious diseases should be notified to the public health authorities so that they are aware of cases and outbreaks. Diseases that are notifiable in England and Wales are listed in Table 2.5.

Relapsing fever
Rubella
Scarlet fever
Smallpox
Tetanus
Tuberculosis
Typhoid fever
Typhus
Viral haemorrhagic fever
Viral hepatitis
Whooping cough
Yellow fever

PRINCIPLES AND BASIC MECHANISMS

Man constantly interacts with the world of microorganisms from birth to death. The majority cause no harm and some play a role in the normal functioning of the mouth, vagina and lower intestinal tract. However, many microorganisms have the potential to produce disease. This may result from inoculation of damaged tissues, tissue invasion, a variety of virulence factors or toxin production.

Specificity

Microorganisms are often highly specific with respect to the organ or tissue they infect. For example, a number of viruses are hepatotropic, such as those responsible for hepatitis A, B, C and E and yellow fever. This predilection for specific sites in the body relates partly to the immediate environment in which the organism finds itself; for example, anaerobic organisms colonize the anaerobic colon, whereas aerobic organisms are generally found in the mouth, pharynx and proximal intestinal tract. Other organisms that show selectivity include:

- *Streptococcus pneumoniae* (respiratory tract)
- *Escherichia coli* (urinary and alimentary tract).

Even within a species of bacterium such as *E. coli,* there are clear differences between strains with regard to their ability to cause gastrointestinal disease (p. 69), which in turn differ from uropathogenic *E. coli* responsible for urinary tract infection.

Within an organ a pathogen may show selectivity for a particular cell type. In the intestine, for example, rotavirus predominantly invades and destroys intestinal

epithelial cells on the upper portion of the villus, whereas reovirus selectively enters the body through the specialized epithelial cells, known as M cells, that cover the Peyer's patches (see p. 287).

Pathogenesis

Figure 2.1 summarizes some of the steps that occur during the pathogenesis of infection. In addition, pathogens have developed a variety of mechanisms to evade host defences. For example, some pathogens produce toxins directed at phagocytes - *Staphylococcus aureus* (a-toxin), *Strep, pyogenes* (streptolysin) and *Clostridium perfringens* (y-toxin), while others such as *Salmonella* spp. and *Listeria monocytogenes* can survive within macrophages. Several pathogens possess a capsule that protects against complement activation *(Strep. pneumoniae).* Antigenic variation is an additional mechanism for evading host defences that is recognized in viruses (antigenic shift and drift in influenza), bacteria (flagella of salmonella and gonococcal pili), and protozoa (surface glycoprotein changes in *Trypanosoma).*

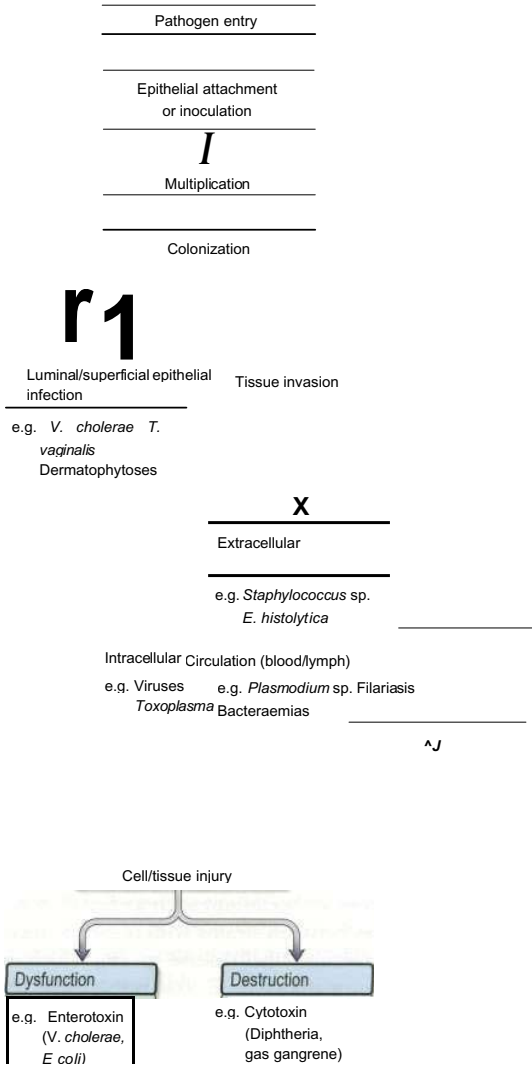

Fig. 2.1 The pathogenesis of infection.

Epithelial attachment

Many bacteria attach to the epithelial substratum by specific organelles called pili (or fimbriae) that contain a surface lectin(s) - a protein or glycoprotein that recognizes specific sugar residues on the host cell. This family of molecules is known as adhesins (see p. 198). Following attachment, some bacteria, such as coagulase-negative staphylococci *(Staph. epidermidis),* produce an extracellular slime layer and recruit additional bacteria, which cluster together to form a biofilm. These biofilms can be difficult to eradicate, and are a frequent cause of medical device-associated infections which affect prosthetic joints and heart valves as well as indwelling catheters. Some viruses (e.g. HIV) and protozoa (e.g. *Plasmodium* spp., *Entamoeba histolytica)* attach to specific target-cell receptors. Other parasites such as hookworm have specific attachment organs (buccal plates) that firmly grip the intestinal epithelium.

Colonization

Following epithelial attachment, pathogens may either remain on the surface epithelium or within the lumen of the organ they have colonized. Tissue invasion may follow.

Invasion may result in:

- an intracellular location for the pathogen (e.g. viruses, *Toxoplasma gondii, Mycobacterium* spp., *Plasmodium* spp.)
- an extracellular location for the pathogen (e.g. pneumococci, £. *coli* and *Entamoeba histolytica)*
- invasion directly into the blood or lymph circulation (e.g. schistosome schistosomula and trypanosomes).

Once the pathogen is firmly established in its target tissue, a series of events follows that usually culminates in damage to the host.

Tissue dysfunction or damage

Microorganisms produce disease by a number of well-defined mechanisms:

Exotoxins and endotoxins

- *Exotoxins* have many diverse activities including inhibition of protein synthesis (diphtheria toxin), neurotoxicity *(Clostridium tetani* and *C. botulinum)* and enterotoxicity, which results in intestinal secretion of water and electrolytes (E. *coli, Vibrio cholerae).*
- *Endotoxin* is a lipopolysaccharide (LPS) in the cell wall of Gram-negative bacteria. It is responsible for many of the features of septic shock (see p. 967), namely hypotension, fever, intravascular coagulation and, at high doses, death. The effects of endotoxin are mediated predominantly by release of tumour necrosis factor.

Staph. aureus presents an excellent example of the repertoire of microbial virulence. The clinical expression of disease varies according to site, invasion and toxin production and is summarized in Table 2.6. Furthermore, host susceptibility to infection may be linked to genetic or acquired defects in host immunity that may complicate intercurrent infection, injury, ageing and metabolic disturbances (Table 2.7).

Host response to infection

Natural defences

The natural host defences to infection are those of an intact surface epithelium with local production of secretions, antimicrobial enzymes (e.g. lysozyme in the eye) and in the stomach, gastric acidity. The mucociliary escalator of the large airways is unique to the lung,

Immunological defences

Antibody and cell-mediated immune mechanisms play a vital role in combating infection. All organisms can initiate secondary immunological mechanisms, such as complement activation, immune complex formation and antibody-mediated cytolysis of cells. The immunological response to infection is described in Chapter 4.

Metabolic and immunological consequences of infection

Fever

Body temperature is controlled by the thermoregulatory centre in the anterior hypothalamus in the floor of the third ventricle. Gram-negative bacteria contain lipo-polysaccharide (LPS) and peptidoglycan, which is also a component of Gram-positive bacterial cell walls. Toll-like receptors (TLR, p. 202) on monocytes and dendritic cells recognize these lipopolysaccharides and generate signals leading to formation of inflammatory cytokines, e.g. IL-1, -6, -12, TNF-oc and many others. These cytokines act on the thermoregulatory centre by increasing prostaglandin (PGE_2) synthesis. The antipyretic effect of salicylates is brought about, at least in part, through its inhibitory effects on prostaglandin synthase.

Fever production has a positive effect on the course of infection. However, for every 1°C rise in temperature, there is a 13% increase in resting metabolic rate and oxygen consumption. Fever therefore leads to increased energy requirements at a time when anorexia leads to decreased food intake. The normal compensatory mechanisms in starvation (e.g. mobilization of fat stores) are inhibited in acute infections. This leads to an increase in skeletal muscle breakdown, releasing amino acids, which, via gluconeogenesis, are used to provide energy.

Tumour necrosis factor (TNF)

TNF-a is released from a variety of phagocytic cells (macrophages/monocytes) and TNF-fS from non-phagocytic cells (lymphocytes, natural killer cells) in response to infections (bacterial endotoxin) and inflammatory stimuli. TNF itself then stimulates the release of a cascade of other mediators involved in inflammation and tissue remodelling, such as interleukins (IL-1 and IL-6), prostaglandins, leukotrienes and corticotropin. TNF is therefore responsible for many of the effects of an infection.

The biological behaviour of the pathogen and the consequent host response are responsible for the clinical expression of disease that often allows clinical recognition. The incubation period following exposure can be helpful (e.g. chickenpox 14-21 days). The site and distribution of a rash may be diagnostic (e.g. shingles) while symptoms of cough, sputum and pleuritic pain point to lobar pneumonia. Fever and meningismus characterize classical meningitis. Infection may remain localized or become disseminated and give rise to the sepsis syndrome and disturbances of protein metabolism

and acid-base balance (Ch. 15). Many infections are self-limiting, and immune and non-immune host defence mechanisms will eventually clear the pathogens. This is generally followed by tissue repair, which may result in complete resolution or leave residual damage.

APPROACH TO THE PATIENT WITH A SUSPECTED INFECTION

Infectious diseases can affect any organ or system, and can cause a wide variety of symptoms and signs. Fever is often regarded as the cardinal feature of infection, but not all febrile illnesses are infections, and not all infectious diseases present with a fever. History-taking and examination should aim to identify the site(s) of infection, and also the likely causative organism(s).

History

A detailed history is taken with specific questions about epidemiological risk factors for infection. These are based on the sources of infection and routes of transmission discussed above.

- Travel history: some diseases are more prevalent in certain geographical locations, and many infections common in the tropics are seen rarely if at all in the UK.
- Food and water history: systemic as well as gastro-enteric infections can be caught via this route.
- Occupational history.
- Animal contact: domestic, farm and wild animals can all be responsible for zoonotic infection.
- Sexual activity: as well as the traditional sexually trans mitted diseases, HIV, hepatitis B and very occasionally hepatitis C can all be transmitted sexually. Some enteric infections are more common among male homosexuals.
- Intravenous drug use: as well as blood-borne viruses, drug injectors are susceptible to a variety of bacterial and fungal infections due to inoculation. Tattooing, body piercing and receipt of blood products (especially outside the UK) are also risk factors for blood-borne viruses.
- Leisure activities: certain pastimes may predispose to water-borne infections or zoonoses.

Clinical examination

A thorough examination covering all systems is required. Skin rashes and lymphadenopathy are common features of infectious diseases, and the ears, eyes, mouth and throat should also be inspected. Infections commonly associated with a rash are listed in Box 2.1. Rectal, vaginal and penile examination is required in sexually transmitted infections.

The fever pattern may occasionally be helpful, e.g. the tertian fever of falciparum malaria, but too much weight should not be placed on the pattern or degree.

Investigations

In some infections such as chickenpox the clinical presentation is so distinctive that no investigations are normally necessary to confirm the diagnosis. Other cases require investigation.

Sox *2.1* Infections commonly associated with a rash

Macular/maculopapular
Measles
Rubella
Enteroviruses
Human herpesvirus 6
Epstein-Barr virus
Cytomegalovirus
Parvovirus

syphilis (chancre) Anthrax
(ulcerating papule)

General investigations (to assess health and identify organ(s) involved)

These will vary depending on circumstances:

- **Blood tests.** Routine blood count, ESR and C-reactive protein, biochemical profile, urea and electrolytes are performed in the majority of cases (Box 2.2).
- **Imaging.** X-ray, ultrasound, echocardiography, CT and MR scanning are used to identify and localize infections. Biopsy or aspiration of tissue for micro biological examination may also be facilitated by ultrasound or CT guidance.
- **Radionuclide scanning** after injection of indium- or technetium-labelled white cells (previously harvested from the patient) may occasionally help to localize infection. It is most effective when the peripheral white cell count is raised, and is of particular value in localizing occult abscesses.

Microbiological investigations (to identify causative organism)

Diagnostic services range from simple microscopy to molecular probes. It is often helpful to discuss the clinical problem with a microbiologist to ensure that appropriate tests are performed, and that specimens are collected and transported correctly.

Microscopy and culture

Specimens to be sent for microscopy and culture (Box 2.3).

Box 2.2 **General investigations for a patient with suspected infection**

Investigation	Possible cause
Full blood count	
Neutrophilia	Bacterial infection
Neutropenia	Viral infection Brucellosis Typhoid Typhus Overwhelming sepsis
Lymphocytosis	Viral infection
Lymphopenia Atypical lymphocytes	HIV infection (not specific) Infectious mononucleosis
Eosinophilia	Invasive parasitic infection
Thrombocytopenia	Overwhelming sepsis Malaria
ESR or C-reactive protein	All
Urea and electrolytes	Potentially deranged in severe illness from any cause
Liver enzymes	
Minor elevation of transferases	Non-specific feature of many infections Mild viral hepatitis Viral hepatitis (usually A, Bor E)
Grossly deranged transferases, elevated bilirubin	
Coagulation	May be deranged in hepatitis, and in overwhelming infection of any type

Box 2.3 **Specimens and indications for microscopy and culture**

Specimen	Investigation	Indication
Blood	Giemsa stain for malaria	Any symptomatic traveller returning from a malarious area
	Stains for other parasites	Specific tropical infections
	Culture	All suspected bacterial infections
Urine	Microscopy and culture	All suspected bacterial infections
	Tuberculosis (TB) culture	Suspected TB
Faeces	Microscopy ± iodine stain	Unexplained leucocytes in urine Suspected protozoal diarrhoea
	Culture	All unexplained diarrhoea
	Electron microscopy/viral culture (not usually necessary to do both)	Suspected viral diarrhoea in children
	Clostridium difficile toxin Culture	Viral meningitis
	Viral culture	Diarrhoea following hospital stay or antibiotic treatment
Throat swabs		Suspected bacterial tonsillitis and pharyngitis Viral meningitis Viral respiratory infections where urgent diagnosis is considered necessary Unusual chest infections;
Sputum	Microscopy and culture	pneumonia Suspected TB
	Auramine stain/TB culture	Immunocompromised patients Suspected fungal infections
	Other special stains/cultures	Suspected meningitis Suspected TB, meningitis
		Immunocompromised patients Suspected fungal infections
Cerebrospinal fluid	Microscopy and culture	Suspected encephalitis or viral or bacterial meningitis
	Auramine stain/TB culture	
	Other special stains/cultures	Meningococcal disease Herpes simplex/zoster
	Polymerase chain reaction	
Rash aspirate: Petechial Vesicular	Microscopy and culture Viral culture	

- *Blood and urine* should routinely be sent for bacterial culture regardless of whether fever is present at the time.
- *Cerebrospinal fluid, sputum and biopsy* specimens are sent if clinically indicated.
- *Special culture techniques* are required for fungi, mycobacteria, and some other bacteria such as *Brucella* spp., and the laboratory must be informed if these are suspected.
- *Faeces* should not routinely be sent for viral investigations: viral gastroenteritis is rare except in infants and the institutionalized elderly, and is self-limiting. Protozoa should be considered as a cause of diarrhoea in returning travellers, immunocompromised patients, toddlers, homosexual men, farm workers, and in any cases of prolonged unexplained diarrhoea. Detection of a specific clostridial toxin is a more reliable test for diarrhoea caused by *Clostridium difficile* than culture of the organism itself. Stool culture is a costly routine test and is often requested indiscriminately.

Immunodiagnostic tests

These can be divided into two types:

- tests that detect viral or bacterial antigen, using a polyvalent antiserum or a monoclonal antibody
- tests that detect serological response to infection.

These investigations are valuable in the identification of organisms that are difficult to culture, especially viruses and fungi, and can also be helpful when antibiotics have been administered before samples were obtained. However, care is needed in the interpretation of serological tests. Elevated antibody titres on a single occasion (especially of IgG) are rarely diagnostic, and in some infections it may be difficult to distinguish between old and acute infection. Paired serological tests a few weeks apart, or specific assays for IgM (indicating an acute infection) are more helpful.

Nucleic acid detection

Specific genes from many pathogenic microorganisms have been cloned and sequenced. Nucleic acid probes can be designed to detect these sequences, identifying pathogen-specific nucleic acid in body fluids or tissue. The utility of this approach has been greatly enhanced by the development of amplification techniques such as the polymerase chain reaction (PCR), which increases the amount of target DNA/RNA in the sample to be tested. However PCR assays for many organisms are still in the process of development.

Treatment

Many infections, particularly those caused by viruses, are self-limiting and require no treatment. The mainstay of treatment for most infectious diseases is antimicrobial chemotherapy. The choice of antibiotic should be governed by:

- the clinical state of the patient
  the likely cause of the infection.

Serious infections may require supportive therapy in addition to antibiotics. It is always preferable to have a definite microbial diagnosis before starting treatment, so that an antibiotic with the most appropriate spectrum of activity and site of action can be used. However, some patients are too unwell to wait for results (which in the case of culture may take days). In diseases such as meningitis or septicaemia delay in treatment may be fatal and therapy must be started on an empirical basis. Appropriate samples for culture should be taken before the first dose of antibiotic, and an antibiotic regimen chosen on the basis of the most likely causative organisms. Usually patients are less unwell, and specific therapy can be deferred pending results. Antibiotic therapy is discussed in more detail on page 30.

Special circumstances

Overseas travellers. A detailed travel itinerary, including any flight stopovers should be taken from anyone who is unwell after arriving in this country from abroad. Previous travel should also be covered as some infections may be chronic or recurrent. It is necessary to find out not just which countries were visited but also the type of environment: a stay in a remote jungle village carries different health risks from a holiday in an air-conditioned coastal holiday resort. Food and water consumption, bathing and swimming habits, animal and insect contact, and contact with human illness all need to be recorded. Enquiry should be made about sexual contacts, drug use and medical treatment (especially parenteral) while abroad. In some parts of the world over 90% of professional sex workers are HIV positive, and hepatitis B and C are very common in parts of Africa and Asia. In addition to the investigations described in the previous section, special tests may be needed depending on the epidemiological risks and clinical signs, and malaria films are mandatory in anyone who is unwell after being in a malarious area. Some of the more common causes of a febrile illness in returning travellers to the UK are listed in Table 2.8.

Table 2.8 **Causes of febrile illness in travellers returning to the UK**

Tropical countries	**Specific geographical areas (see text)**
Malaria	Histoplasmosis
Schistosomiasis	Brucellosis
Dengue	
Tick typhus	**World-wide**
Economically less-developed countries	Pneumonia
Typhoid	URTI
Tuberculosis	UTI
Dysentery	Traveller's diarrhoea
Hepatitis A	Viral infection
Amoebiasis	

URTI, upper respiratory tract infection; UTI, urinary tract infection

Immunocompromised patients. Advances in medical treatment over the past three decades have led to a huge increase in the number of patients living with immunodeficiency states. Cancer chemotherapy, the use of immunosuppressive drugs and the world-wide AIDS epidemic have all contributed to this. The presentation may be very atypical in the immunocompromised patient with few, if any, localizing signs or symptoms. Infection can be due to organisms which are not usually pathogenic, including environmental bacteria and fungi. The normal physiological responses to infection (e.g. fever, neutrophilia) may be diminished or absent. The onset of symptoms may be sudden, and the course of the illness fulminant. A high index of suspicion for infections in people who are known to be immunosuppressed is required. These patients should usually be given early and aggressive antibiotic therapy without waiting for the results of investigations. Samples for culture should be sent before starting treatment, but therapy should not be delayed if this proves difficult. The choice of antibiotics should be guided by the likely causative organisms: these are shown in Box 2.4.

Highly transmissible infections. Relatively few patients with infectious disease present a serious risk to healthcare workers (HCW) and other contacts. However, the appearance of diseases like severe acute respiratory syndrome (SARS), the occasional importation of zoonoses like Lassa fever, and concerns about the bioterrorist use of agents such as smallpox mean that there is still the potential for unexpected outbreaks of life-threatening disease. During the world-wide SARS outbreak in 2003, scrupulous infection control procedures reduced spread of infection. However, in the 'inter-epidemic' period it is difficult to maintain the same level of 'alert'. HCWs should remain vigilant because the early symptoms of many of these diseases are non-specific.

Pyrexia of unknown origin

History, clinical examination and simple investigation will reveal the cause of a fever in most patients. In a small number, however, no diagnosis is apparent despite continuing symptoms. The term pyrexia (or fever) of unknown origin (PUO) is sometimes used to describe this problem. Various definitions have been suggested for PUO: a useful one is 'a fever persisting for > 2 weeks, with no clear diagnosis despite intelligent and intensive investigation'. Patients who are known to have HIV or other immunosuppressing conditions are normally excluded from the definition of PUO, as the investigation and management of these patients is different.

Successful diagnosis of the cause of PUO depends on a knowledge of the likely and possible aetiologies. These have been documented in a number of studies, and are summarized in Box 2.5.

Sox *2.4* Common causes of infection in immunocompromised patients

Deficiency	Causes	Organisms
Neutropenia	Chemotherapy Myeloablative therapy Immunosuppressant drugs	*Escherichia coll Klebsiella pneumoniae Staphylococcus aureus Staph. epidermidis Aspergillus* spp. *Candida* spp.
Cellular immune defects	HIV infection Lymphoma Myeloablative therapy Congenital syndromes	Respiratory syncytial virus Cytomegalovirus Epstein-Barr virus Herpes simplex and zoster *Salmonella* spp. *Mycobacterium* spp. (esp. *M. avium-intracellulare) Cryptococcus neoformans Candida* spp. *Cryptosporidium parvum Pneumocystis carinii Toxoplasma gondii*

Primary HIV infection
Brucellosis
Lyme disease

Malignant disease (10-30%)
Lymphoma
Leukaemia
Renal cell carcinoma
Hepatocellular carcinoma

Collagen vascular disease (15-20%)
Adult Still's disease
Rheumatoid arthritis Systemic lupus erythematosus Wegener's granulomatosis Giant cell arteritis

Miscellaneous (10-25%)
Drug fevers
Thyrotoxicosis
Inflammatory bowel disease
Sarcoidosis
Granulomatous hepatitis
Factitious fever
Familial Mediterranean fever

Undiagnosed (5-25%)

A detailed history and examination is essential, taking into account the possible causes, and the examination should be repeated on a regular basis in case new signs appear. Investigation findings to date should be reviewed, obvious omissions amended and abnormalities followed up. Confirm that the patient does have objective evidence of a raised temperature: this may require admission to hospital if the patient is not already under observation. Some people have an exaggerated circadian temperature variation (usually peaking in the evening), which is not pathological.

The range of tests available is discussed above. Obviously investigation is guided by particular abnormalities on examination or initial test results, but in some cases 'blind' investigation is necessary. Some investigations, especially cultures, should be repeated regularly, and serial monitoring of inflammatory markers such as C-reactive protein allows assessment of progress.

Improvements in imaging techniques have diminished the need for invasive investigations in PUO, and scanning has now superseded the blind diagnostic laparotomy. Ultrasound, echocardiography, CT, MRI, and labelled white cell scanning can all help in establishing a diagnosis if used appropriately: the temptation to scan all patients with PUO from head to toe as a first measure should be avoided. Biopsy of liver and bone marrow may be useful even in the absence of obvious abnormalities, and temporal artery biopsy should be considered in the elderly (p. 583). Bronchoscopy can be used to obtain samples for microbiological and histological examination if sputum specimens are not adequate. Serological tests have greatly improved the diagnosis of infectious causes of PUO, but should be used with caution. The more tests that are done, the greater is the danger of a false positive or misleading result, and serological tests should only be ordered and interpreted in the context of the clinical findings and epidemiology.

Treatment of a patient with a persistent fever is aimed at the underlying cause, and if possible only symptomatic treatment should be used until a diagnosis is made. Blind antibiotic therapy may make diagnosis of an occult infection more difficult, and empirical steroid therapy may mask an inflammatory response without treating the underlying cause. In a few patients no cause for the fever is found despite many months of investigation and follow-up. In most of these the symptoms do eventually settle spontaneously, and if no definite cause has been identified after 2 years the long-term prognosis is good.

ANTIMICROBIAL CHEMOTHERAPY

Principles of use

Antibiotics are among the safest of drugs, especially those used to treat community infections. They have had a major impact on the life-threatening infections and reduce the morbidity associated with surgery and many common infectious diseases. This in turn is, in part, responsible for the overprescribing of these agents which has led to concerns with regard to the increasing incidence of antibiotic resistance.

Most antibiotic prescribing, especially in the community, is empirical. Even in hospital practice, microbiological documentation of the nature of an infection and the susceptibility of the pathogen is generally not available for a day or two. Initial choice of therapy relies on a clinical diagnosis and, in turn, a presumptive microbiological diagnosis. Such 'blind therapy' is directed at the most likely pathogen(s) responsible for a particular syndrome such as meningitis, urinary tract infection or pneumonia. Initial therapy in the severely ill patient is often broad spectrum in order to cover the range of possible pathogens but should be narrowed down once microbiological information becomes available.

Bactericidal versus bacteriostatic

In the majority of infections there is no firm evidence that bactericidal drugs (penicillins, cephalosporins, aminoglycosides) are more effective than bacteriostatic drugs, but it is generally considered necessary to use the former in the treatment of bacterial endocarditis and in patients in whom host defence mechanisms are compromised, particularly in those with neutropenia.

Combinations of drugs are occasionally required for reasons other than providing broad-spectrum cover. Tuberculosis is initially treated with three or four agents to avoid resistance emerging. Synergistic inhibition is achieved by using penicillin and gentamicin in enterococcal endocarditis or gentamicin and ceftazidime in life-threatening pseudomonas infection.

Pharmacokinetic factors

To be successful, sufficient antibiotic must penetrate to the site of the infection. Knowledge of the standard pharmacokinetic considerations of absorption, distribution, metabolism and excretion for the various drugs is required. Difficult sites include the brain, eye and prostate, while loculated abscesses are inaccessible to most agents.

Many mild-to-moderate infections can be treated effectively with oral antibiotics provided that the patient is compliant. Parenteral administration is indicated in the severely ill patient to ensure rapid high blood and tissue concentrations of drug. Some antibiotics can only be administered parenterally, such as the aminoglycosides and extended-spectrum cephalosporins. Parenteral therapy is also required in those unable to swallow or where gastrointestinal absorption is unreliable.

Dose and duration of therapy

This will vary according to the nature, severity and response to therapy.

Prolonged treatment (up to 6 weeks) is necessary for some varieties of infective endocarditis, while pulmonary tuberculosis is treated for at least 6 months. In treating many common infections, improvement occurs within 2-3 days; once the patient is afebrile or the leucocytosis has settled, oral administration should be considered for those commenced on parenteral therapy. Treatment for 5-7 days is adequate for most infections. Shorter-course therapy (3 days or less) is appropriate for those with symptomatic uncomplicated bacteriuria (cystitis). Minimizing the duration of therapy lowers the risks of adverse reactions and superinfection with *Candida* spp. or *Clostridium difficile,* as well as the cost of therapy.

Drugs which are concentrated intracellularly, such as erythromycin, quinolones and tetracyclines are used in treating mycoplasma, brucella and legionella infections.

Renal and hepatic insufficiency

Many drugs require dose reduction in renal failure to avoid toxic accumulation. This applies to the (Madams and especially the aminoglycosides and vancomycin. Tetracyclines, other than doxycycline and minocycline, should be avoided. In those with hepatic insufficiency, caution or dose reduction is required for agents such as isoniazid, ketoconazole, clindamycin, interferon and rifampicin.

Therapeutic drug monitoring

To ensure therapeutic yet non-toxic drug concentrations, serum concentrations of drugs such as the aminoglycosides and vancomycin are monitored, especially in those with impaired or changing renal function. Peak (1 hour post-dose) and trough (pre-dose) serum samples are assayed. However, with the increasing use of once-daily aminoglycoside dosage regimens, random but timed serum assays are being adopted.

Antibiotic chemoprophylaxis

The value of antibiotic chemoprophylaxis has been questioned as there are few controlled trials to prove efficacy (p. 832). However, there are still a number of indications for which the prophylactic use of antibiotics is still advised (Table 2.9). These include surgical procedures where the risk of infection is high (colon surgery) or the consequences of infection are serious (endocarditis, post-splenectomy sepsis). The choice of agent(s) is determined by the likely infectious risk and the established efficacy and safety of the regimen.

***Table* 2.9 Antibiotic chemoprophylaxis**

Clinical problem	Aim	Drug regimen*
Infective endocarditis (IE)	To prevent infection in:	**Dental, oral, respiratory tract or oesophageal procedures**
	High risk, e.g: Previous IE Prosthetic heart valves Mitral valve prolapse with MR or thickened valve leaflets Complex congenital heart disease	Amoxicillin, 3 g oral 1 hour pre-procedure or 2 g IV < 30 min pre-procedure Note: with previous IE add gentamicin 1.5 mg/kg IV < 30 min pre-procedure If allergic to penicillin use clindamicin
	Moderate risks, e.g. Acquired valvular heart disease Non-cyanotic congenital heart defects Structural cardiac abnormalities	**Genitourinary or gastrointestinal procedures** Amoxicillin and gentamicin If allergic to penicillin use vancomicin and gentamicin
	To prevent serious pneumococcal sepsis	Phenoxymethylpenicillin 500 mg 12-hourly
Splenectomy/spleen malfunction		

Cont'd

Table 2.9 (Cont'd) **Antibiotic chemoprophylaxis**

Clinical problem	Aim	Drug regimen*
Rheumatic fever	To prevent recurrence and further cardiac damage	Phenoxymethylpenicillin 250 g x 2 daily or sulfadiazine 1g if allergic to penicillin
Meningitis: Due to meningococci	To prevent infection in close contacts	Adults: rifampicin 600 mg twice-daily for 2 days (Children < 1 year: 5 mg/kg; > 1 year: 10 mg/kg) Alternatives (single dose) ciprofloxacin 500 mg (p.o.) or ceftriaxone 250 mg (i.m)
Due to *H. influenzae* type b	To reduce nasopharyngeal carriage and prevent infection in close contacts	Adults: rifampicin 600 mg daily for 4 days (Children: < 3 months 10 mg/kg; > 3 months 20 mg/kg)
Tuberculosis	To prevent infection in exposed (close contacts) tuberculin-negative individuals, infants of infected mothers and immunosuppressed patients	Oral isoniazid 300 mg daily for 6 months (Children: 5-10 mg/kg daily)

* Unless stated, doses are those recommended in adults
Note: new guidelines for IE laid down by AGREE (Appraisal of Guidelines for Research and Evaluation), http://www.agreecollabration.org/

Mechanisms of action and resistance to antimicrobial agents

Antibiotics act at different sites of the bacterium (Table 2.10).

Resistance to an antibiotic can be the result of:

- impaired or altered permeability of the bacterial cell envelope, e.g. penicillins in Gram-negative bacteria
- active expulsion from the cell by membrane efflux systems
- alteration of the target site (e.g. single point mutations in *E. coli* or a penicillin-binding protein in *Strep, pneumoniae* leading to acquired resistance - see below)
- specific enzymes which inactivate the drug before or after cell entry
- development of a novel metabolic bypass pathway.

Table 2.10 **Site of action of antibiotics**

Site of action	Antibiotic
Cell wall	Penicillin, cephalosporins, vancomycin, monobactams
Inhibits protein synthesis	Macrolides, aminoglycosides, tetracyline, oxazolidinones
Inhibits RNA synthesis	Rifampicin
Inhibits DNA synthesis	Quinolones and metronidazole
Folic acid antagonists	Sulphonamides and trimethoprim

The development or acquisition of resistance to an antibiotic by bacteria invariably involves either a mutation at a single point in a gene or transfer of genetic material from another organism (Fig. 2.2).

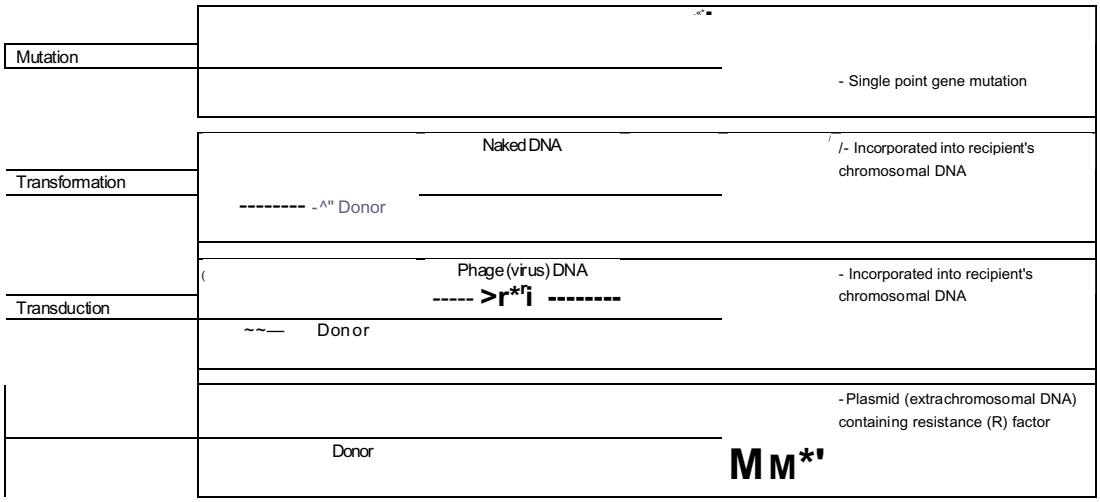

Fig. 2.2 **Some mechanisms for the development of resistance to antimicrobial drugs.** These involve either a single point mutation or transfer of genetic material from another organism (transformation, transduction or R factor transfer).

Larger fragments of DNA may be introduced into a bacterium either by transfer of 'naked' DNA or via a bacteriophage (a virus) DNA vector. Both the former (transformation) and the latter (transduction) are dependent on integration of this new DNA into the recipient chromosomal DNA. This requires a high degree of homology between the donor and recipient chromosomal DNA.

Finally, antibiotic resistance can be transferred from one bacterium to another by conjugation, when extrachromosomal DNA (a plasmid) containing the resistance factor (R factor) is passed from one cell into another during direct contact. Transfer of such R factor plasmids can occur between unrelated bacterial strains and involve large amounts of DNA and often codes for multiple antibiotic resistance.

Transformation is probably the least clinically relevant mechanism, whereas transduction and R factor transfer are usually responsible for the sudden emergence of multiple antibiotic resistance in a single bacterium. Increasing resistance to many antibiotics has developed (Table 2.11).

Table 2.11 Some bacteria that have developed resistance to common antibiotics

Pathogen	Previously fully sensitive to
Streptococcus pneumoniae	Penicillin, erythromycin, cefotaxime
Strep, pyogenes	Erythromycin, tetracycline

ANTIBACTERIAL DRUGS

p-Lactams (penicillins, cephalosporins and monobactams)

Penicillins (Table 2.12)

Structure. The (3-lactams share a common ring structure (Fig. 2.3). Changes to the side-chain of benzylpenicillin (penicillin G) render the phenoxymethyl derivative (penicillin V) acid resistant and allow it to be orally absorbed. The presence of an amino group in the phenyl radical of benzylpenicillin increases its antimicrobial spectrum to include many Gram-negative and Gram-positive organisms. More extensive modification of

Table 2.12 Classification of penicillins

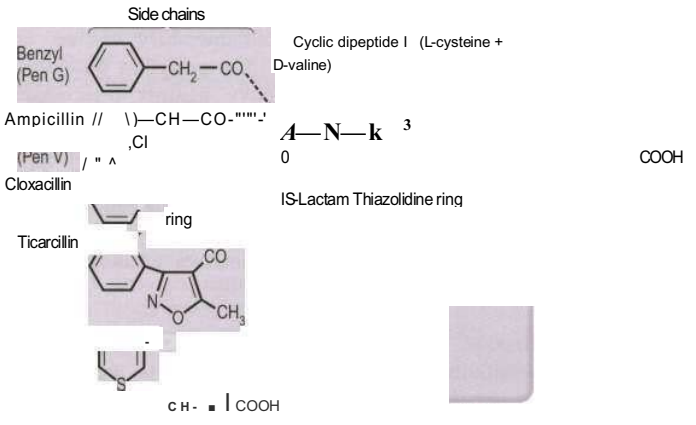

Fig. 2.3 **The structure of penicillins.**

the side-chain (e.g. as in flucloxacillin) renders the drug insensitive to bacterial penicillinase. This is useful in treating infections caused by penicillinase ((3-lactamase)-producing staphylococci.

Mechanisms of action. P-lactams block bacterial cell wall mucopeptide formation by binding to and inactivating specific penicillin-binding proteins (PBPs), which are peptidases involved in the final stages of cell wall assembly and division. Methicillin-resistant *Staph. aureus* (MRSA) (see p. 63) produce a low-affinity PBP which retains its peptidase activity even in the presence of high concentrations of methicillin.

Indications for use. Benzylpenicillin can only be given parenterally and is often the drug of choice for serious infections, notably infective endocarditis, meningococcal, streptococcal, clostridial infections (tetanus, gas gangrene), actinomycosis, anthrax, and spirochaetal infections (syphilis, yaws).

Phenoxymethylpenicillin (penicillin V) is an oral preparation that is used chiefly to treat streptococcal pharyngitis and as prophylaxis against rheumatic fever.

Flucloxacillin is used in infections caused by penicillinase-producing staphylococci.

Ampicillin is susceptible to penicillinase, but its antimicrobial activity includes streptococci, pneumococci and enterococci as well as Gram-negative organisms such as *Salmonella* spp., *Shigella* spp., E. *colt, H. influenzae* and *Proteus* spp. Drug resistance has, however, eroded its efficacy against these Gram-negatives. It is widely used in the treatment of respiratory tract infections. Amoxicillin has similar activity to ampicillin, but is better absorbed when given by mouth.

The extended-spectrum penicillin, ticarcillin is active against pseudomonas infections, as is the acylureido-penicillin piperacillin in combination with sulbactam.

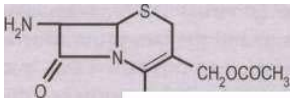
Clavulanic acid is a powerful inhibitor of many bacterial fS-lactamases and when given in combination with an otherwise effective agent such as amoxicillin (co-amoxiclav) or ticarcillin can broaden the spectrum of activity of the drug. Sulbactam acts similarly and is available combined with ampicillin, while tazobactam in combination with piperacillin is effective in appendicitis, peritonitis, pelvic inflammatory disease, and complicated skin infections. The penicillin pi-lactamase combinations are also active against (3-lactamase-producing staphylococci.

Pivmecillinam has significant activity against Gram-negative bacteria including E. *coli, Klebsiella, Enterobacter* and salmonellae but no activity against pseudomonas.

Interactions. Penicillins inactivate aminoglycosides when mixed in the same solution.

Toxicity. Generally, the penicillins are very safe. Hypersensitivity (skin rash (common), urticaria, anaphylaxis), encephalopathy and tubulointerstitial nephritis can occur. Ampicillin also produces a hypersensitivity rash in approximately 90% of patients with infectious mononucleosis who receive this drug. Co-amoxiclav causes a cholestatic jaundice six times more frequently than amoxicillin.

Cephalosporin



B-Lactam ring Dihydrothiazine ring

Fig. 2.4 The structure of a cephalosporin.

Cephalosporins and cephamycins (Fig. 2.4) The cephalosporins have an advantage over the penicillins in that they are resistant to staphylococcal penicillinases (but are still inactive against methicillin-resistant staphylococci) and have a broader range of activity that includes both Gram-negative and Gram-positive organisms, but excludes enterococci and anaerobic bacteria. Ceftazidime and cefpirome are active against *Pseudomonas aeruginosa.* Cefoxitin is a cephamycin.

Indications for use (Table 2.13). These potent broad-spectrum antibiotics are useful for the treatment of serious systemic infections, particularly when the precise nature of the infection is unknown. They are commonly used for serious sepsis in postoperative and immuno-compromised patients, particularly during cytotoxic chemotherapy of leukaemia and other malignancies. They are used in pneumonia, meningitis, peritonitis and urinary tract infections.

Interactions. There are relatively few interactions.

Toxicity. The toxicity is similar to that of the penicillins but is less common. Some 10% of patients are allergic to both groups of drugs. The early cephalosporins caused proximal tubule damage, although the newer derivatives have fewer nephrotoxic effects.

Monobactams

Aztreonam is currently the only member of this class available. It is a synthetic (i-lactam and, unlike the penicillins and cephalosporins, has no ring other than the (i-lactam, hence its description as a monobactam.

Its mechanism of action is by inhibition of bacterial cell wall synthesis. It is resistant to most fi-lactamases and does not induce P-lactamase production.

Indications for use. Aztreonam's spectrum of activity is limited to aerobic Gram-negative bacilli. With the exception of urinary tract infections, aztreonam should be used in combination with metronidazole (for anaerobes) and an agent active against Gram-positive cocci (a

Table 2.13 **Some examples of cephalosporins**

	Activity	Use
First generation	Gram-positive cocci and Gram-negative organisms	Urinary tract infections
Cefalexin (oral)	Penicillin allergy	
Cefradine (oral)		
Cefadroxil (oral)		
Second generation	Extended spectrum	Prophylaxis and treatment of Gram-negative infections and mixed aerobic-anaerobic infections
Cefuroxime	More effective than first generation against £ *coli, Klebsiella* spp. and *Proteus mirabilis,* but less effective against Gram-positive organisms	
Cefamandole		
Cefoxitin Cefaclor (oral) Cefuroxime (oral) Cefprozil (oral)	Includes *Bacteroides fragilis*	Peritonitis
Third generation	Broad-spectrum	Especially severe infection with Enterobacteriaceae, *Pseudomonas aeruginosa* (ceftazidime, cefpirome) and *Neisseria gonorrhoeae, N. meningitidis,* Lyme disease (ceftriaxone)
Cefotaxime	More potent against aerobic Gram-negative bacteria than first or second generation	
Ceftazidime		
Cefpirome		Urinary tract infections and infections with neutropenia
Ceftriaxone		Once daily. Septicaemia, pneumonia, meningitis
Cefpodoxime (oral)		
Cefixime (oral)		
Fourth generation	Aerobic Gram-negative bacteria including *P. aeruginosa*	Febrile, neutropenic patients
Cefepime*		

* Unavailable in the UK

penicillin or erythromycin). It is a useful alternative to aminoglycosides in combination therapy, largely for the treatment of intra-abdominal sepsis.

Toxicity. As for the fS-lactam antibiotics.

Carbapenems

The carbapenems are semisynthetic P-lactams and include imipenem, meropenem and ertapenem. They are currently the most broad spectrum of antibiotics, being active against the majority of Gram-positive and Gram-negative as well as anaerobic bacterial pathogens. Ertapenem, unlike the others, is not active against *Pseudomonas* or *Acinetobacter* spp. They differ in their dosage and frequency of administration. Imipenem is partially inactivated in the kidney by enzymatic inactivation and is therefore administered in combination with cilastatin.

Indications for use. They are used for serious nosocomial infections when multiple-resistant Gram-negative bacilli or mixed aerobe and anaerobe infections are suspected.

Toxicity. This is similar to that of P-lactam antibiotics. Nausea, vomiting and diarrhoea occur in less than 5% of cases. Imipenem may cause seizures and should not be used to treat meningitis; meropenem is safe for this indication.

Aminoglycosides

Structure. These antibiotics are polycationic compounds of amino sugars (Fig. 2.5).

Mechanism of action. Aminoglycosides interrupt bacterial protein synthesis by inhibiting ribosomal function (messenger and transfer RNA).

Indications for use. Streptomycin is bactericidal and is rarely used except for the treatment of tuberculosis. Occasional indications include endocarditis (with penicillin/ampicillin). Neomycin is used only for the topical treatment of eye and skin infections. Even though it is poorly absorbed, prolonged oral administration can produce ototoxicity.

Gentamicin and tobramycin are given parenterally. They are highly effective against many Gram-negative organisms including *Pseudomonas* spp. They are

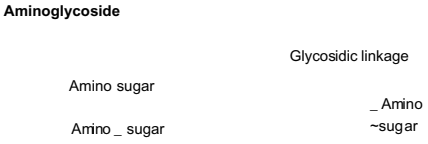


Fig. 2.5 **The structure of an aminoglycoside.**

synergistic with a penicillin against *Enterococcus* spp. Netilmicin and amikacin have a similar spectrum but are more resistant to the aminoglycoside-inactivating enzymes (phosphorylating, adenylating or acetylating) produced by some bacteria. Their use should be restricted to gentamicin-resistant organisms.

Interactions Enhanced nephrotoxicity occurs with other nephrotoxic drugs, ototoxicity with some diuretics, and neuromuscular blockade with curariform drugs.

Toxicity. This is dose-related. Aminoglycosides are nephrotoxic and ototoxic (vestibular and auditory), particularly in the elderly. Therapeutic drug monitoring is necessary in ensuring therapeutic and non-toxic drug concentrations.

Tetracyclines

Structure. These are bacteriostatic drugs possessing a four-ring hydronaphthacene nucleus (Fig. 2.6). Included among the tetracyclines are tetracycline, oxytetracycline, demeclocycline, lymecycline, doxycycline and minocycline.

Mechanism of action. Tetracyclines inhibit bacterial protein synthesis by interrupting ribosomal function (transfer RNA).

Indications for use. Tetracyclines are active against Gram-positive and Gram-negative bacteria but their use is now limited, partly owing to increasing bacterial resistance. A tetracycline is used for the treatment of acne and rosacea. Tetracyclines are also active against *V. cholerae, Rickettsia* spp., *Mycoplasma* spp., *Coxiella burnetii, Chlamydia* spp. and *Brucella* spp. Resistance is now common with *Strep. pneumoniae.*

Interactions. The efficacy of tetracyclines is reduced by antacids and oral iron-replacement therapy.

Toxicity. Tetracyclines are generally safe drugs, but they may enhance established or incipient renal failure, although doxycycline is safer than others in this group.

Tetracycline

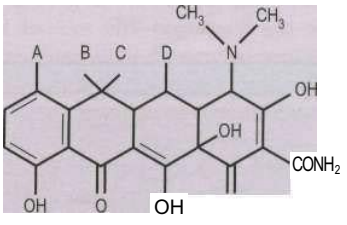

Fig. 2.6 **The structure of a tetracycline.** Substitution of CH_3, OH or H at positions A to D produces variants of tetracycline.

They cause brown discoloration of growing teeth, and thus these drugs are not given to children or pregnant women. Photosensitivity can occur.

Macrolides

Erythromycin

Structure. Erythromycin consists of a lactone ring with unusual sugar side-chains.

Mechanism of action. Erythromycin inhibits protein synthesis by interrupting ribosomal function.

Indications for use. Erythromycin has a similar (but not identical) antibacterial spectrum to penicillin and is useful in individuals with penicillin allergy. It can be given orally or parenterally. It is the preferred agent in the treatment of pneumonias caused by *Legionella* spp. and *Mycoplasma* spp. It is also effective in the treatment of infections due to *Bordetdla pertussis* (whooping cough), *Campylobacter* spp., *Chlamydia* spp. and *Coxiella* spp.

Other macrolides

These include clarithromycin, azithromycin and telithromycin. They have a broad spectrum of activity that includes selective Gram-negative organisms, mycobacteria and *Toxoplasma gondii.* Compared with erythromycin, they have superior pharmacokinetic properties with enhanced tissue and intracellular penetration and longer half-life that allows once or twice daily dosage. Clarithromycin is widely recommended as a component of triple therapy regimens (usually with a proton pump inhibitor and amoxicillin) for the eradication of *Helicobacter pylori.* Azithromycin is used for trachoma (see p. 84).

Interactions. Erythromycin and other macrolides interact with theophyllines, carbamazepine, digoxin and ciclosporin, occasionally necessitating dose adjustment of these agents.

Toxicity. Diarrhoea, vomiting and abdominal pain are the main side-effects of erythromycin (less with clarithromycin and azithromycin) and are, in part, a consequence of the intestinal prokinetic properties of the macrolides. Macrolides may also rarely produce cholestatic jaundice after prolonged treatment. QT_C prolongation is a recognized cardiac effect of the macrolides. This may have serious consequences if the syndrome of 'torsades de pointes' is induced.

Chloramphenicol

Structure. Chloramphenicol is the only naturally occurring antibiotic containing nitrobenzene (Fig. 2.7). This structure probably accounts for its toxicity in humans and for its activity against bacteria.

Chloramphenicol

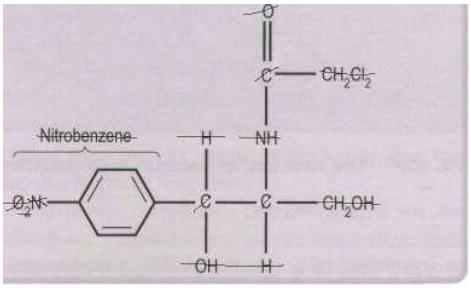

Fig. 2.7 The structure of chloramphenicol.

Mechanism of action. Chloramphenicol competes with messenger RNA for ribosomal binding. It also inhibits peptidyl transferase.

Indications for use. Chloramphenicol is rarely used in developed countries. In developing countries it has been invaluable in the treatment of severe infections caused by *Salmonella typhi* and *S. paratyphi* (enteric fevers) and *H. influenzae* (meningitis and acute epiglottitis) which are still prevalent in countries where Hib vaccination has not been introduced. It is also active against *Yersinia pestis* (plague) and is used topically for the treatment of purulent conjunctivitis. Drug resistance is currently eroding the efficacy of chloramphenicol.

Interactions. Chloramphenicol enhances the activity of anticoagulants, phenytoin and oral hypoglycaemic agents.

Toxicity. Severe irreversible bone marrow suppression is rare but nevertheless now restricts the usage of this drug to only the severely ill patient. Chloramphenicol should not be given to premature infants or neonates because of their inability to conjugate and excrete this drug; high blood levels lead to circulatory collapse and the often fatal 'grey baby syndrome'.

Fusidic acid

Structure. Fusidic acid has a structure resembling that of bile salts (see p. 350).

Mechanism of action. It is a potent inhibitor of bacterial protein synthesis. Its entry into cells is facilitated by the detergent properties inherent in its structure.

Indications for use. Fusidic add is mainly used for penicillinase-producing *Staph. aureus* infections such as osteomyelitis (it is well concentrated in bone) or endo carditis, and for other staphylococcal infections accompanied by septicaemia. The drug is well absorbed orally but is relatively expensive and should be used in combination with another staphylococcal agent to prevent resistance emerging.

Resistance. Resistance may occur rapidly and is the reason why fusidic acid is given in combination with another antibiotic.

Toxicity. Fusidic acid may occasionally be hepatotoxic but is generally a safe drug and if necessary can be given during pregnancy.

Sulphonamides and trimethoprim

Structure. The sulphonamides are all derivatives of the prototype sulphanilamide. Trimethoprim is a 2,4-diaminopyrimidine.

Mechanism of action. Sulphonamides block thymidine and purine synthesis by inhibiting microbial folic acid synthesis. Trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (see Fig. 8.12).

Indications for use. Sulfamethoxazole is mainly used in combination with trimethoprim (as co-trimoxazole). Its use is now largely restricted to the treatment and prevention of *Pneumocystis carinii* infection and listeriosis in developed countries, although it is still in widespread use in developing countries. It may also be used for toxoplasmosis and nocardiosis and as a second-line agent in acute exacerbations of chronic bronchitis and in urinary tract infections. Trimethoprim alone is often used for urinary tract infections and acute-on-chronic bronchitis, as the side-effects of co-trimoxazole are most commonly due to the sulphonamide component. Sulfapyridine in combination with 5-aminosalicylic acid (i.e. sulfasalazine) is used in inflammatory bowel disease.

Resistance. Resistance to sulphonamides is often plasmid-mediated and results from the production of sulphonamide-resistant dihydropteroate synthetase from altered bacterial cell permeability to these agents.

Interactions. Sulphonamides potentiate oral anti-coagulants and hypoglycaemic agents.

Toxicity. Sulphonamides cause a variety of skin eruptions, including toxic epidermal necrolysis, the Stevens—Johnson syndrome, thrombocytopenia, folate deficiency and megaloblastic anaemia with prolonged usage. It can provoke haemolysis in individuals with glucose-6-phosphate dehydrogenase deficiency and therefore should not be used in such people. Co-trimoxazole should also be avoided in the elderly if possible, as deaths have been recorded, probably owing to the sulphonamide component.

Quinolones

The quinolone antibiotics, such as ciprofloxacin, norfloxacin, ofloxacin and levofloxacin, are useful oral broad-spectrum antibiotics, related structurally to nalidixic acid. The latter achieves only low serum

Quinolone

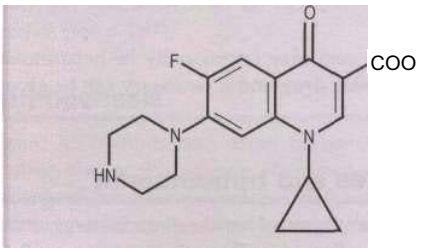

Fig. 2.8 The structure of a quinolone (ciprofloxacin).

concentrations after oral administration and its use is limited to the urinary tract where it is concentrated. Newer quinolones, including moxifloxacin, gemifloxacin and gatifloxacin, have greater activity against Gram-positive pathogens. The structure is shown in Figure 2.8.

Mechanism of action. The quinolone group of bactericidal drugs inhibit bacterial DNA synthesis by inhibiting topoisomerase IV and DNA gyrase, the enzyme responsible for maintaining the superhelical twists in DNA.

Indications for use. The extended-spectrum quinolones such as ciprofloxacin have activity against Gram-negative, including *Pseudomonas aeruginosa,* and some Gram-positive bacteria (e.g. anthrax, p. 82). They are useful in Gram-negative septicaemia, skin and bone infections, urinary and respiratory tract infections, meningococcal carriage, in some sexually transmitted diseases such as gonorrhoea and non-specific urethritis due to *Chlamydia trachomatis,* and in severe cases of travellers' diarrhoea (see p. 70). The newer oral quinolones provide an alternative to (3-lactams in the treatment of community-acquired lower respiratory tract infections.

Resistance. In many countries 10-20% of *E. coli* are resistant.

Interactions. Ciprofloxacin can induce toxic concentrations of theophylline.

Toxicity. Gastrointestinal disturbances, photosensitive rashes and occasional neurotoxicity can occur. Avoid in childhood and pregnancy. Tendon damage including rupture has been reported.

Oxazolidinones

Structure. The oxazolidinones are a novel class of antibacterial agents of which linezolid (Fig. 2.9) is the first to become available. ....

Mechanism of action. The oxazolidinones inhibit protein synthesis by binding to the bacterial 23S ribosomal RNA of the 59S sub-unit, thereby preventing the formation of a functional 70S complex essential to bacterial translation.

Linezolid

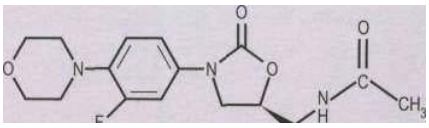

Fig. 2.9 The structure of linezolid, an oxazolidinone.

Indications for use. Linezolid is active against a variety of Gram-positive pathogens including vancomycin-resistant *Enterococcus faecium* (unfortunately resistant organisms have already been reported), methicillin-resistant *Staph. aureus* and penicillin-resistant *Strep. pneumonias.* It is also active against group A and group B streptococci. Clinical experience has demonstrated efficacy in a variety of hospitalized patients with severe to life-threatening infections, such as bacteraemia, hospital-acquired pneumonia and skin and soft tissue infections. It can be given both intravenously and by mouth.

Interactions. Linezolid interacts reversibly as a non-selective inhibitor of monoamine oxidase, and has the potential for interacting with serotoninergic and adrenergic agents.

Toxicity. Side-effects include gastrointestinal disturbances, headache, rash, hypertension and reversible thrombocytopenia. Safety has not yet been shown in pregnancy.

Nitroimidazoles

Structure. These agents are active against anaerobic bacteria and some pathogenic protozoa. The most widely used drug is metronidazole (Fig. 2.10). Others include tinidazole and nimorazole.

Mechanism of action. After reduction of their nitro group to a nitrosohydroxyl amino group by microbial enzymes, nitroimidazoles cause strand breaks in microbial DNA.

Metronidazole

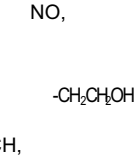

Fig. 2.10 The structure of metronidazole, a nitroimidazole.

Indications for use. Metronidazole plays a major role in the treatment of anaerobic bacterial infections, particularly those due to *Bacteroides* spp. It is also used prophylactically in colonic surgery. It may be given orally, by suppository (well absorbed and cheap) or intravenously (very expensive). It is also the treatment of choice for amoebiasis, giardiasis and infection with *Trichomonas vaginalis.*

Interactions. Nitroimidazoles can produce a disulfiram-like reaction with ethanol and enhance the anticoagulant effect of warfarin.

Toxicity. Nitroimidazoles are tumorigenic in animals and mutagenic for bacteria, although carcinogenicity has not been described in humans. They cause a metallic taste, and polyneuropathy with prolonged use. They should be avoided in pregnancy.

Glycopeptides

The glycopeptides are antibiotics active against Gram-positive bacteria and act by inhibiting cell wall synthesis.

Vancomycin

Vancomycin is given intravenously for methicillin-resistant *Staph. aureus* and other multiresistant Gram-positive organisms. It is also used for treatment and prophylaxis against Gram-positive infections in penicillin-allergic patients. It is used for *Strep, pneumoniae* meningitis when caused by penicillin-resistant strains. By mouth it is an alternative to metronidazole for *Clostridium difficile-associated* colitis. Vancomycin-resistant enterococci (VRE) are now seen, as well as vancomycin-resistant *Staphylococcus* (p. 63).

Toxicity. Vancomycin can cause ototoxicity and nephrotoxicity and thus serum levels should be monitored. Care must be taken to avoid extravasation at the injection site as this causes necrosis and thrombophlebitis. Too rapid infusion can produce symptomatic release of histamine (red man syndrome).

Teicoplanin

This glycopeptide antibiotic is less nephrotoxic than vancomycin. It has more favourable pharmacokinetic properties, allowing once-daily dosage.

Other antibiotics

Clindamycin is not widely used because of its toxic side-effect, antibiotic-associated colitis (pseudomembranous colitis). It is active against Gram-positive cocci including some penicillin-resistant staphylococci. It is also active against anaerobes, especially bacteroides. It is well concentrated in bone and used for osteomyelitis.

Quinupristin and dalfopristin. A combination of these streptogramin antibiotics is used for Gram-positive bacteria which have failed to respond to other antibacterials.

Terbinafine

Other antifungals
Amorolfine (topical only)
5-Flucytosine
Griseofulvin

ANTITUBERCULOSIS DRUGS

These are described on page 932. Kifampicin is also used in other infections apart from tuberculosis.

ANTIFUNGAL DRUGS (Table 214)

Polyenes

Polyenes react with the sterols in fungal membranes, increasing permeability and thus damaging the organism. The most potent is amphotericin, which is used intravenously in severe systemic fungal infections. Nephrotoxicity is a major problem and dosage levels must take background renal function into account. Liposomal amphotericin is less toxic but very expensive. Nystatin is not absorbed through mucous membranes and is therefore useful for the treatment of oral and enteric candidiasis and for vaginal infection. It can only be given orally or as pessaries.

Azoles

Imidazoles such as ketoconazole, miconazole and clotrimazole are broad-spectrum antifungal drugs. They are predominantly fungistatic and act by inhibiting fungal sterol synthesis, resulting in damage to the cell wall. Ketoconazole is active orally but can produce liver damage. It is effective in candidiasis and deep mycoses including histoplasmosis and blastomycosis but not in aspergillosis and cryptococcosis.

Clotrimazole and miconazole are used topically for the treatment of ringworm and cutaneous and genital candidiasis. Econazole and tioconazole are used for the topical treatment of cutaneous and vaginal candidiasis and dermatophyte infections.

Triazoles. These include fluconazole, voriconazole and itraconazole. Fluconazole is noted for its ability to enter CSF and is used for candidiasis and for the treatment of central nervous system (CNS) infection with *Cryptococcus neoformans.* Itraconazole fails to penetrate CSF. It is the agent of choice for non-life-threatening blastomycosis and histoplasmosis. It is also moderately effective in invasive aspergillosis. Toxicity is mild. The problem associated with

poor absorption of the capsules in the absence of food has been overcome with the liquid formulation. Voriconazole has broad-spectrum activity that includes *Candida, Ctyptococcus* and *Aspergillus* spp. and other filamentous fungi. It is available for oral and intravenous use. Adverse effects include rash, visual disturbance and abnormalities of liver enzymes. It is indicated for invasive aspergillosis and severe Candida infections unresponsive to amphoteracin and fluconazole respectively.

Allylamines

Terbinafine has antifungal and anti-inflammatory activity orally and is useful for the treatment of superficial mycoses such as dermatophyte infections, onychomycosis and cutaneous candidiasis. A topical formulation is also available to treat fungal skin infections.

Echinocandins

This is a new class of antifungals which act by inhibiting the cell wall polysaccharide, glucan. Caspofungin is active against *Candida* spp. and *Aspergillus* spp. and is indicated for serious aspergillosis unresponsive to other drugs. It is administered intravenously.

Other antifungals

Flucytosine. The fluorinated pyridine derivative, flucytosine, is used in combination with amphotericin B for systemic fungal infection. Side-effects are uncommon, although it may cause bone marrow suppression. It is active when given orally or parenterally.

Griseofulvin. Griseofulvin, a naturally occurring antifungal, is widely used for the treatment of more extensive superficial mycoses and onychomycosis.

Amorolfine. Amorolfine is available for the topical treatment of fungal skin and nail infections.

ANTIVIRAL DRUGS

Drugs for HIV infection are discussed on page 144.

Nucleoside analogues

Aciclovir. Aciclovir (Fig. 2.11) is an acyclic nucleoside analogue which acts as a chain terminator of herpesvirus DNA synthesis. This drug is converted to aciclovir monophosphate by a virus-encoded thymidine kinase produced by alpha herpesviruses, herpes simplex types 1 and 2 and varicella zoster virus (Table 2.15). Conversion to the triphosphate is then achieved by cellular enzymes. Aciclovir triphosphate competes with deoxyguanine triphosphate and the drug is incorporated into the growing chains of herpesvirus DNA. This highly specific mode of activity, targeted only to virus-infected cells, means that aciclovir has very low toxicity. Intravenous, oral and topical preparations are available for the treatment of herpes simplex and varicella zoster virus infections (Table 2.15).

Aciclovir

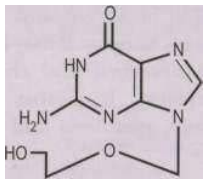

Fig. 2.11 **The structure of aciclovir.**

Table 2.15 **Antiviral agents (for drugs against HIV see Table 2.53)**

Drug	Use
Nucleoside analogues	
Aciclovir	Topical - HSV infection
	Oral and intravenous - VZV and HSV
Famciclovir	Oral - VZV and HSV
Valaciclovir	Oral - VZV and HSV
Ganciclovir	Intravenous and oral - CMV
Valganciclovir	Oral - CMV
Adefovir	Oral - HBV infection
Cidofovir	Intravenous - CMV
Pyrophosphate analogues	
Foscarnet	Intravenous - CMV
Adamantanes	
Amantadine	Oral - influenza A
Neuraminidase inhibitors	
Zanamivir	Topical (inhalation) - influenza A and B
Oseltamivir	Oral - influenza A and B
Ribavirin	Topical (inhalation) - RSV
	Oral - Lassa fever, hepatitis C
Palivizumab	Prevention of RSV
Alpha-interferon (INF-a)	HBV, HCV, some malignancies (e.g. renal cell carcinoma)
(Pegylated INF-a)	(Given once weekly)

A pro-drug of aciclovir, valaciclovir, has been developed. Coupling of the amino acid valine to the acyclic side-chain of aciclovir allows better intestinal absorption. The valine is removed by enzymic action and aciclovir is released into the circulation. A similar pro-drug of a related nucleoside analogue (penciclovir) is the antiherpes drug, famciclovir. The mode of action and efficacy of famciclovir are similar to those of aciclovir.

Ganciclovir. This guanine analogue is structurally similar to aciclovir, with extension of the acyclic side-chain by a carboxymethyl group. It is active against herpes simplex viruses and varicella zoster virus *by* the same mechanism as aciclovir. In addition, phosphorylation by a protein kinase encoded by the UL97 region of

cytomegalovirus renders it potently active against this virus. Thus ganciclovir is currently the first-line treatment for cytomegalovirus disease. Intravenous and oral preparations are available as is an oral pro-drug, valganciclovir. Unlike aciclovir, ganciclovir has a significant toxicity profile including neutropenia, thrombocytopenia and the likelihood of sterilization by inhibiting spermatogenesis. For this reason, it is reserved for the treatment or prevention of life- or sight-threatening cytomegalovirus infection.

Cidofovir. This is a phosphonate derivative of an acyclic nucleoside which is a DNA polymerase chain inhibitor. It is administered intravenously for the treatment of severe cytomegalovirus (CMV) infections in patients with AIDS. It is given with probenecid, and as it is nephrotoxic, particular attention should be given to hydration and to monitoring renal function.

Adefovir dipivoxil is used in the treatment of chronic hepatitis B (see p. 372).

Pyrophosphate analogues

Foscarnet (sodium phosphonoformate) is a simple pyrophosphate analogue which inhibits viral DNA polymerases. It is active against herpesviruses and its main roles are as a second-line treatment for severe cytomegalovirus disease and for the treatment of aciclovir-resistant herpes simplex infection. It is given intravenously and the potential for severe side-effects, particularly renal damage, limits its use.

Amantadine. Amantadine is a synthetic symmetrical amine which is active prophylactically and therapeutically against influenza A virus (it is inactive against influenza B virus). Its prophylactic efficacy is similar to that of influenza vaccine and it is occasionally used to prevent the spread of influenza A in institutions such as nursing homes. Although CNS side-effects such as insomnia, dizziness and headache may occur (it is also used as a treatment for Parkinson's disease), these are not usually produced by the lower doses currently recommended.

Neuraminidase inhibitors

Two drugs that inhibit the action of the neuraminidase of influenza A and B have been introduced. Zanamavir is administered by inhalation and oseltamivir is an oral preparation. Both have been shown to be effective in reducing the duration of illness in influenza.

Ribavirin

This synthetic purine nucleoside derivative which interferes with 5'-capping of messenger RNA, is active against several RNA viruses. It is administered by a small-particle aerosol generator (SPAG) to infants with acute respiratory syncytial virus (RSV) infection. In a clinical trial in Sierra Leone it was shown to reduce the mortality of Lassa fever virus infection. Individuals with hepatitis C virus infection, treated with alpha-interferon-ribavirin combinations, have lower relapse rates than those receiving interferon alone.

Palivizumab

This monoclonal antibody is specifically indicated to prevent seasonal respiratory syncytial virus (RSV) infection in infants at high risk of this infection. It is administered by intramuscular injection.

Interferons (see also p. 202)

These are naturally occurring proteins produced by virus-infected cells, macrophages and lymphocytes. Interferons are stimulated by a number of factors, including viral nucleic acid, and render uninfected cells resistant to infection with the same - or in some circumstances different - viruses. They have been synthesized commercially by either culture of lymphoblastoid cells or by recombinant DNA technology and are licensed for therapeutic use.

The potency of INF-cx has been enhanced by coupling the protein with polyethylene glycol. The resulting PEG interferon given once weekly has been shown to improve the response to treatment of hepatitis B and C.

IMMUNIZATION AGAINST INFECTIOUS DISEASES

Although effective antimicrobial chemotherapy is available for many diseases, the ultimate aim of any infectious disease control programme is to prevent infection occurring. This is achieved either by:

- eliminating the source or mode of transmission of an infection (p. 22)
- reducing host susceptibility to environmental pathogens.

Immunization, immunoprophylaxis and immunotherapy

Immunization has changed the course and natural history of many infectious diseases. Passive immunization by administering preformed antibody, either in the form of immune serum or purified normal immunoglobulin, provides short-term immunity and has been effective in both the prevention (immunoprophylaxis) and treatment (immunotherapy) of a number of bacterial and viral diseases (Table 2.16). The active immunization schedule currently recommended is summarized in Box 2.6. Long-lasting immunity is achieved only by active immunization with a live attenuated or an inactivated organism (Table 2.17). Active immunization may also be performed with microbial toxin (either native or modified) - that is, a toxoid. Immunization should be kept up to date with booster doses throughout life. Travellers to developing countries, especially if visiting rural areas, should in addition enquire about further specific immunizations.

In 1974 the World Health Organization introduced the Expanded Programme on Immunization (EPI). Twenty years later more than 80% of the world's children had been immunized against tuberculosis, diphtheria, tetanus, pertussis, polio and measles. It is hoped that poliomyelitis will shortly be eradicated world-wide, which will match the past success of global smallpox eradication. Introduction of conjugate vaccines against *Haemophilus influenzae* type b (Hib) has proved highly effective in controlling invasive *H. influenzae* infection, notably meningitis (see p.!

Protection for travellers to developing/tropical countries

There has been a huge increase in the number of people travelling to developing countries, mainly for recreation and leisure. The risk of infection depends on the area to be visited, the type of activity and the underlying health of the traveller. Advice should therefore always be based on an individual assessment.

Protection for travellers can be divided into three categories:

- Personal protection, e.g.
  - insect repellent
  - bed netting
  - avoidance of animals
  - care with food and drink
- Chemoprophylaxis, e.g. antimalarials
- Immunization, e.g.
  - yellow fever
  - hepatitis A and B
  - typhoid.

Because situations and risks can change rapidly, websites (which can be regularly updated) are often the best source of advice on travel health. ■■■- : ■,. i;; -,r : :

VIRAL INFECTIONS: AN INTRODUCTION

Viruses are much smaller than other infectious agents (see Tables 2.18 and 2.20) and contain either DNA or RNA, not both as in bacteria and other microorganisms. Since they are metabolically inert, they must live intracellularly, using the host cell for synthesis of viral proteins and nucleic acid. Viruses have a central nucleic acid core surrounded by a protein coat that is antigenically unique for a particular virus. The protein coat (capsid) imparts a helical or icosahedral structure to the virus. Some viruses also possess an envelope consisting of lipid and protein.

Hepatitis viruses are discussed on page 362.

DNA VIRUSES

Details of the structure, size and classification of human DNA viruses are shown in Table 2.18.

ADENOVIRUSES

Adenovirus infection commonly presents as an acute pharyngitis, and extension of infection to the larynx and trachea in infants may lead to croup. By school age the majority of children show serological evidence of previous infection. Certain subtypes produce an acute conjunctivitis associated with pharyngitis. In adults, adenovirus causes acute follicular conjunctivitis and rarely pneumonia that is clinically similar to that produced by *Mycoplasma pneumoniae* (see p. 924). Adenoviruses have also been implicated as a cause of gastroenteritis (see p. 52) without respiratory disease and may be responsible for acute mesenteric lymphadenitis in children and young adults. Mesenteric adenitis due to adenoviruses may lead to intussusception in infants.

HERPESVIRUSES

Members of the herpesviruses are important causes of a wide range of human diseases. Details are summarized in Table 2.19. The hallmark of all herpesvirus infections is the ability of the viruses to establish latent (or silent) infections that then persist for the life of the individual.

Herpes simplex virus (HSV) infection
(Kg.2.12)

Two types of HSV have been identified: HSV-1 is the major cause of herpetic stomatitis, herpes labialis ('cold sore'), keratoconjunctivitis and encephalitis, whereas

' Signifies primary infection

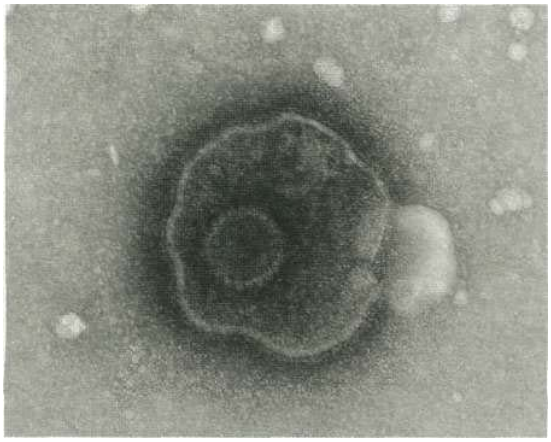

Fig. 2.12 Electronmicrograph of herpes simplex virus.

HSV-2 causes genital herpes and may also be responsible for systemic infection in the immunocompromised host. These divisions, however, are not rigid, for HSV-1 can give rise to genital herpes and HSV-2 can cause pharyngitis.

The portal of entry of HSV-1 infection is usually via the mouth or occasionally the skin. The primary infection may go unnoticed or may produce a severe inflammatory reaction with vesicle formation leading to painful ulcers (gingivostomatitis; see Fig. 2.13). The virus then remains latent, most commonly in the trigeminal ganglia, but may be reactivated by stress, trauma, febrile illnesses and ultraviolet radiation, producing the recurrent form of the disease known as herpes labialis ('cold sore'). Approximately 70% of the population are infected with HSV-1 and recurrent infections occur in one-third of individuals.

Fig. 2.13 Primary herpes simplex type 1 (gingivostomatitis).

Reactivation often produces localized paraesthesiae in the lip before the appearance of a cold sore.

Complications of HSV-1 infection include transfer to the eye (dendritic ulceration, keratitis), acute encephalitis (p. 1167), skin infections such as herpetic whitlow, and erythema multiforme (see p. 1342).

In genital herpes the primary infection is usually more severe and recurrences are common. The virus remains latent in the sacral ganglia and during recurrence can produce a radiculomyelopathy, with pain in the groin, buttocks and upper thighs. Primary anorectal herpes infection is common in male homosexuals (see p. 125).

Immunocompromised patients such as those receiving intensive cancer chemotherapy or those with the acquired immunodeficiency syndrome (AIDS) may develop disseminated HSV infection involving many of the viscera. In severe cases death may result from hepatitis and encephalitis.

Neonates may develop primary HSV infection following vaginal delivery in the presence of active genital HSV infection in the mother. The disease in the baby varies from localized skin lesions to widespread visceral disease often with encephalitis. Caesarean section should therefore be considered if active genital HSV infection is present during labour.

Humoral antibody develops following primary infection, but mononuclear cell responses are probably more important in preventing dissemination of disease.

The clinical picture, diagnosis and treatment are described on page 132.

Varicella zoster virus (VZV) infection

VZV produces two distinct diseases, varicella (chickenpox) and herpes zoster (shingles). The primary infection is chickenpox. It usually occurs in childhood, the virus entering through the mucosa of the upper respiratory tract. It should be noted that in some countries (e.g. the Indian subcontinent) a different epidemiological pattern exists with most infections occurring in adulthood. Chickenpox rarely occurs twice in the same individual.

Infectious virus is spread from fresh skin lesions by direct contact or airborne transmission and the period of infectivity in chickenpox extends from 2 days before the appearance of the rash until the skin lesions are all at the crusting stage. Following recovery from chickenpox the virus then remains latent in dorsal root and cranial nerve ganglia.

Clinical features of chickenpox

Fourteen to twenty-one days after exposure to VZV, a brief prodromal illness of fever, headache and malaise heralds the eruption of chickenpox, characterized by the rapid progression of macules to papules to vesicles to pustules in a matter of hours (Fig. 2.14). In young children the prodromal illness may be very mild or absent. The illness tends to be more severe in older children and can be debilitating in adults. The lesions occur on the face, scalp and trunk, and to a lesser extent on the extremities. It is characteristic to see skin lesions at all stages of development on the same area of skin. Fever subsides as soon as new lesions cease to appear. Eventually the pustules crust and heal without scarring.

Important complications of chickenpox include pneumonia, which generally begins 1-6 days after the skin eruption, and bacterial superinfection of skin lesions. Pneumonia is more common in adults than in children and cigarette smokers are at particular risk. Pulmonary symptoms are usually more striking than the physical findings, although a chest radiograph usually shows diffuse changes throughout both lung fields. CNS involvement occurs in about 1 per 1000 cases and most commonly presents as an acute truncal cerebellar ataxia. The immunocompromised are susceptible to disseminated infection with multiorgan involvement.

Clinical features of shingles

Shingles (see p. 1321) occurs at all ages but is most common in the elderly, producing skin lesions similar to chickenpox, although classically they are unilateral and restricted to a sensory nerve (dermatomal) distribution (Fig. 2.15). Shingles never occurs as a primary infection but results from reactivation of latent VZV from dorsal

Fig. 2.14 Chickenpox in an adult. Generalized VZV.

Fig. 2.15 Shingles - VZV affecting a dermatome. Reproduced with kind permission of Imperial College School of Medicine.

root and/ or cranial nerve ganglia. The onset of the rash of shingles is usually preceded by severe dermatomal pain, indicating the involvement of sensory nerves in its pathogenesis. Virus is disseminated from freshly formed vesicles and may cause chickenpox in susceptible contacts.

Diagnosis

The diseases are usually recognized clinically but can be confirmed by electronmicroscopy, immunofluorescence or culture of vesicular fluid and by serology.

Prophylaxis and treatment

Chickenpox usually requires no treatment in healthy children and infection results in lifelong immunity. However, the disease may be fatal in the immunocompromised, who can be offered protection, after exposure to the virus, with zoster immune immunoglobulin (ZIG).

Anyone with chickenpox who is over the age of 16 years should be considered for antiviral therapy with aciclovir, or a similar drug, if they present within 72 hours of onset. Women in pregnancy are prone to severe chickenpox and, in addition, there is a risk of intrauterine infection with structural damage to the fetus (mainly in the mid trimester - risk rate 2%). For these reasons prophylactic ZIG is recommended for women in pregnancy exposed to varicella zoster virus and, if chickenpox develops, aciclovir treatment should be given. (NB: aciclovir has not been licensed for use in pregnant women.) If a woman has chickenpox at term, her baby should be protected by ZIG if delivery occurs within 5 days of the onset of the mother's illness. An effective varicella vaccine is used in many parts of the USA; it is available on a named-patient basis in the UK.

Shingles is also treated with aciclovir and the duration of lesion formation and time to healing can be reduced by early treatment. Aciclovir, valaciclovir and famciclovir have all been shown to reduce the burden of zoster-associated pain when treatment is given in the acute phase. Shingles involving the ophthalmic division of the trigeminal nerve has an associated incidence of acute and chronic ophthalmic complications of 50%. Early treatment with aciclovir reduces this to 20% or less. As for chickenpox, all immunocompromised individuals should be given aciclovir at the onset of shingles.

Cytomegalovirus (CMV) infection

Infection with CMV is found world-wide and has its most profound effects as an opportunistic infection in the immunocompromised, particularly in recipients of bone-marrow and solid organ transplants and in patients with AIDS. Over 50% of the adult population have serological evidence of latent infection with the virus, although infection is generally symptomless. As with all herpesviruses, the virus persists for life, usually as a latent infection in which the naked DNA is situated extrachromosomally in the nuclei of the cells in the endothelium of the arterial wall and in T lymphocytes.

Clinical features

In healthy adults CMV infection is usually asymptomatic but may cause an illness similar to infectious mononucleosis, with fever, occasionally lymphocytosis with atypical lymphocytes, and hepatitis with or without jaundice. The Paul-Bunnell test for heterophile antibody is negative. Infection may be spread by kissing, sexual intercourse or blood transfusion, and transplacentally to the fetus. Disseminated fatal infection with widespread visceral involvement occurs in the immunocompromised (see p. 138) and may cause encephalitis, retinitis, pneumonitis and diffuse involvement of the gastrointestinal tract.

Intrauterine infection usually occurs in primary infection acquired during pregnancy and may have serious consequences in the fetus; CNS involvement may cause microcephaly and motor disorders. Jaundice and hepatosplenomegaly are common, and thrombocytopenia and haemolytic anaemia also occur. Evidence of CNS involvement may be provided by demonstration of periventricular calcification on X-ray.

Diagnosis

Serological tests can identify latent (IgG) or primary (IgM) infection. The virus can also be identified in tissues by the presence of characteristic intranuclear 'owl's eye' inclusions (Fig. 2.16) on histological staining and by direct immunofluorescence. Culture in human embryo fibroblasts is usually slow but diagnosis can be accelerated by immunofluorescent detection of antigen in the cultures. The polymerase chain reaction, which can be quantitative, provides a sensitive way of detecting CMV in blood and other body fluids.

Treatment

In the immunocompetent, infection is usually self-limiting and no specific treatment is required. In the immunosuppressed, ganciclovir (5mg/kg daily for 14-21 days) reduces retinitis and gastrointestinal damage and can eliminate CMV from blood, urine and respiratory

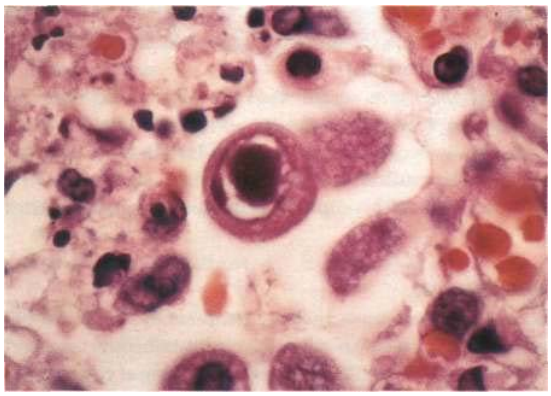

Fig. 2.16 Typical 'owl-eye' inclusion-bearing cell infected with cytomegalovirus.

secretions. It is less effective against pneumonitis. In patients who are continually immunocompromised, particularly those with AIDS, maintenance therapy may be necessary. Drug resistance has been reported in AIDS patients and transplant recipients. Bone marrow toxicity is common. No antiviral drugs are currently available for routine treatment of CMV in neonates and the toxicity of ganciclovir prohibits its use in most cases. Two other drugs, foscarnet and cidofovir, are available for the treatment of CMV infection but both are nephrotoxic and their use should be restricted to those with severe disease.

Epstein-Barr virus (EBV) infection

This virus causes an acute febrile illness known as infectious mononucleosis (glandular fever), which occurs world-wide in adolescents and young adults. EBV is probably transmitted in saliva and by aerosol.

Clinical features

The predominant symptoms are fever, headache, malaise and sore throat. Palatal petechiae and a transient macular rash are common, the latter occurring in 90% of patients who have received ampicillin (inappropriately) for the sore throat. Cervical lymphadenopathy, particularly of the posterior cervical nodes, and splenomegaly are characteristic. Mild hepatitis is common, but other complications such as myocarditis, meningitis, encephalitis, mesenteric adenitis and splenic rupture are rare.

Although some young adults remain debilitated and depressed for some months after infection, the evidence for reactivation of latent virus in healthy individuals is controversial, although this is thought to occur in immunocompromised patients. Following primary infection, EBV remains latent in resting memory B lymphocytes. It has been shown in vitro that of nearly 100 viral genes expressed during replication, approximately only 10 are expressed in the latently infected B cells. Severe, often fatal infectious mononucleosis may result from a rare X-linked immunoproliferative syndrome affecting young boys. Those who survive have an increased risk of hypogammaglobulinaemia and/or lymphoma.

EBV is the cause of oral hairy leucoplakia in AIDS patients and is the major aetiological agent responsible for Burkitt's lymphoma, nasopharyngeal carcinoma, post-transplant lymphoma, and the immunoblastic lymphoma of AIDS patients and Hodgkin's lymphoma. Different levels of expression of EBV latency genes occur in the various clinical conditions caused by the virus.

Diagnosis

EBV infection should be strongly suspected if atypical mononuclear cells (glandular fever cells) are found in the peripheral blood. It can be confirmed during the second week of infection by a positive Paul-Bunnell reaction, which detects heterophile antibodies (IgM) that agglutinate sheep erythrocytes. False-positives can occur in other conditions such as viral hepatitis, Hodgkin's lymphoma and acute leukaemia. The Monospot test is a sensitive and easily performed screening test for heterophile antibodies. Specific EBV IgM antibodies indicate recent infection by the virus. Clinically similar illnesses are produced by CMV and toxoplasmosis but these can be distinguished serologically.

Treatment

The majority of cases require no specific treatment and recovery is rapid. Corticosteroid therapy is advised when there is neurological involvement (e.g. encephalitis, meningitis, Guillain-Barre syndrome) or when there is marked thrombocytopenia or haemolysis.

Human herpesvirus type 6 (HHV-6)

This human herpesvirus infects CD4+ T lymphocytes, occurs world-wide, and exists as a latent infection in over 85% of the adult population. It is spread by contact with oral secretions. The virus causes roseola infantum (exanthem subitum) which presents as a high fever followed by generalized macular rash in infants. HHV-6 is a common cause of febrile convulsions, and aseptic meningitis or encephalitis may occur as rare complications. Reactivation in the immunocompromised may lead to severe pneumonia.

Treatment

Supportive management only is recommended for the common infantile disease. Ganciclovir can be used in the immunocompromised.

Human herpesvirus type 7 (HHV-7)

This virus is similar to HHV-6 in being a T lymphotropic herpesvirus. It is also present as a latent infection in over 85% of the adult population and it is known to infect CD4+ helper T cells by using the CD4 antigen (the main receptor employed by HIV). The full spectrum of disease due to HHV-7 has not yet been fully characterized, but, like HHV-6, it is known to cause roseola infantum in infants.

Human herpesvirus type 8 (Kaposi's sarcoma-associated herpesvirus)

This human herpesvirus is strongly associated with the aetiology of classical and AIDS-related Kaposi's sarcoma. Antibody prevalence is high in those with tumours but relatively low in the general population of most industrialized countries. High rates of infection (> 50% population) have been described in central and southern Africa and this matches the geographic distribution of Kaposi's sarcoma before the era of AIDS. HHV-8 can be sexually transmitted among homosexual men, through heterosexual sex and through exposure to blood from needle sharing. It is thought that salivary transmission may be the predominant route in Africa. HHV-8 RNA transcripts have been detected in Kaposi's sarcoma cells and in circulating mononuclear cells from patients with the tumour. This virus may also have a pathogenetic role in primary pulmonary hypertension.

PAPOVAVIRUSES

These viruses tend to produce chronic infections, often with evidence of latency. They are capable of inducing neoplasia in some animal species and were among the first viruses to be implicated in tumorigenesis. Human papillomaviruses, of which there are at least 70 types, are responsible for the common wart and have been implicated in the aetiology of carcinoma of the cervix (mainly types 16 and 18) and oral cancer (type 16). The human BK virus, a polyomavirus, is generally found in immunocompromised individuals and may be detected in the urine of 15-40% of renal transplant patients, in patients receiving cytotoxic chemotherapy, and in those with immunodeficiency states. A related virus, JC, is the cause of progressive multifocal leucoencephalopathy (PML) which presents as dementia in the immunocompromised and is due to progressive cerebral destruction resulting from accumulation of the virus in brain tissue.

For genital warts see page 126.

HUMAN PARVOVIRUS B19

Human parvovirus B19 produces erythema infectiosum (fifth disease), a common infection in schoolchildren. The rash is typically on the face (the 'slapped-cheek' appearance). The patient is well and the rash can recur over weeks or months. Asymptomatic infection occurs in 20% of children. Moderately severe self-limiting arthropathy (see p. 573) is common if infection occurs in adulthood. Aplastic crisis may occur in patients with chronic haemolysis (e.g. sickle cell disease). Chronic infection with anaemia occurs in immunocompromised subjects. Hydrops fetalis (3% risk) and spontaneous abortion (9% risk) may result from infection during the first and second trimesters of pregnancy.

POXVIRUSES

Smallpox (variola)

This disease was eradicated in 1977 following an aggressive vaccination policy and careful detection of new cases coordinated by the World Health Organization. Its possible use in bioterrorism has resulted in the reintroduction of smallpox vaccination in some countries (p. 1031).

Monkeypox

This is a rare zoonosis that occurs in small villages in the tropical rainforests in several countries of western and central Africa. Its clinical effects, including a generalized vesicular rash, are indistinguishable from smallpox, but person-to-person transmission is unusual. Serological surveys indicate that several species of squirrel are likely to represent the animal reservoir.

Cowpox

Cowpox produces large vesicles which are classically on the hands in those in contact with infected cows. The lesions are associated with regional lymphadenitis and fever. Cowpox virus has been found in a range of species including domestic and wild cats, and the reservoir is thought to exist in a range of rodents.

Vaccinia virus

This is a laboratory virus and does not occur in nature in either humans or animals. Its origins are uncertain but it has been invaluable in its use as the vaccine to prevent smallpox. Vaccination is now not recommended except for laboratory personnel handling certain poxviruses for experimental purposes or in contingency planning to manage a deliberate release of smallpox virus. It is being assessed experimentally as a possible carrier for new vaccines.

Orf

This poxvirus causes contagious pustular dermatitis in sheep and hand lesions in humans (see p. 1322).

Molluscum contagiosum

This is discussed on page 1322.

RNA VIRUSES

PICORNAVIRUSES

Poliovirus infection (poliomyelitis)

Poliomyelitis occurs when a susceptible individual is infected with poliovirus type 1, 2 or 3. These viruses have a propensity for the nervous system, especially the anterior horn cells of the spinal cord and cranial nerve motor neurones. Poliomyelitis is found world-wide but its incidence has decreased dramatically following improvements in sanitation, hygiene and the widespread use of polio vaccines. Spread is usually via the faeco-oral route, as the virus is excreted in the faeces.

Clinical features

The incubation period is 7-14 days. Although polio is essentially a disease of childhood, no age is exempt. The clinical manifestations vary considerably.

Inapparent infection

Inapparent infection is common and occurs in 95% of infected individuals.

Abortive poliomyelitis

Abortive poliomyelitis occurs in approximately 4—5% of cases and is characterized by the presence of fever, sore throat and myalgia. The illness is self-limiting and of short duration.

Non-paralytic poliomyelitis

Non-paralytic poliomyelitis has features of abortive poliomyelitis as well as signs of meningeal irritation, but recovery is complete.

Paralytic poliomyelitis

Paralytic poliomyelitis occurs in approximately 0.1% of infected children (1.3% of adults). Several factors predispose to the development of paralysis:

- male sex
- exercise early in the illness
- trauma, surgery or intramuscular injection, which localize the paralysis
- recent tonsillectomy (bulbar poliomyelitis).

This form of the disease is characterized initially by features simulating abortive poliomyelitis. Symptoms subside for 4-5 days, only to recur in greater severity with

signs of meningeal irritation and muscle pain, which is most prominent in the neck and lumbar region. These symptoms persist for a few days and are followed by the onset of asymmetric paralysis without sensory involvement. The paralysis is usually confined to the lower limbs in children under 5 years of age and the upper limbs in older children, whereas in adults it manifests as paraplegia or quadriplegia.

Bulbar poliomyelitis

Bulbar poliomyelitis is characterized by the presence of cranial nerve involvement and respiratory muscle paralysis. Soft palate, pharyngeal and laryngeal muscle palsies are common.

Aspiration pneumonia, myocarditis, paralytic ileus and urinary calculi are late complications of poliomyelitis.

Diagnosis

The diagnosis is a clinical one. Distinction from Guillain-Barre syndrome is easily made by the absence of sensory involvement and the asymmetrical nature of the paralysis in poliomyelitis. Laboratory confirmation and distinction between the wild virus and vaccine strains is achieved by virus culture, neutralization and temperature marker tests.

Treatment

Treatment is supportive. Bed rest is essential during the early course of the illness. Respiratory support with intermittent positive-pressure respiration is required if the muscles of respiration are involved. Once the acute phase of the illness has subsided, occupational therapy, physiotherapy and occasionally surgery have important roles in patient rehabilitation.

Prevention and control

Immunization has dramatically decreased the prevalence of this disease world-wide and global eradication of the virus, coordinated by the World Health Organization, is expected within the next 1-2 years. However, there have been recent outbreaks in West Africa where cultural taboos have disrupted the polio vaccination campaign and recently in the Sudan. Trivalent oral poliovaccine (OPV) (active virus) is currently used (see Box 2.6); occasionally, inactivated poliovirus vaccine (IPV) is used intramuscularly for the immunocompromised and their family contacts and for women in pregnancy. Recent studies using inactivated poliovirus vaccine have revealed greater potency than the original Salk IPV. The greater reliability of IPV in hot climates and the scientific and ethical problems of continuing to use OPV in countries free from poliomyelitis, mean that IPV is to be introduced for immunization schedules in the UK in the future.

Coxsackievirus, echovirus and other enterovirus infections

These viruses are spread by the faeco-oral route. They each have a number of different types and are responsible for a broad spectrum of disease involving the skin and mucous membranes, muscles, nerves, the heart (Table 2.21) and, rarely, other organs, such as the liver and pancreas. They are frequently associated with pyrexial illnesses and are the most common cause of aseptic meningitis.

Herpangina

This disease is mainly caused by Coxsackie A viruses and presents with a vesicular eruption on the fauces, palate and uvula. The lesions evolve into ulcers. The illness is usually associated with fever and headache but is short-lived, recovery occurring within a few days.

Hand, foot and mouth disease

This disease is mainly caused by Coxsackievirus A16 or A10. Oral lesions are similar to those seen in herpangina but may be more extensive in the oropharynx. Vesicles and a maculopapular eruption also appear, typically on

+++, often causes; ++, sometimes causes; +/arely causes; ±, possibly causes

the palms of the hands and the soles of the feet, but also on other parts of the body. This infection commonly affects children. Recovery occurs within a week.

Neurological disease

Other enteroviruses in addition to poliovirus can cause a broad range of neurological disease, including meningitis, encephalitis, and a paralytic disease characteristic of poliomyelitis.

Heart and muscle disease

Enteroviruses are cause of acute myocarditis and pericarditis, from which, in general, there is complete recovery. However, these viruses can also cause chronic congestive cardiomyopathy and, rarely, constrictive pericarditis.

Skeletal muscle involvement, particularly of the intercostal muscles, is a feature of *Bornholm disease,* a febrile illness usually due to Coxsackievirus B. The pain may be of such an intensity as to mimic pleurisy or an acute abdomen. The infection affects both children and adults and may be complicated by meningitis or cardiac involvement.

Rhinovirus infection

Rhinoviruses are responsible for the common cold (see p. 895). Chimpanzees and humans are the only species to develop the common cold. ICAM-1 is the cellular receptor (p. 199) for rhinovirus and it is only in these two species that the specific binding domain is present. Peak incidence rates occur in the colder months, especially spring and autumn. There are multiple rhinovirus immunotypes (>100), which makes vaccine control impracticable. In contrast to enteroviruses, which replicate at 37°C, rhinoviruses grow at 33°C (the temperature of the upper respiratory tract), which explains the localized disease characteristic of common colds.

REOVIRUSES

Reovirus infection

Reovirus infection occurs mainly in children, causing mild respiratory symptoms and diarrhoea. A few deaths have been reported following disseminated infection of brain, liver, heart and lungs.

Rotavirus infection

Rotavirus (Latin *rota* = wheel) is so named because of its electronmicroscopic appearance with a characteristic circular outline with radiating spokes (Fig. 2.17). It is responsible world-wide for both sporadic cases and epidemics of diarrhoea, and is currently one of the most important causes of childhood diarrhoea. More than 870 *000* children under the age of 5 years are estimated to die annually in resource-deprived countries, compared with 75-150 in the USA. The prevalence is higher during the winter months in non-tropical areas. Asymptomatic

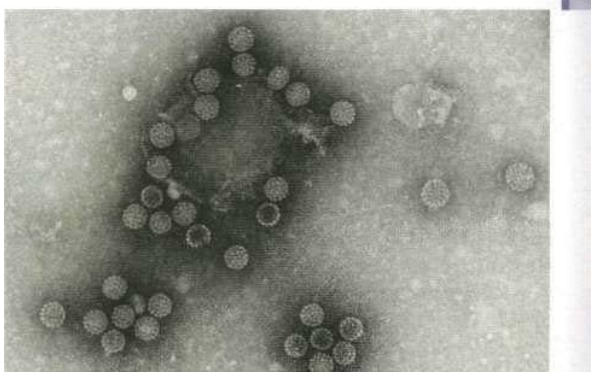

Fig. 2.17 Electronmicrograph of human rotavirus.

infections are common, and bottle-fed babies are more likely to be symptomatic than those that are breast-fed.

Adults may become infected with rotavirus but symptoms are usually mild or absent. The virus may, however, cause outbreaks of diarrhoea in patients on care of the elderly wards.

Clinical features

The illness is characterized by vomiting, fever, diarrhoea, and the metabolic consequences of water and electrolyte loss.

Diagnosis and treatment

The diagnosis can be established by ELISA for the detection of rotavirus antigen in faeces and by electronmicroscopy of faeces. Histology of the jejunal mucosa in children shows shortening of the villi, with crypt hyperplasia and mononuclear cell infiltration of the lamina propria.

Treatment is directed at overcoming the effects of water and electrolyte imbalance with adequate oral rehydration therapy and, when indicated, intravenous fluids (see Box 2.9). Antibiotics should not be prescribed.

Rhesus-human reassortant vaccines have been developed whereby a human rotavirus VP7 is expressed on the surface of a rhesus rotavirus. The tetravalent vaccine contains three reassortants for human rotavirus G-types 1, 2 and 4 plus the rhesus rotavirus (G-type 3). This vaccine (IRRV-TV; rhesus (human) rotavirus - tetravalent vaccine) has been shown to give high levels of protection in children in resource-deprived countries. Although initially licensed by the FDA in the USA, it has been withdrawn owing to an increased incidence of intussusception in the vaccinees. :■ .

Other viruses

Other viruses associated with gastroenteritis are shown in Table 2.22. These include members of two major families which can be recognized by their electronmicroscopic appearance. Caliciviruses, which include the noraviruses

Table 2.22 Viruses associated with gastroenteritis

Rotavirus (groups A, B, C, D and E)
Enteric adenovirus (types 40 and 41)
Noravirus (Norwalk-like viruses of calicivirus family)
Astrovirus

(previously known as Norwalk agent, a small round structured virus) and astroviruses, are responsible for winter vomiting. Although gastroenteritis viruses are normally spread by the faeco-oral route, aerosol spread also occurs.

TOGAVI RUSES

This family comprises three genera: the rubiviruses, which include rubella virus; and the alphaviruses and flaviviruses, which each include some of the arthropod-borne viruses.

Rubella

Rubella ('German measles') is caused by a spherical, enveloped RNA virus which is easily killed by heat and ultraviolet light. While the disease can occur sporadically, epidemics are not uncommon. It has a world-wide distribution. Spread of the virus is via droplets; maximum infectivity occurs before and during the time the rash is present.

Clinical features

The incubation period is 14-21 days, averaging 18 days. The clinical features are largely determined by age, with symptoms being mild or absent in children under 5 years.

During the prodrome the patient may develop malaise and fever. Mild conjunctivitis and lymphadenopathy may be present. The distribution of the lymphadenopathy is characteristic and involves particularly the suboccipital, postauricular and posterior cervical groups of lymph nodes. Small petechial lesions on the soft palate (Forchheimer spots) are suggestive but not diagnostic. Splenomegaly may be present.

The eruptive or exanthematous phase usually occurs within the first 7 days of the initial symptoms. The rash first appears on the forehead and then spreads to involve the trunk and the limbs. It is pinkish red, macular and discrete, although some of these lesions may coalesce (Fig. 2.18). It usually fades by the second day and rarely persists beyond the third day after its appearance.

Complications

Complications are rare. They include superadded pulmonary bacterial infection, arthralgia, haemorrhagic manifestations due to thrombocytopenia, encephalitis and the congenital rubella syndrome. Rubella affects the fetuses of up to 80% of all women who contract the infection during the first trimester of pregnancy. The incidence of congenital abnormalities diminishes in the second trimester and no ill-effects result from infection in the third trimester.

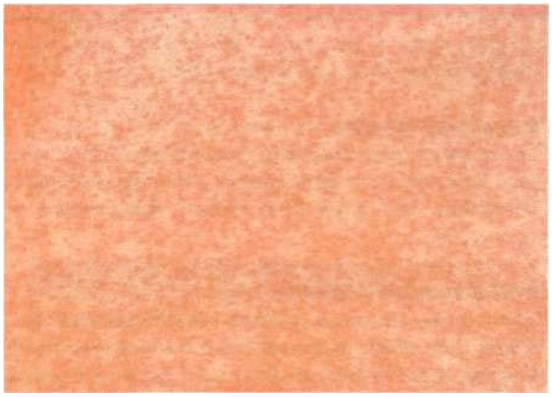

Fig. 2.18 Rubella rash.

Congenital rubella syndrome is characterized by the presence of fetal cardiac malformations, especially patent ductus arteriosus and ventricular septal defect, eye lesions (especially cataracts), microcephaly, mental retardation and deafness.

The expanded rubella syndrome consists of the manifestations of the congenital rubella syndrome plus other effects including hepatosplenomegaly, myocarditis, interstitial pneumonia and metaphyseal bone lesions.

Diagnosis and treatment

The diagnosis may be suspected clinically, but laboratory diagnosis is essential to distinguish the illness from other virus infections (e.g. echovirus) and drug rashes. This is achieved by demonstrating a rising antibody titre (measured using the sensitive haemagglutination-inhibiting antibody (HAI) test or ELISA) in two successive blood samples taken 14 days apart or by the detection of rubella-specific IgM. The virus can be cultured from throat swabs (or oral fluid samples), urine and, in the case of intrauterine infection, the products of conception. Treatment is supportive.

Prevention

Human immunoglobulin can decrease the symptoms of this already mild illness, but does not prevent the teratogenic effects. Several live attenuated rubella vaccines have been used with great success in preventing this illness and these have been successfully combined with the measles and mumps (MMR) vaccine. The side-effects of vaccination have been dramatically decreased by using vaccines prepared in human embryonic fibroblast cultures (RA 27/3 vaccine). Use of the vaccine is contraindicated during pregnancy or if there is a likelihood of pregnancy within 3 months of immunization. Inadvertent use of the vaccine during pregnancy has not, however, revealed a risk of teratogenicity.

Arbovirus (arthropod-borne) infection

Arboviruses are zoonotic viruses, with the possible exception of the O'nyong-nyong fever virus of which

humans are the only known vertebrate hosts. They are transmitted through the bites of insects, especially mosquitoes, and ticks. Over 385 viruses are classified as arboviruses. *Culex, Aedes* and *Anopheles* mosquitoes account for the transmission of the majority of these viruses.

Although most arbovirus diseases are generally mild, epidemics are frequent and when these occur the mortality is high. In general, the incubation period is less than 10 days. The illness tends to be biphasic and, as in other viral fevers, pyrexia, conjunctival suffusion, a rash, retro-orbital pain, myalgia and arthralgia are common. Lymphadenopathy is seen in dengue. Lifelong immunity to a particular virus is usual. In some of these viral fevers, haemorrhage is a feature (Table 2.23). Increased vascular permeability, capillary fragility and consumptive coagulopathy have been implicated as causes of the haemorrhage. Encephalitis resulting from cerebral invasion may be prominent in some fevers.

Alphaviruses
The 24 viruses of this group are all transmitted by mosquitoes; eight result in human disease. These viruses are globally distributed and tend to acquire their names from the location where they were first isolated (such as Ross River, Eastern Venezuelan, and Western encephalitis viruses) or by the local expression for a major symptom caused by the virus (such as chikungunya, meaning 'doubled up'). Infection is characterized by fever, skin rash, arthralgia, myalgia and sometimes encephalitis.

* Most of these are arboviruses. Some (e.g. hantavirus, Lassa fever) have a rodent vector. The source and transmission route of filoviruses is not known.

Flaviviruses
There are 60 viruses in this group, some of which are transmitted by ticks and others by mosquitoes.

Yellow fever

Yellow fever, caused by a flavivirus, results in an illness of widely varying severity so that the disease is under-reported. It is a disease confined to Africa (90% of cases) and South America between latitudes 15° N and 15° S. For poorly understood reasons, yellow fever has not been reported from Asia, despite the fact that climatic conditions are suitable and the vector, *Aedes aegypti,* is common. The infection is transmitted in the wild by *A. africanus* in Africa and the *Haemagogus* species in South and Central America. Extension of infection to humans (via the mosquito or from monkeys) leads to the occurrence of 'jungle' yellow fever. *A. aegypti,* a domestic mosquito which lives in close relationship to humans, is responsible for human-to-human transmission in urban areas (urban yellow fever). Once infected, a mosquito remains so for its whole life.

Clinical features

The incubation period is 3-6 days. When the infection is mild, the disease is indistinguishable from other viral fevers such as influenza or dengue.

Three phases in the severe (classical) illness are recognized. Initially the patient presents with a high fever of acute onset, usually 39^0°C, which then returns to normal in 4-5 days. During this time, headache is prominent. Retrobulbar pain, myalgia, arthralgia, a flushed face and suffused conjunctivae are common. Epigastric discomfort and vomiting are present when the illness is severe. Relative bradycardia (Faget's sign) is present from the second day of illness. The patient then makes an apparent recovery and feels well for several days. Following this 'phase of calm' the patient again develops increasing fever, deepening jaundice and hepatomegaly. Ecchymosis, bleeding from the gums, haematemesis and melaena may occur. Coma, which is usually a result of uraemia or haemorrhagic shock, occurs for a few hours preceding death. The mortality rate is up to 40% in severe cases. The pathology of the liver shows mid-zone necrosis, and eosinophilic degeneration of hepatocytes (Councilman bodies) (see p. 362).

Diagnosis and treatment

The diagnosis is established by a careful history of travel and vaccination status, and by isolation of the virus (when possible) from blood during the first 3 days of illness. Serodiagnosis is possible, but in endemic areas cross-reactivity with other flaviviruses is a problem.

Treatment is supportive. Bed rest (under mosquito nets), analgesics, and maintenance of fluid and electrolyte balance are important.

Prevention and control

Yellow fever is an internationally notifiable disease. It is easily prevented using the attenuated 17D chick embryo

vaccine. Vaccination is not recommended for children under 9 months and immunosuppressed patients unless there are compelling reasons. For the purposes of international certification, immunization is valid for 10 years, but protection lasts much longer than this and probably for life. The WHO Expanded Programme of Immunization includes yellow fever vaccination in endemic areas.

Dengue

This is the commonest arthropod-borne viral infection in humans: over 100 million cases occur every year in the tropics, with over 10 000 deaths from dengue haemorrhagic fever. Dengue is caused by a flavivirus and is found mainly in Asia, South America and Africa, although it has been reported from the USA. Four different antigenic varieties of dengue virus are recognized and all are transmitted by the daytime-biting *A. aegypti* which breed in standing water in refuse dumps in inner cities. *A. albopictus* is a less common transmitter. Humans are infective during the first 3 days of the illness (the viraemic stage). Mosquitoes become infective about 2 weeks after feeding on an infected individual, and remain so for the rest of their lives. The disease is usually endemic. Immunity after the illness is partial.

Clinical features

The incubation period is 5-6 days following the mosquito bite. Asymptomatic or mild infections are common. Two clinical forms are recognized.

Classic dengue fever

Classic dengue fever is characterized by the abrupt onset of fever, malaise, headache, facial flushing, retrobulbar pain which worsens on eye movements, conjunctival suffusion and severe backache, which is a prominent symptom. Lymphadenopathy, petechiae on the soft palate and skin rashes may also occur. The rash is transient and morbilliform. It appears on the limbs and then spreads to involve the trunk. Desquamation occurs subsequently. Cough is uncommon. The fever subsides after 3—4 days, the temperature returns to normal for a couple of days, and then the fever returns, together with the features already mentioned, but milder. This biphasic or 'saddleback' pattern is considered characteristic. Severe fatigue, a feeling of being unwell and depression are common for several weeks after the fever has subsided.

Dengue haemorrhagic fever (DHF)

Dengue haemorrhagic fever is a severe form of dengue fever and is believed to be the result of two or more sequential infections with different dengue serotypes. It is a disease of children and has been described almost exclusively in South East Asia. The disease has a mild start, often with symptoms of an upper respiratory tract infection. This is then followed by the abrupt onset of shock and haemorrhage into the skin and ear, epistaxis, haematemesis and melaena known as the dengue shock syndrome. Serum complement levels are depressed and there is laboratory evidence of a consumptive coagulopathy.

Diagnosis and treatment

Isolation of dengue virus by tissue culture in sera obtained during the first few days of illness is diagnostic. Demonstration of rising antibody titres by neutralization (most specific), haemagglutination inhibition 'ELISA' or complement-fixing antibodies in sequential serum samples is evidence of dengue virus infection. Blood tests show leucopenia and thrombocytopenia.

Treatment is supportive with analgesics and adequate fluid replacement; in DHF, blood transfusion may be necessary.

Prevention

Travellers should be advised to sleep under impregnated nets but this is not very effective as the mosquito bites in daytime. Topical insect repellents should be used. Adult mosquitoes should be destroyed by sprays, and breeding sites should be eradicated.

Rift Valley fever

Rift Valley fever, caused by a flavivirus, is primarily an acute febrile illness of livestock - sheep, goats and camels. It is found in southern and eastern Africa. The vector in East Africa is *Culex pipiens* and in southern Africa, *Aedes cabdlus*. Following an incubation period of 3-6 days, the patient has an acute febrile illness that is difficult to distinguish clinically from other viral fevers. The temperature pattern is usually biphasic. The initial febrile illness lasts *2-A* days and is followed by a remission and a second febrile episode. Complications are indicative of severe infection and include retinopathy, meningoencephalitis, haemorrhagic manifestations and hepatic necrosis. Mortality approaches 50% in severe forms of the illness. Treatment is supportive.

Japanese encephalitis

Japanese encephalitis is a mosquito-borne encephalitis caused by a flavivirus. It has been reported most frequently from the rice-growing countries of South East Asia and the Far East. *Culex tritaeniorhynchus* is the most important vector and this feeds mainly on pigs as well as birds such as herons and sparrows. Humans are accidental hosts.

As with other viral infections, the clinical manifestations are variable. The onset is heralded by severe rigors. Fever, headache and malaise last 1-6 days. Weight loss is prominent. In the acute encephalitic stage the fever is high (38^1 °C), neck rigidity occurs and neurological signs such as altered consciousness, hemiparesis and convulsions develop. Mental deterioration occurs over a period of 3^ days and culminates in coma. Mortality varies from 7-40% and is higher in children. Residual neurological defects such as deafness, emotional lability and hemiparesis occur in about 70% of patients who have had CNS involvement. Convalescence is prolonged.

Antibody detection in serum and CSF by IgM capture ELISA is a useful rapid diagnostic test. An inactivated mouse brain vaccine is effective and available. Treatment is supportive.

West Nile virus

In 1999, the West Nile virus was first recognized in the western hemisphere (New York, USA) and it had previously been reported in Africa, Asia and parts of Europe. The outbreak in the USA produced thousands of symptomatic and symptomless infections with 1% resulting in encephalitis. It is spread by mosquitoes and infects birds, humans and horses. It can also be transmitted with blood transfusions, breast-feeding and organ donation.

BUNYAVIRUSES

Bunyaviruses belong to a large family of more than 200 viruses, most of which are arthropod-borne.

Congo-Crimean haemorrhagic fever

This is found mainly in Asia and Africa. The primary hosts are cattle and hares and the vectors are the *Hyalomma* ticks. Following an incubation period of 3-6 days there is an influenza-like illness with fever and haemorrhagic manifestations. The mortality is 10-50%.

Hantaviruses

Hantaviruses are enzootic viruses of wild rodents which are spread by aerosolized excreta and not by insect vectors. The most severe form of this infection is Korean haemorrhagic fever (or haemorrhagic fever with renal syndrome - HFRS). This condition has a mortality of 5-10% and is characterized by fever, shock and haemorrhage followed by an oliguric phase. Milder forms of the disease are associated with related viruses (e.g. Puumala virus) and may present as nephropathia epidemica, an acute fever with renal involvement. It is seen in Scandinavia and in other European countries in people who have been in contact with bank voles. In the USA, a new hantavirus (transmitted by the deer mouse) termed Sin Nombre was identified as the cause of outbreaks of acute respiratory disease in adults, referred to as hantavirus pulmonary syndrome (HPS). Other hantavirus types and rodent vector systems have been associated with this syndrome.

Diagnosis of hantavirus infection is made by an ELISA technique for specific antibodies.

ORTHOMYXOVIRUSES

Influenza

Three types of influenza virus are recognized: A, B and C. The influenza virus is a spherical or filamentous enveloped virus. Haemagglutinin (H), a surface glycopeptide, aids attachment of the virus to the wall of susceptible host cells at specific receptor sites. Cell penetration, probably by pinocytosis, and release of replicated viruses from the cell surface is effected by budding through the cell membrane facilitated by the action of the enzyme neuraminidase (N) which is also present on the viral envelope. ISH subtypes (H1-H15) and nine N subtypes (N1-N9) have been identified for influenza A viruses but only HI, H2, H3 and Nl and N2 have established stable lineages in the human population since 1918.

- Influenza A is generally responsible for pandemics and epidemics.
- Influenza B often causes smaller or localized and milder outbreaks, such as in camps or schools.
- Influenza C rarely produces disease in humans.

Antigenic shift describes the capacity of influenza A to develop new antigenic variants at irregular intervals. This results from genetic recombination of the RNA of the virus (which is arranged in eight segments) with that of an animal orthomyxovirus.

Antigenic drift (minor changes in influenza A and B viruses) results from point mutations leading to amino acid changes in the two surface glycoproteins, haemagglutinin (H) and neuraminidase (N), which induce humoral immunity.

Thus, changes due to antigenic shift or drift render the individual's immune response less able to combat the new variant.

Major shifts in the antigenic make-up of influenza A viruses provide the necessary conditions for major pandemics, whereas minor antigenic drifts give rise to less severe epidemics because immunity in the population is less blunted.

The most serious pandemic of influenza occurred in 1918, and was associated with more than 20 million deaths world-wide. In 1957, a major shift in the antigenic make-up of the virus led to the appearance of influenza A2 type H2-N2, which caused a world-wide pandemic. A further pandemic occurred in 1968 owing to the emergence of Hong Kong influenza type H3-N2, and minor antigenic drifts have caused outbreaks around the world ever since. In 1997, avian H5-N1 strain of influenza A was found in humans and represented a major change in viral surface antigens. Avian flu re-emerged in 2004-5.

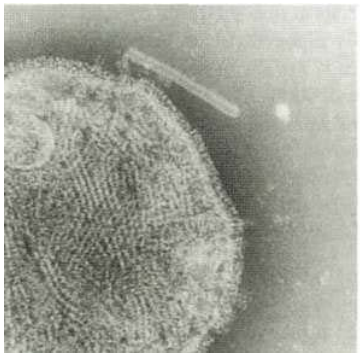
Purified haemagglutinin and neuraminidase from recently circulating strains of influenza A and B viruses are incorporated in current vaccines.

Sporadic cases of influenza and outbreaks among groups of people living in a confined environment are frequent. The incidence increases during the winter months. Spread is mainly by droplet infection but fomites and direct contact have also been implicated.

The clinical features, diagnosis, treatment and prophylaxis of influenza are discussed on page 898.

PARAMYXOVIRUSES

These are a heterogeneous group of enveloped viruses of varying size that are responsible for parainfluenza, mumps, measles and other respiratory infections (Fig. 2.19).



Electronmicrograph of a paramyxovirus

Fig. 2.19
(mumps).

Parainfluenza

Parainfluenza is caused by the parainfluenza viruses types I-IV; these have a world-wide distribution and cause acute respiratory disease. Type IV appears to be less virulent than the other types and has been linked only to mild upper respiratory diseases in children and adults.

Parainfluenza is essentially a disease of children and presents with features similar to the common cold. When severe, a brassy cough with inspiratory stridor and features of laryngotracheobronchitis (croup) are present. Fever is usually present for 2-3 days and may be more prolonged if pneumonia develops. The development of croup is due to submucosal oedema and consequent airway obstruction in the subglottic region. This may lead to cyanosis, subcostal and intercostal recession and progressive airway obstruction. Infection in the immunocompromised is usually prolonged and may be severe. Treatment is supportive with oxygen, humidification and sedation when required. The role of steroids is controversial.

Measles **(rubeola)**

Measles is a highly communicable disease that occurs world-wide. With the introduction of aggressive immunization policies, the incidence of measles has fallen dramatically in the West, but it still remains one of the most common childhood infections in resource-deprived countries, where it is associated with a high morbidity and mortality. It is spread by droplet infection and the period of infectivity is from 4 days before until 2 days after the onset of the rash. , ,

Clinical features

The incubation period is 8-14 days. Two distinct phases of the disease can be recognized.

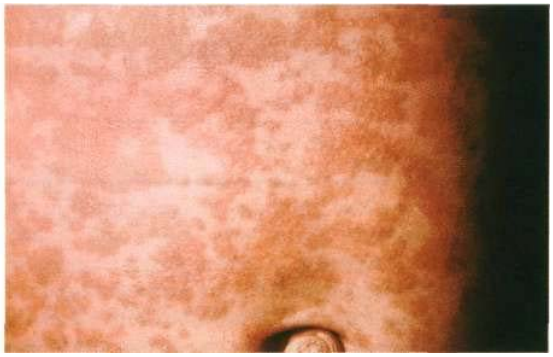


Fig. 2.20 Measles. Courtesy of Dr MW McKendrick, Royal Hallamshire Hospital, Sheffield.

Typical measles

m *The pre-emptive and catarrhal stage.* This is the stage of viraemia and viral dissemination. Malaise, fever, rhinorrhoea, cough, conjunctival suffusion and the pathognomonic Koplik's spots are present during this stage. Koplik's spots are small, greyish, irregular lesions surrounded by an erythematous base and are found in greatest numbers on the buccal mucous membrane opposite the second molar tooth. They occur a day or two before the onset of the rash.

■ *The eruptive or exanthematous stage.* This is characterized by the presence of a maculopapular rash that initially occurs on the face, chiefly the forehead, and then spreads rapidly to involve the rest of the body (Fig. 2.20). At first the rash is discrete but later it may become confluent and patchy, especially on the face and neck. It fades in about 1 week and leaves behind a brownish discoloration.

Although measles is a relatively mild disease in the healthy child, it carries a high mortality in the malnourished and in those who have other diseases. Complications are common in such individuals and include bacterial pneumonia, bronchitis, otitis media and gastroenteritis. Less commonly, myocarditis, hepatitis and encephalomyelitis may occur. In those who are malnourished or those with defective cell-mediated immunity, the classical maculopapular rash may not develop and widespread desquamation may occur. The virus also causes the rare condition, subacute sclerosing panencephalitis, which may follow measles infection occurring early in life (<18 months of age). Persistence of the virus with reactivation pre-puberty results in accumulation of virus in the brain, progressive mental deterioration and a fatal outcome (see p. 1240).

Maternal measles, unlike rubella, does not cause fetal abnormalities. It is, however, associated with spontaneous abortions and premature delivery.

Atypical measles

In the past, a severe illness called atypical measles occurred in individuals given an inactivated vaccine (now withdrawn). This vaccine conferred incomplete protection and on exposure to the wild measles virus they developed

high fever, myalgia, abdominal pain and a variety of skin rashes which could be mistaken for scarlet fever, meningococcal disease or varicella. Pneumonia was invariably present and pulmonary infiltrates persisted for years in some cases.

Diagnosis and treatment

Most cases of measles are diagnosed clinically but, if necessary, immunofluorescence, virus culture and serological tests (complement fixation test (CFT), haemagglutination inhibition tests) are used to confirm the diagnosis.

Treatment is supportive. Antibiotics are indicated only if secondary bacterial infection occurs.

Prevention

A previous attack of measles confers a high degree of immunity and second attacks are uncommon. Normal human immunoglobulin given within 5 days of exposure effectively aborts an attack of measles. It is indicated for previously unimmunized children below 3 years of age, during pregnancy, and in those with debilitating disease.

Active immunization. Children are immunized with the combined mumps-measles-rubella (MMR) vaccine (Box 2.6).

Mumps

Mumps is the result of infection with a paramyxovirus. It is spread by droplet infection, by direct contact or through fomites. Humans are the only known natural hosts. The peak period of infectivity is 2-3 days before the onset of the parotitis and for 3 days afterwards.

Clinical features

The incubation period averages 18 days. Although no age is exempt, it is primarily a disease of school-aged children and young adults; it is uncommon before the age of 2 years. The prodromal symptoms are non-specific and include fever, malaise, headache and anorexia. This is usually followed by severe pain over the parotid glands, with either unilateral or bilateral parotid swelling. The enlarged parotid glands obscure the angle of the mandible and may elevate the ear lobe, which does not occur in cervical lymph node enlargement. Trismus due to pain is common at this stage. Submandibular gland involvement occurs less frequently.

Complications

CNS involvement is the most common extrasalivary-gland manifestation of mumps. Clinical meningitis occurs in 5% of all infected patients, and 30% of patients with CNS involvement have no evidence of parotid gland involvement.

Epididymo-orchitis develops in about one-third of patients who develop mumps after puberty. Bilateral testicular involvement results in sterility in only a small percentage of these patients. Pancreatitis, oophoritis, myocarditis, mastitis, hepatitis and polyarthritis may also occur.

Diagnosis and treatment

The diagnosis of mumps is on the basis of the clinical features. In doubtful cases, serological demonstration of a fourfold rise in antibodies detected by complement fixation or indirect haemagglutination or neutralization tests on acute and convalescent sera is diagnostic. Virus can be isolated in cell culture from saliva, throat swab, urine and CSF and identified by immunofluorescence or haemadsorption.

Treatment is supportive. Attention should be given to adequate nutrition and mouth care. Analgesics should be used to relieve pain. .. ■

Prevention

Active immunization. Children are immunized with the MMR vaccine (Box 2.6). Vaccination is contraindicated in immunosuppressed individuals, during pregnancy, or in those with severe febrile illnesses.

Respiratory syncytial virus infection

Respiratory syncytial virus (RSV) is a paramyxovirus that causes many respiratory infections in epidemics each winter. It is a common cause of bronchiolitis in infants, which is complicated by pneumonia in approximately 10% of cases. The infection normally starts with upper respiratory symptoms. After an interval of 1-3 days a cough and low-grade fever may develop. The onset of bronchiolitis is characterized by dyspnoea and hyper-expansion of the chest with subcostal and intercostal recession. The disease may be severe and potentially fatal in babies with underlying cardiac or respiratory disease. RSV infection has been associated with the occurrence of sudden infant death syndrome (SIDS). Immunity is short-lived and, consequently, reinfection can occur throughout life. RSV is occasionally the cause of outbreaks of pneumonia in the elderly and in the immunocompromised.

Transfer of infection between children in hospital commonly occurs unless infected patients are isolated or cohorted. Meticulous attention to handwashing and other infection control measures reduces the risk of transmission by staff members.

Diagnosis and treatment

Immunofluorescence on nasopharyngeal aspirates, virus culture and serology are the usual ways of confirming the diagnosis.

Treatment is generally supportive, but aerosolized ribavirin can be given to severe cases, particularly those with underlying cardiac or respiratory disease see p. 41).

Prevention

No vaccine is available for RSV but high-risk children (including those with bronchopulmonary dysplasia and congenital heart disease) can be protected against severe disease by monthly administration of either a hyper-immune globulin against RSV, or a humanized monoclonal antibody Palivizumab, during the winter months (see p. 41).

Metapneumovirus

This recently discovered virus causes approximately 20% of lower respiratory tract infections in infants and young children.

Hendra and Nipah viruses

Hendra virus (formerly called equine morbillivirus) and Nipah virus are newly recognized zoonotic viruses that have caused disease in humans who have been in contact with infected animals (horses and pigs respectively). The viruses are named after the locations where they were first isolated, Hendra in Australia and Nipah in Malaysia, and both are classified as paramyxoviruses. Hendra virus has caused severe respiratory distress in horses and humans and Nipah virus caused a major outbreak of viral encephalitis (265 cases and 105 deaths) in Malaysia between September 1998 and April 1999. Treatment of these conditions is largely supportive, although there is some evidence that early treatment with ribavirin may reduce the severity of the diseases.

CORONAVIRUSES

Human coronaviruses were first isolated in the mid 1960s and the majority of isolates (related to the reference strains 229E and OC43) have been associated with common colds. In November 2002, an apparently new viral disease occurred in China (Guangdong province) and this spread rapidly in other parts of the Far East and also in Canada (Toronto and Vancouver).

This disease, known as 'severe acute respiratory syndrome' (SARS-COV) of which bronchopneumonia has been a major feature, is caused by a previously unknown coronavirus. Similarity of this virus to coronaviruses isolated from civet cats, raccoons and ferret badgers indicates the likelihood that SARS is a zoonotic disease.

The epidemic was finally brought under control in the summer of 2003 and by then there had been > 8000 cases with approximately 800 deaths.

RHABDOVIRUSES

Rabies

Rabies is a major problem in some countries, and established infection is invariably fatal. It is a genotype 1, single-stranded RNA virus of the Lyssavirus genus. The rabies virus is bullet-shaped and has spike-like structures arising from its surface containing glycoproteins that cause the host to produce neutralizing, haemagglutination-inhibiting antibodies. The virus has a marked affinity for nervous tissue and the salivary glands. It exists in two major epidemiological settings:

- *Urban rabies* is most frequently transmitted to humans through rabid dogs and, less frequently, cats.
- *Sylvan (wild) rabies* is maintained in the wild by a host of animal reservoirs such as foxes, skunks, jackals, mongooses and bats.

With the exception of Australia, New Zealand and the Antarctic, human rabies has been reported from all continents. Transmission is usually through the bite of an infected animal. However, the percentage of rabid bites leading to clinical disease ranges from 10% (on the legs) to 80% (on the head). Other forms of transmission, if they occur, are rare.

Having entered the human body, the virus replicates in the muscle cells near the entry wound. It penetrates the nerve endings and travels in the axoplasm to the spinal cord and brain. In the CNS the virus again proliferates before spreading to the salivary glands, lungs, kidneys and other organs via the autonomic nerves.

There have been only two recorded cases of survival from clinical rabies.

Clinical features

The incubation period is variable and may range from a few weeks to several years; on average it is 1-3 months. In general, bites on the head, face and neck have a shorter incubation period than those elsewhere. In humans, two distinct clinical varieties of rabies are recognized:

- furious rabies - the classic variety
- dumb rabies - the paralytic variety.

Furious rabies

The only characteristic feature in the prodromal period is the presence of pain and tingling at the site of the initial wound. Fever, malaise and headache are also present. About 10 days later, marked anxiety and agitation or depressive features develop. Hallucinations, bizarre behaviour and paralysis may also occur. Hyper-excitability, the hallmark of this form of rabies, is precipitated by auditory or visual stimuli. Hydrophobia (fear of water) is present in 50% of patients and is due to severe pharyngeal spasms on attempting to eat or drink. Aerophobia (fear of air) is considered pathognomonic of rabies. Examination reveals hyperreflexia, spasticity, and evidence of sympathetic overactivity indicated by pupillary dilatation and diaphoresis.

The patient goes on to develop convulsions, respiratory paralysis and cardiac arrhythmias. Death usually occurs in 10-14 days.

Dumb rabies

Dumb rabies, or paralytic rabies, presents with a symmetrical ascending paralysis resembling the Guillain-Barre syndrome. This variety of rabies commonly occurs after bites from rabid bats.

Diagnosis

The diagnosis of rabies is generally made clinically. Skin-punch biopsies are used to detect antigen with an immunofluorescent antibody test on frozen section. Viral RNA can be isolated using the reverse transcription polymerase chain reaction (RT-PCR). Isolation of viruses from saliva or the presence of antibodies in blood or CSF may establish the diagnosis. The corneal smear test is not recommended as it is unreliable. The classic Negri bodies

are detected at post-mortem in 90% of all patients with rabies; these are eosinophilic, cytoplasmic, ovoid bodies, 2-10 run in diameter, seen in greatest numbers in the neurones of the hippocampus and the cerebellum. The diagnosis should be made pathologically on the biting animal using RT-PCR, immunofluorescence assay (IFA) or tissue culture of the brain.

Treatment

Once the CNS disease is established, therapy is symptomatic as death is virtually inevitable. The patient should be nursed in a quiet, darkened room. Nutritional, respiratory and cardiovascular support may be necessary. Drugs such as morphine, diazepam and chlorpromazine should be used liberally in patients who are excitable.

Prevention

Pre-exposure prophylaxis. This is given to individuals with a high risk of contracting rabies, such as laboratory workers, animal handlers and veterinarians. Two doses of human diploid cell vaccine (HDCV) 1.0 mL deep subcutaneously or intramuscularly given 4 weeks apart provides effective immunity. A reinforcing dose is given after 12 months and additional reinforcing doses are given every 1-3 years depending on the risk of exposure. Vaccines of nervous-tissue origin are still used in some parts of the world. These, however, are associated with significant side-effects and are best avoided if HDCV is available.

Postexposure prophylaxis. The wound should be cleaned carefully and thoroughly with soap and water and left open. Human rabies immunoglobulin should be given immediately (20 IU/kg); half should be injected around the area of the wound and the other half should be given intramuscularly. Five 1.0 mL doses of HDCV should be given intramuscularly: the first dose is given on day 0 and is followed by injections on days 3, 7,14 and 28. Reaction to the vaccine is uncommon.

Control of rabies

Domestic animals should be vaccinated if there is any risk of rabies in the country. In the UK, control has been by quarantine of imported animals and no indigenous case of rabies has been reported for many years. The quarantine laws are under revision at the present time. The Pet Travel Scheme (PETS) introduced as a pilot scheme in 2000 enables certain pet animals to enter or re-enter Great Britain without quarantine if they come from qualifying countries via designated routes, are carried by authorized transport companies, and meet the conditions of the scheme. Wild animals in 'at risk' countries must be handled with great care.

RETROVIRUSES

Retroviruses (Table 2.24) are distinguished from other RNA viruses by their ability to replicate through a DNA intermediate using an enzyme, reverse transcriptase.

Table 2.24 **Human lymphotropic retroviruses**

Subfamily	Virus	Disease
Lentivirus	HIV-1	AIDS
	HIV-2	AIDS
Oncovirus	HTLV-1*	Adult T cell leukaemia/ lymphoma
	HTLV-2	Tropical spastic paraparesis Myelopathy

*HTLV, human T cell lymphotropic virus

HIV-1 and the related virus, HIV-2, are further classified as lentiviruses ('slow' viruses) because of their slowly progressive clinical effects.

HIV-1 and HIV-2 are discussed on page 130.

HTLV-1 causes adult T cell leukaemia/lymphoma and tropical spastic paraparesis (see p. 1193).

ARENAVIRUSES

Arenaviruses are pleomorphic, round or oval viruses with diameters ranging from 50—300 nm. The virion surface has club-shaped projections, and the virus itself contains a variable number of characteristic electron-dense granules that represent residual, non-functional host ribosomes. The prototype virus of this group is lymphocytic choriomeningitis virus, which is a natural infection of mice. Arenaviruses are also responsible for Argentinian and Bolivian haemorrhagic fevers and Lassa fever.

Lassa fever

This illness was first documented in the town of Lassa, Nigeria, in 1969 and is confined to sub-Saharan West Africa (Nigeria, Liberia and Sierra Leone). The multi-mammate rat, *Mastomys natalensis,* is known to be the reservoir. Humans are infected by ingesting foods contaminated by rat urine or saliva containing the virus. Person-to-person spread by body fluids also occurs. Only 10-30% of infections are symptomatic.

Clinical features

The incubation period is 7-18 days. The disease is insidious in onset and is characterized by fever, myalgia, severe backache, malaise and headache. A transient maculopapular rash may be present. A sore throat, pharyngitis and lymphadenopathy occur in over 50% of patients. In severe cases epistaxis and gastrointestinal bleeding may occur - hence the classification of Lassa fever as a viral haemorrhagic fever. The fever usually lasts 1-3 weeks and recovery within a month of the onset of illness is usual. However, death occurs in 15-20% of hospitalized patients, usually from irreversible hypo-volaemic shock.

Diagnosis

The diagnosis is established by serial serological tests (including the Lassa virus-specific IgM titre) or by

culturing the virus from the throat, serum or urine. Molecular diagnosis by means of the reverse transcriptase polymerase chain reaction has become available and this provides a sensitive and reasonably rapid diagnostic test.

Treatment

Treatment is supportive. In addition, clinical benefit and reduction in mortality can be achieved with ribavirin therapy, if given in the first week.

In non-endemic countries, strict isolation procedures should be used, the patient ideally being nursed in a flexible-film isolator. Specialized units for the management of Lassa fever and other haemorrhagic fevers have been established in the UK. As Lassa fever virus and other causes of haemorrhagic fever (Marburg/ Ebola and Congo-Crimean haemorrhagic fever viruses) have been transmitted from patients to staff in healthcare situations, great care should be taken in handling specimens and clinical material from these patients.

Lymphocytic choriomeningitis **(LCM)** ___

This infection is a zoonosis, the natural reservoir of LCM virus being the house mouse. Infection is characterized by:

- non-nervous-system illness, with fever, malaise, myalgia, headache, arthralgia and vomiting
- aseptic meningitis in addition to the above symptoms.

Occasionally, a more severe form occurs, with encephalitis leading to disturbance of consciousness.

This illness is generally self-limiting and requires no specific treatment.

MARBURG VIRUS DISEASE AND EBOLA VIRUS DISEASE

These severe, haemorrhagic, febrile illnesses are discussed together because their clinical manifestations are similar. The diseases are named after Marburg in Germany and the Ebola river region in the Sudan and Zaire where these viruses first appeared. The natural reservoir for these viruses has not been identified and the precise mode of spread from one individual to another has not been elucidated.

Epidemics have occurred periodically in recent years, mainly in sub-Saharan Africa. The mortality from Marburg and Ebola has ranged from 25% to 90% and recovery is slow in those who survive.

The illness is characterized by the acute onset of severe headache, severe myalgia and high fever, followed by prostration. On about the fifth day of illness a non-pruritic maculopapular rash develops on the face and then spreads to the rest of the body. Diarrhoea is profuse and is associated with abdominal cramps and vomiting. Haematemesis, melaena or haemoptysis may occur between the seventh and sixteenth day. Hepatosplenomegaly and facial oedema are usually present. In Ebola virus disease, chest pain and a dry cough are prominent symptoms.

Treatment is symptomatic. Convalescent human serum appears to decrease the severity of the attack.

POSTVIRAL/CHRONIC FATIGUE SYNDROME

(see also p. 1281)

Viral illnesses have been implicated aetiologically, including those due to EBV, Coxsackie B viruses, echoviruses, CMV and hepatitis A virus. Non-viral causes such as allergy to *Candida* spp. have also been proposed.

The proportion of patients with 'organic' diagnoses remains uncertain. Studies have suggested that two-thirds of patients with a symptom duration of more than 6 months have an underlying psychiatric disorder.

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES (TSE OR PRION DISEASE)

Transmissible spongiform encephalopathies are caused by the accumulation in the nervous system of a protein, termed a 'prion', which is an abnormal isoform Pr Pres of a normal, host protein (Pr Pc).

Although familial forms of prion disease are known to exist, these conditions can be transmissible, particularly if brain tissue enters another host. There is no convincing evidence for the presence of nucleic acid in association with prions; thus these agents cannot be considered orthodox viruses and it is the abnormal prion protein itself that is infectious and can trigger a conversion of the normal protein into the atypical isoform. After infection, a long incubation period is followed by CNS degeneration associated with dementia or ataxia which invariably leads to death. Histology of the brain reveals spongiform change with an accumulation of the abnormal prion protein in the form of amyloid plaques.

The human prion diseases are Creutzfeldt-Jakob disease, including the sporadic, familial, iatrogenic and variant forms of the disease, Gerstmann-Straussler-Scheinker syndrome, fatal familial insomnia, and kuru.

- *Creutzfeldt-Jakob disease* (CJD) usually occurs sporadically world-wide with an annual incidence of one per million of the population. Although, in most cases, the epidemiology remains obscure, transmission to others has occurred as a result of administration of human cadaveric growth hormone or gonadotrophin, from dura mater and corneal grafting, and in neurosurgery from reuse of contaminated instruments and electrodes (iatrogenic CJD).
- *Variant CJD.* In the UK, knowledge that large numbers of cattle with the prion disease, bovine spongiform encephalopathy (BSE) had gone into the human food chain, led to enhanced surveillance for emergence of the disease in humans. The evidence is convincing, based on transmission studies in mice and on glycosylation patterns of prion proteins, that this has occurred and, to date, there have been approximately 150 confirmed and suspected cases of variant CJD

(human BSE) in the UK and 12 in the rest of the world. In contrast to sporadic CJD, which presents with dementia at a mean age of onset of 60 years, variant CJD presents with ataxia, dementia, myoclonus and chorea at a mean age of onset of 29 years (Fig. 2.21).

- *Cerstmann-Straussler-Scheinker syndrome* and *fatal familial insomnia* are rare prion diseases usually occurring in families with a positive history. The pattern of inheritance is as an autosomal dominant with some degree of variable penetrance.
- *Kuru* was described and characterized in the Fore highlanders in NE New Guinea. Transmission was associated with ritualistic cannibalism of deceased relatives. With the cessation of cannibalism by 1960, the disease has gradually diminished and recent cases had all been exposed to the agent before 1960.

The infectious agents of prion disease have remarkable characteristics. In the infected host there is no evidence of inflammatory, cytokine or immune reactions. The agent is highly resistant to decontamination, and infectivity is not reliably destroyed by autoclaving or by treatment with formaldehyde and most other gas or liquid disinfectants. It is very resistant to *y* irradiation. Autoclaving at a high temperature (134-137°C for 18 minutes) is used for decontamination of instruments, and hypochlorite (20 000 p.p.m. available chlorine) or 1 molar sodium hydroxide are used for liquid disinfection. Uncertainty about the reliability of any methods for safe decontamination of surgical instruments has necessitated the introduction of guidelines for patient management.

RIAL INFECTIONS

Classification of bacteria

Bacteria are unicellular organisms (prokaryotes). A small fraction are of medical importance. Unusual infections may result from exposure under circumstances of altered host defences, notably in the severely immunocompromised patient.

Bacteria have traditionally been classified according to the Gram stain which distinguishes Gram-positive from Gram-negative organisms. Using light microscopy, these can then largely be divided into cocci and bacilli (rods). Some have a spiral appearance (spirochaetes) while others, such as *Clostridium* spp., may contain spores (Table 2.25). The cell wall arrangement of Gram-positive cocci contains a phospholipid bilayer surrounded by peptidoglycan made up of repeating units of *N*-acetylglucosamine and N-acetylmuramic acid. In contrast, Gram-negative bacilli possess a second outer lipid bilayer containing protein and lipopolysaccharide (endotoxin). Some pathogens are encapsulated, which is an anti-phagocytic virulence factor.

Bacteria can often be cultured in broth or on solid agar. Those growing in the absence of oxygen are strict anaerobes (e.g. *Bacteroides* spp.), whilst oxygen-dependent bacteria are known as aerobes (e.g. *Pseudomonas* spp.). Many pathogens can tolerate reduced concentrations of oxygen (e.g. E. *coli).* Some organisms are more demanding in their growth requirements and require special laboratory media (e.g. *Mycoplasma* spp. and *Mycobacterium* spp.); others require more prolonged incubation (e.g. *Brucella* spp.).

Genetic classification is defining bacteria in terms of DNA sequence information and has led to the reclassification of several bacteria. DNA fingerprinting is also being increasingly applied to distinguishing similar isolates, which has applications in defining the epidemiology of infection.

Diagnosis and management of bacterial infections

The history and examination usually localizes the infection to a specific organ or body site. A systemic response may accompany such localized disease or, in the

case of bloodstream infections, be the primary mode of presentation. The microbiological diagnosis is difficult to establish in most community-managed infections, and even in hospital where there is ready access to diagnostic laboratories only a minority of infections are documented. For these reasons, a clinical approach to bacterial diseases has been adopted.

SKIN AND SOFT TISSUE INFECTION

Superficial infections

Infections of the skin and the soft tissues beneath are common. These are usually fungal (see p. 1322) or bacterial. Although a wide range of bacteria have been recovered from skin and soft tissue infections (Table 2.26), the majority are caused by the Gram-positive cocci *Staphylococcus aureus* and *Streptococcus pyogenes*. Staphylococci are part of the normal microflora of the human skin and

Table 2.26 **Bacterial causes of superficial skin and soft tissue infection**

Cellulitis		Skin and subcutaneous tissue	*Staph. aureus* *Strep, pyogenes* Group C and G streptococci
Erysipelas		Skin	*Strep, pyogenes*
Ecthyma		Skin and subcutaneous tissue	*Strep, pyogenes* *Staph. aureus*

nasopharynx; up to 25% of people are carriers of *S. aureus,* which is the species responsible for the majority of staphylococcal infections. Although soft tissue infections are the most common manifestation of *S. aureus* disease, numerous other sites can be affected (Table 2.6).

The classification of soft tissue infections is complex, because imprecise and overlapping terms are in use. The commonly encountered infections (Table 2.27) are described in more detail on page 1318.

The majority of skin and superficial soft tissue infections are due to bacteria on the skin surface penetrating the dermis or the subcutaneous tissues. Infection can take place via hair follicles, insect bites, cuts and abrasions, or skin damaged by superficial fungal infection. Sometimes infection is introduced by an animal bite or a penetrating foreign body: in these cases more unusual organisms may be found. A number of factors predispose to cellulitis and other soft tissue infections (Table 2.28).

Pasteurellosis

Pasteurella multocida is found in the oropharynx of up to 90% of cats and 70% of dogs. It can cause soft tissue infections following animal bites. Although the infection initially resembles other forms of cellulitis, there is a much higher incidence of spread to deeper tissues, resulting in osteomyelitis, tenosynovitis or septic arthritis. The organism is sensitive to penicillin, but as infections following animal bites are often polymicrobial, co-amoxiclav is used.

Table 2.28 Predisposing factors for skin and soft tissue infection

Diabetes mellitus
Chronic lymphoedema
Peripheral vascular disease
Steroid treatment
Malnutrition
Some immunodeficiency states (e.g. Job's syndrome)
Nasal carriage of *Staphylococcus aureus*

Meticillin-resistant *Staphylococcus aureus* (MRSA)

S. *aureus* are commonly resistant to penicillin, and isolated resistance to other P-lactam antibiotics such as meticillin and flucloxacillin has been recognized since the development of the first semisynthetic penicillins in the early 1960s. However, in the last 25 years, strains of MRSA with resistance to a much wider range of antibiotics have emerged. In some cases only the glycopeptide antibiotics vancomycin and teicoplanin are effective, and a few organisms have been isolated with decreased sensitivity even to these. Vancomycin-insensitive *Staphylococcus aureus* (VISA) develop because the organism produces a thick cell wall by changing the synthesis of cell wall material. Vancomycin resistant *Staphylococcus aureus* (VRSA) acquires resistance by receiving the van A gene from vancomycin-resistant enterococci (see Fig. 2.2). Two classes of antibiotics, the streptogramins (e.g. quinupristin with dalfopristin) and the oxazolidinones (e.g. linezolid) are effective against Gram-positive bacteria, including MRSA. They should usually be reserved for multi-resistant organisms. Control of the use of antibiotics in hospitals and good infection control policies are vital to prevent spread.

MRSA is usually found as a harmless skin commensal, especially in hospitalized patients or nursing home residents. However, it can cause a variety of infections in soft tissues and elsewhere, and can cause death. It is particularly associated with surgical wound infections. Eradication of the organism is difficult, and people who are known to be colonized should be isolated from those at risk of significant infection. Topical treatment with antibiotics is often used, but is of limited efficacy. Hand-washing is more effective.

Cat scratch disease

Cat scratch disease is a zoonosis caused by *Bartonella henselae.* Asymptomatic bacteraemia is relatively common in domestic and especially feral cats, and human infection is probably due to direct inoculation from the claws or via cat flea bites. Regional lymphadenopathy appears

1-2 weeks after infection; the nodes become tender and may suppurate. Histology of the nodes shows granuloma formation, and the illness may be mistaken for mycobacterial infection or lymphoma. There are usually few systemic symptoms in immunocompetent patients, although more severe disease may be seen in the immunocompromised. In these patients tender cutaneous or subcutaneous nodules are seen (bacillary angiomatosis) which may ulcerate. The lymphadenopathy resolves spontaneously over weeks or months, although surgical drainage of very large suppurating nodes may be necessary. *B. henselae* is sensitive to doxycycline, but the clinical benefit of treatment is unproven.

Toxin-mediated skin disease

A number of skin conditions, although caused by bacteria, are mediated by exotoxins rather than direct local tissue damage.

Staphylococcal scalded skin syndrome

The scalded skin syndrome is caused by a toxin-secreting strain of *S. aureus*. It principally affects children under the age of 5. The toxin, exfoliatin, causes intra-epidermal cleavage at the level of the stratum corneum leading to the formation of large flaccid blisters that shear readily. It is a relatively benign condition, and responds to treatment with flucloxacillin.

Toxic shock syndrome (TSS)

TSS is usually due to toxin-secreting staphylococci, but toxin-secreting streptococci have also been implicated. Although historically associated with vaginal colonization and tampon use in women, this is not always the case. The exotoxin (normally toxic shock syndrome toxin 1, TSST-1) causes abrupt onset of fever and shock, with a diffuse macular rash and desquamation of the palms and soles. Many patients are severely ill and mortality is about 10%. Treatment is mainly supportive, although the organism should be eradicated.

Scarlet fever (see p. 65)

Deep soft tissue infections

Infections of the deeper soft tissues are much less common than superficial infections, and tend to be more serious. Usually they are related to penetrating injuries or to surgery, and the causative organisms relate to the nature of the wound.

Necrotizing fasciitis

Necrotizing fasciitis is a fulminant, rapidly spreading infection associated with widespread tissue destruction and a high mortality. There are two forms. Type 1, caused by a mixture of aerobic and anaerobic bacteria, is usually seen following abdominal surgery or in diabetics. Type 2, caused by group A streptococci, arises spontaneously in previously healthy people. Both types are characterized by severe pain at the site of initial infection, rapidly followed by tissue necrosis. Infection tracks rapidly along the tissue planes, causing spreading erythema, pain and sometimes crepitus. The only chance of survival is with urgent surgical debridement and aggressive antibiotic therapy. Type 2 necrotizing fasciitis is treated with high doses of benzylpenicillin and clindamycin; type 1 with a broad-spectrum combination.

Gas gangrene

Gas gangrene is caused by deep tissue infection with *Clostridium* spp., especially *C. perfringens*, and follows contaminated penetrating injuries. It is particularly associated with battlefield wounds, but is also seen in intravenous drug users, and following surgery. The initial infection develops in an area of necrotic tissue caused by the original injury; toxins secreted by the bacteria kill surrounding tissue and enable the anaerobic organism to spread rapidly. Toxins are also responsible for the severe systemic features of gas gangrene. Treatment consists of urgent surgical removal of necrotic tissue, and treatment with benzylpenicillin and clindamycin.

RESPIRATORY TRACT INFECTIONS

Infections of the respiratory tract are divided **into** infections of the upper and lower respiratory tract, which are separated by the carina. In health, the lower respiratory tract is normally sterile owing to a highly efficient defence system (p. 881). Infections of the upper respiratory tract are particularly common in childhood when they are usually the result of virus infection. The paranasal sinuses and middle ear are contiguous structures and can be involved secondary to viral infections of the nasopharynx. The lower respiratory tract is frequently compromised by smoking, air pollution, aspiration of upper respiratory tract secretions and chronic lung disease, notably chronic bronchitis and chronic obstructive pulmonary disease. Infections of the respiratory tract are defined clinically, sometimes radiologically, as in the case of pneumonia, and by appropriate microbiological sampling.

Upper respiratory tract infections

- The common cold (acute coryza) (p. 895)
- Sinusitis (p. 1158)
- Rhinitis (p. 895)
- Pharyngitis (p. 898).

Fig. 2.22 Scarlet fever rash, showing desquamation.

Scarlet fever

Scarlet fever occurs when the infectious organism (usually a group A streptococcus) produces erythrogenic toxin in an individual who does not possess neutralizing antitoxin antibodies.

Clinical features

The incubation period of this relatively mild disease, which mainly affects children, is *2-4* days following a streptococcal infection, usually in the pharynx. Regional lymphadenopathy, fever, rigors, headache and vomiting are present. The rash, which blanches on pressure, usually appears on the second day of illness; it initially occurs on the neck but rapidly becomes punctate, erythematous and generalized. It is typically absent from the face, palms and soles, and is prominent in the flexures. The rash usually lasts about 5 days and is followed by extensive desquamation of the skin (Fig. 2.22). The face is flushed, with characteristic circumoral pallor. Early in the disease the tongue has a white coating through which prominent bright red papillae can be seen ('strawberry tongue'). Later the white coating disappears, leaving a raw-looking, bright red colour ('raspberry tongue'). The patient is infective for 10-21 days after the onset of the rash, unless treated with penicillin.

Scarlet fever may be complicated by peritonsillar or retropharyngeal abscesses and otitis media.

Diagnosis

The diagnosis is established by the typical clinical features and culture of a throat swab. Elevated anti-streptolysin O and anti-DNase B levels in convalescent serum are indicative of streptococcal infection.

Treatment

Penicillin is the drug of choice and is given orally as phenoxymethylpenicillin 500 mg four times daily for 10 days. Individuals allergic to penicillin can be treated effectively with erythromycin 250 mg four times daily for 10 days. Treatment is usually effective in preventing rheumatic fever (p. 76) and acute glomerulonephritis (p. 629), which are non-suppurative complications of streptococcal pharyngitis. Unlike acute rheumatic fever, streptococcal nephritis may also complicate streptococcal skin infection.

Prevention

Chemoprophylaxis with penicillin or erythromycin should be given in epidemics.

Diphtheria

Diphtheria caused by *Corynebacterium diphtheriae* occurs world-wide. Its incidence in the West has fallen dramatically following widespread active immunization, but it is epidemic in Russia and Eastern Europe. Transmission is mainly through airborne droplet infection and rarely through fomites.

C. *diphtheriae* is a Gram-positive bacillus. Only strains which carry the tox+ gene, are capable of toxin production. The toxin has two subunits, A and B. Subunit A is responsible for clinical toxicity. Subunit B serves only to transport the toxin component to specific receptors, present chiefly on the myocardium and in the peripheral nervous system. Humans are the only natural hosts.

Clinical features

Diphtheria was formerly a disease of childhood but is increasingly affecting adults in countries where childhood immunization has been interrupted as in Russia and Eastern Europe. The incubation period is 2-7 days. The manifestations may be regarded as local (due to the membrane) or systemic (due to exotoxin). The presence of a membrane, however, is not essential to the diagnosis. The illness is insidious in onset and is associated with tachycardia but only low-grade fever. If complicated by infection with other bacteria such as *Strep, pyogenes,* fever is high and spiking.

Nasal diphtheria is characterized by the presence of a unilateral, serosanguineous nasal discharge that crusts around the external nares.

Pharyngeal diphtheria is associated with the greatest toxicity and is characterized by marked tonsillar and pharyngeal inflammation and the presence of a membrane. This tough greyish yellow membrane is formed by fibrin, bacteria, epithelial cells, mononuclear cells and polymorphs, and is firmly adherent to the underlying tissue. Regional lymphadenopathy, often tender, is prominent and produces the so-called 'bull-neck'.

Laryngeal diphtheria is usually a result of extension of the membrane from the pharynx. A husky voice, a brassy cough, and later dyspnoea and cyanosis due to respiratory obstruction are common features.

Clinically evident myocarditis occurs, often weeks later, in patients with pharyngeal or laryngeal diphtheria. Acute circulatory failure due to myocarditis may occur in convalescent individuals around the tenth day of illness and is usually fatal. Neurological manifestations occur either early in the disease (palatal and pharyngeal wall paralysis) or several weeks after its onset (cranial nerve palsies, paraesthesiae, polyneuropathy or, rarely, encephalitis).

Cutaneous diphtheria is increasingly being seen in association with burns and in individuals with poor

***Box 2.7* Antitoxin administration**

Many antitoxins are heterologous and therefore dangerous
Hypersensitivity reactions are common

Prior to treatment
Question patient about:
(a) allergic conditions (e.g. asthma, hay fever)
(b) previous antitoxin administration.

Read instructions on antitoxin package carefully.
Always give a subcutaneous test dose.

personal hygiene. Typically the ulcer is punched-out with undermined edges and is covered with a greyish white to brownish adherent membrane. Constitutional symptoms are uncommon.

Diagnosis

This must be made on clinical grounds since therapy is usually urgent and bacteriological results of culture studies and toxin production cannot be awaited.

Treatment

The patient should be isolated and bed rest advised. Antitoxin therapy is the only specific treatment. It must be given promptly to prevent further fixation of toxin to tissue receptors, since fixed toxin is not neutralized by antitoxin. Depending on the severity, 20 000-100 000 units of horse-serum antitoxin should be administered intramuscularly after an initial test dose to exclude any allergic reaction. Intravenous therapy may be required in a very severe case. There is a risk of acute anaphylaxis after antitoxin administration and of serum sickness 2-3 weeks later (Box 2.7). However, the risk of death outweighs the problems of anaphylaxis. Antibiotics should be administered concurrently to eliminate the organisms and thereby remove the source of toxin production. Benzylpenicillin 1.2 g four times daily is given for 1 week. The cardiac and neurological complications need intensive therapy.

Prevention

Diphtheria is prevented by active immunization in childhood (see p. 42). Booster doses should be given to those travelling to endemic areas if more than 10 years has elapsed following their primary course of immunization. All contacts of the patient should have throat swabs sent for culture; those with a positive result should be treated with penicillin or erythromycin and active immunization or a booster dose of toxoid given.

Pertussis (whooping cough)

Pertussis occurs world-wide. Humans are both the natural hosts and reservoirs of infection. The disease is caused by *Bordetella pertussis* which is a Gram-negative coccobacillus. *B. parapertussis* and *B. bronchiseptica* produce milder infections. Pertussis is highly contagious and is spread by droplet infection. In its early stages it is indistinguishable from other types of upper respiratory tract infection. Epidemic disease occurred in the UK when the safety of the whooping cough vaccine was questioned. Currently, uptake exceeds 95% and the disease is uncommon.

Clinical features

The incubation period is 7-10 days. It is a disease of childhood, with 90% of cases occurring below 5 years of age. However, no age is exempt.

During the catarrhal stage the patient is highly infectious, and cultures from respiratory secretions are positive in over 90% of patients. Malaise, anorexia, mucoid rhinorrhoea and conjunctivitis are present. The paroxysmal stage, so called because of the characteristic paroxysms of coughing, begins about a week later. Paroxysms with the classic inspiratory whoop are seen only in younger individuals in whom the lumen of the respiratory tract is compromised by mucus secretion and mucosal oedema. The whoop results from air being forcefully drawn through the narrowed tract. These paroxysms usually terminate in vomiting. Conjunctival suffusion and petechiae and ulceration of the frenulum of the tongue are usual. Lymphocytosis due to the elaboration of a lymphocyte-promoting factor by *B. pertussis* is characteristic; lymphocytes may account for over 90% of the total white blood cell count. This stage lasts approximately 2 weeks and may be associated with several complications, including pneumonia, atelectasis, rectal prolapse and inguinal hernia. Cerebral anoxia may occur, especially in younger children, resulting in convulsions. Bronchiectasis is a rare sequel.

Diagnosis

The diagnosis is suggested clinically by the characteristic whoop and a history of contact with an infected individual. It is confirmed by isolation of the organism. Cultures of swabs of nasopharyngeal secretions result in a higher positive yield than cultures of 'cough plates'.

Treatment

If the disease is recognized in the catarrhal stage, erythromycin will abort or decrease the severity of the infection. In the paroxysmal stage, antibiotics have little role to play in altering the course of the illness.

Prevention and control

Affected individuals should be isolated to prevent contact with others, e.g. in hostels and boarding schools. Pertussis is an easily preventable disease and effective active immunization is available (Box 2.6). Convulsions and encephalopathy have been reported as rare complications of vaccination but they are probably less frequent than after whooping cough itself. Any exposed susceptible infant should receive prophylactic erythromycin.

Acute epiglottitis (p. 898)

This has been virtually eliminated among children in those countries which have introduced *Haemophilus influenzae* vaccine, as in the UK. Occasionally, infections are being recognized in adults. The clinical features are described on page 898.

Acute laryngotracheobronchitis (p.

Influenza (pp. 55 and

Lower respiratory tract infections

Pneumonia: community-acquired (p. 922); hospital-acquired (p. 929); in immunocompromised persons (p. 926).

Psittacosis (ornithosis)

Although originally thought to be limited to the psittacine birds (parrots, parakeets and macaws), it is known that the disease is widely spread amongst many species of birds, including pigeons, turkeys, ducks and chickens (hence the broader term 'ornithosis'). Human infection is related to exposure to infected birds and is therefore a true zoonosis. The causative organism, *Chlamydia psittaci,* is excreted in avian secretions; it can be isolated for prolonged periods **from birds** who have apparently recovered from infection. The organism gains entry to the human host by inhalation.

Clinical features and treatment

These are discussed on page 925.

Other respiratory infections (see also p. 925)

Chlamydia pneumoniae causes a relatively mild pneumonia in young adults, clinically resembling infection caused by *Mycoplasma pneumoniae.* Diagnosis can be confirmed by specific IgM serology. Treatment is with erythromycin 500 mg 6-hourly, tetracycline 500 mg every 6—8 hours, or a fluoroquinolone, e.g. ciprofloxacin 500 mg twice daily.

Other chlamydial infections include trachoma (p. 84), lymphogranuloma venereum (p. 122) and other genital infections.

Legionnaires' disease. This is caused by *Legionella pneumophila* and other *Legionella* spp. It is described on page 925.

Lung abscess (p. 929).

Tuberculosis (pp. 86 and 930).

GASTROINTESTINAL INFECTIONS

Gastroenteritis

The **most common** form **of** acute gastrointestinal infection is gastroenteritis, causing diarrhoea with or without vomiting. Children in the developing world can expect, on average, three to six bouts of severe diarrhoea every year. Although oral rehydration programmes have cut the death toll significantly, at least 2.25 million people die every year as a direct result of diarrhoeal disease. In the western world diarrhoea is both less common and less likely to cause death. However, it remains a major cause of morbidity, especially in the elderly. Other groups who are at increased risk of infectious diarrhoea include travellers to developing countries, homosexual men, and infants in day care facilities. Viral gastroenteritis (p. 51) is a common cause of diarrhoea and vomiting in young children but is rarely seen in adults. Protozoal and helminthic gut infections (p. 109) are rare in the West but relatively common in developing countries. The most common cause of significant adult gastroenteritis worldwide is bacterial infection.

Mechanisms

Bacteria can cause diarrhoea in three different ways (Table 2.29). Some species may employ more than one of these methods.

Table 2.29 **Pathogenic mechanisms of bacterial gastroenteritis**

Pathogenesis	Mode of action	Clinical presentation	Examples
Mucosal adherence	Effacement of intestinal mucosa	Moderate watery diarrhoea	Enteropathogenic E *coli* (EPEC)
Mucosal invasion	Penetration and destruction of mucosa	Dysentery	*Shigella* spp. *Campylobacter* spp. Enteroinvasive E *coli* (EIEC)
Toxin production			
Enterotoxin	Fluid secretion without mucosal damage	Profuse watery diarrhoea	*Vibrio cholerae Salmonella* spp. *Campylobacter* spp. Enterotoxigenic E *coli* (ETEC) *Bacillus cereus Staphylococcus aureus* producing enterotoxin B *Clostridium perfringens* type A
Cytotoxin	Damage to mucosa	Dysentery	*Salmonella* spp. *Campylobacter* spp. Enterohaemorrhagic *E. coli* 0157 (EHEC)

Mucosal adherence

Most bacteria causing diarrhoea must first adhere to specific receptors on the mucosa. A number of different molecular adhesion mechanisms have been elaborated; for example, adhesions at the tip of the pili or fimbriae which protrude from the bacterial surface aid adhesion. For some pathogens this is merely the prelude to invasion or toxin production but others such as enteropathogenic *Escherichia coli* (EPEC) cause attachment-effacement mucosal lesions on EM and produce a secretory diarrhoea directly as a result of adherence. Enteroaggregative E. *coli* (EAggEC) adhere in an aggregative pattern with the bacteria clumping on the cell surface and its toxin causes persistent diarrhoea in developing countries. Diffusely adhering E. *coli* (DAEC) adheres in a uniform manner and may also cause diarrhoea in children and in developing countries.

Mucosal invasion

Invasive pathogens such as *Shigella* spp., enteroinvasive E. *coli* (EIEC) and *Campylobacter* spp. penetrate into the intestinal mucosa. They destroy the epithelial cells and produce the symptoms of dysentery: low-volume bloody diarrhoea, with abdominal pain.

Toxin production

Gastroenteritis can be caused by different types of bacterial toxins:

- *Enterotoxins,* produced by the bacteria adhering to the intestinal epithelium, induce excessive fluid secretion into the bowel lumen, leading to watery diarrhoea, without physically damaging the mucosa, e.g. cholera, enterotoxigenic E. *coli* (ETEC). Some enterotoxins preformed in the food primarily cause vomiting, e.g. *Staph. aureus* and *Bacillus cereus. A* typical example of this is 'fried rice poisoning', in which B. *cereus* toxin is present in cooked rice left standing overnight at room temperature.
- *Cytotoxins* damage the intestinal mucosa and, in some cases, vascular endothelium as well.

Clinical syndromes

Bacterial gastroenteritis can be divided on clinical grounds into two broad syndromes: *watery diarrhoea* (usually due to enterotoxins, or adherence), and *dysentery* (usually due to mucosal invasion and damage) (Box 2.8). With some pathogens such as *Campylobacter jejuni* there may be overlap between the two syndromes.

Salmonella

Gastroenteritis can be caused by many of the numerous serotypes of salmonella (all of which are members of a single species, *S. choleraesuis),* but the most commonly implicated are *S. enteritidis* and *S. typhimurium.* These organisms, which are found all over the world, are commensals in the bowels of livestock (especially poultry) and in the oviducts of chicken. They are usually transmitted to man in contaminated foodstuffs.

Box *2.8* Bacterial causes of watery diarrhoea and dysentery

Watery diarrhoea

Bacillus cereus — plus profuse vomiting
Staphylococcus aureus
Vibrio cholerae
Enterotoxigenic *Escherichia coli* (ETEC)
Enteropathogenic *Escherichia coli* (EPEC)
Salmonella spp.
Campylobacter jejuni
Clostridium perfringens
Clostridium difficile

Dysentery

Shigella spp.
Salmonella spp.
Campylobacter spp.
Enteroinvasive *Escherichia coli* (EIEC)
Enterohaemorrhagic *Escherichia coli* (EHEC)
Yersinia enterocolitica
Vibrio parahaemolyticus
Clostridium difficile

Salmonellae can affect both the large and small bowel, and induce diarrhoea both by production of enterotoxins and by epithelial invasion. The typical symptoms commence abruptly 12-48 hours after infection and consist of nausea, cramping abdominal pain, diarrhoea, and sometimes fever. The diarrhoea can vary from profuse and watery to a bloody dysentery syndrome. Spontaneous resolution usually occurs in 3-6 days, although the organism may persist in the faeces for several weeks. Bacteraemia occurs in 1-4% of cases and is more common in the elderly and the immunosuppressed. Occasionally bacteraemia is complicated by metastatic infection, especially of atheroma on vascular endothelium, with potentially devastating consequences. In healthy adults salmonella gastroenteritis is usually a relatively minor illness, but young children and the elderly are at risk of significant dehydration.

Specific diagnosis is made by culturing the organism from blood or faeces, but management is usually empirical. Antibiotic therapy (ciprofloxacin 500 mg twice daily) may decrease the duration and severity of symptoms, but is rarely warranted (see Box 2.10).

Campylobacter jejuni

C. jejuni is also a zoonotic infection, existing as a bowel commensal in many species of livestock. It is found world-wide, and is a common cause of childhood gastroenteritis in developing countries. Adults in these countries may be tolerant of the organism, excreting it asymptomatically. In the West it is a common cause of sporadic food-borne outbreaks of diarrhoea, especially in the summer when barbecued beefburgers are a frequent vehicle.

Like salmonella, campylobacter can affect large and small bowel and can cause a wide variety of symptoms. The incubation period is usually 2-4 days, after which

there is an abrupt onset of nausea, diarrhoea and abdominal cramps. The diarrhoea is usually profuse and watery, but an invasive haemorrhagic colitis is sometimes seen. Bacteraemia is very rare, and infection is usually self-limiting in 3-5 days. Diagnosis is made from stool cultures. If symptoms are severe, azithromycin 500 mg once daily is the drug of choice (see Box 2.10).

Shigella

Shigellae are enteroinvasive bacteria which cause classical bacillary dysentery. The principal species causing gastroenteritis are *S. dysenteriae, S. flexneri* and *S. sonnet,* which are found with varying prevalence in different parts of the world. All cause a similar syndrome, as a result of damage to the intestinal mucosa. Some strains of *S. dysenteriae* also secrete a cytotoxin affecting vascular endothelium. Although shigellae are found world-wide, transmission is strongly associated with poor hygiene. The organism is spread from person to person, and only small numbers need to be ingested to cause illness (< 200, compared to 10^4 for campylobacter and > 10^5 for salmonella). Bacillary dysentery is far more prevalent in the developing world, where the main burden falls on children.

Symptoms start 24-48 hours after ingestion and typically consist of frequent small-volume stools containing blood and mucus. Dehydration is not as significant as in the secretory diarrhoeas, but systemic symptoms and intestinal complications are worse. The illness is usually self-limiting in 7-10 days, but in children in developing countries the mortality may be as high as 20%. Antibiotic treatment decreases the severity and duration of diarrhoea, and possibly reduces the risk of further transmission (see Box 2.10). Resistance to antibiotics is widespread: in some areas amoxicillin or co-trimoxazole may still be effective, but in many places nalidixic acid or ciprofloxacin is needed.

Enteroinvasive *Escherichia coli* (EIEC)

This causes an illness indistinguishable from shigellosis. Definitive diagnosis is made by stool culture.

Enterohaemorrhagic *Escherichia coli* (EHEC)

EHEC (usually serotype O157:H7, and also known as verotoxin-producing E. *coli,* or VTEC) is a well recognized cause of gastroenteritis in man. It is a zoonosis usually associated with cattle, and there have been a number of major outbreaks (notably in Scotland and Japan) associated with contaminated food. EHEC secrete a toxin (Shiga-like toxin 1) which affects vascular endothelial cells in the gut and in the kidney. After an incubation period of 12-48 hours it causes diarrhoea (frequently bloody), associated with abdominal pain and nausea. Some days after the onset of symptoms the patient may develop thrombotic thrombocytopenic purpura (p. 471) or haemolytic uraemic syndrome (HUS, p. 636). This is more common in children, and may lead to permanent renal damage or death. Treatment is mainly supportive: there is evidence that antibiotic therapy might precipitate HUS by causing increased toxin release.

Enterotoxigenic *Escherichia coli* (ETEC)

ETEC produce both heat-labile and heat-stable enterotoxins which stimulate secretion of fluid into the intestinal lumen. The result is watery diarrhoea of varying intensity, which usually resolves within a few days. Transmission is normally from person to person via contaminated food. The organism is common in developing countries, and is a major cause of travellers' diarrhoea (see below).

Vibrio

Cholera, due to *Vibrio cholerae* is the prototypic pure enterotoxigenic diarrhoea: it is described on page 84.

Vibrio parahaemolyticus causes acute watery diarrhoea after eating raw fish or shellfish that has been kept for several hours without refrigeration. Explosive diarrhoea, abdominal cramps and vomiting occurs with a fever in 50%. It is self-limiting, lasting up to 10 days.

Yersiniosis

Yersinia enterocolitica infection is a zoonosis of a variety of domestic and wild mammals. Human disease can arise either via contaminated food products, e.g. pork, or from direct animal contact. Y *enterocolitica* can cause a range of gastroenteric symptoms including watery diarrhoea, dysentery, and mesenteric adenitis. The illness is usually self-limiting, but ciprofloxacin may shorten the duration. Y *pseudotuberculosis* is a much less common human pathogen: it causes mesenteric adenitis and terminal ileitis.

Staphylococcus aureus

Some strains of *Staph. aureus* can produce a heat-stable toxin (enterotoxin B) which causes massive secretion of fluid into the intestinal lumen. It is a common cause of food-borne gastroenteritis in Europe and the USA, outbreaks usually occurring as a result of poor food hygiene. Because the toxin is preformed in the contaminated food, onset of symptoms is rapid, often within *1-A* hours of consumption. There is violent vomiting, followed within hours by profuse watery diarrhoea. Symptoms have usually subsided within 24 hours.

Bacillus cereus

B. cereus produces two toxins. One produces watery diarrhoea up to 12 hours after ingesting the organism. The other toxin is preformed in food and causes severe vomiting, e.g. 'fried rice poisoning' (p. 72).

Clostridial infections

C. *difficile* is found as part of the normal bowel flora in 3—5% of the population and even more commonly in hospitalized people. *C. difficile* produces two toxins: toxin A is an enterotoxin and toxin B is cytotoxic and causes bloody diarrhoea. It usually causes illness after other bowel commensals have been eliminated by antibiotic therapy. Almost all antibiotics have been linked with C. *difficile* diarrhoea, which can begin anything from 2 days to a month after taking antibiotics. Elderly hospitalized patients are most frequently affected.

Symptoms can range from mild diarrhoea to haemorrhagic colitis: sometimes the ulcerated colonic mucosa may be covered by a membrane-like material (pseudomembranous colitis). The diagnosis is made by detecting A or B toxins in the stools by ELBA techniques. Treatment is with metronidazole 400 mg three times daily or oral vancomycin 125 mg four times daily; causative antibiotics should be discontinued if possible. The disease is usually more severe in the elderly, and can cause intractable diarrhoea leading to death.

Clostridium perfringens infection is due to inadequately cooked food, usually meat or poultry allowed to cool for a long time during which the spores germinate. The ingested organism produces an enterotoxin causing watery diarrhoea with severe abdominal pain, usually without vomiting.

Travellers' diarrhoea

Travellers' diarrhoea is defined as the passage of three or more unformed stools per day in a resident of an industrialized country travelling in a developing nation. Infection is usually food- or water-borne, and younger travellers are most often affected (probably reflecting behaviour patterns). Reported attack rates vary from country to country, but approach 50% for a 2-week stay in many tropical countries. The disease is usually benign and self-limiting: treatment with quinolone antibiotics may hasten recovery but is not normally necessary. Prophylactic antibiotic therapy may also be effective for short stays, but should not be used routinely. The common causative organisms are listed in Table 2.30.

Table 2.30 Common causes of travellers' diarrhoea (TD)

Organism	Frequency (varies from country to country)
ETEC	30-70%
Shigella spp.	0-15%
Salmonella spp.	0-10%
Campylobacter spp.	0-15%
Viral pathogens	0-10%
Giardia intestinalis	0-3%

ETEC, enterotoxigenic *Escherichia coli*

Management of acute gastroenteritis

In children, untreated diarrhoea has a high mortality due to dehydration, especially in hot climates. Death and serious morbidity are less common in adults but still occur, particularly in developing countries and in the elderly. The mainstay of treatment for all types of gastroenteritis is oral rehydration solutions (ORS): antibiotics have a subsidiary role in some cases (Fig. 2.23; Boxes 2.9 and 2.10 and p. 85). The use and formulation of ORS are discussed under cholera on p. 85. It should also be remembered that other diseases, notably urinary tract infections and chest infections in the elderly, and malaria at any age, can present with acute diarrhoea.

Food poisoning

Food poisoning is a legally notifiable disease in England and Wales, and is defined as 'any disease of an infective or toxic nature caused by or thought to be caused by the consumption of food and water'. Not all cases of gastroenteritis are food poisoning, as the pathogens are not always food- or water-borne. Common bacterial causes of food poisoning are listed in Table 2.31. Food poisoning may also be caused by a number of non-infectious organic and inorganic toxins (Table 2.32). Illnesses such as botulism (p. 73) are also classified as food poisoning, even though they do not primarily cause gastroenteritis. Listeriosis is described on p. 78.

Box 2.10 **Antibiotics in adult acute bacterial gastroenteritis**

Condition	Indications	Drug of choice	Alternatives	Benefits
Dysentery	Most patients	Ciprofloxacin 500 mg twice daily	Nalidixic acid 1 g four times daily Ampicillin 500 mg four times daily Co-trimoxazole 960 mg twice daily	Relieve symptoms Shorten illness Decrease transmission
Cholera	All patients	Ciprofloxacin	Tetracycline 250 mg four times daily Nalidixic acid Co-trimoxazole	Relieve symptoms Shorten illness Decrease transmission
Empirical therapy of watery diarrhoea	Ciprofloxacin Severe symptoms Prolonged illness Elderly patients Immunosuppressed		Azithromycin 500 mg once daily Co-trimoxazole	Relieve symptoms Shorten illness May decrease complications
Travellers' diarrhoea	Rarely used	Ciprofloxacin	Co-trimoxazole	Relieve symptoms Shorten illness
Treatment of confirmed *Salmonella, Shigella, Campylobacter*	Symptoms not improving (rarely needed)	Ciprofloxacin Azithromycin	Erythromycin Co-trimoxazole	May shorten illness
Clostridium difficile	Most cases (unless symptoms resolved)	Metronidazole 400 mg three times daily	Vancomycin 125 mg four times daily	Relieve symptoms Shorten illness

The increase in reported food poisoning in developed countries is at least in part due to changes in the production and distribution of food. Livestock raised and slaughtered under modern intensive farming conditions is frequently contaminated with salmonella or campylobacter. However, the main problem is not at this stage. Only 0.02-0.1% of the eggs from a flock of chickens infected with *S. enteritidis* will be affected, and then only at a level of less than 20 cells per egg - harmless to most healthy individuals. It is flaws in the processing, storage and distribution of food products which allow massive amplification of the infection, resulting in extensive

contamination. The internationalization of food supply encourages widespread and distant transmission of the resulting infections.

Enteric fever (p

Other gastrointestinal infections

Gastric infection with *Helicobacter pylori* is discussed on page 283, Whipple's disease on page 305, and bacterial peritonitis on page 344.

Table 2.31 Bacterial causes of food poisoning

Organism	Source/vehicles	Incubation period	Symptoms	Diagnosis	Recovery
Staphylococcus aureus	Man - contaminated food and water	2-4 h	Diarrhoea, vomiting and dehydration	Culture organism in vomitus or remaining food	<24 h
E. coli	Salads, water, ice	24 h	Watery diarrhoea	Stool culture	1-4 days
E. coli 0157:H7	Cattle - meat, milk	12-48 h	Watery diarrhoea ± haemorrhagic colitis, HUS	Stool culture	10-12 days
Yersinia enterocolitica	Milk, pork	2-14 h	Abdominal pain, vomiting, diarrhoea	Stool culture	2-30 days
Bacillus cereus	Environment - rice, ice-cream, chicken	1-6 h 6-14 h	Vomiting Diarrhoea	Culture organism in faeces and food	Rapid
Clostridium perfringens	Environment - contaminated food	8-22 h	Watery diarrhoea and cramping pain	Culture organism in faeces and food	2-3 days
Listeria monocytogenes	Environment - milk, raw vegetables dairy products, unpasteurized cheese	[9]	Colic, diarrhoea and vomiting	Stool culture	?
Vibrio parahaemolyticus	Seafood	2-48 h	Diarrhoea, vomiting	Stool, food	2-10 days
Clostridium botulinum	Environment - bottled or canned food	18-24h	Brief diarrhoea and paralysis due to neuromuscular blockade	Demonstrate toxin in food or faeces	10-14 days
Salmonella spp.	Cattle and poultry - eggs, meat	12-48h	Abrupt diarrhoea, fever and vomiting	Stool culture	Usually 3-6 days, but may be up to 2 weeks
Campylobacter jejuni	Cattle and poultry - meat, milk	48-96 h	Diarrhoea ± blood, fever, malaise and abdominal pain	Stool culture	3-5 days
Shigella spp.	Man - contaminated food and water	24-48 h	Acute watery, bloody diarrhoea	Stool culture	7-10 days

HUS, haemolytic uraemic syndrome

Table 2.32 Organic toxins causing food poisoning (see p. 1020)

Toxin	Source	Illness
Scombotoxin	Tuna, mackerel	Histamine fish poisoning
Ciguatoxin	Barracuda, snapper	Ciguatera (diarrhoea and paraesthesia)
Dinoflagellate plankton toxin	Shellfish	Neurotoxic shellfish poisoning
Haemagglutinins	Inadequately-prepared dried kidney beans	Diarrhoea and vomiting
Unknown	Buffalo fish	Haff disease (toxic rhabdomyolysis)
Phallotoxins, amatoxins	Mushrooms	Various

INFECTIONS OF THE CARDIOVASCULAR SYSTEM

Infective endocarditis (p.

INFECTIONS OF THE NERVOUS SYSTEM

The central and peripheral nervous systems can be affected by a variety of microorganisms either directly or via toxins, e.g. viral (p. 1239), protozoal (p. 95) and prion diseases (pp. 60 and 1242).

Bacterial meningitis (see p. 1236)

The most common bacterial disease affecting the central nervous system is acute meningitis, which causes about 175 000 deaths per year, predominantly in the developing world. Epidemic meningitis due to *Neisseria meningitidis* (usually group A) is common in a broad belt across sub-Saharan Africa and is also seen in parts of Asia. In Europe and North America bacterial meningitis is usually sporadic, with B and C strains predominating. A conjugate vaccine for serogroup C meningococcus has resulted in a fall in the number of cases of C meningitis in those countries where it is now part of the childhood immunization schedule, such as the UK.

Streptococcus pneumoniae is the other major cause throughout the world, while tuberculous meningitis (p. 1238) is common in sub-Saharan Africa and parts of Asia.

Haemophilus influenzae b (Hib) was once a common cause of meningitis in children, but since an effective vaccine has been available, serious *H. influenzae* infections have become rare in western countries. Many developing countries have also instituted immunization programmes, but invasive *H. influenzae* infection remains common in some parts of the world.

Other less common causes of meningitis in adults include group B streptococci, *Listeria monocytogenes* (see p. 78), *Staph. aureus,* and Gram-negative bacilli. These organisms are usually associated with an underlying illness or immunocompromising condition, or with a cerebrospinal fluid leak.

Cerebral abscess

This is covered on page 1243.

Toxin-mediated infections

Botulism

Clostridium botulinum is a common environmental organism, and produces spores which can survive heating to 100°C. It causes botulism, an illness caused by contamination of canned or bottled foodstuff, in which the anaerobic organism can multiply and elaborate a neurotoxin. After ingestion the toxin causes profound neuromuscular blockade, leading to autonomic and motor paralysis. The first symptoms, occurring 18-24 hours after ingestion, are nausea and diarrhoea. These are followed by cranial nerve palsies and then progressive symmetrical paralysis, leading to respiratory failure.

The diagnosis is usually clinical, and is confirmed by detection of toxin in faeces or in the contaminated food. Treatment is mainly supportive, with mechanical ventilation if necessary. Antitoxin is available in some countries (including the UK); the risk of anaphylaxis is relatively high, and it should only be used in severe cases. A subcutaneous test dose should be given before intravenous or intramuscular injection. Antibiotics have no proven role. The overall mortality from botulism is high, but patients who survive the acute paralysis can make a full recovery.

Botulism may also follow the contamination of wounds and street heroin injection with *C. botulinum,* and in infants may be related to bowel colonization by the organism.

Tetanus

Tetanus is also due to a toxin-secreting clostridium: *C. tetani.* The organism is found in soil, and illness usually results from a contaminated wound. The injury itself may be trivial and disregarded by the individual. It has also complicated intravenous drug misuse. In developing countries neonatal tetanus follows contamination of the umbilical stump, often after dressing the area with dung.

The organism is not invasive, and clinical manifestations of the disease are due to the potent neurotoxin, tetanospasmin. Tetanospasmin acts on both the a and 8 motor systems at synapses, resulting in disinhibition. It also produces neuromuscular blockade and skeletal muscle spasm, and acts on the sympathetic nervous system. The end result is marked flexor muscle spasm and autonomic dysfunction.

Clinical features

The incubation period varies from a few days to several weeks. The most common form of the disease is generalized tetanus. General malaise is rapidly followed by trismus (lockjaw) due to masseter muscle spasm. Spasm of the facial muscles produces the characteristic grinning expression known as risus sardonicus. If the disease is severe, painful reflex spasms develop, usually within 24-72 hours of the initial symptoms. The interval between the first symptom and the first spasm is referred to as the 'onset time'. The spasms may occur spontaneously but are easily precipitated by noise, handling of the patient, or by light. Respiration may be impaired because of laryngeal spasm; oesophageal and urethral spasm lead to dysphagia and urinary retention, respectively, and there is arching of the neck and back muscles (opisthotonus). Autonomic dysfunction produces tachycardia, a labile blood pressure, sweating and cardiac arrhythmias. Patients with tetanus are mentally alert.

Death results from aspiration, hypoxia, respiratory failure, cardiac arrest or exhaustion. Mild cases with rigidity usually recover. Poor prognostic indicators include short incubation period, short onset time, and extremes of age.

Localized tetanus is a milder form of the disease. Pain and stiffness are confined to the site of the wound, with increased tone in the surrounding muscles. Recovery usually occurs.

Cephalic tetanus is uncommon but invariably fatal. It usually occurs when the portal of entry of *C. tetani* is the middle ear. Cranial nerve abnormalities, particularly of the seventh nerve, are usual. Generalized tetanus may or may not develop.

Neonatal tetanus is usually due to infection of the umbilical stump. Failure to thrive, poor sucking,

grimacing and irritability are followed by the rapid development of intense rigidity and spasms. Mortality approaches 100%. One aim of the WHO Expanded Programme on Immunization (EPI) is to eliminate this condition by immunizing all women of childbearing age, providing clean delivery facilities and strengthening surveillance in high-risk areas.

Diagnosis

Few diseases resemble tetanus in its fully developed form, and the diagnosis is therefore usually clinical. Rarely, C. *tetani* is isolated from wounds. Phenothiazine overdosage, strychnine poisoning, meningitis and tetany can occasionally mimic tetanus.

Management

Suspected tetanus. Any wound must be cleaned and debrided if necessary, to remove the source of toxin. Human tetanus immunoglobin 250 units should be given along with an intramuscular injection of tetanus toxoid. If the patient is already protected a single booster dose of the toxoid is given; otherwise the full three-dose course of adsorbed vaccine is given (see below).

Established tetanus management is supportive medical and nursing care. Improvement in this area has contributed more than any other single measure to the decrease in the mortality rate from 60% to nearer 20%. Patients are nursed in a quiet, isolated, well-ventilated, darkened room. Benzodiazepines are used to control spasm and sedate the patient; if the airway is compromised intubation and mechanical ventilation may be necessary.

Antibiotics and antitoxin should be administered, even in the absence of an obvious wound. Intravenous metronidazole is the drug of choice, although penicillin is also effective. Human tetanus immunoglobulin (HTIG) 500 IU should be given by intramuscular injection to neutralize any circulating toxin. If HTIG is not available, immune equine tetanus immunoglobulin 10 000 IU should be given intramuscularly: this is probably as effective as HTIG, but there is a high incidence of severe allergic reactions. If the patient recovers, active immunization should be instituted, as immunity following tetanus is incomplete.

Prevention

Tetanus is an eminently preventable disease and all persons should be immunized regardless of age. Those who work in a contaminated environment, such as farmers, are particularly at risk and should have regular booster injections. Active immunization with the alum-adsorbed toxoid should be given. Initially two doses of 0.5 mL of the toxoid are given intramuscularly with an 8-week interval. The third dose is given 6-12 months later as a booster. Subsequent boosters are required at 5-year intervals. Infant immunization schedules in all countries include tetanus (Box 2.6). Protection by passive immunization with either the equine or human anti-tetanus immunoglobulin is short-lived, lasting only about 2 weeks.

SYSTEMIC/MULTISYSTEM INFECTIONS

Many infections are confined to a particular body organ or system, owing to the metabolic requirements of the organism, the route of infection, or the response of host defences. Other infections can potentially affect several systems or the entire body. Under unusual circumstances such as altered host immunity, infections which are normally circumscribed may become systemic. This section describes those infections which commonly cause multisystem disease in an immunocompetent host.

Bacteraemia and septicaemia

Bacteraemia, the transient presence of organisms in the blood, can occur in healthy people without causing symptoms. It can follow surgery, dental treatment, and even tooth-brushing. Bacteraemia can also occur from the bowel or bladder, especially in the presence of local inflammation. Unless a site of metastatic infection is established (such as the heart valves), most organisms are rapidly cleared from the blood.

Septicaemia. Some invading bacteria such as *Staph. aureus* or E. *coli* are less likely to be dealt with by the immune system and more likely to cause disease. Illness arising from such blood-borne infection is called septicaemia, and may occur in isolation or secondary to a focal infection. Septicaemia usually causes severe systemic symptoms including high fever, rigors, hypotension, myalgia and headache. It can also lead to the establishment of metastatic foci of infection and, in its most severe form, to septic shock.

Patients presenting with symptoms and signs suggesting septicaemia should be examined carefully for

Table 2.33 Causes of septicaemia in a previously healthy adult

Site of origin	Usual pathogen(s)
Skin	*Staphylococcus aureus* and other Gram-positive cocci
Urinary tract	*Escherichia coli* and other aerobic Gram-negative rods
Respiratory tract	*Streptococcus pneumoniae*
Gall bladder or bowel	*Enterococcus faecalis, E. coli* and other Gram-negative rods
Pelvic organs	*Bacteroides fragilis Neisseria gonorrhoeae,* anaerobes

Table 2.34 Causes of septicaemia in hospitalized patients

Clinical problem	Usual pathogen(s)
Urinary catheter	*Escherichia coli, Klebsiella* spp., *Proteus* spp., *Serratia* spp., *Pseudomonas* spp.
Intravenous catheter	*Staphylococcus aureus* and *Staph. epidermidis, Klebsiella* spp., *Pseudomonas* spp., *Candida albicans*
Peritoneal catheter	*Staph. epidermidis*
Post-surgery:	
Wound infection	*Staph. aureus, E. coli,* anaerobes
Deep infection	(depending on site) Depends on anatomical location
Burns	Gram-positive cocci, *Pseudomonas* spp., *Candida albicans*
Immunocompromised patients	Any of the above

evidence of a source: common sites of infection and organisms leading to septicaemia are listed in Tables 2.33 and 2.34. Because of the potential severity of septicaemia, treatment with antibiotics should usually be started empirically as soon as appropriate cultures have been taken. The choice of agent is governed by the likely pathogen: if there are no clues, a broad-spectrum regimen should be used (e.g. piperacillin plus gentamicin, or cefotaxime, with or without metronidazole). In hospital units with epidemic MRSA infection, it is common practice to add vancomycin or teicoplanin to this empiric regimen. Antibiotic therapy should be reviewed daily as the illness progresses and the results of investigations become available. The general management of septic shock is covered on page 978.

Meningococcal septicaemia

Neisseria meningitidis is found world-wide, in five major serogroups. In sub-Saharan Africa and parts of Asia where group A meningococcus is prevalent it usually causes epidemic disease. Groups Y and W can also cause epidemic infection, while groups B and C (which are the predominant strains in Europe and North America) tend to be sporadic. In England and Wales approximately 2000 cases of meningococcal disease are reported annually.

Man is the only known reservoir for the organism, which is carried asymptomatically in the nasopharynx of 5-20% of the general population. Meningococcal disease occurs when the bacteria invade the nasal mucosa and enter the bloodstream: this only happens in a small percentage of those colonized. Invasion depends on both host and bacterial factors. It is more likely to take place soon after colonization has taken place, and following viral upper respiratory infections.

Clinical features

Invasive meningococcal infection may cause meningitis, septicaemia, or both. Meningitic disease (see p. 1236) usually presents with the classical triad of headache, fever, and neck stiffness. Vomiting, diminished consciousness, and focal neurological signs occur, although some patients, especially in the early stages, only have mild symptoms. Meningococcal septicaemia causes the typical features of septic shock such as fever, myalgia, and hypotension (p. 967), and may be accompanied by a petechial or haemorrhagic rash (Fig. 2.24). In some cases the patient can deteriorate rapidly, with shock, disseminated intravascular coagulation, and multiorgan failure.

Diagnosis

The presence of meningitis and septicaemia with a typical rash is strongly suggestive of meningococcal disease. Gram-negative diplococci may be seen on Gram stain of CSF or of aspirate from petechiae, and meningococci can also be cultured from CSF or blood, or detected by PCR. A rising titre of antibody to meningococcal outer membrane protein (OMP) can also be used in diagnosis.

Management

N. meningitidis is sensitive to benzylpenicillin, chloramphenicol, and third-generation cephalosporins: antibiotic treatment for meningococcal meningitis should be started *immediately* (see emergency box 21.1, page 1238) and continued parenterally for 7 days. Meningococcal septicaemia should be managed in the same way as any

ny. 2.24 **Meningococcal infections, showing a purpuric rash.**

other septicaemic illness (p. 973). The mortality from meningococcal septicaemia in developed countries is currently approximately 10%, while that from meningococcal meningitis alone is less than 5% (see below). Mild neurological sequelae (especially vestibular nerve damage) are common, but serious brain damage is relatively unusual.

The meningococcal C conjugate vaccine has led to an overall reduction of meningococcal C disease in the UK but unfortunately an increase in infection of other serotypes may occur. A serogroup B vaccine is not available. A combined A and C vaccine is also available (p. 42).

For close contacts of a case of meningococcal disease, household and 'kissing' contacts should be given prophylaxis with oral rifampicin or ciprofloxacin to eradicate the bacteria from the nasopharynx. In the case of group C disease, contacts should be offered immunization.

Rheumatic fever

Rheumatic fever is an inflammatory disease that occurs in children and young adults (the first attack usually occurs at between 5 and 15 years of age) as a result of infection with group A streptococci. It affects the heart, skin, joints and central nervous system. It is common in the Middle and Far East, eastern Europe and South America. It is rare in the UK, western Europe and North America. This decline in the incidence of rheumatic fever (from 10% of children in the 1920s to 0.01% today) parallels the reduction in all streptococcal infections and is largely due to improved hygiene and the use of antibiotics.

Pharyngeal infection with group A streptococcus is followed by the clinical syndrome of rheumatic fever. This is thought to develop because of an autoimmune reaction triggered by molecular mimicry between the cell wall M proteins of the infecting *Strep, pyogenes* and cardiac myosin and laminin. The condition is not due to direct infection of the heart or to the production of a toxin.

Pathology

All three layers of the heart may be affected. The characteristic lesion of rheumatic carditis is the Aschoff nodule, which is a granulomatous lesion with a central necrotic area occurring in the myocardium, particularly in the subendocardium of the left ventricle. Small, warty vegetations may develop on the endocardium, particularly on the heart valves. This leads to some degree of valvular regurgitation. A serofibrinous effusion characterizes the acute pericarditis that occurs.

The synovial membranes are acutely inflamed during rheumatic fever, and subcutaneous nodules (which are also granulomatous lesions) are seen in the acute stage of the disease.

Clinical features

The disease presents suddenly, with fever, joint pains, malaise and loss of appetite. The clinical features depend on the organs that are involved. Diagnosis relies on the presence of two or more major clinical manifestations or one major manifestation plus two or more minor features. These are known as the Duckett Jones criteria (Table 2.35). Carditis manifests as:

Table 2.35 **Revised Duckett Jones criteria for the diagnosis of rheumatic fever. The diagnosis is made on the basis of two or more major criteria or one major plus two or more minor criteria**

Major criteria
Carditis
Polyarthritis
Chorea
Erythema marginatum
Subcutaneous nodules
Minor criteria
Fever
Arthralgia
Previous rheumatic fever
Raised ESR/C-reactive protein
Leucocytosis
Prolonged PR interval on ECG
Plus evidence of antecedent streptococcal infection, e.g. positive throat cultures for group A streptococci, elevated antistreptolysin O titre (> 250 U) or other streptococcal antibodies, or a history of recent scarlet fever

ESR, erythrocyte sedimentation rate

- new or changed heart murmurs
- development of cardiac enlargement or cardiac failure
- appearance of a pericardial effusion and ECG changes of pericarditis (raised ST segments) or myocarditis (inverted or flattened T waves), first-degree or greater AV block or other cardiac arrhythmias
- transient diastolic mitral (Carey-Coombs) murmur due to mitral valvulitis.

Non-cardiac features include the following:

- There is usually a fever with an apparently excessive tachycardia.
- The arthritis associated with rheumatic fever is classically a fleeting migratory polyarthritis affecting large joints such as the knees, elbows, ankles and wrists. The joints are swollen, red and tender. As the inflammation in one joint recedes, another becomes affected. Once the acute inflammation disappears, the rheumatic process leaves the joints normal.
- Sydenham's chorea (or St Vitus' dance, see p. 1232) is involvement of the central nervous system that develops late after a streptococcal infection. Sufferers are noticeably 'fidgety' and display spasmodic, unintentional choreiform movements. Speech is often affected.
- Skin manifestations include erythema marginatum, a transient pink rash with slightly raised edges, which occurs in 20% of cases. The erythematous areas found mostly on the trunk and limbs coalesce into crescent- or ring-shaped patches. Subcutaneous nodules, which are painless, pea-sized, hard nodules beneath the skin, may also occur, particularly over tendons, joints and bony prominences.

Investigations

- **Throat swabs** are cultured for the group A streptococcus.
- **Serological** changes may indicate a recent streptococcal infection. The antistreptolysin O titre, and sometimes others such as the antistreptokinase titre, are performed.
- **Non-specific indicators of inflammation** such as the ESR and the C-reactive protein levels are usually elevated.
- **Cardiac investigations,** e.g. ECG, echocardiogram.

Treatment

Patients with fever, active arthritis or active carditis should be completely rested in bed. When the clinical syndrome has subsided (e.g. no pyrexia, normal pulse rate, normal ESR, normal white cell count) the patient may be mobilized.

Residual streptococcal infections should be eradicated with oral phenoxymethylpenicillin 500 mg four times daily for 1 week. This therapy should be administered even if nasal or pharyngeal swabs do not culture the streptococci.

High-dose salicylate (preferably acetylsalicylate, i.e. aspirin) therapy is given to the limit of tolerance determined by the development of tinnitus. If carditis is present, systemic corticosteroids are given. Prednisolone 60-120 mg in four divided doses each day is administered until the clinical syndrome is improved and the ESR has fallen to normal. Steroids are then tapered off over 2-4 weeks. However, the efficacy of steroids is unproven.

Recurrences are most common when persistent cardiac damage is present, and are prevented by the continued administration of oral phenoxymethylpenicillin 250 mg twice daily until the age of 20 years or for 5 years after the latest attack (see p. 32). A sulphonamide (e.g. sulfadiazine) may be used if the patient is allergic to penicillin. Any streptococcal infection that does develop should be treated very promptly.

Prognosis

More than 50% of those who suffer acute rheumatic fever with carditis will later (after 10-20 years) develop chronic rheumatic valvular disease, predominantly affecting the mitral and aortic valves (Table 13.35).

Leptospirosis

Leptospirosis is a zoonosis caused by the spirochaete *Leptospim interrogans.* There are over 200 serotypes: the main types affecting humans are *L. i. icterohaemorrhagiae* (rodents), *L. i. canicola* (dogs and pigs), *L. i. hardjo* (cattle), and L.;'. *pomona* (pigs and cattle). Leptospires are excreted in the animal urine, and enter the host through a skin abrasion or through intact mucous membranes. Leptospirosis can also be caught by ingestion of contaminated water. The organism can survive for many days in warm fresh water, and for up to 24 hours in sea water.

In England and Wales only about 30 cases of leptospirosis are reported every year (although many mild infections probably go undiagnosed), and it remains largely an occupational disease of farmers, vets, and others who work with animals. In some parts of the world (e.g. Hawaii, where the annual incidence is about 130/100 000) it is associated with a variety of recreational activities which bring people into closer contact with rodents. Outbreaks of leptospirosis have also been associated with flooding.

Clinical features

Weil, in 1886, described a severe illness consisting of jaundice, haemorrhage, and renal impairment caused by L. *i. icterohaemorrhagiae,* but fortunately 90-95% of infections are subclinical or cause only a mild fever. The incubation period of leptospirosis is usually 7-14 days, and the illness typically has two phases. A Ieptospiraemic phase, which lasts for up to a week, is followed after a couple of days' interval by an immunological phase. The first phase is characterized by severe headache, malaise, fever, anorexia and myalgia. Most patients have conjunctival suffusion. Hepatosplenomegaly, lymphadenopathy and various skin rashes are sometimes seen. The second phase is usually mild. Fifty per cent of patients have meningism, about a third of whom have a CSF lymphocytosis. The majority of patients recover uneventfully at this stage.

In severe disease there may not be a clear distinction between phases. Following the initial symptoms, patients progressively develop hepatic and renal failure, haemolytic anaemia, and circulatory collapse. Cardiac failure and pulmonary haemorrhage may also occur. Even with full supportive care the mortality is around 10%, rising to 15-20% in the elderly.

Diagnosis

The diagnosis is usually a clinical one. Leptospires can be cultured from blood or CSF during the first week of illness, but culture requires special media and may take several weeks. A minority of patients may also excrete the organism in their urine from the second week onwards. Specific IgM antibodies start to appear from the end of the first week and the diagnosis is often made retrospectively with a microscopic agglutinating test (MAT) showing a four-fold rise. There is typically a leucocytosis and in severe infection, thrombocytopenia and an elevated creatine phosphokinase.

Management

Early antibiotic therapy will limit the progress of the disease, but treatment should still be initiated whatever the stage of the infection. Oral doxycycline may be used in mild cases: intravenous penicillin or erythromycin is given in more severe disease. Intensive supportive care is needed for those patients who develop hepatorenal failure.

Brucellosis

Brucellosis (Malta fever, undulant fever) is a zoonosis and has a world-wide distribution, although it has been virtually eliminated from cattle in the UK. The highest incidence is in the Mediterranean countries, the Middle

East and the tropics; there are about 500 000 new cases diagnosed per year.

The organisms usually gain entry into the human body via the mouth; less frequently they may enter via the respiratory tract, genital tract or abraded skin. The bacilli travel in the lymphatics and infect lymph nodes. This is followed by haematogenous spread with ultimate localization in the reticuloendothelial system. Spread is usually by the ingestion of raw milk from infected cattle or goats, although occupational exposure is also common. Person-to-person transmission is rare. -.■■ :•

Clinical features

The incubation period of acute brucellosis is 1-3 weeks. The onset is insidious, with malaise, headache, weakness, generalized myalgia and night sweats. The fever pattern is classically undulant, although continuous and intermittent patterns are also seen. Lymphadenopathy, hepatosplenomegaly and spinal tenderness sacro-iliitis (20-30%) may be present; arthritis, osteomyelitis, epididymo-orchitis (up to 40%), meningoencephalitis and endocarditis have all been described.

Untreated brucellosis can give rise to chronic infection, lasting a year or more. This is characterized by easy fatiguability, myalgia, and occasional bouts of fever and depression. Splenomegaly is usually present. Occasionally infection can lead to localized brucellosis. Bones and joints, spleen, endocardium, lungs, urinary tract and nervous system may be involved. Systemic symptoms occur in less than one-third.

Diagnosis

Blood (or bone marrow) cultures are positive during the acute phase of illness in 50% of patients (higher in *B. melitensis),* but prolonged culture is needed. If using automated blood culture systems (BACTEC) incubate longer than the usual 5-7 days. This is less helpful in chronic disease where serological tests are of greater value. The brucella agglutination test, which demonstrates a fourfold or greater rise in titre (> 1 in 160) over a 4-week period, is highly suggestive of brucellosis. However, non-agglutinating IgG and IgA molecules can block the agglutinating reaction (prozone phenomenon) and the test should be carried out to a high dilution to avoid this. An elevated serum IgG level is evidence of current or recent infection; a negative test excludes chronic brucellosis. In localized brucellosis antibody titres are low, and diagnosis is usually established by culturing the organisms from the involved site. PCR for detection of Brucella in blood gives a rapid diagnosis, and along with measurement of IgG or IgM antibodies by ELISA, are highly sensitive and specific. , : . ;.': :,

Management and prevention

Brucellosis is treated with a combination of doxycycline 200 mg daily and rifampicin 600-900 mg daily for 6 weeks, but relapses occur. Alternatively, tetracycline can be combined with streptomycin, which is usually given for only the first 2 weeks of treatment. Prevention and control involve careful attention to hygiene when handling infected animals, vaccination with the eradication of infection in animals, and pasteurization of milk. No vaccine is available for use in humans.

Listeriosis

Listeria monocytogenes is an environmental organism which is widely disseminated in soil and decayed matter. It affects both animals and man: the most common route of human infection is in contaminated foodstuffs. The organism can grow at temperatures as low as 4°C, and the most commonly implicated foods are unpasteurized soft cheeses, raw vegetables and chicken pates. Listeriosis is a rare but serious infection affecting mainly neonates, pregnant women, the elderly, and the immunocompromised. *L. monocytogenes* has also been recognized as a cause of self-limiting food-borne gastroenteritis in healthy adults, but the incidence of this is unknown.

In pregnant women listeria causes a flu-like illness, but infection of the fetus can lead to septic abortion, premature labour, and stillbirth. Early treatment of listeria in pregnancy may prevent this, but the overall fetal loss rate is about 50%. Listeria in the elderly and the immunocompromised usually causes meningoencephalitis, although septicaemia and a variety of other focal infections have been described.

The diagnosis is established by culture of blood, CSF, or other body fluids. The treatment of choice for adult listeriosis is ampicillin plus gentamicin. Co-trimoxazole is also effective, but the organism is resistant to cephalosporins.

Q fever

Q (query) fever is a zoonosis caused by the rickettsia-like organism *Coxiella burnetii.* Infection is widespread in domestic, farm and other animals, birds and arthropods: spread is mainly by ticks. Modes of transmission to humans are by dust, aerosol, and unpasteurized milk from infected cows. The formation of spores means that C. *burnetii* can survive in extreme environmental conditions for long periods. The infective dose is very small, so that minimal animal contact is required. One reported outbreak occurred among inhabitants of a village through which infected sheep had passed.

Clinical features

Symptoms begin insidiously *2-A* weeks after infection. Fever is accompanied by flu-like symptoms with myalgia and headache. The acute illness usually resolves spontaneously but pneumonia or hepatitis may develop. Occasionally infection can become chronic, with endocarditis, myocarditis, uveitis, osteomyelitis or other focal infections.

C. burnetii is an obligate intracellular organism, and does not grow on standard culture media. Diagnosis is made serologically using an immunofluorescent assay. Antibody tests for two different bacterial antigens allow distinction between acute and chronic infection; a nested PCR assay is now available. , : >

Management

Treatment with doxycycline 200 mg daily (or a quinolone as an alternative) reduces the duration of the acute illness, but it is not known whether this correlates with eradication of the organism. For chronic Q fever, including endocarditis, doxycycline is often combined with rifampicin or clindamycin. Even prolonged courses of treatment may not clear the infection.

Lyme disease

Lyme disease is caused by a spirochaete *Borrelia burgdorferi,* which has at least 11 different genomic species. It is a zoonosis of deer and other wild mammals. The syndrome was first recognized and named following an 'outbreak' of arthritis in the town of Lyme, Connecticut, in the mid-1970s. Since then the disease has increased in both incidence and detection: it is now known to be widespread in the USA, Europe, Russia and the Far East. Infection is transmitted from animal to man by ixodid ticks, and is most likely to occur in rural wooded areas in spring and early summer.

Clinical features

The first stage of the illness, which follows 7-10 days after infection, is characterized by the skin lesion, erythema migrans at the site of the tick bite. This is often accompanied by headache, fever, malaise, myalgia, arthralgia and lymphadenopathy. Many people have no further illness after this. A second stage may follow weeks or months later, when some patients develop neurological symptoms (meningoencephalitis, cranial or polyneuropathies), radiculopathies, cardiac problems (conduction disorders, myocarditis) or arthritis. These manifestations, which are often fluctuant and changing, usually resolve spontaneously over months or years. Some patients, however, develop chronic and persistent neurological disease (e.g. paraparesis) or rheumatological disease (Tate Lyme disease'). Acrodermatitis chronica atrophicans, usually on the backs of the hands and feet can occur if the disease does not resolve spontaneously.

Diagnosis

The clinical features and epidemiological considerations are usually strongly suggestive. The diagnosis can only rarely be confirmed by isolation of the organisms from blood, skin lesions or CSF. IgM antibodies are detectable in the first month, and IgG antibodies are invariably present late in the disease. Commercial tests (ELISA, immunofluorescence, haemagglutination) are available but false positive results do occur. A genuine positive IgG may be a marker of previous exposure rather than of ongoing infection.

Management

Amoxicillin or doxycycline given early in the course of the disease shortens the duration of the illness in approximately 50% of patients. Late disease should be treated with *1-A* weeks of intravenous benzylpenicillin or ceftriaxone. However, treatment is unsatisfactory, and preventative measures are necessary. In tick-infested areas, repellents and protective clothing should be worn. Prompt removal of any tick is essential as infection is unlikely to take place until the tick has been attached for more than 48 hours. Ticks should be grasped with forceps near to the point of attachment to the skin and then withdrawn by gentle traction. Antibiotic prophylaxis following a tick bite is not usually justified, even in areas where Lyme disease is common. A vaccine was available but has recently been withdrawn.

Tularaemia

Tularaemia is due to infection by *Fmncisella tularensis,* a Gram-negative organism. It is primarily a zoonosis, acquired mainly from rodents. Infection is normally transmitted by arthropod vectors, including ticks and blood-sucking flies. Humans may be infected by this route or by handling infected animals, when the micro-organisms enter through minor abrasions or mucous membranes. Occasionally infection occurs from contaminated water or from eating uncooked meat. The disease is widely distributed in North America, Northern Europe and Asia. It is relatively rare, occurring mainly in hunters, trappers, and others in close contact with animals.

The incubation period of 2-7 days is followed by a generalized illness. The most common presentation is ulceroglandular tularaemia. A papule occurs at the site of inoculation. This ulcerates and is followed by tender, suppurative lymphadenopathy. Rarely this can be followed by bacteraemia, leading to septicaemia, pneumonia, or meningitis. These forms of the disease carry a high mortality if untreated.

Diagnosis is by culture of the organism or by a rising titre seen on a bacterial agglutination test.

Tularaemia should be treated with streptomycin or gentamicin.

BACTERIAL INFECTIONS SEEN IN DEVELOPING AND TROPICAL COUNTRIES

SKIN, SOFT TISSUE AND EYE DISEASE

Leprosy

Leprosy (Hansen's disease) is caused by the acid-fast bacillus *Mycobacterium leprae.* Unlike other mycobacteria, it does not grow in artificial media or even in tissue culture. Apart from the nine-banded armadillo, man is the only natural host of *M. leprae,* although it can be grown in the footpads of mice.

The WHO campaign to control leprosy has been hugely successful, with more than 13 million people having been cured of the disease. The number of people with active leprosy has fallen from 5.4 million in 1985 to about 600 000, largely as the result of supervised multi-drug treatment regimens. India has 70% of the world cases with Brazil having the next highest. It is also common across Africa and Asia.

The precise mode of transmission of leprosy is still uncertain but it is likely that nasal secretions play a role. Infection is related to poverty and overcrowding. Once an individual has been infected, subsequent progression to clinical disease appears to be dependent on several factors. Males appear to be more susceptible than females, and there is evidence from twin studies of a genetic susceptibility. The main factor, however, is the response of the host's cell-mediated immune system.

Two *polar types* of leprosy are recognized (Ridley-Jopling system) (Fig. 2.25):

- *Tuberculoid leprosy,* a localized disease that occurs in individuals with a high degree of cell-mediated immunity (CMI). The T cell response to the antigen releases interferon which activates macrophages to destroy the bacilli (Thl response) but with associated destruction of the tissue. The lepromin test (see below) is positive.
- *Lepromatous leprosy,* a generalized disease that occurs in individuals with impaired CMI (Fig. 2.25). Here the tissue macrophages fail to be activated and the bacilli multiply intracellularly. Th2 cytokines are produced (see p. 208). The lepromin test is negative.

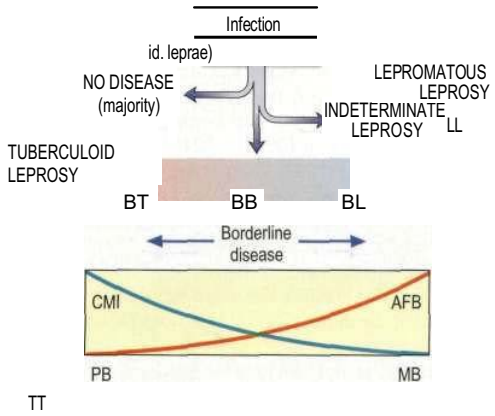

Fig. 2.25 **Clinical spectrum of leprosy with the combined Ridley-Jopling and WHO classification.** BT, borderline tuberculoid; BB, borderline; BL, borderline lepromatous; CMI, cell-mediated immunity; AFB, acid-fast bacilli; PB, paucibacillary; MB, multibacillary. Modified from Jacobson R (1999) Krahenbuhl JL *Lancet* 353: 655.

The WHO classification of leprosy depends on the number of skin lesions and the number of bacilli detected on the skin smears: paucibacillary leprosy has 5 or fewer skin lesions with no bacilli; multibacillary leprosy has 6 more lesions which may have bacilli.

In practice many patients will fall between these two extremes and some may move along the spectrum as the disease progresses or is treated.

Clinical features

The incubation period varies from 2-6 years, although it may be as short as a few months or as long as 20 years. The onset of leprosy is generally insidious. Acute onset is known to occur, and patients may present with a transient rash, with features of an acute febrile illness, with evidence of nerve involvement, or with any combination of these. The major signs of leprosy are:

- Skin lesions, usually anaesthetic (generally tuberculoid).
- Thickened peripheral nerves, nerves of predilection which are superficial or lie in fibro-osseous tunnels - ulnar (elbow), median (wrist), radial cutaneous (wrist), common peroneal (knee), posterior tibial and sural (ankle), facial (crossing zygomatic arch) and greater auricular (posterior triangle of the neck).

The spectrum of disease can be divided into five clinical groups.

Tuberculoid leprosy (TT)

In tuberculoid leprosy the infection is localized because the patient has unimpaired cell-mediated immunity. The characteristic, usually single, skin lesion is a hypo-pigmented, anaesthetic patch with thickened, clearly demarcated edges, central healing, and atrophy. The face, gluteal region and extremities are most commonly affected. The nerve leading to the hypopigmented patch, and the regional nerve trunk, are often thickened and tender. Unlike other parts of the body, a tuberculoid patch on the face is not anaesthetic. Nerve involvement leads to marked muscle atrophy. Tuberculoid lesions are known to heal spontaneously. The prognosis is good.

Borderline tuberculoid (BT) leprosy

This resembles TT but skin lesions are usually more numerous, smaller, and may be present as small 'satellite' lesions around larger ones. Peripheral but not cutaneous nerves are thickened, leading to deformity of hands and feet.

Borderline (BB) leprosy

Skin lesions are numerous, varying in size and form (macules, papules, plaques). The annular, rimmed lesion

with punched-out, hypopigmented anaesthetic centre is characteristic (Fig. 2.26). There is widespread nerve involvement and limb deformity (Fig. 2.27).

Borderline lepromatous (BL) leprosy
There are a large number of florid asymmetrical skin lesions of variable form, which are strongly positive for acid-fast bacilli. Skin between the lesions is normal and often negative for bacilli.

Lepromatous leprosy (LL)
Although practically every organ can be involved, the changes in the skin are the earliest and most obvious manifestation. Peripheral oedema and rhinitis are the earliest symptoms. The skin lesions predominantly occur on the face, the gluteal region and the upper and lower limbs. They may be macules, papules, nodules or plaques: of these, the macule is the first to appear. Infiltration is most noticeable in the ear lobes. Thinning of the lateral margins of the eyebrows is characteristic. The mucous membranes are frequently involved, resulting in nasal stuffiness, laryngitis and hoarseness of the voice. Nasal septal perforation with collapse of the nasal cartilages produces a saddle-nose deformity. With progression of the disease the typical leonine fades due to infiltration of the skin becomes apparent. Glove and stocking anaesthesia, gynaecomastia, testicular atrophy, ichthyosis and nerve palsies (facial, ulnar, median and radial) develop late in the disease. Neurotrophic atrophy affecting the phalanges leads to the gradual disappearance of fingers. Nerve involvement is less pronounced than in TT.

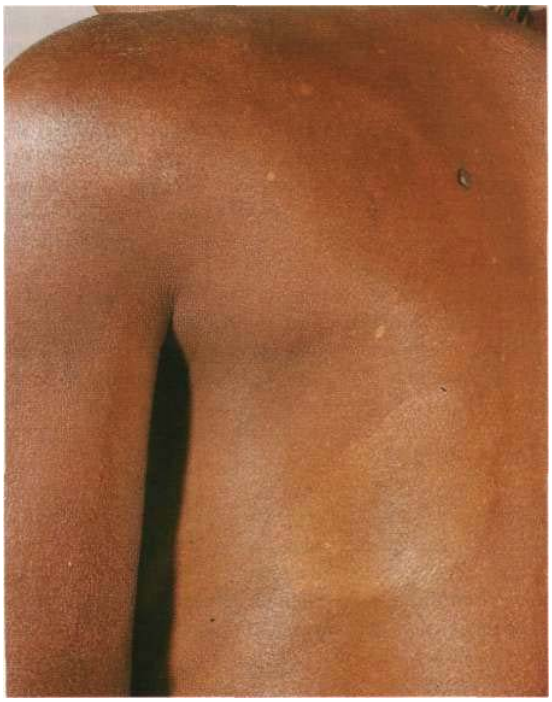

Fig. 2.26 Multiple asymmetrical hypopigmented anaesthetic patches. Courtesy of Dr P Matondo, Zambia.

Fig. 2.27 Leprosy - claw hand due to median and ulnar nerve damage.

Lepra reactions
These are immunologically mediated acute reactions that occur in patients with the borderline or lepromatous spectrum of disease, usually during treatment. Two forms are recognized.

Non-lepromatous lepra reaction (type I lepra reaction).
This is seen following treatment of patients with borderline disease; it is a type IV delayed hypersensitivity reaction. Both upgrading (or reversal) reactions (i.e. a clinical change towards a more tuberculoid form) and downgrading reactions (i.e. a change towards the lepromatous form) can occur. Neurological deficits such as an ulnar nerve palsy may occur abruptly.

Erythema nodosum leprosum (ENL; type II lepra reaction). This is a humoral antibody response to an antigen-antibody complex (i.e. a type III hypersensitivity reaction). It is seen in 50% of patients with treated LL. ENL is characterized by fever, arthralgia, iridocyclitis, crops of painful, subcutaneous erythematous nodules, and other systemic manifestations. It may last from a few days to several weeks.

Diagnosis

The diagnosis of leprosy is essentially clinical with:

- hypopigmented/reddish patches with loss of sensation
- thickening of peripheral nerves
- acid-fast bacilli (AFB) seen on skin-slit smears/ biopsy. Small slits are made in pinched skin and the fluid obtained is smeared on a slide and stained for AFB.

Patients should be examined carefully for skin lesions in adequate natural light. Occasionally nerve biopsies are helpful. Detection of M. *leprae* DNA is possible in all forms of leprosy using the polymerase chain reaction, and can be used to assess the efficacy of treatment.

Management

Multidrug therapy (MDT) is essential because of developing drug resistance (up to 40% of bacilli in some areas are resistant to dapsone). Much shorter courses of treatment are now being used: the current WHO recommended drug regimens for leprosy are shown in Box 2.11 but

Box 2.11 **Recommended treatment regimens for leprosy in adults (modified WHO guidelines)**

Multibacillary leprosy (LL, BL, BB)
Rifampicin 600 mg once-monthly, supervised
Clofazimine 300 mg once-monthly, supervised
Clofazimine 50 mg daily, self-administered
Dapsone 100 mg daily, self-administered
Treatment continued for 12 months

Paucibacillary leprosy (BT, TT)
Rifampicin 600 mg once-monthly, supervised
Dapsone 100 mg daily, self-administered
Treatment continued for 6 months

Single lesion paucibacillary leprosy
Rifampicin 600 mg
Ofloxacin 400 mg as a single dose
Minocycline 100 mg j

LL, lepromatous; BL, borderline lepromatous; BB, borderline; BT, borderline tuberculoid; TT, tuberculoid

longer therapy may be required in severe cases. Follow up including skin smears is essential.

Patient education is essential. Patients should be taught self-care of their anaesthetic hands and feet to prevent ulcers. If ulcers develop, no weight-bearing should be permitted. Cheap canvas shoes with cushioned insoles are protective.

Leprosy should be treated in specialist centres with adequate physiotherapy and occupational therapy support. Surgery and physiotherapy also play a role in the management of trophic ulcers and deformities of the hands, feet and face.

Treatment of lepra reactions. This is urgent, as irreversible eye and nerve damage can occur. Antileprosy therapy must be continued. Type II lepra reactions (ENL) can be treated with analgesics, chloroquine, clofazimine and antipyretics. Thalidomide was prevously used for ENL and is effective. However, because of its teratogenicity, it is no longer recommended by WHO. Prednisolone 40-60 mg daily for 3-6 months is effective in type I reactions.

Prevention

The prevention and control of leprosy depends on rapid treatment of infected patients, particularly those with LL and BL, to decrease the bacterial reservoir.

Anthrax

Anthrax is caused by *Bacillus anthracis*. The spores of these Gram-positive bacilli are extremely hardy and withstand extremes of temperature and humidity. The organism is capable of toxin production and this property correlates most closely with its virulence. The disease occurs world-wide. Epidemics have been reported in The Gambia, in both North and South America and in southern Europe. Transmission is through direct contact with an infected animal; infection is most frequently seen in farmers, butchers, and dealers in wool and animal hides. Spores can also be ingested or inhaled. There have been recent cases in the USA due to the deliberate release of anthrax spores as a bioterrorist weapon (p. 1031).

Clinical features

The incubation period is 1-10 days. Cutaneous anthrax is the most common. The small, erythematous, maculopapular lesion is initially painless. It may subsequently vesiculate and ulcerate, with formation of a central black eschar. The illness is self-limiting in the majority of patients, but occasionally perivesicular oedema and regional lymphadenopathy may be marked, and toxaemia can occur.

Inhalational anthrax (woolsorter's disease) follows inhalation of spores, and bioterrorism should be suspected. A febrile illness is accompanied by non-productive cough and retrosternal discomfort; pleural effusions are common. Untreated, the mortality is about 90%, and in the recent cases in the USA it was 45% despite treatment.

Gastrointestinal anthrax is due to consumption of undercooked, contaminated meat. It presents as severe gastroenteritis; haematemesis and bloody diarrhoea can occur. Toxaemia, shock and death may follow.

Diagnosis

The diagnosis is established by demonstrating the organism in smears from cutaneous lesions or by culture of blood and other body fluids. Serological confirmation can be made using ELISAs detecting antibodies to both the organism and a toxin.

Management

Ciprofloxacin is considered the best treatment. In mild cutaneous infections, oral therapy for 2 weeks is adequate but therapy for 60 days was used in the recent outbreaks in the USA. In more severe infections high doses of intravenous antibiotics are needed, along with appropriate supportive care. Any suspected case should be reported to the relevant authority.

Control

Any infected animal that dies should be burned and the area in which it was housed disinfected. Where animal husbandry is poor, mass vaccination of animals may prevent widespread contamination, but needs to be repeated annually. A human vaccine is available for those at high risk, and prophylactic antibiotics may be indicated following exposure. Some countries are establishing public health policies to deal with the deliberate release of anthrax spores.

Mycobacterial ulcer (Buruli ulcer)

Buruli ulcer is seen world-wide in rural areas in the tropical rainforests. *Mycobacterium ulcerans*, the causative organism, is found in pools and rivers, and infection is usually due to bathing, swimming or collecting water. A

small subcutaneous nodule at the site of infection gradually ulcerates, involving subcutaneous tissue, muscle and fascial planes. The ulcers are usually large with undermined edges and markedly necrotic bases due to mycolactone. Smears taken from necrotic tissue generally reveal numerous acid-fast bacilli. The only effective treatment is wide surgical excision with skin grafts, but this is often unavailable in areas where the disease is prevalent. Antituberculous therapy is ineffective.

Endemic treponematoses (bejel, yaws and pinta)

These diseases are found in various parts of the tropics and subtropics, mainly in impoverished rural areas (Fig. 2.28). The WHO treated over 50 million cases in the 1950s and 1960s, reducing the prevalence of these diseases, but subsequently there has been a resurgence of infection. The latest estimate of global prevalence is 2.5 million cases. Improvements in sanitation and an increase in living standards will be required to eradicate the diseases completely as organisms are transmitted by bodily contact, usually in children.

Clinical features

Yaws

Yaws (caused by *Treponema pertenue)* is the most widespread and common of the endemic treponemal diseases. It is spread by direct contact, the organism entering through damaged skin. After an incubation period of weeks or months a primary inflammatory reaction occurs at the inoculation site, from which organisms can be isolated. Dissemination of the organism leads to multiple papular lesions containing treponemes; these skin lesions usually involve the palms and soles. There may also be bone involvement, particularly affecting the long bones and those of the hand.

Approximately 10% of those infected go on to develop late yaws. Bony gummatous lesions may progress to cause gross destruction and disfigurement, particularly of the skull and facial bones, the interphalangeal joints and the long bones. Plantar hyperkeratosis is characteristic. Like syphilis, there may be a latent period between the early and late phases of the disease, but visceral, neurological and cardiovascular problems do not occur.

Bejel (endemic syphilis)

Bejel is seen in Africa and the Middle East. The causative organism *(Treponema endemicum)* enters through abrasions in the skin or from contaminated drinking vessels. It differs from venereal syphilis in that a primary lesion is not commonly seen. The late stages resemble syphilis, but cardiological and neurological manifestations are rare.

Pinta

Pinta, caused by *Treponema carateum,* is restricted mainly to Central and South America. It is milder than the other trepanomatoses and is confined to the skin. The primary lesion is a pruritic red papule, usually on the hand or foot. It may become scaly but never ulcerates and is generally associated with regional lymphadenopathy. In the later stages similar lesions can continue to occur for up to

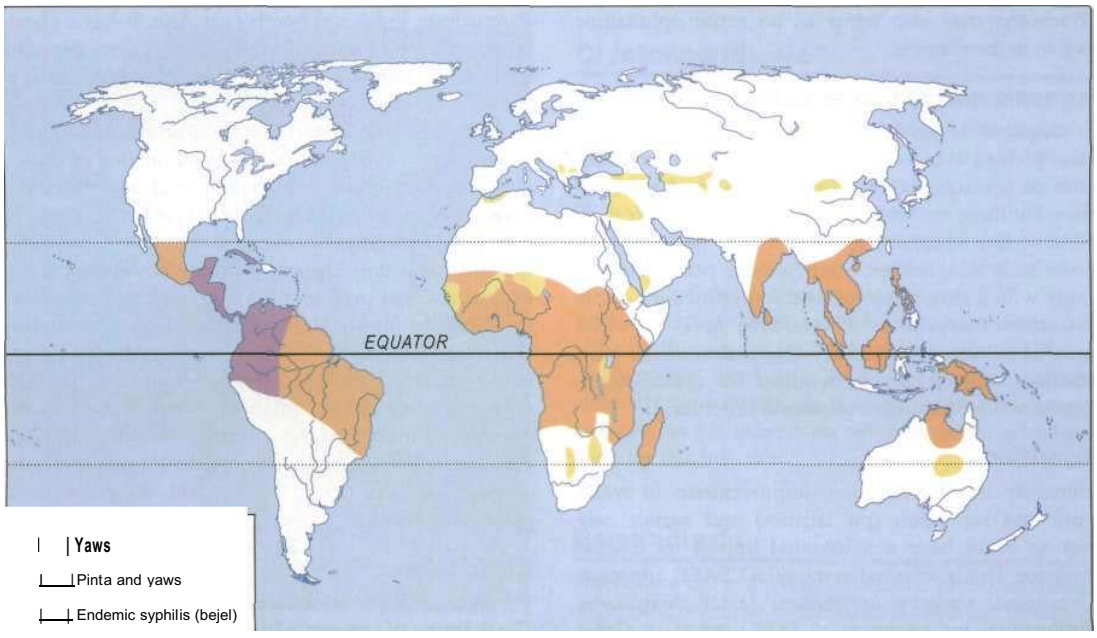

Fig. 2.28 **Bejel, yaws and pinta - geographical distribution.**

1 year, associated with generalized lymphadenopathy. Eventually the lesions heal leaving hyperpigmented or depigmented patches.

Diagnosis and management

In endemic areas the diagnosis is usually clinical. The causative organism can be identified from the exudative lesions under dark-ground microscopy. Serological tests for syphilis are positive but do not differentiate between the conditions.

The treatment is with long-acting penicillin (e.g. intramuscular benzathine penicillin, 1.2 million units) given as a single dose. Doxycycline is used when penicillin is ineffective or contra-indicated.

Trachoma

Trachoma, caused by the intracellular bacterium *Chlamydia trachomatis,* is the most common cause of blindness in the world. It is estimated that there are 150 million current infections, and 6 million people who have been blinded by trachoma. It is a disease of poverty which is found mainly in the tropics and the Middle East: it is entirely preventable. Trachoma commonly occurs in children, and is spread by direct transmission or by flies. Isolated infection is probably self-limiting, and it is repeated infection which leads to chronic eye disease.

Clinical features

Infection is bilateral and begins in the conjunctiva, with marked follicular inflammation and subsequent scarring. Scarring of the upper eyelid causes entropion, leaving the cornea exposed to further damage with the eyelashes rubbing against it (trichiasis). The corneal scarring that eventually occurs leads to blindness.

Trachoma may also occur as an acute ophthalmic infection in the neonate.

Diagnosis and management

The diagnosis is generally established by the typical clinical picture. It can be confirmed by cell culture techniques or species-specific fluorescent monoclonal antibodies, but these are rarely available in endemic areas.

Tetracycline ointment applied locally each day for 6—8 weeks is effective but compliance is poor. Systemic therapy with a single dose of azithromycin 20 mg/kg is the treatment of choice. In endemic areas repeated courses of therapy are necessary. Once infection has been controlled, surgery may be required for eyelid reconstruction and for treatment of corneal opacities.

Prevention

Community health education, improvements in water supply and sanitation (pit latrines) and earlier case reporting could have a substantial impact on disease prevalence. This is reflected in the WHO 'SAFE' approach to trachoma: surgery, antibiotics, facial cleanliness, environmental improvement. A WHO target is global eradication by 2020.

GASTROINTESTINAL INFECTIONS

mm:

Cholera

Cholera is caused by the curved, flagellated Gram-negative bacillus, *Vibrio cholerae.* The organism is killed by temperatures of 100 °C in a few seconds but can survive in ice for up to 6 weeks. One major pathogenic serogroup possesses a somatic antigen (Ol) with two biotypes: classical and El Tor. The El Tor biotype replaced the classical biotype as the major cause of the seventh pandemic which began in the 1960s. Infection with the El Tor biotype generally causes milder symptoms, but can still cause severe and life-threatening disease.

The fertile, humid Gangetic plains of West Bengal have traditionally been regarded as the home of cholera. However, a series of pandemics have spread the disease across the world, usually following trade routes. The seventh pandemic has affected large areas of Asia, North Africa, Kenya and southern Europe. It has spread to South and Central America in recent years, claiming thousands of lives. A new serogroup (O139 Bengal) is now responsible for an increasing number of cases in Bangladesh, India and South East Asia. It has a characteristic pattern of antibiotic resistance (sulfamethoxazole, trimethoprim and streptomycin), and may prove to be the cause of the next pandemic.

Transmission is by the faeco-oral route. Contaminated water plays a major role in the dissemination of cholera, although contaminated foodstuffs and contact carriers may contribute in epidemics. Achlorhydria or hypochlorhydria facilitates passage of the cholera bacilli into the small intestine. Here they proliferate, elaborating an exotoxin which produces massive secretion of isotonic fluid into the intestinal lumen (see p. 332). Cholera toxin also releases serotonin (5-HT) from enterochromaffin cells in the gut, which activates a neural secretory reflex in the enteric nervous system. This may account for at least 50% of cholera toxin's secretory activity. *V. cholerae* also produces other toxins (zona occludens toxin, ZOT, and accessory cholera toxin, ACT) which contribute to its pathogenic effect.

Clinical features

The incubation period varies from a few hours to 6 days. The majority of patients with cholera have a mild illness that cannot be distinguished clinically from diarrhoea

due to other infective causes. Classically, however, three phases are recognized in the untreated disease.

The *evacuation phase* is characterized by the abrupt onset of painless, profuse, watery diarrhoea, associated with vomiting in the severe forms. 'Rice water' stools, so called because of mucus flecks floating in the watery stools, are typical of this stage.

If appropriate supportive treatment is not given, the patient passes on to the *collapse phase.* This is characterized by features of circulatory shock (cold clammy skin, tachycardia, hypotension and peripheral cyanosis) and dehydration (sunken eyes, hollow cheeks and a diminished urine output). The patient, though apathetic, is usually lucid. Muscle cramps may be severe. Children may present with convulsions owing to hypoglycaemia. At this stage renal failure and aspiration of vomitus present major problems.

If the patient survives the collapse stage the *recovery phase* starts, with a gradual return to normal clinical and biochemical parameters in 1-3 days.

Diagnosis

This is largely clinical. Examination of freshly passed stools may demonstrate rapidly motile organisms. This is not diagnostic, as *Cmnpylobacter jejuni* may also give a similar appearance. However, demonstration of the rapidly motile vibrios by dark-field illumination and subsequent inhibition of their movement with type-specific antisera is diagnostic. Stool and rectal swabs should be taken for culture.

Management

The mainstay of treatment is rehydration, and with appropriate and effective rehydration therapy mortality has decreased to less than 1%. Oral rehydration is usually adequate, but intravenous therapy is occasionally required.

Oral rehydration solutions (ORS) are based on the observation that glucose (and other carbohydrates) enhances sodium and water absorption in the small intestine, even in the presence of secretory loss due to toxins. Additions such as amylase-resistant starch to glucose-based ORS have been shown to increase the absorption of fluid. Cereal-based electrolyte solutions have been found to be as effective as sugar/salt ORS, and actually reduce stool volume as well as rehydrating. The WHO has recently recommended the use of reduced osmolarity ORS for all types of diarrhoea, although concerns remain about the risk of hyponatraemia. Suitable solutions for rehydration are listed in Box 2.9 (p. 71).

Mildly dehydrated individuals are given ORS 50 mL/kg in the first 4 hours, followed by a maintenance dose of 100 mL/kg daily until the diarrhoea stops. For moderate dehydration, ORS 100 mL/kg is given within the first 4 hours followed by 10-15 mL/kg/hour.

Intravenous rehydration is required only for severely dehydrated individuals with features of collapse. Several litres of intravenous fluid (Ringers Lactate) are usually required to overcome the features of shock. Maintenance of hydration is effectively carried out by oral rehydration solutions.

Antibiotics such as tetracycline 500 mg four times daily for 3 days help to eradicate the infection, decrease stool output, and shorten the duration of the illness. Drug resistance is becoming an increasing problem, and ciprofloxacin is now used more frequently.

Immunization is now recommended by the WHO in potential or actual outbreak situations. Live attenuated and killed vaccine (both oral) are available: neither protect against the 0139 strain. Chemoprophylaxis with tetracycline 500 mg twice-daily for 3 days for adults, or 125 mg daily for children, is effective. The best preventative measures, however, are good hygiene and improved sanitation.

Enteric fever

Over 16 million new cases of enteric fever occur worldwide, mainly in India and Africa, causing 600 000 deaths per year. Enteric fever is an acute systemic illness characterized by fever, headache, and abdominal discomfort. *Typhoid,* the typical form of enteric fever, is caused by *Salmonella typhi. A* similar but generally less severe illness known as paratyphoid is due to infection with *S. paratyphi* A, B, or C. Man is the only natural host for S. *typhi,* which is transmitted in contaminated food or water. The incubation period is 10-14 days.

Clinical features

After ingestion, the bacteria invade the small bowel wall via Peyer's patches, from where they spread to the regional lymph nodes and then to the blood. The onset of illness is insidious and non-specific, with intermittent fever, headache, and abdominal pain. Physical findings in the early stages include abdominal tenderness, hepatosplenomegaly, lymphadenopathy, and a scanty maculopapular rash ('rose spots'). Without treatment (and occasionally even after treatment) serious complications can arise, usually in the third week of illness. These include meningitis, lobar pneumonia, osteomyelitis, intestinal perforation and intestinal haemorrhage. The fourth week of the illness is characterized by gradual improvement, but in developing countries up to 30% of those infected will die, and 10% of untreated survivors will relapse. This compares with a mortality rate of 1—2% in the USA.

After clinical recovery 5-10% of patients will continue to excrete *S. typhi* for several months: these are termed convalescent carriers. Between 1% and 4% will continue to carry the organism for more than a year: this is chronic carriage. The usual site of carriage is the gall bladder, and chronic carriage is associated with the presence of gallstones. However, in parts of the Middle East and Africa where urinary schistosomiasis is prevalent, chronic carriage of *S. typhi* in the urinary bladder is also common.

Diagnosis

The definitive diagnosis of enteric fever requires the culture of *S. typhi* or S. *paratyphi* from the patient. Blood

culture is positive in most cases in the first 2 weeks. Culture of intestinal secretions, faeces, and urine is also used, although care must be taken to distinguish acute infection from chronic carriage. Bone marrow culture is more sensitive than blood culture, but is rarely required except in patients who have already received antibiotics. Leucopenia is common but non-specific. Serological tests such as the Widal antigen test are of little practical value and are easily misinterpreted. ■

Management

Increasing antibiotic resistance is seen in isolates of *S. typhi,* especially in the Indian subcontinent. Chloramphenicol, co-trimoxazole and amoxicillin may all still be effective in some cases, but quinolones (e.g. ciprofloxacin 500 mg twice daily) are now the treatment of choice, although increased resistance to these agents is being seen: in such cases azithromycin may be effective. Infection from the Indian subcontinent, Middle East and South East Asia is often resistant to multiple antibacterial agents. The patient's temperature may remain elevated for several days after starting antibiotics, and this alone is not a sign of treatment failure. Prolonged antibiotic therapy may eliminate the carrier state, but in the presence of gall bladder disease it is rarely effective. Cholecystectomy is not usually justified on clinical or public health grounds.

Prevention

This is mainly through improved sanitation and clean water. Travellers should avoid drinking untreated water, ice in drinks and eating ice creams. Vaccination with injectable inactivated or oral live attenuated vaccines gives partial protection.

SYSTEMIC INFECTIONS

Tuberculosis

Tuberculosis is caused by *Mycobacterium tuberculosis,* and occasionally M. *bovis* or *M. africanum.* These are slow-growing bacteria, and unlike other mycobacteria, are facultative intracellular organisms. The prevalence of tuberculosis increases with poor social conditions, inadequate nutrition, and overcrowding. In developing countries it is most commonly acquired in childhood.

The impact of tuberculosis in the developing world has been magnified in the past 20 years by the emergence of the HIV pandemic (p. 129) (Fig. 2.29).

Widespread misuse of antibiotics, combined with the breakdown of healthcare systems in parts of Africa, Russia and East Europe, has led to the emergence of drug-resistant tuberculosis. The most serious form, known as multidrug-resistant tuberculosis (MDRTB), is caused by bacteria that are resistant to both rifampicin and isoniazid, two drugs which form the mainstay of treatment. MDRTB is very difficult to treat, and has a significant mortality even with the best medical care.

In most people, the initial primary tuberculosis is asymptomatic or causes only a mild illness.

Occasionally the primary infection progresses locally to a more widespread lesion. Haematogenous spread at this stage may give rise to miliary tuberculosis.

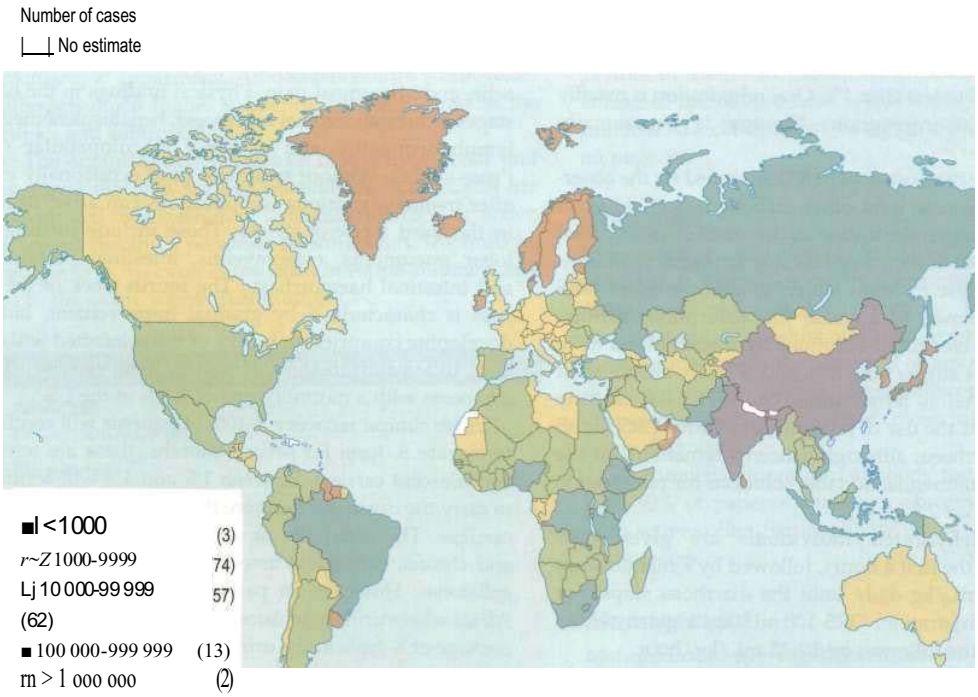

Fig. 2.29 **Tuberculosis - geographical distribution.** From Frieden TR, Sterling TR, Munsiff SS et al. (2003) Tuberculosis. Reprinted with permission from Elsevier *(Lancet* **362:** 888).

Tuberculosis in the adult may be the result of reactivation of old disease (post-primary tuberculosis), primary infection, or more rarely reinfection.

Pulmonary tuberculosis is the most common form; this is described on page 306, along with the chemotherapeutic regimens. Tuberculosis also affects other parts of the body:

- The gastrointestinal tract, mainly the ileocaecal area, but occasionally the peritoneum, producing ascites (see p. 344).
- The genitourinary system. The kidneys are most commonly involved, but tuberculosis can also cause painless, craggy swellings in the epididymis, and salpingitis, tubal abscesses, and infertility in females.
- The central nervous system, causing tuberculous meningitis and tuberculomas (p. 1238).
- The skeletal system, leading to septic arthritis and osteomyelitis.
- The skin, giving rise to lupus vulgaris.
- The eyes, where it can cause choroiditis or iridocyclitis.
- The pericardium, producing constrictive pericarditis (p. 856).
- The adrenal glands, causing destruction and producing Addison's disease.
- Lymph nodes. This is a common mode of presentation, especially in young adults and children. Any group of lymph nodes may be involved, but hilar and para-tracheal lymph nodes are the most common. Initially the nodes are firm and discrete but later they become matted and can suppurate with sinus formation. Scrofula is the term used to describe massive cervical lymph node enlargement with discharging sinuses. Mycobacterial lymph node disease may also be caused by non-tuberculous mycobacteria.

Non-tuberculous mycobacterial infections

The majority of mycobacterial species are environmental organisms, and are rarely pathogenic. Some have been found to cause disease in man, particularly in immuno-compromised patients or those with pre-existing chronic lung disease (Table 2.36).

Table 2.36 **Non-tuberculous mycobacteria causing disease in man**

Clinical	Common cause	Rare cause
Chronic lung disease	*Mycobacterium avium-intracellulare* *M. kansasii*	*M. malmoense* *M. xenopi*
Local lymphadenitis	*M. avium-intracellulare* *M. scrofulaceum*	*M. malmoense* *M. fortuitum*
Skin and soft tissue infection		
Fish tank granuloma	*M. marinum*	
Abscesses, ulcers, sinuses	*M. fortuitum* *M. chelonae*	*M. haemophilum*
Bone and joint infection	*M. kansasii* *M. avium-intracellulare*	*M. scrofulaceum*
Disseminated infection (in HIV)	*M. avium-intracellulare*	

Plague

Plague is caused by *Yersinia pestis,* a Gram-negative bacillus. Sporadic cases of plague (as well as occasional epidemics) occur world-wide: about 2500 cases per year are reported to the WHO, with a 10% mortality. The majority of cases are seen in sub-Saharan Africa, although the disease is occasionally seen in developed countries in people undertaking outdoor pursuits. The main reservoirs are woodland rodents, which transmit infection to domestic rats *(Rattus rattus).* The usual vector is the rat flea, *Xenopsylla cheopis.* These fleas bite humans when there is a sudden decline in the rat population. Occasionally, spread of the organisms may be through infected faeces being rubbed into skin wounds, or through inhalation of droplets.

Clinical features

Four clinical forms are recognized: bubonic, pneumonic, septicaemic and cutaneous.

Bubonic plague

This is the most common form and occurs in about 90% of infected individuals. The incubation period is about 1 week. The onset of illness is acute, with high fever, chills, headache, myalgia, nausea, vomiting and, when severe, prostration. This is rapidly followed by the development of lymphadenopathy (buboes), most commonly involving the inguinal region. Characteristically these are matted and tender, and suppurate in 1-2 weeks. Petechiae, ecchymoses and bleeding from the gastrointestinal tract, the respiratory tract and the genitourinary tract may occur. Mental confusion follows the development of toxaemia.

Pneumonic plague

This is characterized by the abrupt onset of features of a fulminant pneumonia with bloody sputum, marked respiratory distress, cyanosis and death in almost all affected patients.

Septicaemic plague

This presents as an acute fulminant infection with evidence of shock and disseminated intravascular coagulation (DIC). If left untreated, death usually occurs in 2—5 days. Lymphadenopathy is unusual.

Cutaneous plague

This presents either as a pustule, eschar or papule or an extensive purpura, which can become necrotic and gangrenous.

Diagnosis

A rapid diagnostic test on samples (bubo aspirate, sputum) has been developed. This is an easy to read,

hand held immunodermatographic dipstick assay relying on conjugated gold particles to detect Y pesfi's-specific Fl capsular antigen. It has an extremely high sensitivity and specificity. The diagnosis can also be established by demonstrating the organism in lymph node aspirates, in blood cultures or on examination of sputum.

Management

Treatment is urgent and should be instituted before the results of culture studies are available. The treatment of choice is intramuscular streptomycin 1 g twice daily or gentamicin 2 mg/kg i.v. three times daily for 10 days. Oral tetracycline 500 mg four times daily and chloramphenicol are also effective.

Prevention

Prevention of plague is largely dependent on the control of the flea population. Outhouses, or huts, should be sprayed with insecticides that are effective against the local flea. During epidemics rodents should not be killed until the fleas are under control, as the fleas will leave dead rodents to bite humans. Tetracycline 500 mg four times daily or sulphonamides 2^1 g daily for 7 days are effective chemoprophylactic agents. A partially effective formalin-killed vaccine is available for use by travellers to plague-endemic areas.

Relapsing fevers

These conditions are so named because, after apparent recovery from the initial infection, one or more recurrences may occur after a week or more without fever. They are caused by spirochaetes of the genus *Borrelia*.

Clinical features

Louse-borne relapsing fever (caused by B. *recurrentis)* is spread by body lice, and only humans are affected. Classically it is an epidemic disease of armies and refugees, although it is also endemic in the highlands of Ethiopia, Yemen and Bolivia. Lice are spread from person to person when humans live in close contact in impoverished conditions. Infected lice are crushed by scratching, allowing the spirochaete to penetrate through the skin. Symptoms begin 3-10 days after infection and consist of a high fever of abrupt onset with rigors, generalized myalgia and headache. A petechial or ecchymotic rash may be seen. The general condition then deteriorates, with delirium, hepatosplenomegaly, jaundice, haemorrhagic problems and circulatory collapse. Although complete recovery may occur at this time, the majority experience one or more relapses of diminishing intensity over the weeks following the initial illness. The severity of the illness varies enormously, and some cases have only mild symptoms. However, in some epidemics mortality has exceeded 50%.

Tick-borne relapsing fever is caused by B. *duttoni* and other *Borrelia* species, spread by soft (argasid) ticks. Rodents are also infected, and humans are incidental hosts, acquiring the spirochaete from the saliva of the infected tick. This disease is mainly found in countries where traditional mud huts are the form of shelter, but is occasionally associated with old houses and camp sites in the USA. The illness is generally similar to the louse-borne disease, although neurological involvement is more common.

Diagnosis and management

Spirochaetes can be demonstrated microscopically in the blood during febrile episodes: organisms are more numerous in louse-borne relapsing fever. Treatment is usually with tetracycline or doxycycline (see p. 36). A severe Jarisch-Herxheimer reaction (p. 124) occurs in many patients, often requiring intensive nursing care and intravenous fluids.

Prevention

Control of infection relies on elimination of the vector. Ticks live for years and remain infected, passing the infection to their progeny. These reservoirs of infection should be controlled by spraying houses with insecticides and by reducing the number of rodents. Patients infested with lice should be deloused by washing with a suitable insecticide. All clothes must be thoroughly disinfected.

Typhus

Typhus is the collective name given to a group of diseases caused by *Rickettsia* species (Table 2.37). Rickettsia (and the closely related Orientiae) are small intracellular bacteria that are spread to humans by arthropod vectors,

Table 2.37 **Infections caused by rickettsiae**

Disease	Organism	Reservoir	Vector
Typhus fever group			
Epidemic typhus	*Rickettsia prowazekii*	Man	Human body louse
Endemic (murine) typhus	*R. typhi*	Rodents	Rat flea
Scrub typhus	*Orientia tsutsugamushi*	Trombiculid mite	Trombiculid mite
Spotted fever group			
African tick typhus	*R. africae*	Various mammals	Hard tick
Mediterranean spotted fever	*R. conorii*	Rodents, dog	Hard tick
Rocky Mountain spotted fever	*R. ricketsii*	Rodents	Hard tick
Rickettsial pox	*R. akari*	Rodents	Mite
Flea-borne spotted fever	*R. felis*	Various mammals	Flea

including body lice, fleas, hard ticks, and larval mites. Rickettsiae inhabit the alimentary tract of these arthropods and the disease is spread to the human host by inoculation of their faeces through broken human skin, generally produced by scratching. Rickettsiae multiply intracellularly and can enter most mammalian cells, although the main lesion produced is a vasculitis due to invasion of endothelial cells of small blood vessels. Multisystem involvement is usual.

Clinical features

Typhus fever group

Epidemic typhus

The vector of epidemic typhus is the human body louse, and like louse-borne relapsing fever, epidemics are associated with war and refugees. Outbreaks have occurred in Africa, Central and South America, and Asia.

The incubation period of 1-3 weeks is followed by an abrupt febrile illness associated with profound malaise and generalized myalgia. Headache is severe and there may be conjunctivitis with orbital pain. A measles-like eruption appears around the fifth day, the macules increasing in size and eventually becoming purpuric in character. At the end of the first week, signs of meningo-encephalitis appear and CNS involvement may progress to stupor or coma, sometimes with extrapyramidal involvement. At the height of the illness, splenomegaly, pneumonia, myocarditis, and gangrene at the peripheries may be evident. Oliguric renal failure occurs in fulminating disease, which is usually fatal. Recovery begins in the third week but is generally slow. The disease may recur many years after the initial attack owing to rickettsiae that lie dormant in lymph nodes. The recrudescence is known as Brill-Zinsser disease. The factors that precipitate recurrence are not clearly defined, although other infections may play a role.

Endemic (murine) typhus

This is an infection of rodents that is inadvertently spread to humans by rat fleas. The disease closely resembles epidemic typhus but is much milder and rarely fatal.

Scrub typhus

Found throughout Asia and the Western Pacific, this disease is spread by larval trombiculid mites (chiggers). An eschar (a black, crusted, necrotic papule) can often be found at the site of the bite. The clinical illness is very variable, ranging from a mild illness to fulminant and potentially fatal disease. The more severe cases resemble epidemic typhus. Unlike other types of typhus the organism is passed on to subsequent generations of mites, which consequently act as both reservoir and vector.

Spotted fever group « v >

A variety of *Rickettsia* species, collectively known as the spotted fever group rickettsiae, cause the illnesses known as spotted fevers. In all except for rickettsial pox (which is transmitted by a rodent mite) the vector is a hard tick. Although the causative organism and the name of the illness vary from place to place the clinical course is common to all. After an incubation period of 4—10 days an eschar may develop at the site of the bite in association with regional lymphadenopathy. There is abrupt onset of fever, myalgia and headache, accompanied by a maculo-papular rash which may become petechial. Neurological, haematological and cardiovascular complications occur as in epidemic typhus, although these are uncommon.

Diagnosis

The diagnosis is generally made on the basis of the history and clinical course of the illness. It can be confirmed serologically by the indirect fluorescent antibody test (the most sensitive and specific), or the latex agglutination test. The Weil-Felix agglutination test, although previously widely used, is not specific or sensitive.

Treatment and prevention

Doxycycline or tetracycline given for 5-7 days is the treatment of choice. Ciprofloxacin is also effective. Doxycycline 200 mg weekly protects against scrub typhus; it is reserved for highly endemic areas. Rifampicin is also used when resistance to tetracycline has occurred. Seriously ill patients need intensive care. Control of typhus is achieved by eradication of the arthropod vectors. Lice and fleas can be eradicated from clothing by insecticides (0.5% malathion or DDT). Control of rodents is necessary in endemic typhus and some of the spotted fevers. Areas of vegetation infested with trombiculid mites can be cleared by chemical spraying from the air. Bites from ticks and mites should be avoided by wearing protective clothing on exposed areas of the body. The likelihood of infection from ticks is related to the duration of feeding, and in high-risk areas the body should be inspected twice a day and any ticks removed (p. 79).

Bartonellosis and ehrlichiosis

Bartonella spp. and *Ehrlichia* spp. are intracellular bacteria closely related to the rickettsiae. A number of human diseases can be caused by these organisms; like rickettsial disease, infection is usually spread from animals via an arthropod vector (Table 2.38).

Carrion's disease

This disease is restricted mainly to the habitat of its main vector, the sandfly, in the river valleys of the Andes mountains at an altitude of 500-3000 m. Two clinical presentations are seen, which may occur alone or consecutively. *Oroya fever* is an acute febrile illness causing myalgia, arthralgia, severe headache, and confusion, followed by a haemolytic anaemia. *Verruga peruana* consists of eruptions of reddish-purple haemangiomatous nodules, resembling bacillary angiomatosis. It may follow 4-6 weeks after Oroya fever, or be the presenting feature of infection. Spontaneous resolution may occur over a period of months or years. Carrion's disease is

Table 2.38 Human infections caused by *Bartonella* spp. and *Ehrlichia* spp.

Disease	Organism	Reservoir	Vector
Bartonella	*Bartonella bacilliformis*	Unknown	Sandfly
Carrion's disease	*B. henselae*	Cat	Cat flea
Cat scratch disease	*B. henselae*	Cat	Cat flea
Bacillary angiomatosis	*B. quintana*	Human	Body louse
Trench fever			
Ehrlichia	*Ehrlichia chafeensis*	Deer	Hard ticks
Human ehrlichiosis	*A. phagocytophilum**	Small mammals and deer	Hard ticks
'Human granulocytic ehrlichia' (HE)			

*Formerly known as *Ehrlichia phagocytophilia*

frequently complicated by superinfection, especially with *Salmonella* spp.

The diagnosis is made by culturing bacilli from blood or peripheral lesions. Serological tests have been developed but are not widely available.

Treatment with chloramphenicol or tetracycline is very effective in acute disease, but less so in verruga peruana.

Cat-scratch disease and bacillary angiomatosis

These are described on page 63.

Trench fever

Trench fever is caused by *Bartonella quintana,* and transmitted by human body lice. It is mainly seen in refugees and the homeless. It is characterized by cyclical fever (typically every 5 days), chills, and headaches, accompanied by myalgia and pretibial pain. The disease is usually self-limiting but it can be treated with erythromycin or doxycycline if symptoms are severe.

Melioidosis

The term melioidosis refers to infections caused by the Gram-negative bacteria *Burkholderia pseudomallei.* This environmental organism, which is found in soil and surface water, is distributed widely in the tropics and subtropics. The majority of clinical cases of melioidosis occur in South East Asia. Infection follows inhalation or direct inoculation. More than half of all patients with melioidosis have predisposing underlying disease: it is particularly common in diabetics.

B. pseudomallei causes a wide spectrum of disease, and the majority of infections are probably subclinical. Illness may be acute or chronic, localized or disseminated, but one form of the disease may progress to another and individual patients may be difficult to categorize. The most serious form is septicaemic melioidosis, which is often complicated by multiple metastatic abscesses: this is frequently fatal. Serological tests are available, but definitive diagnosis depends on isolating the organism from blood or appropriate tissue. *B. pseudomallei* has extensive intrinsic antibiotic resistance. The most effective agent is ceftazidime, which is given intravenously for *2-4* weeks; this should be followed by several months of co-amoxiclav to prevent relapses.

Actinomycosis

Actinomyces spp. are Gram-positive, branching higher bacteria which are normal mouth and intestine commensals; they are particularly associated with poor mouth hygiene. Actinomyces have a world-wide distribution but are a rare cause of disease in the West.

Clinical features

- *Cervicofacial actinomycosis,* the most common form, usually occurs following dental infection or extraction. It is often indolent and slowly progressive, associated with little pain, and results in induration and localized swelling of the lower part of the mandible. Lymphadenopathy is uncommon. Occasionally acute inflammation occurs. Sinuses and tracts develop with discharge of 'sulphur' granules.
- *Thoracic actinomycosis* follows inhalation of organisms, usually into a previously damaged lung. The clinical picture is not distinctive and is often mistaken for malignancy or tuberculosis. Symptoms such as fever, malaise, chest pain and haemoptysis are present. Empyema occurs in 25% of patients and local extension produces chest-wall sinuses with discharge of 'sulphur' granules.
- *Abdominal actinomycosis* most frequently affects the caecum. Characteristically, a hard indurated mass is felt in the right iliac fossa. Later, sinuses develop. The differential diagnosis includes malignancy, tuberculosis, Crohn's disease and amoeboma. The incidence of pelvic actinomycosis appears to be increasing with wider use of intrauterine contraceptive devices.

Occasionally actinomycosis becomes disseminated to involve any site.

Diagnosis and management

Diagnosis is by microscopy and culture of the organism. Treatment often involves surgery as well as antibiotics: penicillin is the drug of choice. Intravenous penicillin 2.4 g 4-hourly is given for 4-6 weeks, followed by oral penicillin for some weeks after clinical resolution. Tetracyclines are also effective.

Nocardia infections

Nocardia spp. are Gram-positive branching bacteria, which are found in soil and decomposing organic matter. *N. asteroides,* and less often *N. brasiliensis,* are the main human pathogens.

Clinical features

Mycetoma is the most common illness. This is a result of local invasion by *Nocardia* spp. and presents as a painless swelling, usually on the sole of the foot (Madura foot). The swelling of the affected part of the body continues inexorably. Nodules gradually appear which eventually rupture and discharge characteristic 'grains', which are colonies of organisms. Systemic symptoms and regional lymphadenopathy are rare. Sinuses may occur several years after the onset of the first symptom. A similar syndrome may be produced by other branching bacteria, and also by species of eumycete fungi such as *Madurella mycetomi* (p. 95).

Pulmonary disease, which follows inhalation of the organism, presents with cough, fever, and haemoptysis: it is usually seen in the immunocompromised. Pleural involvement and empyema occur. In severely immunosuppressed patients initial pulmonary infection may be followed by disseminated disease.

Diagnosis and management

The diagnosis is often difficult to establish, as *Nocardia* is not easily detected in sputum cultures or on histological section. Severe pulmonary or disseminated infection may require parenteral treatment: effective agents include ceftriaxone and amikacin. Local infection is usually treated with prolonged courses of oral sulphonamides, combined with surgical drainage of pus if necessary.

FUNGAL INFECTIO,

Morphologically, fungi can be grouped into three major categories:

- yeasts and yeast-like fungi, which reproduce by budding
- moulds, which grow by branching and longitudinal extension of hyphae

Table 2.39 **Common fungal infections**

Systemic	**Subcutaneous**
Histoplasmosis	Sporotrichosis Subcutaneous zygomycosis Chromoblastomycosis Mycetoma
Cryptococcosis	
Coccidioidomycosis	
Blastomycosis	
Zygomycosis (mucormycosis)	**Superficial**
Candidiasis	Dermatophytosis Superficial candidiasis *Malassezia* infections
Aspergillosis	
Pneumocystis carinii (previously classed as a protozoan)	

- dimorphic fungi, which behave as yeasts in the host but as moulds in vitro (e.g. *Histoplasma capsulatum* and *Sporothrix schenckii).*

Despite the fact that fungi are ubiquitous, systemic fungal infections are uncommon, although increasing in selected populations of patients such as the immunocompromised and transplant patients, those managed in high dependency units and in those with severe immunodeficiency, including HIV. Fungal infections are transmitted by inhalation of spores or by contact with the skin. Opportunistic mycoses can cause disease in immunocompromised patients. Fungi do not produce endotoxin, but exotoxin (e.g. aflatoxin) production has been documented in vitro. Fungi may also produce allergic pulmonary disease. Some fungi such as *Candida albicans* are human commensals. Diseases are usually divided into systemic, subcutaneous or superficial (Table 2.39).

SYSTEMIC FUNGAL INFECTIONS

Candidiasis

Candidiasis is the most common fungal infection in humans and is predominantly caused by *Candida albicans* although other species of *Candida* are increasingly recognized. *Candida* are small asexual fungi. Most species that are pathogenic to humans are normal oropharyngeal and gastrointestinal commensals. Candidiasis is found world-wide.

Clinical features

Any organ in the body can be invaded by Candida, but vaginal infection and oral thrush are the most common forms. This latter is seen in the very young, in the elderly, following antibiotic therapy and in those who are immunosuppressed. Candidal oesophagitis presents with painful dysphagia. Cutaneous candidiasis typically occurs in intertriginous areas. It is also a cause of paronychia. Balanitis and vaginal infection are also common (see p. 127).

Chronic mucocutaneous candidiasis is a rare manifestation, usually occurring in children, and is associated with a T cell defect. It presents with hyperkeratotic

plaque-like lesions on the skin, especially the face, and on the fingernails. It is associated with several endocrinopathies, including hypothyroidism and hypoparathyroidism. Dissemination of candidiasis may lead to haematogenous spread, with meningitis, pulmonary involvement, endocarditis or osteomyelitis.

Diagnosis and treatment

The fungi can be demonstrated in scrapings from infected lesions, tissue secretions or in invasive disease, from blood cultures.

Treatment varies depending on the site and severity of infection. Oral lesions respond to nystatin, oral amphotericin B or fluconazole. For systemic infections, parenteral therapy with fluconazole, itraconazole or amphotericin B is necessary. Polysymptomatic patients often complaining of widespread candidiasis can have a psychiatric disorder (see p. 1283).

Histoplasmosis

Histoplasmosis is caused by *Histoplasma capsulatum,* a non-encapsulated, dimorphic fungus. Spores can survive in moist soil for several years, particularly when it is enriched by bird and bat droppings. Histoplasmosis occurs world-wide but is only commonly seen in Ohio and the Mississippi river valley regions where over 80% of the population have been subclinically exposed. Transmission is mainly by inhalation of the spores, particularly when clearing out attics, barns and bird roosts or exploring caves.

Clinical features

Figure 2.30 summarizes the pathogenesis, main clinical forms and sequelae of histoplasma infection. Primary pulmonary histoplasmosis is usually asymptomatic. The only evidence of infection is conversion of a histoplasmin skin test from negative to positive, and radiological features similar to those seen with the Ghon primary complex of tuberculosis (see p. 930). Calcification in the lungs, spleen and liver occurs in patients from areas of high endemicity. When symptomatic, primary pulmonary histoplasmosis generally presents as a mild influenza-like illness, with fever, chills, myalgia and cough. The systemic symptoms are pronounced in severe disease.

Complications such as atelectasis, secondary bacterial pneumonia, pleural effusions, erythema nodosum and erythema multiforme may also occur.

Chronic pulmonary histoplasmosis is clinically indistinguishable from pulmonary tuberculosis (see p. 931). It is usually seen in white males over the age of 50 years. Radiologically, pulmonary cavities, infiltrates and characteristic fibrous streaking from the periphery towards the hilum are seen.

The presentation of disseminated histoplasmosis resembles disseminated tuberculosis clinically. Fever, lymphadenopathy, hepatosplenomegaly, weight loss, leucopenia and thrombocytopenia are common. Rarely, features of meningitis, hepatitis, hypoadrenalism, endocarditis and peritonitis may dominate the clinical picture.

Diagnosis

Definitive diagnosis is possible only by culturing the fungi or by demonstrating them on histological sections.

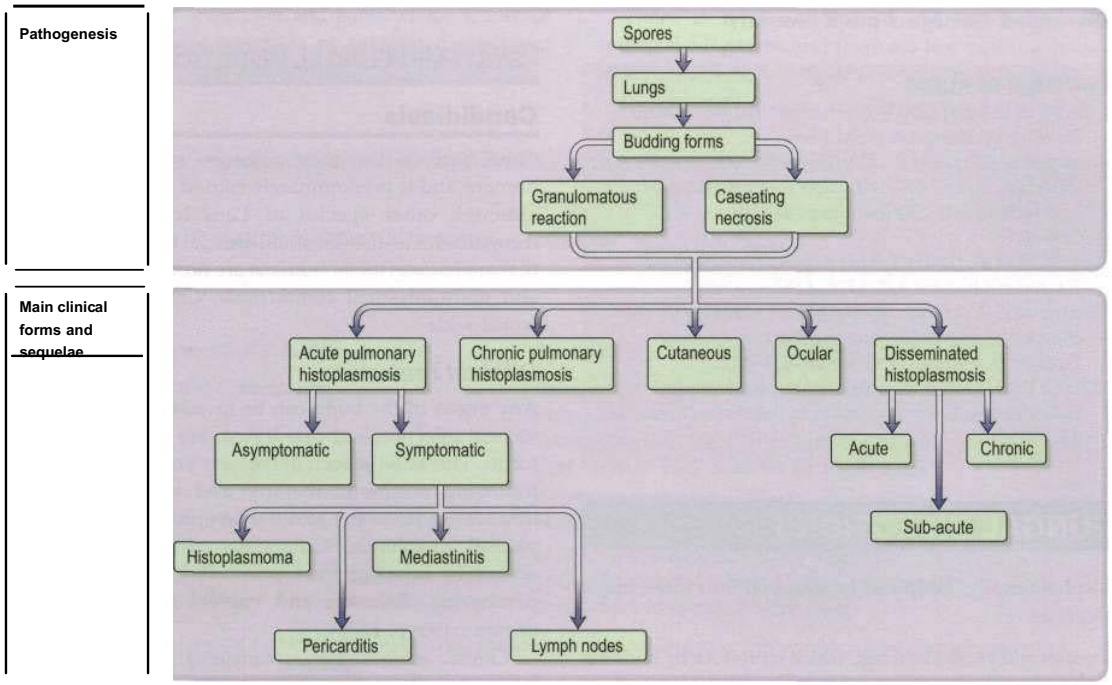

Fig. 2.30 Histoplasma infection. Summary of pathogenesis, main clinical forms and sequelae.

The histoplasmin skin test is of limited diagnostic value and can be negative in acute disseminated disease. Antibodies usually develop with 3 weeks of the onset of illness and are best detected by complement-fixation, immunodiffusion or radioimmunoassay.

Definitive diagnosis is possible only by culturing the fungi or by demonstrating them on histological sections. The histoplasmin skin test is of limited diagnostic value and can be negative in acute disseminated disease. Antibodies usually develop within 3 weeks of the onset of illness and are best detected by the complement-fixation, immunodiffusion or the counter-immunoelectrophoretic tests.

Management

Only symptomatic acute pulmonary histoplasmosis, chronic histoplasmosis and acute disseminated histoplasmosis require therapy. Itraconazole or ketoconazole are indicated for moderate disease. Severe infection is treated with intravenous amphotericin B to a total dose of 1.5 g followed by itraconazole. Patients with AIDS usually require treatment with parenteral amphotericin B followed by lifelong maintenance therapy with itraconazole 200 mg twice daily. Surgical excision of histoplasmomas (pulmonary granuloma due to *H. capsuhtum)* or chronic cavitatory lung lesions and release of adhesions following mediastinitis are often required.

African histoplasmosis

This is caused by *Histoplasma duboisii,* the spores of which are larger than those of *H. capsulatum.* Skin lesions (e.g. abscesses, nodules, lymph node involvement and lytic bone lesions) are prominent. Pulmonary lesions do not occur. Treatment is similar to that for *H. capsulatum* infection.

Aspergillosis

Aspergillosis is caused by one of several species of dimorphic fungi of the genus *Aspergillus.* Of these, *A. fumigatus* is the most common, although A. *flavus* and *A. niger* are also recognized. These fungi are ubiquitous in the environment and are commonly found on decaying leaves and trees. Humans are infected by inhalation of the spores. Disease manifestation depends on the dose of the spores inhaled as well as the immune response of the host. Three major forms of the disease are recognized:

- Bronchopulmonary allergic aspergillosis (see p. 939) shows symptoms suggestive of bronchial asthma.
- Aspergilloma (see p. 940) is sometimes referred to as a pulmonary mycetoma.
- Invasive aspergillosis, which occurs in immunosuppressed patients and presents as acute pneumonia, meningitis or an intracerebral abscess, lytic bone lesions, and granulomatous lesions in the liver; less commonly endocarditis, paranasal *Aspergillus* granuloma or keratitis may occur. Urgent treatment with intravenous amphotericin B is required.

The diagnosis and treatment are described in more detail on page 939.

Cryptococcosis

Cryptococcosis is caused by the yeast-like fungus, *Cryptococcus neoformans.* It has a world-wide distribution and appears to be spread by birds, especially pigeons, in their droppings. The spores gain entry into the body through the respiratory tract, where they elicit a granulomatous reaction. Pulmonary symptoms are, however, uncommon; meningitis which usually occurs in those with HIV or lymphoma is the usual mode of presentation and often develops subacutely. Less commonly, lung cavitation, hilar lymphadenopathy, pleural effusions and occasionally pulmonary fibrosis occur. Skin and bone involvement is rare.

Diagnosis and treatment

This is established by demonstrating the organisms in appropriately stained tissue sections. A positive latex cryptococcal agglutinin test performed on the CSF is diagnostic of cryptococcosis.

Amphotericin B (0.7mg/kg daily i.v.) alone or in combination with flucytosine (100-200 mg/kg daily) for 2 weeks followed by fluconazole 400 mg daily has reduced the mortality of this once universally fatal condition. Therapy should be continued for 3 months if meningitis is present. Fluconazole has greater CSF penetration and is used when toxicity is encountered with amphotericin B and flucytosine and as maintenance therapy in immunocompromised patients, especially those with HIV in whom the recommended treatment is followed by lifelong fluconazole 200 mg daily, unless they are responding to HAART.

Coccidioidomycosis

Coccidioidomycosis is caused by the non-budding spherical form (spherule) of *Coccidioides immitis.* This is a soil saprophyte and is found in the southern USA, Central America and parts of South America. Humans are infected by inhalation of the thick-walled barrel-shaped spores called arthrospores. Occasionally epidemics of coccidioidomycosis have been documented following dust storms.

Clinical features

The majority of patients are asymptomatic and the infection is only detected by the conversion of a skin test using coccidioidin (extract from a culture of mycelial growth of C. *immitis)* from negative to positive. Acute pulmonary coccidioidomycosis presents, after an incubation period of about 10 days, with fever, malaise, cough and expectoration. Erythema nodosum, erythema multiforme, phlyctenular conjunctivitis and, less commonly, pleural effusions may occur. Complete recovery is usual.

Pulmonary cavitation with haemoptysis, pulmonary fibrosis, meningitis, lytic bone lesions, hepatosplenomegaly, skin ulcers and abscesses may occur in severe disease.

Diagnosis

Because of the high infectivity of this fungus, and consequent risk to laboratory personnel, serological tests (rather than culture of the organism) are widely used for diagnosis. These include the highly specific latex agglutination and precipitin tests (IgM) which are positive within 2 weeks of infection and decline thereafter.

A positive complement-fixation test (IgG) performed on the CSF is diagnostic of coccidioidomycosis meningitis within 4-6 weeks and may remain positive for many years.

Treatment

Mild pulmonary infections are self-limiting and require no treatment, but progressive and disseminated disease requires urgent therapy. Ketoconazole or itraconazole 400 mg daily for 6 months is the treatment of choice for primary pulmonary disease with more prolonged courses for cavitating or fibronodular disease. Fluconazole in high dose (600-1000 mg daily) is given for meningitis. Amphotericin B is indicated for life-threatening infection. Surgical excision of cavitatory pulmonary lesions or localized bone lesions may be necessary. When occurring in those with HIV, amphotericin B, followed by maintenance itraconazole or fluconazole is indicated.

Blastomycosis

Blastomycosis is a systemic infection caused by the biphasic fungus *Blastomyces dermatitidis.* Although initially believed to be confined to certain parts of North America, it has been reported in Canada, Africa, Israel, Eastern Europe and Saudi Arabia.

Clinical features

Blastomycosis primarily involves the skin, where it presents as non-itchy papular lesions that later develop into ulcers with red verrucous margins. The ulcers are initially confined to the exposed parts of the body but later involve the unexposed parts as well. Atrophy and scarring may occur. Pulmonary involvement presents as a solitary lesion resembling a malignancy or gives rise to radiological features similar to the primary complex of tuberculosis. Systemic symptoms such as fever, malaise, cough and weight loss are usually present. Bone lesions are common and present as painful swellings.

Diagnosis and treatment

The diagnosis is confirmed by demonstrating the organism in histological sections or by culture, although results can be negative in 30-50% of cases. Enzyme immunoassay may be helpful although there is some cross-reactivity of antibodies to blastomyces with histoplasma.

Itraconazole is preferred for treating mild to moderate disease in the immunocompetent for periods up to 6 months. Ketoconazole or fluconazole are useful alternatives. In severe or unresponsive disease and in the immunocompromised, amphotericin B is indicated.

Invasive zygomycosis

Invasive zygomycosis (mucormycosis) is rare and is caused by several fungi, including *Mucor* spp., *Khizopus* spp. and *Absidia* spp. It occurs in severely ill patients. The hallmark of the disease is vascular invasion with marked haemorrhagic necrosis.

Rhinocerebral mucormycosis is the most common form. Nasal stuffiness, facial pain and oedema, and necrotic, black nasal turbinates are characteristic. It is rare and is mainly seen in diabetics with ketoacidosis. Other forms include pulmonary and disseminated infection (immunosuppressed), gastrointestinal infection (in malnutrition), and cutaneous involvement (in burns).

Treatment is with amphotericin B and sometimes judicious debridement. This condition is invariably fatal if left untreated.

SUBCUTANEOUS INFECTIONS

Sporotrichosis

Sporotrichosis is due to the saprophytic fungus *Sporothrix schenckii,* which is found world-wide. Infection usually follows cutaneous inoculation, at the site of which a reddish, non-tender, maculopapular lesion develops - referred to as 'plaque sporotrichosis'. Pulmonary involvement and disseminated disease rarely occur.

Treatment with saturated potassium iodide (10-12 mL daily orally for adults) is curative in the cutaneous form. Itraconazole 100-200 mg/day for 3-6 months is a useful alternative.

Subcutaneous zygomycosis

Subcutaneous zygomycosis, a disease seen in children in Africa and Indonesia, is caused by several filamentous fungi of the *Basidiobolus* genus. The disease usually remains confined to the subcutaneous tissues and muscle fascia. It presents as a brawny, woody infiltration involving the limbs, neck and trunk. Less commonly, the pharyngeal and orbital regions may be affected.

Treatment is with saturated potassium iodide solution given orally.

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is caused by fungi of the genera *Phialophora, Cladosporium* and *Fonsecaea.* These are found mainly in tropical and subtropical countries. It presents initially as a small papule, usually at the site of a previous injury. This persists for several months before ulcerating. The lesion later becomes warty and encrusted and gradually spreads. Satellite lesions may be present. Itching is frequent. The drug of choice is flucytosine, sometimes in combination with ketoconazole or amphotericin B. Itraconazole may also prove effective. Cryosurgery is used to remove local lesions.

Mycetoma (Madura foot)

Mycetoma may be due to subcutaneous infection with fungi *(Eumycetes* spp.) or bacteria (see p. 91). Infection results in local swelling which may discharge through sinuses. Bone involvement may follow.

Treatment is with ketoconazole or antibacterials according to the aetiological agent.

Pneumocystis carinii infection

Genetic analysis has shown this organism to be homologous with fungi. It exists as a trophozoite which is probably motile and reproduces by binary fission. After invasion the trophozoite wall thickens and forms a cyst. On maturation further division takes place to yield eight merozoites which after cell wall rupture develop into trophozoites. Infection probably occurs in infancy but in otherwise healthy infants it remains undetected. It is usually cleared from the lungs. P. *carinii* disease in adults is associated with immunodeficiency states, particularly AIDS, and is discussed on page 136.

SUPERFICIAL INFECTIONS

Dermatophytosis

Dermatophytoses are chronic fungal infections of keratinous structures such as the skin, hair or nails. *Trichophyton* spp., *Microsporum* spp., *Epidermophyton* spp. and *Candida* spp. can also infect keratinous structures.

Malassezia infection

Malassezia spp. are found on the scalp and greasy skin and are responsible for seborrhoeic dermatitis, pityriasis versicolor (hypo- or hyperpigmented rash on trunk) and *Malassezia* folliculitis (itchy rash on back).

Treatment is with topical antifungals or oral ketoconazole if infection is extensive.

PROTOZOAL INFECTIONS

Protozoa are unicellular eukaryotic organisms. They are more complex than bacteria, and belong to the animal kingdom. Although many protozoa are free-living in the environment some have become parasites of vertebrates, including man, often developing complex life cycles involving more than one host species. In order to be transmitted to a new host, some protozoa transform into hardy cyst forms which can survive harsh external conditions. Others are transmitted by an arthropod vector, in which a further replication cycle takes place before infection of a new vertebrate host. Major protozoan parasites of man are listed in Table 2.40.

BLOOD AND TISSUE PROTOZOA

Malaria

Human malaria can be caused by four species of the genus *Plasmodium: P. falciparum, P. vivax, P. ovale, P. malariae.* Ocassionally other species of malaria usually found in primates can affect man. Malaria probably originated from animal malarias in central Africa, but was spread around the globe by human migration. Public health measures and changes in land use have eradicated malaria in most developed countries, although the potential for malaria transmission still exists in many areas. Five hundred million people are infected every year,

Table 2.40 Major protozoal diseases of man

Blood	Tissues	Gastrointestinal tract
Malaria	Leishmaniasis	Giardiasis
Trypanosomiasis	Toxoplasmosis	Amoebiasis
		Cryptosporidiosis

and over one million die yearly. Twenty five thousand international travellers per year are infected.

Epidemiology

Malaria is transmitted by the bite of female anopheline mosquitoes. The parasite undergoes a temperature-dependent cycle of development in the gut of the insect, and its geographical range therefore depends on the presence of the appropriate mosquito species and on adequate temperature. The disease occurs in endemic or epidemic form throughout the tropics and subtropics (Fig. 2.31) except for areas above 2000 m: Australia, the USA, and most of the Mediterranean littoral are also malaria-free. In hyperendemic areas (51-75% rate of parasitaemia, or palpable spleen in children 2-9 years of age) and holoendemic areas (> 75% rate) where transmission of infection occurs year round, the bulk of the mortality is seen in infants. Those who survive to adulthood acquire significant immunity; low-grade parasitaemia is still present, but causes few symptoms. In mesoendemic areas (11-50%) there is regular seasonal transmission of malaria. Mortality is still mainly seen in infants, but older children and adults may develop chronic ill health due to repeated infections. In hypoendemic areas (0-10%), where infection occurs in occasional epidemics, little immunity is acquired and the whole population is susceptible to severe and fatal disease.

Malaria can also be transmitted in contaminated blood transfusions. It has occasionally been seen in injecting drug users sharing needles and as a hospital-acquired infection related to contaminated equipment. Rare cases are acquired outside the tropics when mosquitoes are transported from endemic areas ('airport malaria'), or when the local mosquito population becomes infected by a returning traveller.

Parasitology

The female mosquito becomes infected after taking a blood meal containing gametocytes, the sexual form of the malarial parasite (Fig. 2.32). The developmental cycle in the mosquito usually takes 7-20 days (depending on temperature), culminating in infective sporozoites migrating to the insect's salivary glands. The sporozoites are inoculated into a new human host, and those which are not destroyed by the immune response are rapidly taken up by the liver. Here they multiply inside hepatocytes as merozoites: this is pre-erythrocytic (or hepatic) sporogeny. After a few days the infected hepatocytes rupture, releasing merozoites into the blood from where they are rapidly taken up by erythrocytes. In the case of *P. vivax* and *P. ovale,* a few parasites remain dormant in the liver as hypnozoites. These may reactivate at any time subsequently, causing relapsing infection.

Inside the red cells the parasites again multiply, changing from merozoite, to trophozoite, to schizont, and finally appearing as 8-24 new merozoites. The erythrocyte ruptures, releasing the merozoites to infect further cells. Each cycle of this process, which is called erythrocytic schizogony, takes about 48 hours in P. *falciparum, P. vivax* and P. *ovale,* and about 72 hours in P. *malariae. P. vivax* and P. *ovale* mainly attack reticulocytes and young erythrocytes, while P. *malariae* tends to attack older cells; P. *falciparum* will parasitize any stage of erythrocyte.

A few merozoites develop not into trophozoites but into gametocytes. These are not released from the red

cells until taken up by a feeding mosquito to complete the life cycle.

Pathogenesis

The pathology of malaria is related to anaemia, cytokine release, and in the case of *P. falciparum,* widespread organ damage due to impaired microcirculation. The anaemia seen in malaria is multifactorial (Table 2.41). In P. *falciparum* malaria, red cells containing schizonts adhere to the lining of capillaries in the brain, kidneys, gut, liver and other organs. As well as causing mechanical obstruction these schizonts rupture, releasing toxins and stimulating further cytokine release.

After repeated infections partial immunity develops, allowing the host to tolerate parasitaemia with minimal ill effects. This immunity is lost if there is no further infection for a couple of years. Certain genetic traits also confer some immunity to malaria. People who lack the Duffy antigen on the red cell membrane (a common finding in West Africa) are not susceptible to infection with *P. vivax*. Certain haemoglobinopathies (including sickle cell trait) also give some protection against the severe effects of malaria: this may account for the persistence of these otherwise harmful mutations in tropical countries. Iron deficiency may also have some protective effect. The spleen appears to play a role in controlling infection, and splenectomized people are at risk of overwhelming malaria. Some individuals appear to have a genetic predisposition for developing cerebral malaria following infection with *P. falciparum*. Pregnant women are especially susceptible to severe disease.

Folate depletion

Clinical features

Typical malaria is seen in non-immune individuals. This includes children in any area, adults in hypoendemic areas, and any visitors from a non-malarious region.

The normal incubation period is 10-21 days, but can be longer. The most common symptom is fever, although malaria may present initially with general malaise, headache, vomiting, or diarrhoea. At first the fever may be continual or erratic: the classical tertian or quartan fever only appears after some days. The temperature often reaches 41 °C, and is accompanied by rigors and drenching sweats.

P. *vivax or P. ovale infection*

The illness is relatively mild. Anaemia develops slowly, and there may be tender hepatosplenomegaly. Spontaneous recovery usually occurs within 2-6 weeks, but hypnozoites in the liver can cause relapses for many years after infection. Repeated infections often cause chronic ill health due to anaemia and hyperreactive splenomegaly.

P. malariae infection

This also causes a relatively mild illness, but tends to run a more chronic course. Parasitaemia may persist for years, with or without symptoms. In children, P. *malariae* infection is associated with glomerulonephritis and nephrotic syndrome.

P. *falciparum infection*

This causes, in many cases, a self-limiting illness similar to the other types of malaria, although the paroxysms of fever are usually less marked. However it may also cause serious complications (Box 2.12), and the vast majority of malaria deaths are due to P. *falciparum*. Patients can deteriorate rapidly, and children in particular progress from reasonable health to coma and death within hours. A high parasitaemia (> 1% of red cells infected) is an indicator of severe disease, although patients with apparently low parasite levels may also develop complications. Cerebral malaria is marked by diminished consciousness, confusion, and convulsions, often progressing to coma and death. Untreated it is universally fatal. *Blackwater fever* is due to widespread intravascular haemolysis, affecting both parasitized and unparasitized red cells, giving rise to dark urine.

Hyperreactive malarial splenomegaly (tropical splenomegaly syndrome, TSS)

This is seen in older children and adults in areas where malaria is hyperendemic. It is associated with an exaggerated immune response to repeated malaria infections, and is characterized by anaemia, massive splenomegaly, and elevated IgM levels. Malaria parasites are scanty or absent. TSS usually responds to prolonged treatment with prophylactic antimalarial drugs.

Diagnosis

Malaria should be considered in the differential diagnosis of anyone who presents with a febrile illness in, or having recently left, a malarious area. Falciparum malaria is unlikely to present more than 3 months after exposure, even if the patient has been taking prophylaxis, but vivax malaria may cause symptoms for the first time up to a year after leaving a malarious area.

Diagnosis is usually made by identifying parasites on a Giemsa-stained thick or thin blood film (thick films are more difficult to interpret, and it may be difficult to speciate the parasite, but they have a higher yield). At least three films should be examined before malaria is declared unlikely. An alternative microscopic method is quantitative buffy coat analysis (QBC), in which the centrifuged buffy coat is stained with a fluorochrome which Tights up' malarial parasites. A number of antigen-detection methods for identifying malarial proteins and enzymes have been developed. Some of these are available in card or dipstick form, and are potentially suitable for use in resource-poor settings. Serological tests are of no diagnostic value.

Parasitaemia is common in endemic areas, and the presence of parasites does not necessarily mean that malaria is the cause of the patient's symptoms. Further investigation, including a lumbar puncture, may be needed to exclude bacterial infection.

Management

The drug of choice for susceptible parasites is chloroquine (Box 2.13). P. *vivax, P. ovale* and P. *malariae are* almost always sensitive to this drug, the only exception being some strains of P. *vivax* from Oceania.

There is now widespread chloroquine resistance among P. *falciparum,* and there are few parts of the world where all infections will be susceptible. Despite this, cost

Box 2.13 **Drug treatment of uncomplicated malaria in adults**

Type of malaria	Drug treatment	
Plasmodium vivax, P. ovale, P. malariae, CQ-sensitive *falciparum*	Chloroquine: *P.*	600 mg 300 mg 6 hours later 300 mg 24 hours later 300 mg 24 hours later

and availability mean that chloroquine is still the most commonly used antimalarial.

Treatment should ideally be based on a knowledge of local sensitivity, but this is often not known. In developed countries P. *falciparum* is commonly treated with quinine, usually as quinine sulphate. In mild cases this can be given orally, but in more severe illness it is given by intravenous infusion. Tinnitus and nausea are predictable side-effects of quinine, and do not require dose reduction unless severe. Some resistance to quinine is emerging, and another antimalarial (either Fansidar (pyrimethamine/sulfadoxine) or tetracycline) should be given at the end of the course of quinine.

Other available antimalarial drugs include mefloquine, artemisinin derivatives, and the fixed-dose combination preparations Malarone (atovaquone/proguanil), coartemether (artemether/lamufantrine), and Lapdap (chlorproguanil/dapsone). The way in which these drugs should be distributed and used, particularly in the poorer developing countries, is still a matter for debate. Multidrug combinations are available but costly (e.g. Artemisinin combination therapy ACT). These extend the usefulness of existing drugs and limit the development of resistance to new agents. Trials of these combination therapies are being completed.

Severe malaria, indicated by the presence of any of the complications discussed above, or a parasite count above 1% in a non-immune patient, is a medical emergency. Quinine should be given intravenously as shown in Emergency box 2.1: the loading dose should be omitted if the patient has already received quinine or mefloquine. Intensive care facilities may be needed, including mechanical ventilation and dialysis. Severe anaemia may require transfusion. Careful monitoring of fluid balance is essential: both pulmonary oedema and prerenal failure are common. Hypoglycaemia can be induced both by the infection itself and by quinine treatment. Superadded bacterial infection is common. In very heavy infections (parasitaemia > 10%), there may be a role for exchange transfusion, if the facilities are available.

Following successful treatment of P. *vivax* or P. *ovale* malaria, it is necessary to give a 2- to 3-week course of primaquine (15 mg daily) to eradicate the hepatic hypnozoites and prevent relapse. This drug can precipitate haemolysis in patients with G6PD deficiency (p. 446).

Prevention and control

As with many vector-borne diseases, control of malaria relies on a combination of case treatment, vector eradication, and personal protection from vector bites, e.g. insecticide treated nets. Mosquito eradication is usually achieved either by the use of insecticides, house spraying with DDT, or by manipulation of the habitat (e.g. marsh drainage). After some initial successes, a

WHO campaign to eliminate malaria foundered in the mid-1960s. Since then the emergence of both parasite resistance to drugs and mosquito resistance to insecticides has rendered the task more difficult. However, malaria is once again a priority for the WHO, which announced a new 'Roll Back Malaria' campaign in 1998.

Non-immune travellers to malarious areas should take measures to avoid insect bites, such as using insect repellent and sleeping under mosquito nets. Antimalarial prophylaxis should also be taken in most cases, although this is never 100% effective (Box 2.14). The precise choice of prophylactic regimen depends both on the individual traveller and on the specific itinerary; further details can be found in National Formularies or from travel advice centres. Despite considerable efforts, there is still no effective vaccine available for malaria.

Trypanosomiasis

African trypanosomiasis (sleeping sickness)

Sleeping sickness is caused by trypanosomes transmitted to humans by the bite of the tsetse fly (genus *Glossina).* It is endemic in a belt across sub-Saharan Africa, extending to about 14° N and 20° S: this marks the natural range of the tsetse fly. Two subspecies of trypanosome cause human sleeping sickness: *Trypanosoma brucei gambiense (Gambian sleeping sickness'),* and *T. b. rhodesiense (Rhodesian sleeping sickness').*

Epidemiology

West African sleeping sickness is found from Uganda in Central Africa, west to Senegal and south as far as Angola. Man is the major reservoir, and infection is transmitted by riverine *Glossina* species (e.g. *G. palpalis).* Sleeping sickness due to T. *b. rhodesiense* occurs in East and Central Africa from Ethiopia to Botswana. It is a zoonosis of both wild and domestic animals. In endemic situations it is maintained in game animals and transmitted by savanna flies such as G. *morsitans.* Epidemics are usually related to cattle, and the vectors are riverine flies.

Recent political upheavals and wars have both disrupted established treatment and control programmes, and led to large population movements. This has resulted in major epidemics of T. *b. gambiense* disease in Angola and the Democratic Republic of Congo, and *T. b. rhodesiense* in Uganda. Although the majority of cases are unreported the prevalence may be as high as 500 000 cases per year, with about 65 000 deaths.

Parasitology

Tsetse flies bite during the day, and unlike most arthropod vectors both males and females take blood meals. An infected insect may deposit metacyclic trypomastigotes (the infective form of the parasite) into the subcutaneous tissue. These cause local inflammation ('trypanosomal chancre') and regional lymphadenopathy. Within 2-3 weeks the organisms invade the bloodstream, subsequently spreading to all parts of the body including , the brain.

Clinical features

T. b. gambiense causes a chronic, slowly progressive illness. Episodes of fever and lymphadenopathy occur over months or years, and hepatosplenomegaly may develop. Eventually infection reaches the central nervous system, causing headache, behavioural changes, confusion, and daytime somnolence. As the disease progresses patients may develop tremors, ataxia, convulsions and hemiplegias; eventually coma and death supervene. Histologically there is a lymphocytic meningoencephalitis, with scattered trypanosomes visible in the brain substance.

T. b. rhodesiense sleeping sickness is a much more acute disease. Early systemic features may include myocarditis, hepatitis and serous effusions, and patients can die before the onset of CNS disease. If they survive, cerebral involvement occurs within weeks of infection, and is rapidly progressive.

Diagnosis

Trypanosomes may be seen on Giemsa-stained smears of thick or thin blood films, or of lymph node aspirate. Blood films are usually positive in *T. b. rhodesiense,* but may be negative in *T. b. gambiense:* concentration techniques may increase the yield. The quantitative buffy coat test (QBC, see p. 98) developed for diagnosing malaria is also used to identify trypanosomes. Serological tests are useful for screening for infection: the card agglutination test for trypanosomiasis (CATT) is a robust and easy-to-use field assay. Examination of cerebrospinal fluid is essential in patients with evidence of trypanosomal infection. CNS involvement causes lymphocytosis and elevated protein in the CSF, and parasites may be seen in concentrated specimens.

Management

The treatment of sleeping sickness has remained largely unchanged for more than 40 years, although there have been developments in the management of *T. b. gambiense* infection. In both forms, treatment is usually effective if given before the onset of CNS involvement, but much less so in neurological disease. The drug of choice in early trypanosomiasis is suramin, given intravenously at a dose of 20 mg/kg at 5 to 7-day intervals up to a total dose of 5 g. Severe reactions are relatively common, and a test dose of 100 mg is usually given prior to this regimen. Intramuscular pentamidine is effective against *T. b. gambiense* only: a number of different regimens are in use. A single dose of suramin should be given to patients with parasitaemia prior to lumbar puncture, to avoid inoculation into the CSF.

The only effective drugs which penetrated the CSF in trypanocidal concentrations were the arsenicals, of which the most widely used is melarsoprol. These are given intravenously; a variety of dosing schedules are in use. Melarsoprol is extremely toxic: 2-10% of patients develop an acute encephalopathy, with a 50-75% mortality, and peripheral neuropathy and hepatorenal toxicity are also

common. Prednisolone 1 mg/kg/day decreases the treatment-related mortality by 50% in T. *b. gambiense* infection; it has not been fully assessed in *T. b. rhodesiense* disease. Between 3-6% of patients relapse following melarsoprol treatment. In *T. b. gambiense* sleeping sickness, eflornithine (difluoromethylornithine) is effective, clearing parasites from blood and CSF: it has a variable effect on *T. b. rhodesiense* infection. Eflornithine is much less toxic than the arsenical drugs, but cost prevents it from being used as a first-line treatment in most cases.

Control

The morbidity and mortality of sleeping sickness could be considerably reduced by early detection and treatment of cases. Control programmes have been effective in some areas, but many have been discontinued because of lack of funding, or political upheaval. As in many vector-borne diseases, prevention depends largely on elimination, control or avoidance of the vector. Again this requires considerable coordination and money, and has only been implemented in a few places.

South American trypanosomiasis (Chagas' disease)

Chagas' disease is widely distributed in rural areas of South and Central America. It is caused by *Trypanosoma cruzi,* which is transmitted to humans in the faeces of blood-sucking reduviid bugs (also called cone-nose, or assassin bugs). The bugs, which live in mud or thatch buildings, feed on a variety of vertebrate hosts at night, defecating as they do so. Faeces infected with T. *cruzi* trypomastigotes are rubbed in through skin abrasions, mucosa or conjunctiva. The parasites spread in the bloodstream, before entering host cells and multiplying. Cell rupture releases them back into the circulation, where they can be taken up by a feeding bug. Further multiplication takes place in the insect gut, completing the trypanosome life cycle. Human infection can also occur via contaminated blood transfusion, or occasionally by transplacental spread.

Clinical features

Acute infection, which usually occurs in children, often passes unnoticed. A firm reddish papule is sometimes seen at the site of entry, associated with regional lymphadenopathy. In the case of conjunctival infection there is swelling of the eyelid, which may close the eye (Romana's sign). There may be fever, lymphadenopathy, hepatosplenomegaly, and rarely meningoencephalitis. Acute Chagas' disease is occasionally fatal in infants, but normally there is full recovery within a few weeks or months.

After a latent period of many years, some people go on to develop *chronic Chagas' disease.* The pathogenesis of this is unclear: it is possibly due to an autoimmune response triggered by the initial infection, although recently the demonstration of parasites on PCR has thrown doubt on this mechanism. The heart is commonly affected, with conduction abnormalities, arrhythmias, aneurysm formation and cardiac dilatation. Gastrointestinal involvement leads to progressive dilatation of parts of the gastrointestinal tract: this commonly results in megaoesophagus (causing dysphagia and aspiration pneumonia) and megacolon (causing severe constipation).

Diagnosis

Trypanosomes may be seen on a stained blood film during the acute illness. In chronic disease, parasites may be detected by xenodiagnosis: infection-free reduviid bugs are allowed to feed on the patient, and the insect gut subsequently examined for parasites. Serological tests can detect both acute and chronic Chagas' disease.

Management and control

Nifurtimox is the drug of choice for treating Chagas' disease, but it is variably available throughout the world. Benznidazole (5-10 mg/kg/day for 60 days) is also used. The cure rate is about 80% in acute infection. Both are toxic with adverse reactions in up to 50% of patients. The drug treatment of chronic infection is controversial, as most of the tissue damage is thought to be immune-mediated and there is little clinical evidence that parasite elimination influences the outcome. Antiarrhythmic drugs and pacemakers may be needed in cardiac disease, and surgical treatment is sometimes needed for gastrointestinal complications. In the long term, prevention of Chagas' disease relies on improved housing and living conditions. In the interim, local vector control programmes may be effective and the countries of the 'Southern Cone' of South America have a joint programme to control the disease by spraying houses with insecticide.

Leishmaniasis

This group of diseases is caused by protozoa of the genus *Leishmania,* which are transmitted by the bite of the female phlebotomine sandfly (Table 2.42). Leishmaniasis

Table 2.42 *Leishmania* species causing visceral and cutaneous disease in man

is seen in localized areas of Africa, Asia (particularly India and Bangladesh), Europe, the Middle East and South and Central America. Certain parasite species are specific to each geographical area. The clinical picture is dependent on the species of parasite, and on the host's cell-mediated immune response. Asymptomatic infection, in which the parasite is suppressed or eradicated by a strong immune response, is common in endemic areas, as demonstrated by a high incidence of positive leishmanin skin tests. Symptomatic infection may be confined to the skin (sometimes with spread to the mucous membranes), or widely disseminated throughout the body (visceral leishmaniasis). Relapse of previously asymptomatic infection may be seen in patients who become immunocompromised, especially those with HIV infection.

In some areas leishmania is primarily zoonotic, whereas in others, man is the main reservoir of infection. In the vertebrate host the parasites are found as oval amastigotes (Leishman-Donovan bodies). These multiply inside the macrophages and cells of the reticuloendothelial system, and are then released into the circulation as the cells rupture. Parasites are taken into the gut of a feeding sandfly (genus *Phlebotomus* in the Old World, genus *Lutzomyia* in the New World), where they develop into the flagellate promastigote form. These migrate to the salivary glands of the insect, where they can be inoculated into a new host.

Visceral leishmaniasis

Clinical features

Visceral leishmaniasis (kala azar) is caused by *L. donovani, L. infantum* or *L. chagasi,* and is prevalent in localized areas of Asia, Africa, the Mediterranean littoral and South America. In India, where man is the main host, the disease occurs in epidemics. In most other areas it is endemic, and it is mainly children and visitors to the area who are at risk. The main animal reservoirs in Europe and Asia are dogs and foxes, while in Africa it is carried by various rodents.

The incubation period is usually 1-2 months, but may be several years. The onset of symptoms is insidious, and the patient may feel quite well despite markedly abnormal physical findings. Fever is common, and although usually low-grade, it may be high and intermittent. The liver, and especially the spleen, become enlarged; lymphadenopathy is common in African kala azar. The skin becomes rough and pigmented. If the disease is not treated, profound pancytopenia develops, and the patient becomes wasted and immunosuppressed. Death usually occurs within a year, and is normally due to bacterial infection or uncontrolled bleeding.

Diagnosis

Specific diagnosis is made by demonstrating the parasite in stained smears of aspirates of bone marrow, lymph node, spleen or liver. The organism can also be cultured from these specimens. Specific serological tests are positive in 95% of cases. Pancytopenia, hypoalbuminaemia and hypergammaglobulinaemia are common. The leishmanin skin test is negative, indicating a poor cell-mediated immune response.

Management

The most widely used drugs for visceral leishmaniasis are the pentavalent antimony salts (e.g. sodium stibogluconate, which contains 100 mg of antimony per mL), given intravenously or intramuscularly at a dose of 20 mg of antimony per kg for 21 days. In India, meglumine antimonate is used. Resistance to antimony salts is increasing, and relapses may occur following treatment. The drug of choice where resources permit is intravenous amphotericin B (preferably given in the liposomal form). However, this drug is expensive and not widely available in many areas where the disease is prevalent. Intravenous pentamidine is also effective, and an oral drug, miltefosine, has been shown in India to be highly effective. Intercurrent bacterial infections are common and should be treated with antibiotics. Blood transfusion may occasionally be required.

Successful treatment may be followed in a small proportion of patients by a skin eruption called *post-kala azar dermal leishmaniasis* (PKDL). It starts as a macular maculopapular nodular rash which spreads over the body. It is most often seen in the Sudan and India. Current trials are looking at the use of miltefosine for treating PKDL.

Cutaneous leishmaniasis

Cutaneous leishmaniasis is caused by a number of geographically localized species, which may be zoonotic or anthroponotic. Following a sandfly bite, leishmania amastigotes multiply in dermal macrophages. The local response depends on the species of leishmania, the size of the inoculum, and the host immune response. Single or multiple painless nodules occur on exposed areas within 1 week to 3 months following the bite. These enlarge and ulcerate with a characteristic erythematous raised border. An overlying crust may develop. The lesions heal slowly over months or years, sometimes leaving a disfiguring scar.

L. major and *L. tropica* are found in Russia and Eastern Europe, the Middle East, Central Asia, the Mediterranean littoral, and sub-Saharan Africa. The reservoir for *L. major* is desert rodents, while *L. tropica* has a mainly urban distribution with dogs and humans as reservoirs. *L. aethiopica* is found in the highlands of Ethiopia and Kenya, where the animal reservoir is the hyrax. The skin lesions usually heal spontaneously with scarring: this may take a year or more in the case of *L. tropica.* Leishmaniasis recidivans is a rare chronic relapsing form caused by *L. tropica.*

L. mexicana is found predominantly in Mexico, Guatemala, Brazil, Venezuela and Panama: infection usually runs a benign course with spontaneous healing within 6 months. *L. braziliensis* infections (which are seen throughout tropical South America) also usually heal spontaneously, but may take longer.

L. mexicana amazonensis and *L. aethiopica* may occasionally cause diffuse cutaneous leishmaniasis. This is rare,

and is characterized by diffuse infiltration of the skin by Leishman-Donovan bodies. Visceral lesions are absent.

Diagnosis and treatment

The diagnosis can often be made clinically in a patient who has been in an endemic area. Giemsa stain on a split-skin smear will demonstrate leishmania parasites in 80% of cases. Biopsy tissue from the edge of the lesion can be examined histologically, and parasites identified by PCR; culture is less often successful. The leishmanin skin test is positive in over 90% of cases, but does not distinguish between active and resolved infection. Serology is unhelpful.

Small lesions usually require no treatment. Large lesions or those in cosmetically sensitive sites can sometimes be treated locally, by curettage, cryotherapy or topical antiparasitic agents. In other cases, systemic treatment (as for visceral leishmaniasis) is required, although treatment is less successful as antimonials are poorly concentrated in the skin; *L. aethiopica* is not sensitive to antimonials.

Mucocutaneous leishmaniasis

Mucocutaneous leishmaniasis occurs in 3-10% of infections with *L. b. braziliensis,* and is commonest in Bolivia and Peru. The cutaneous sores are followed months or years later by indurated or ulcerating lesions affecting mucosa or cartilage, typically on the lips or nose ('espundia'). The condition can remain static, or there may be progression over months or years affecting the nasopharynx, uvula, palate and upper airways.

Diagnosis and treatment

Biopsies usually show only very scanty organisms, although parasites can be detected by PCR; serological tests are frequently positive.

Amphotericin B is the treatment of choice if available, although systemic antimonial compounds are widely used; miltefosine may also be effective. Relapses are common following treatment. Patients may die because of secondary bacterial infection, or occasionally laryngeal obstruction.

Prevention

Prevention of leishmaniasis relies on control of vectors and/ or reservoirs of infection. Insecticide spraying, control of host animals, and treating infected humans may all be helpful. Personal protection against sandfly bites is also necessary, especially in travellers visiting endemic areas.

Toxoplasmosis

Toxoplasmosis is caused by the intracellular protozoan parasite *Toxoplasma gondii.* The sexual form of the parasite lives in the gut of the definitive host, the cat, where it produces oocysts. After a period of maturing in the environment, these oocysts become the source of infection for secondary hosts which may ingest them. In the secondary hosts (which include man, cattle, sheep, pigs, rodents, and birds) there is disseminated infection. Following a successful immune response the infection is controlled, but dormant parasites remain encysted in host tissue for many years. The life cycle is completed when carnivorous felines eat infected animal tissue. Humans are infected either from contaminated cat faeces, or by eating undercooked infected meat; transplacental infection may also occur.

Clinical features

Toxoplasmosis is common: seroprevalence in adults in the UK is about 25%, rising to 90% in some parts of Europe. Most infections are asymptomatic or trivial. Symptomatic patients usually present with lymphadenopathy, mainly in the head and neck. There may be fever, myalgia, and general malaise; occasionally there are more severe manifestations including hepatitis, pneumonia, myocarditis, and choroidoretinitis. Lymphadenopathy and fatigue can sometimes persist for months after the initial infection.

Congenital toxoplasmosis may also be asymptomatic, but can produce serious disease. Clinical manifestations include microcephaly, hydrocephalus, encephalitis, convulsions and mental retardation. Choroidoretinitis is common; occasionally this may be the only feature.

Immunocompromised patients, especially those with HIV infection, are at risk of serious infections with *T. gondii.* In acquired immunodeficiency states this is usually due to reactivation of latent disease (p. 137).

Diagnosis

Diagnosis is usually made serologically. IgG antibodies detectable by the Sabin-Feldman dye test remain positive for years; acute infection can be confirmed by demonstrating a rising titre of specific IgM.

Management

Acquired toxoplasmosis in an immunocompetent host rarely requires treatment. In those with severe disease (especially eye involvement) sulfadiazine 2-^1 g daily and pyrimethamine 25 mg daily are given for 4 weeks, along with folinic acid. The management of pregnant women with toxoplasmosis aims to decrease the risk of fetal complications. Treatment of early infection (before the parasite has crossed the placenta) with spiramycin cuts the rate of fetal infection significantly. If the fetus has already been infected, treatment with sulfadiazine and spiramycin (± pyrimethamine, which is itself teratogenic) appears to decrease the severity of complications. Infected infants should be treated from birth. The treatment of toxoplasmosis in HIV-positive patients is covered on page 137.

Babesiosis

Babesiosis is a tick-borne parasitic disease, diagnosed most commonly in North America and Europe. It is a zoonosis of rodents and cattle, and is occasionally transmitted to humans: infection is more common and more severe in those who are immunocompromised following splenectomy. The causative organisms are the

plasmodium-like *Babesia microti* (rodents) and *B. divergens* (cattle).

The incubation period averages 10 days. In patients with normal splenic function, the symptoms are mild and usually comprise fever, nausea, myalgia, chills, vomiting and abdominal pain. Hepatosplenomegaly and haemolytic anaemia may also be present. In splenectomized individuals, systemic symptoms are more pronounced and haemolysis is associated with haemoglobinuria, jaundice and renal failure. Examination of a peripheral blood smear may reveal the characteristic plasmodium-like organisms.

The standard treatment was a combination of quinine 650 mg and clindamycin 600 mg orally three times daily for 7 days but a regimen of atovaquone and azithromycin is as effective, with fewer adverse reactions.

GASTROINTESTINAL PROTOZOA

The major gastrointestinal parasites of man are shown in Table 2.43.

Amoebiasis

Amoebiasis is caused by *Entamoeba histolytica.* The organism formerly known as E. *histolytica* is now known to consist of two distinct species: E. *histolytica,* which is pathogenic, and E. *dispar,* which is non-pathogenic. Cysts of the two species are identical, but can be distinguished by molecular techniques after culture of the trophozoite. *E. histolytica* can be distinguished from all amoebae except E. *dispar,* and from other intestinal protozoa, by microscopic appearance. Amoebiasis occurs world-wide, although much higher incidence rates are found in the tropics and subtropics.

The organism exists both as a motile trophozoite and as a cyst that can survive outside the body. Cysts are transmitted by ingestion of contaminated food or water, or spread directly by person-to-person contact. Trophozoites emerge from the cysts in the small intestine and then pass on to the colon, where they multiply.

Microspora
Enterocytozoon bieneusi
Encephalitozoon spp.

Clinical features

It is believed that many individuals can carry the pathogen without obvious evidence of clinical disease (asymptomatic cyst passers). However, this may be due in some cases to the misidentification of non-pathogenic E. *dispar* as E. *histolytica,* and it is not clear how often true E. *histolytica* infection is symptomless. In affected people E. *histolytica* trophozoites invade the colonic epithelium, probably with the aid of their own cytotoxins and proteolytic enzymes. The parasites continue to multiply and finally frank ulceration of the mucosa occurs. If penetration continues, trophozoites may enter the portal vein, via which they reach the liver and cause intrahepatic abscesses. This invasive form of the disease is serious and may even be fatal.

The incubation period of intestinal amoebiasis is highly variable and may be as short as a few days or as long as several months. The usual course is chronic, with mild intermittent diarrhoea and abdominal discomfort. This may progress to bloody diarrhoea with mucus, and is sometimes accompanied by systemic symptoms such as headache, nausea and anorexia. Less commonly, infection may present as acute amoebic dysentery, resembling bacillary dysentery or acute ulcerative colitis.

Complications are unusual, but include toxic dilatation of the colon, chronic infection with stricture formation, severe haemorrhage, amoeboma, and amoebic liver abscess. Amoebomas, which develop most commonly in the caecum or rectosigmoid region, are sometimes mistaken for carcinoma. They may bleed, cause obstruction or intussuscept. Amoebic liver abscesses often develop in the absence of a recent episode of colitis. Tender hepatomegaly, a high swinging fever and profound malaise are characteristic, although early in the course of the disease both symptoms and signs may be minimal. The clinical features are described in more detail on page 392.

Diagnosis

Microscopic examination of fresh stool or colonic exudate obtained at sigmoidoscopy is the simplest way of diagnosing colonic amoebic infection. To confirm the diagnosis motile trophozoites containing red blood cells must be identified: the presence of amoebic cysts alone does not imply disease. Sigmoidoscopy and barium enema examination may show colonic ulceration but are rarely diagnostic.

The amoebic fluorescent antibody test is positive in at least 90% of patients with liver abscess and in 60-70% with active colitis. Seropositivity is low in asymptomatic cyst passers.

Management

Metronidazole 800 mg three times daily for 5 days is given in amoebic colitis; a lower dose (400 mg three times daily for 5 days) is usually adequate in liver abscess. Tinidazole is also effective: dehydroemetine and chloroquine are alternative drugs, but are rarely used. After treatment of the invasive disease, the bowel should

be cleared of parasites with a luminal amoebicide such as diloxanide furoate.

Prevention

Amoebiasis is difficult to eradicate because of the substantial human reservoir of infection. The only progress will be through improved standards of hygiene and better access to clean water. Cysts are destroyed by boiling, but chlorine and iodine sterilizing tablets are not always effective.

Giardiasis

Giardia intestinalis is a flagellate (Fig. 2.33) that is found world-wide. It causes small intestinal disease, with diarrhoea and malabsorption. Prevalence is high throughout the tropics, and it is the most common parasitic infection in travellers returning to the UK. In certain parts of Europe, and in some rural areas of North America, large water-borne epidemics have been reported. Person-to-person spread may occur in day nurseries and residential institutions. Like E. *histolytica,* the organism exists both as a trophozoite and a cyst, the latter being the form in which it is transmitted.

The organism sometimes colonizes the small intestine and may remain there without causing detriment to the host. In other cases, severe malabsorption may occur which is thought to be related to morphological damage to the small intestine. The changes in villous architecture are usually mild partial villous atrophy; subtotal villous atrophy is rare. The mechanism by which the parasite causes alteration in mucosal architecture and produces diarrhoea and intestinal malabsorption is unknown: there is evidence that the morphological damage may be immune-mediated. Bacterial overgrowth has also been found in association with giardiasis and may contribute to fat malabsorption.

Fig. 2.33 *Giardia intestinalis* on small intestinal mucosa. Courtesy of Dr A Phillips, Department of Electron Microscopy, Royal Free Hospital, London.

Clinical features

Many individuals excreting giardia cysts have no symptoms. Others become ill within 1-3 weeks after ingesting cysts: symptoms include diarrhoea, often watery in the early stage of the illness, nausea, anorexia, and abdominal discomfort and bloating. In most people affected, these resolve after a few days, but in some the symptoms persist. Stools may then become paler, with the characteristic features of steatorrhoea. If the illness is prolonged, weight loss ensues, which can be marked. *Chronic giardiasis* frequently seen in developing countries can result in growth retardation in children.

Diagnosis

Both cysts and trophozoites can be found in the stool, but negative stool examination does not exclude the diagnosis since the parasite may be excreted at irregular intervals. The parasite can also be seen in duodenal aspirates (obtained either at endoscopy or with an Enterotest capsule), and in histological sections of jejunal mucosa.

Management

Metronidazole 2 g as a single dose on 3 successive days will cure the majority of infections, although sometimes a second or third course is necessary. Alternative drugs include tinidazole, mepacrine and albendazole. Preventative measures are similar to those outlined above for E. *histolytica.*

Cryptosporidiosis

This organism is found world-wide, cattle being the major natural reservoir. It has also been demonstrated in supplies of drinking water in the UK. The parasite is able to reproduce both sexually and asexually; it is transmitted by oocysts excreted in the faeces.

In healthy individuals cryptosporidiosis is a self-limiting illness. Acute watery diarrhoea is associated with fever and general malaise lasting for 7-10 days. In immunocompromised patients, especially those with HIV, diarrhoea is severe and intractable (see p. 138).

Diagnosis is usually made by faecal microscopy, although the parasite can also be detected in intestinal biopsies. As yet there is no effective antimicrobial treatment for this infection.

Balantidiasis

Balantidium coli is the only ciliate that produces clinically significant infection in humans. It is found throughout the tropics, particularly in Central and South America, Iran, Papua New Guinea and the Philippines. It is usually carried by pigs, and infection is most common in those

communities that live in close association with swine. Its life cycle is identical to that of E. *histolytica*. *B. coli* causes diarrhoea, and sometimes a dysenteric illness with invasion of the distal ileal and colonic mucosa. Trophozoites rather than cysts are found in the stool. Treatment is with tetracycline or metronidazole.

Blastocystis hominis infection

B. hominis is a strictly anaerobic protozoan pathogen that inhabits the colon. For decades its pathogenicity for humans was questioned, but there is increasing evidence that it may cause diarrhoea. It is sensitive to metronidazole.

Cyclospora cayetanensis infection

Cyclospom cayetanensis, a coccidian protozoal parasite, was originally recognized as a cause of diarrhoea in travellers to Nepal. It has been detected in stool specimens from immunocompetent and immunodeficient people world-wide. Infection is usually self-limiting, but can be treated with co-trimoxazole.

Microsporidiosis

Protozoa of the phylum Microspore a can cause diarrhoea in patients with HIV/AIDS (see p. 138).

HELMINTHIC INFECTIONS

Worm infections are very common in developing countries, causing much disease in both humans and domestic animals. They are frequently imported into industrialized countries. The most common human helminth infections are listed in Table 2.44.

Helminths are the largest internal human parasite. They reproduce sexually, generating millions of eggs or larvae. *Nematodes* and *trematodes* have a mouth and intestinal tract, while *cestodes* absorb nutrients directly through the outer tegument. All worms are motile, although once the adults are established in their definitive site they rarely migrate further. Adult helminths may be very long-lived: up to 30 years in the case of the schistosomes.

Many helminths have developed complex life cycles, involving more than one host. Both primary and intermediate hosts are often highly specific to a particular species of worm. In some cases of human infection man is the primary host, while in others, humans are a non-specific intermediary or coincidentally infected.

NEMATODES

Human infections can be divided into:

- Tissue-dwelling worms including the filarial worms, and the Guinea worm *Dracunculus medinensis.*
- Human intestinal worms, including the human hook worms, the common roundworm *(Ascaris lumbricoides)* and *Strongyloides stercoralis,* which are the most common helminthic parasites of man. The adult worms live in the human gut, and do not usually invade tissues, but many species have a complex life cycle involving a migratory larval stage.
- Zoonotic nematodes which accidentally infect man and are not able to complete their normal life cycle. They often become 'trapped' in the tissues, causing a potentially severe local inflammatory response.

Tissue-dwelling worms

Filariasis

Several nematodes belonging to the superfamily Filarioidea can infect humans. The adult worms are long and threadlike, ranging from 2 cm to 50 cm in length; females are generally much larger than males. Larval stages are inoculated by various species of biting flies, each specific to a particular parasite. The adult worms which develop from these larvae mate, producing millions of offspring (microfilariae), which migrate in the blood or skin. These are taken up by feeding flies, in which the remainder of the life cycle takes place. Disease, which may be caused by either the adult worms or by microfilariae, is caused by host immune response to the parasite and is characterized by massive eosinophilia. Adult worms are long-lived (10—15 years), and reinfection is common, so that disease tends to be chronic and progressive.

Lymphatic filariasis

Lymphatic filariasis, which may be caused by different species of filarial worm, has a scattered distribution in the tropics and subtropics (Table 2.45). Nearly 1 billion people in developing countries are at risk. *Wuchereria bancrofti* is transmitted to man by a number of mosquito species, mainly *Culex fatigans.* Adult female worms (which are 5—10 cm long) live in the lymphatics, releasing large numbers of microfilariae into the blood. Generally this occurs at night, coinciding with the nocturnal feeding

Table 2.44 Helminths commonly infecting man

	Helminth	Common name/disease caused
Nematodes (roundworms)		
Tissue-dwelling worms	*Wuchereria bancmfti*	Filariasis

Table 2.45 Diseases caused by the filarial worms

Organism	Adult worm	Microfilariae	Major vector	Clinical signs	Distribution
Wuchereria bancmfti	Lymphatics	Blood	*Culex* species	Fever Lymphangitis Elephantiasis	Tropics
Brugia timori/malayi	Lymphatics	Blood	*Mansonia* species	Fever Lymphangitis Elephantiasis	East and South East Asia, South India, Sri Lanka
Loa loa	Subcutaneous	Blood	*Chrysops* species	'Calabar' swellings Urticaria	West and Central Africa
Onchocerca	Subcutaneous	Skin, eye	*Simulium* species	Subcutaneous nodules Eye disease	Africa, South America
Mansonella perstans	Retroperitoneal	Blood	*Culicoides* species	Allergic eosinophilia	Sub-Saharan Africa, South America

pattern of *C. fatigans*. Non-periodic forms of *W. bancmfti,* transmitted by day-biting species of mosquito, are found in the South Pacific. *Brugia malayi* (and the closely related *B. timori)* are very similar to *W. bancmfti,* exhibiting the same nocturnal periodicity. The usual vectors are mosquitoes of the genus *Mansonia,* although other mosquitoes have been implicated.

Clinical features

Following the bite of an infected mosquito, the larvae enter the lymphatics and are carried to regional lymph nodes. Here they grow and mature for 6-18 months.

Adult worms produce allergic lymphangitis. The clinical picture depends on the individual immune response, which in turn may depend on factors such as

age at first exposure. In endemic areas many people have asymptomatic infection. Sometimes early infection is marked by bouts of fever accompanied by pain, tenderness and erythema along the course of affected lymphatics. Involvement of the spermatic cord and epididymis are common in Bancroftian filariasis. These acute attacks subside spontaneously in a few days, but usually recur. Recurrent episodes cause intermittent lymphatic obstruction, which in time can become fibrotic and irreversible. Obstructed lymphatics may rupture, causing cellulitis and further fibrosis; there may also be chylous pleural effusions and ascites. Over time there is progressive enlargement, coarsening, and fissuring of the skin, leading to the classical appearances of elephantiasis. The limbs or scrotum may become hugely swollen. Eventually the adult worms will die, but the lymphatic obstruction remains and tissue damage continues. Elephantiasis takes many years to develop, and is only seen in association with recurrent infection in endemic areas.

Occasionally the predominant features of filarial infection are pulmonary. Microfilariae become trapped in the pulmonary capillaries, generating intense local allergic response. The resulting pneumonitis causes cough, fever, weight loss, and shifting radiological changes, associated with a high peripheral eosinophil count. This is known as *tropical pulmonary eosinophilia* (see p. 940).

Diagnosis

The diagnosis of filariasis is usually made on clinical grounds, supported by a high eosinophil count. Serological tests are sensitive, especially in the earlier stages, but can cross-react with other nematodes: they become negative 1-2 years after effective treatment. PCR assays are being developed. Microfilariae start to appear in the peripheral blood about a year after infection, and may be detected on a stained nocturnal blood film. Parasitological diagnosis is difficult in established elephantiasis. The clinical picture is usually diagnostic, but similar lymphatic damage may occasionally be caused by silicates absorbed through the feet from volcanic soil.

Treatment

Diethylcarbamazine (DEC) kills both adult worms and microfilariae. Serious allergic responses may occur as the parasites are killed, and particular care is needed when using DEC in areas endemic for loiasis. Old multi-dose regimens are now being replaced by single-dose treatment often in combination with albendazole. Associated bacterial infections should be treated promptly, and reconstructive surgery may be needed to remove excess tissue. Mass chemotherapy can decrease the prevalence and severity of infection in endemic areas and 80 million people have already been treated under the WHO eradication programme. Early diagnosis and treatment prevent the development of elephantiasis. These approaches must be combined with vector control to achieve permanent results, while individual protection depends on avoidance of mosquito bites.

Loiasis

Loiasis, seen in humid forest areas of West and Central Africa and affects 3-13 million people - in some areas, up to 40% of the population. It is caused by infection with *Loa loa.* This is a small (3-7 cm) filarial worm which is found in the subcutaneous tissues. The microfilariae circulate in the blood during the day, but cause no direct symptoms. The vectors are day-biting flies of the genus *Chrysops,* known as the tabanid fly (horse or deer fly).

Adult worms migrate around the body in subcutaneous tissue planes. Worms do not replicate in humans and may be present for years, frequently without causing symptoms. From time to time localized, tender, hot, soft tissue swellings occur due to hypersensitivity (Calabar swellings) often near to a joint. These are produced in response to the passage of a worm and usually subside over a few days or weeks. There may also be more generalized urticaria and pruritus. Occasionally a worm may be seen crossing the eye under the conjunctiva; they may also enter retro-orbital tissue, causing severe pain. Short-term residents of endemic areas often have more severe manifestations of the disease.

Microfilariae may be seen on stained blood films, although these are often negative. Serological tests are relatively insensitive, and cross-react with other microfilariae. There is usually massive eosinophilia. DEC may cause severe allergic reactions (including fever, urticaria, myalgia, and occasionally encephalitis) associated with parasite killing and is being replaced by newer agents. Ivermectin in single doses of 200^00 ug/kg is effective: it may occasionally cause severe reactions. Albendazole, which causes a more gradual reduction in microfilarial load, may be preferable in heavily-infected patients. Drug reactions are more likely if there is a high microfilarial load, or if there is co-infection with *Onchocerca volvulus.* Mass treatment with either DEC or ivermectin can decrease the transmission of infection, but the mainstay of prevention is vector avoidance and control.

Onchocerciasis

Onchocerciasis (river blindness) affects 18 million people world-wide, mostly in West and Central Africa. It also occurs in the Yemen, and parts of Central and South America. It is the result of infection with *Onchocerca volvulus.* Infection is transmitted by day-biting flies of the genus *Simulium:* principally *S. damnosum* in West Africa, S. *neavei* in East Africa, and S. *metallicum* in America.

Pathogenesis

Infection occurs when larvae are inoculated by the bite of an infected fly. The worms mature in 2-4 months, and can live for more than 15 years. Adult worms, which can reach lengths of 50 cm (although less than 0.5 mm in diameter), live in the subcutaneous tissues. They may form fibrotic nodules, especially over bony prominences and sites of trauma. Huge numbers of microfilariae are distributed in the skin, and may invade the eyes. Live microfilariae cause relatively little harm, but dead parasites may cause severe allergic reactions, with

hyaline necrosis and loss of tissue collagen and elastin. In the eye a similar process causes conjunctivitis, sclerosing keratin's, uveitis, and secondary glaucoma. Choroidoretinitis is also occasionally seen.

Clinical features

Symptoms usually start about a year after infection. Initially there is generalized pruritus, with urticaria and fleeting oedema. Subcutaneous nodules (which can be detected by ultrasound) start to appear, and in dark-skinned individuals, hypo- and hyperpigmentation from excoriation and inflammatory changes. Over time more chronic inflammatory changes appear, with roughened, inelastic skin. Superficial lymph nodes become enlarged, and in the groin may hang down in loose folds of skin ('hanging groin'). Eye disease, which is associated with chronic heavy infection, usually first manifests as itching and conjunctival irritation. This gradually progresses to more extensive eye disease and eventually to blindness. Short-term travellers are unlikely to become infected as the black flies are not efficient vectors of the disease.

Diagnosis

In endemic areas the diagnosis can often be made clinically, especially if supported by finding eosinophilia on a blood film. In order to identify parasites, skin snips taken from the iliac crest or shoulder are placed in saline under a cover slip. After 4 hours, microscopy will show microfilariae wriggling free on the slide. If this is negative, DEC can be applied topically under an occlusive dressing: this will provoke an allergic rash in the majority of infected people (modified Mazzotti reaction) but this is not routinely performed as it is unpleasant. Slit-lamp examination of the eyes may reveal the microfilariae. Serological tests are frequently positive in endemic areas, but this does not imply current infection. ELISA and Western blots have been used. Tests may be negative in expatriates with a low worm load.

Management and prevention

Ivermectin, in a single dose of 150 μg/kg, kills microfilariae and prevents their return for 6-12 months. There is little effect on adult worms, so annual (or more frequent) retreatment is needed. In patients co-infected with *Loa loa,* ivermectin may occasionally induce severe allergic reactions, including a toxic encephalopathy.

Since 1974 the WHO Onchocerciasis Control Programme has had a considerable impact on onchocerciasis in West Africa. A combination of vector control measures and, more recently, mass treatment with ivermectin, has led to a decrease in both infection rates and progression to serious disease. Humans are the only host but measures are required over a long period because of the longevity of the worm (10-15 years).

Mansonellosis

Mansonella perstans is a filarial worm transmitted by biting midges of the genus *Culicoides.* Small numbers of microfilariae are found in the blood, and although they do not cause serious disease there may be minor allergic reactions and an eosinophilia.

Dracunculiasis

Infection with the Guinea worm, *Dracunculus medinensis,* occurs when water fleas containing the parasite larvae are swallowed in contaminated drinking water. Ingested larvae mature, penetrate the intestinal wall, and mate, after which the male usually dies. The female worm, which can reach over a metre in length, migrates through connective and subcutaneous tissue for 9-18 months before surfacing, usually on the skin of the leg. An allergic blister forms, and then bursts, exposing the anterior end of the worm. The uterus of the worm ruptures, releasing larvae: the worm is attracted to the surface by cooling, and so the larvae are likely to be deposited in water. They are ingested by the small crustacean water fleas, and the cycle is completed. The disease is found in sub-Saharan Africa, Egypt, the Arabian peninsula, and parts of Central Asia (India is now Guinea worm free). It is usually acquired by people collecting water at water holes.

A persistent skin ulcer may develop at the site of rupture: bacterial infection is common, and tetanus can occur. If the worm is broken there may be a systemic allergic reaction.

The diagnosis is usually clinical.

The traditional treatment, extracting the worm over several days by winding it round a stick, is probably still the most effective. The worm should not be damaged. Antibiotics may be needed to control secondary infection. Anthelminthic drugs are of little value.

Water fleas (and thus infective larvae) can be removed from drinking water by chemical treatment or by simple filtration. Large-scale eradication programmes have been in place for several years and the incidence *oi* infecticm has fallen dramatically, with only 75 000 cases reported in the year 2000: 75% of these were from the Sudan. Man is the only host of *D. medinensis,* and it should therefore be possible to completely eradicate this parasite.

Human intestinal nematodes

Adult intestinal nematodes (also sometimes referred to as soil-transmitted helminths, or geohelminths) live in the human gut. There are two main types of life cycle, both including a soil-based stage. In some cases infection is spread by ingestion of eggs (which often require a period of maturation in the environment), while in others the eggs hatch in the soil and larvae penetrate directly through the skin of a new host (Fig. 2.34). *Ascaris lumbricoides* deviates from the simplified life cycle shown in that the larvae invade the duodenum and enter the venous system, via which they reach the lungs. They are eventually expectorated and swallowed, entering the intestine where they complete their maturation. Strongyloides is also unusual, in that it is the only nematode that is able to complete its life cycle in humans. Larvae may hatch before leaving the colon, and so are able to reinfect the host by penetrating the intestinal wall and entering the venous system.

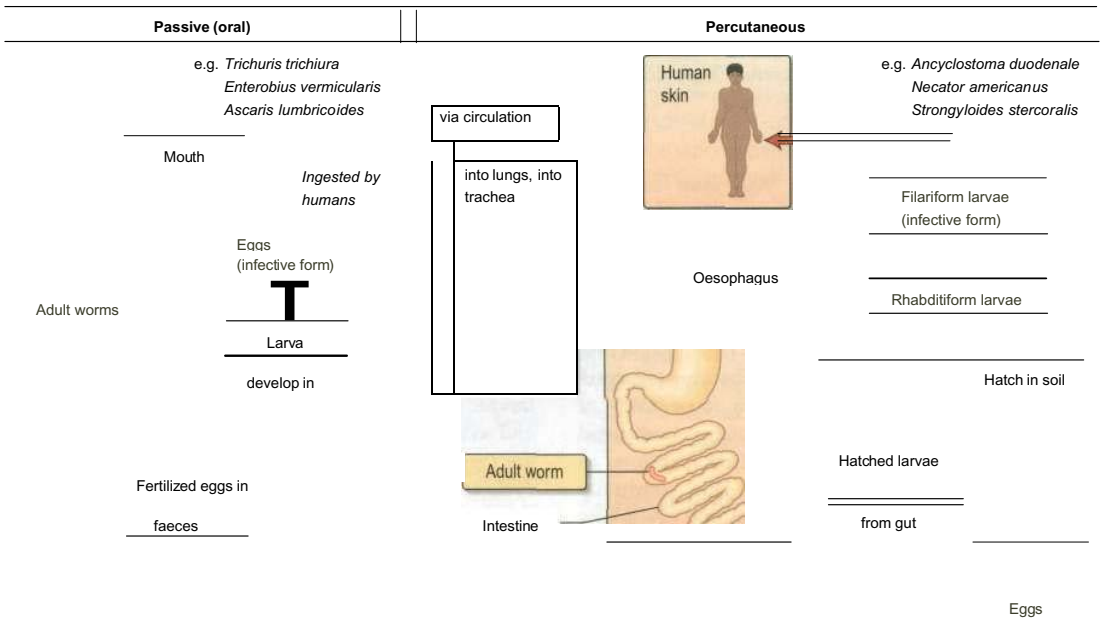

Fig. 2.34 A schematic life cycle of intestinal nematodes.

Ascariasis (roundworm infection)

A. lumbricoides is a pale yellow worm, 20-35 cm in length (Fig. 2.35). It is found world-wide but is particularly common in poor rural communities, where there is heavy faecal contamination of the immediate environment. Larvae migrate through the tissues to the lungs before being expectorated and swallowed; adult worms are found in the small intestine. Ova are deposited in faeces, and require a 2- to 4-month maturation in the soil before they are infective.

Infection is usually asymptomatic, although heavy infections are associated with nausea, vomiting, abdominal discomfort and anorexia. Worms can sometimes obstruct the small intestine, the most common site being at the ileocaecal valve. They may also occasionally invade the appendix, causing acute appendicitis, or the bile duct, resulting in biliary obstruction and suppurative cholangitis. Larvae in the lung may produce pulmonary eosinophilia. Heavy infection in children, especially those who are already malnourished, may have significant effects on nutrition and development. Serious morbidity and mortality are rare in ascariasis, but the huge number of people infected means that on a global basis roundworm infection causes a significant burden of disease, especially in children.

Fig. 2.35 ***Ascaris lumbricoides,*** **approximately 20 cm long.**

Ascaris eggs can be identified in the stool, and occasionally adult worms emerge from the mouth or the anus. They may also be seen on barium enema studies. Appropriate drug treatments are shown in Box 2.15. Very rarely, surgical or endoscopic intervention may be required for intestinal or biliary obstruction.

Threadworm *(Enterobius vermicularis)*

E. vermicularis is a small (2-12 mm) worm, which is common throughout the world. Larval development takes place mainly in the small intestine, and adult worms are normally found in the colon. The gravid female deposits eggs around the anus causing intense itching, especially at night. Unlike *A. lumbricoides,* the eggs do not require a maturation period in soil, and infection is often directly transmitted from anus to mouth via the hands. Eggs may also be deposited on clothing and bed linen, and are subsequently either ingested or inhaled. Apart from discomfort and local excoriation, infection is usually harmless.

Ova can be collected either using a moistened perianal swab, or by applying adhesive cellophane tape to the perianal skin. They can then be identified by microscopy.

The most commonly used drugs in the UK are mebendazole and piperazine (Box 2.15). However, isolated treatment of an affected person is often ineffective. Other family members (especially small children) may also need to be treated, and the whole family should be given advice about personal hygiene. Two courses of treatment 2 weeks apart may break the cycle of autoinfection.

Whipworm *(Trichuris trichiura)*

Infections with whipworm are common world-wide, especially in poor communities with inadequate sanitation.

Box 2.15 **Drugs used for treating human intestinal nematodes (single dose unless otherwise stated)**

		Ascaris	Hookworm	*Enterobius*	*Trichuris*	*Strongyloides*

++, highly effective; +, moderately effective; -, ineffective; n/a, drug not used for this indication/no data available

* Twice daily for 3 days in strongyloidiasis

t WHO recommended dose for developing countries; in UK commonly given as 100 mg single dose for threadworm, or 100 mg twice daily for 3 days for whipworm

* Once daily for 2 days

Adult worms, which are 3-5 cm long, inhabit the terminal ileum and caecum, although in heavy infection they are found throughout the large bowel. The head of the worm is embedded in the intestinal mucosa. Ova are deposited in the faeces, and require a maturation period of 3-4 weeks in the soil before becoming infective.

Infection is usually asymptomatic, but mucosal damage can occasionally be so severe that there is colonic ulceration, dysentery, or rectal prolapse.

Diagnosis is made by finding ova on stool microscopy, or occasionally by seeing adult worms on sigmoidoscopy. Drug treatment is shown in Box 2.15.

Hookworm infection

Hookworm infections, caused by the human hookworms *Ancylostoma duodenale* and *Necator americanus,* are found world-wide. They are relatively rare in developed countries, but very common in areas with poor sanitation and hygiene: overall about 25% of the world's population are affected. Hookworm infection is a major contributing factor to anaemia in the tropics. *A. duodenale* is found mainly in East Asia, North Africa and the Mediterranean, while *N. americanus* is the predominant species in South and Central America, South East Asia and sub-Saharan Africa.

Adult worms (which are about 1 cm long) live in the duodenum and upper jejunum, where they are often found in large numbers. They attach firmly to the mucosa using the buccal plate, feeding on blood. Eggs passed in the faeces develop in warm moist soil, producing infective filariform larvae. These penetrate directly through the skin of a new host, and are carried in the bloodstream to the lungs. Having crossed into the alveoli, the parasites are expectorated and then swallowed, thus arriving at their definitive home.

Clinical features

Local irritation as the larvae penetrate the skin ('ground itch') may be followed by transient pulmonary signs and symptoms, often accompanied by eosinophilia. Light infections, especially in a well-nourished person, are often asymptomatic. Heavier worm loads may be associated with epigastric pain and nausea, resembling peptic ulcer disease. Chronic heavy infection, particularly on a background of malnourishment, may cause iron deficiency anaemia. Blood loss has been estimated at about 0.15 mL/worm/day for *A. duodenale,* and 0.03 mL/worm/day for *N. americanus;* other factors may also be involved in the development of anaemia, which may be accompanied by hypoproteinaemia. Heavy infection in children is associated with delays in physical and mental development.

Diagnosis and treatment

The diagnosis is made by finding eggs on faecal microscopy. In infections heavy enough to cause anaemia these will be present in large numbers. The aim of treatment in endemic areas is reduction of worm burden rather than complete eradication: albendazole or mebendazole, which can both be given as a single dose, are the best drugs (Box 2.15). The WHO is promoting mass treatment programmes for schoolchildren in many parts of the world, together with treatment for schistosomiasis where appropriate.

Strongyloidiasis

Strongyloides stercoralis is a small (2 mm long) worm which lives in the small intestine. It is found in many parts of the tropics and subtropics, and is especially common in Asia. Eggs hatch in the bowel, and larvae are found in the stool. Usually these are non-infective rhabditiform larvae, which require a further period of maturation in the soil before they can infect a new host, but sometimes this maturation can occur in the large bowel. Infective filariform larvae can therefore penetrate directly through the perianal skin, reinfecting the host. In this way autoinfection may continue for years or even decades. Some war veterans who were imprisoned in the Far East during the Second World War have been found to have active strongyloidiasis over 50 years later. After skin penetration the life cycle is similar to that of the hookworm, except that the adult worms may burrow into the intestinal mucosa, causing a local inflammatory response.

Clinical features

Skin penetration by *S. stercoralis* causes a similar local dermatitis to hookworm. In autoinfection this manifests as a migratory linear weal around the buttocks and lower abdomen (cutaneous larva currens). In heavy infections damage to the small intestinal mucosa can cause malabsorption, diarrhoea and even perforation. There is usually a persistent eosinophilia. In patients who are immunosuppressed (e.g. by corticosteroid therapy or intercurrent illness) filariform larvae may penetrate directly through the bowel wall in huge numbers, causing an overwhelming and usually fatal generalized infection (the strongyloidiasis hyperinfestation syndrome). This condition is often complicated by septicaemia due to bowel organisms.

Diagnosis and treatment

Motile larvae may be seen on stool microscopy, especially after a period of incubation. Serological tests are also useful. The best drug for treating strongyloidiasis is ivermectin (200 Hg/kg daily for 2 days); albendazole and tiabendazole are also used.

Zoonotic nematodes

A number of nematodes which are principally parasites of animals may also affect man. The most common are described below.

Trichinosis

The normal hosts of *Trichinella spiralis,* the cause of trichinosis, include pigs, bears and warthogs. Man is infected by eating undercooked meat from these animals. Ingested larvae mature in the small intestine, where adults release new larvae which penetrate the bowel wall and migrate through the tissues. Eventually these larvae encyst in striated muscle.

Light infections are usually asymptomatic. Heavier loads of worms produce gastrointestinal symptoms as the adults establish themselves in the small intestine, followed by systemic symptoms as the larvae invade. The latter include fever, oedema, and myalgia. Massive infection may occasionally be fatal, but usually the symptoms subside once the larvae encyst.

The diagnosis can usually be made from the clinical picture, associated eosinophilia, and serological tests. If necessary it can be confirmed by muscle biopsy a few weeks after infection. Albendazole (20 mg/kg for 7 days) given early in the course of the illness will kill the adult worms and decrease the load of larvae reaching the tissues. Analgesia and steroids may be needed for symptomatic relief.

Toxocariasis (visceral larva migrans)

Eggs of the dog roundworm, *Toxocara canis,* are occasionally ingested by humans, especially children. The eggs hatch and the larvae penetrate the small intestinal wall and enter the mesenteric circulation, but are then unable to complete their life cycle in a 'foreign' host. Many are held up in the capillaries of the liver, where they generate a granulomatous response, but some may migrate into other tissues including lungs, striated muscle, heart, brain, and eye. In most cases infection is asymptomatic, and the larvae die without causing serious problems. In heavy infections there may be generalized symptoms (fever and urticaria) and eosinophilia, as well as focal signs related to the migration of the parasites. Pulmonary involvement may cause bronchospasm and chest X-ray changes. Ocular infection may produce a granulomatous swelling mimicking a retinoblastoma, while cardiac or neurological involvement may occasionally be fatal. Rarely, larvae survive in the tissues for many years, causing symptoms long after infection.

Isolation of the larvae is difficult, and the diagnosis is usually made serologically. Albendazole 400 mg daily for a week is the most effective treatment.

Cutaneous larva migrans (CLM)

CLM is caused by the larvae of the non-human hookworms *Ancylostoma braziliense* and *A. caninum.* Like human hookworms, these hatch in warm moist soil, and then penetrate the skin. In man they are unable to complete a normal life cycle, and instead migrate under the skin for days or weeks until they eventually die. The wandering of the larva is accompanied by a clearly-defined, serpiginous, itchy rash ('creeping eruption'), which progresses at the rate of about 1 cm per day. There are usually no systemic symptoms. The diagnosis is purely clinical. Single larvae may be treated with a 10% solution of topical tiabendazole; multiple lesions may require systemic therapy with tiabendazole or albendazole or ivermectin.

TREMATODES

Trematodes (flukes) are flat leaf-shaped worms. They have complex life cycles, often involving fresh water snails and intermediate mammalian hosts. Disease is caused by the inflammatory response to eggs or to the adult worms.

Water-borne flukes

Schistosomiasis

Schistosomiasis affects over 200 million people in the tropics and subtropics, most of whom live in sub-Saharan Africa. Chronic infection causes significant morbidity, and after malaria it has the most socio-economic impact of any parasitic disease. Schistosomiasis is largely a disease of the rural poor, but has also been associated with major development projects such as dams and irrigation schemes.

Parasitology and pathogenesis

There are three main species of schistosome which commonly cause disease in man: *Schistosoma mansoni, S. haematobium,* and *S. japonicum. S. intercalatum* and *S. mekongi* are less important. The geographical distribution is shown in Figure 2.36. Eggs are passed in the urine or faeces of an infected person, and hatch in fresh water to release the miracidia (Fig. 2.37). These ciliated organisms penetrate the tissue of the intermediate host, a species of water snail specific to each species of schistosome. After multiplying in the snail, large numbers of fork-tailed cercariae are released back into the water, where they can survive for 2-3 days. During this time the cercariae can penetrate the skin or mucous membranes of the definitive host, man. Transforming into schistosomulae, they pass through the lungs before reaching the portal vein, where they mature into adult worms (the male is about 20 mm long, and the female a little larger). Worms pair in the portal vein before migrating to their final destination: mesenteric veins in the case of S. *mansoni* and *S. japonicum,* and the vesicular plexus for *S. haematobium.* Here they may remain for many years, producing vast numbers of eggs. The majority of these are released in urine or faeces, but a small number become embedded in the bladder or bowel wall, and a few are carried in the circulation to the liver or other distant sites.

The pathology of schistosome infection varies with species and stage of infection. In the early stages there may be local and systemic allergic reactions to the migrating parasites. As eggs start to be deposited there may be a local inflammatory response in the bowel or bladder, while ectopic eggs may produce granulomatous lesions anywhere in the body. Chronic heavy infection, in

fi3

which large numbers of eggs accumulate in the tissues, leads to fibrosis, calcification, and in some cases, dysplasia and malignant change. Morbidity and mortality are related to duration of infection and worm load, as well as to the species of parasite. Children in endemic areas tend to have the heaviest worm load, because of both increased exposure to infection, and differences in the immune response between adults and children.

Clinical features

Cercarial penetration of the skin may cause local dermatitis ('swimmer's itch'). After a symptom-free period of *3-i* weeks, systemic allergic features may develop, including fever, rash, myalgia, and pneumonitis (Katayama fever). These allergic phenomena are common in non-immune travellers, but are rarely seen in local populations, who are usually exposed to infection from early childhood onwards. If infection is sufficiently heavy, symptoms from egg deposition may start to appear 2-3 months after infection.

S. *haematobium infection (bilharzia).* The earliest symptom is usually painless terminal haematuria. As bladder inflammation progresses there is increased urinary frequency and groin pain. Obstructive uropathy develops, leading to hydronephrosis, renal failure, and recurrent urinary infection. There is a strong association between chronic urinary schistosomiasis and squamous cell bladder carcinoma. The genitalia may also be affected, and ectopic eggs may cause pulmonary or neurological disease.

S. *mansoni* usually affects the large bowel. Early disease produces superficial mucosal changes, accompanied by blood-stained diarrhoea. Later the mucosal damage becomes more marked, with the formation of rectal polyps, deeper ulceration, and eventually fibrosis and stricture formation. Ectopic eggs are carried to the liver, where they cause an intense granulomatous response. Hepatitis is followed by progressive periportal fibrosis, leading to portal hypertension, oesophageal varices and splenomegaly (p. 392). Hepatocellular function is usually well preserved.

S. *japonicum,* unlike the other species, infects numerous other mammals apart from man. It is similar to *S. mansoni,* but infects both large and small bowel, and produces a greater number of eggs. Disease therefore tends to be more severe, and rapidly progressive. Hepatic involvement is more common, and neurological involvement is seen in about 5% of cases.

Diagnosis

Schistosomiasis is suggested by relevant symptoms following fresh water exposure in an endemic area. In the early allergic stages the diagnosis can only be made clinically. When egg deposition has started, the characteristic eggs (with a terminal spine in the case of *S. haematobium,* and a lateral spine in the other species) can be detected on microscopy. In *S. haematobium* infection, the best specimen for examination is a filtered mid-day urine sample. Parasites may also be found in semen, and in rectal snip preparations. S. *mansoni* and *S. japonicum* eggs can usually be found in faeces or in a rectal snip. Serological tests are available, and may be useful in the diagnosis of travellers returning from endemic areas, although the test may not become positive for 12 weeks after infection: a parasitological diagnosis should always be made if possible. X-rays, ultrasound examinations, and endoscopy may show abnormalities of the bowel or urinary tract in chronic disease, although these are non-specific. Liver biopsy may show the characteristic periportal fibrosis.

Management

The aim of treatment in endemic areas is to decrease the worm load and therefore minimize the chronic effects of egg deposition. It may not always be possible (or even desirable) to eradicate adult worms completely, and reinfection is common. However, a 90% reduction in egg output has been achieved in mass treatment programmes, and in light infections where there is no risk of re-exposure the drugs are usually curative. The most widely used is praziquantel (40 mg/kg as a single dose), which is effective against all species of schistosome, well-tolerated, and reasonably cheap.

Prevention

Prevention of schistosomiasis is difficult, and relies on a combination of approaches. Mass treatment of the population (especially children) will decrease the egg load in the community. Health education programmes, the provision of latrines, and access to a safe water supply should decrease the contact with infected water. Attempts to eradicate the snail host have generally been unsuccessful, although man-made bodies of water can often be made less 'snail-friendly'. Travellers should be advised to avoid potentially infected water. Oral artemether is safe and shows a prophylactic effect against *S. mansoni.*

Food-borne flukes

Many flukes infect man via ingestion of an intermediate host, often fresh water fish.

Paragonimiasis

Over 20 million people are infected with lung flukes of the genus *Paragonimus.* The adult worms (of which the major species is *P. westermani)* live in the lungs, producing eggs which are expectorated or swallowed and passed in

the faeces. Miracidia emerging from the eggs penetrate the first intermediate host, a fresh water snail. Larvae released from the snail seek out the second intermediate host, fresh water Crustacea, in which they encyst as metacercariae. Humans and other mammalian hosts become infected after consuming uncooked shellfish. Cercariae penetrate the small intestinal wall, and migrate directly from the peritoneum to the lungs across the diaphragm. Having established themselves in the lung, the adult worms may survive for 20 years.

The common clinical features are fever, cough and mild haemoptysis. In heavy infections the disease may progress, sometimes mimicking pneumonia or pulmonary tuberculosis. Ectopic worms may cause signs in the abdomen or the brain.

The diagnosis is made by detection of ova on sputum or stool microscopy. Serological tests are also available. Radiological appearances are variable and non-specific. Treatment is with praziquantel 25 mg/kg three times daily for 3 days. Prevention involves avoidance of inadequately cooked shellfish.

Liver flukes

The human liver flukes, *Clonorchis sinensis, Opisthorchis felineus,* and *O. viverrini,* are almost entirely confined to East and South East Asia, where they infect more than 20 million people. Adults live in the bile ducts, releasing eggs into the faeces. The parasite requires two intermediate hosts, a fresh water snail and a fish, and humans are infected by consumption of raw fish. The cycle is completed when excysted worms migrate from the small intestine into the bile ducts.

Infection is often asymptomatic, but may be associated with cholangitis and biliary carcinoma. The diagnosis is made by identifying eggs on stool microscopy. Treatment is with a single dose of praziquantel (40 mg/kg), and infection can be avoided by cooking fish adequately.

Other fluke infections

Man can also be infected with a variety of animal flukes, notably the liver fluke *Fasciola hepatica,* and the intestinal fluke *Fasciolopsis bush.* Both require a water snail as an intermediate host; cercariae encyst on aquatic vegetation, and then are consumed by animals or man. After ingestion, *F. hepatica* penetrates the intestinal wall before migrating to the liver: during this stage it causes systemic allergic symptoms. After reaching the bile ducts, it causes similar problems to those of the other liver flukes. F. *buski* does not migrate after it excysts, and causes mainly bowel symptoms.

The best treatment for F. *buski* is praziquantel 25 mg/kg, three doses in 24 hours, and for F. *hepatica,* triclabendazole 10 mg/kg as a single dose (which may need repeating).

CESTODES

Cestodes (tapeworms) are ribbon-shaped worms which vary from a few millimetres to several metres in length. Adult worms live in the human intestine, where they attach to the epithelium using suckers on the anterior portion (scolex). From the scolex arises a series of progressively developing segments, called proglottids. The mature distal segments contain eggs, which may either be released directly into the faeces, or are carried out with an intact detached proglottid. The eggs are consumed by intermediate hosts, after which they hatch into larvae (oncospheres). These penetrate the intestinal wall of the host (pig or cattle) and encyst in the tissues. Man ingests the cysts in undercooked meat or fish, and the cycle is completed when the parasites excyst in the stomach and develop into adult worms in the small intestine. Infections are usually solitary, but several adult tapeworms may coexist. The exceptions to this life cycle are the dwarf tapeworm, *Hymenolepis nana,* which has no intermediate host and is transmitted from person to person by the faeco-oral route and *Taenia solium* which produces cysticercosis (see below).

Taenia saginata

T. saginata, the beef tapeworm, may reach a length of several metres. It is common in all countries where undercooked beef is eaten. The adult worm causes few if any symptoms. Infection is usually discovered when proglottids are found in faeces or on underclothing, often causing considerable anxiety. Ova may also be seen on stool microscopy. Infection can be cleared with a single dose of praziquantel (10 mg/kg). It can be prevented by careful meat inspection, or by thorough cooking of beef.

Taenia solium and cysticercosis

T. solium, the pork tapeworm, is generally smaller than *T. saginata,* although it can still reach 6 metres in length. It is particularly common in South America, South Africa, China, and parts of South East Asia. As with *T. saginata* infection is usually asymptomatic. The ova of the two species are identical, but the proglottids can be distinguished on inspection.

Tapeworms are mainly acquired by eating uncooked pork while cysticercosis follows the ingestion of eggs from contaminated food and water. Faeco-oral autoinfection can occur but is rare. Patients with tapeworms do not usually develop cysticercosis and patients with cysticercosis do not usually harbour tapeworms. Following the ingestion of eggs, the larvae are liberated, penetrate the intestinal wall, and are carried to various parts of the body where they develop into cysticerci (Fig. 2.38). These are cysts, 0.5-1 cm diameter, containing the scolex of a new adult worm. Common sites for cysticerci include subcutaneous tissue, skeletal muscle and brain.

Superficial cysts may be felt under the skin, but usually cause no significant symptoms. Cysts in the brain can cause a variety of problems including epilepsy, personality change, hydrocephalus and focal neurological signs (p. 1241). These may only appear many years after infection.

Muscle cysts tend to calcify, and are often visible on X-rays. Cutaneous cysts can be excised and examined. Brain cysts are less prone to calcification, and are often

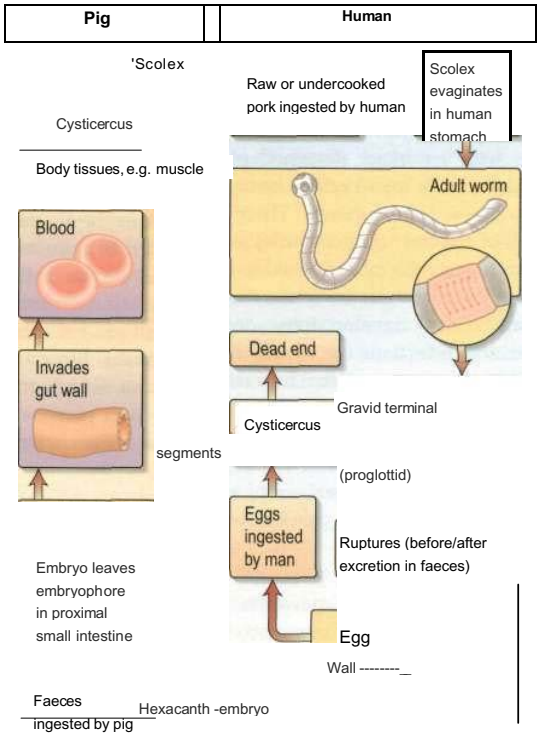

fig. 2.38 A schematic life cycle of *Taenia solium.*

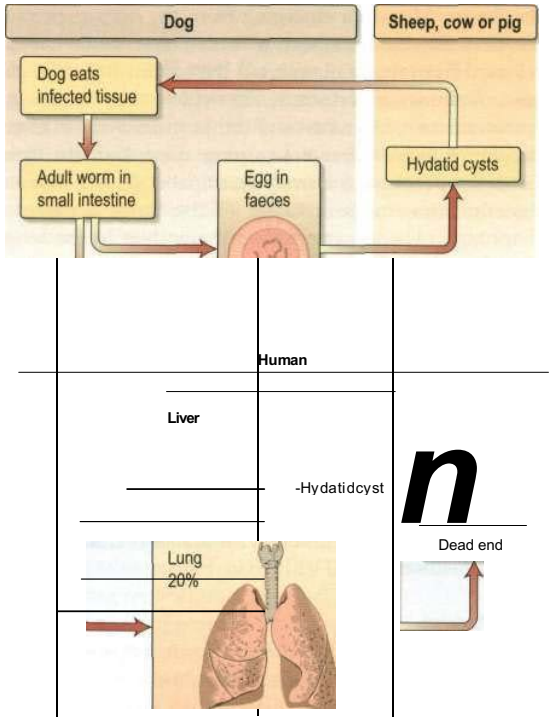

Fig. 2.39 A schematic life cycle of *Echinococcus granulosus.*

only seen on CT or MRI scan. Serological tests may support the diagnosis.

Treatment is again with praziquantel: niclosamide 1 g repeated after 2 hours is also effective. There is no evidence that drug treatment should be accompanied by a purgative, as was previously believed.

Treatment of cerebral cysticercosis (p. 1241)

The role of anthelminthics in cysticercosis remains controversial. Even in neurocysticercosis there is little evidence of benefit, although symptomatic patients with viable neurocysts should probably be treated. Albendazole 15 mg/kg daily for 8-20 days is the drug of choice; the alternative is praziquantel 50 mg/kg daily (in divided doses) for 15 days.

Successful treatment is accompanied by increased local inflammation, and corticosteroids should be given during and after the course of anthelminthic. Anticonvulsants should be given for epilepsy, and surgery may be indicated if there is hydrocephalus. Prevention of cysticercosis depends on good hygiene, as well as on the eradication of human *T. solium* infection.

Diphyllobothrium latum

Infection with the fish tapeworm, D. *latum,* is common in northern Europe and Japan, owing to the consumption of raw fish. The adult worm reaches a length of several metres, but like the other tapeworms usually causes no symptoms. A megaloblastic anaemia (due to competitive utilization of B_{12} by the parasite) may occur. Diagnosis and treatment are the same as for *Taenia* species.

Hydatid disease

Hydatid disease occurs when humans become an intermediate host of the dog tapeworm, *Echinococcus granulosus* (Fig. 2.39). The adult worm lives in the gut of domestic and wild canines, and the larval stages are usually found in sheep, cattle and camels. Man may become infected either from direct contact with dogs, or from food or water contaminated with dog faeces. After ingestion the parasites excyst, penetrate the small intestine wall, and are carried to the liver and other organs in the bloodstream. A slow-growing, thick-walled cyst is formed, inside which further larval stages of the parasite develop. The life cycle cannot be completed unless the cyst is eaten by a dog. Hydatid disease is prevalent in areas where dogs are used in the control of livestock, especially sheep. It is common in Australia, Argentina, the Middle East, and parts of East Africa; small foci of infection are still found in North Wales and rural Scotland.

Symptoms depend mainly on the site of the cyst. The liver is the most common organ affected (60%), followed by the lung (20%), kidneys (3%), brain (1%) and bone (1 %). The symptoms are those of a slowly growing benign tumour. Pressure on the bile ducts may cause jaundice. Rupture into the abdominal cavity, pleural cavity or biliary tree may occur. In the latter situation, intermittent jaundice, abdominal pain and fever associated with

eosinophilia result. A cyst rupturing into a bronchus may result in its expectoration and spontaneous cure, but if secondary infection supervenes a chronic pulmonary abscess will form. Focal seizures can occur if cysts are present in the brain. Renal involvement produces lumbar pain and haematuria. Calcification of the cyst occurs in about 40% of cases.

A related parasite of foxes, *E. multilocularis,* causes a similar but more severe infection, alveolar hydatid disease. These cysts are invasive and metastases may occur.

The diagnosis and treatment of hydatid liver disease are described on page 392.

ARTHROPOD ECTOPARASITES

Arthropods, which include the arachnid ticks and mites as well as insects, may be responsible for human disease in several ways.

Local hypersensitivity reactions

Local lesions may be caused by hypersensitivity to allergens in arthropod saliva. This common reaction, known as papular urticaria, is non-specific and is seen in the majority of people in response to the bite of a variety of blood-sucking arthropods including mosquitoes, bugs, ticks, lice, and mites. Occasionally tick bites may cause a more severe systemic allergic response, especially in previously sensitized individuals.

Most of these parasites alight on man only to feed, but some species of lice live in very close proximity to the skin: body lice in clothing, and head and pubic lice on human hairs (p. 1325).

Resident ectoparasite infections

Other ectoparasites are actually resident within the skin, causing more specific local lesions.

Scabies (p. 1325)

Jiggers

Jiggers is due to infection with the jigger flea, *Tunga penetrans,* and is common throughout South America and Africa. The pregnant female flea burrows into the sole of the foot, often between the toes. The egg sac grows to about 0.5 cm in size, before the eggs are discharged onto the ground. The main danger is bacterial infection or tetanus. The flea should be removed with a needle or scalpel, and the area kept clean until it heals.

Myiasis

Myiasis is caused by invasion of human tissue by the larva of certain flies, principally the Tumbu fly, *Cordylobia anthropophaga* (found in sub-Saharan Africa), and the human botfly, *Dermatobia hominis* (Central and South America). The larvae, which hatch from eggs laid on laundry and linen, burrow into the skin to form boil-like lesions: a central breathing orifice may be visible. Again, the main risk is secondary infection. It is not always easy to extract the larva: covering it with petroleum jelly may bring it up in search of air.

Systemic envenoming

Many arthropods can cause local or systemic illness through envenoming, i.e. injection of venom.

The main role of arthropods in causing human disease is as vectors of parasitic and viral infections. Some of these infections are shown in Table 2.4, and discussed in detail elsewhere.

SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) are among the most common causes of illness in the world and remain epidemic in all societies. The public health, social and economic consequences are extensive, both of the acute infections and their longer-term sequelae. There has been a recent sharp increase in the incidence of STIs in the UK (as in the rest of the world). New presentations at genitourinary medicine (GUM) clinics in the UK rose by 37% from 1 546 812 in 2002 to 2 125 243 in 2003.

Between 1997 and 2002 there has been an increase in both gonorrhoea (97%) and syphilis (716%) infections. There has been a steady rise in the incidence of *Chlamydia trachomatis* with a 103% increase over the same time period. Viral conditions, particularly herpes simplex virus (HSV) and human papillomavirus, have also increased substantially. Increased numbers may also reflect recent public health campaigns promoting STI screening and the use of increasingly sensitive diagnostic tests. Substantial rises in human immunodeficiency virus (HIV) infection in the UK have further heightened awareness of STIs. In 2002 over 49 000 adults were estimated to have HIV, with up to one-third being unaware of their infection. Many people attend GUM clinics to seek information, advice and checks of their sexual health, but have no active STI.

Those most likely to acquire STIs are young people, homo- and bisexual men and black and ethnic minority populations. Changes in incidence reflect high-risk sexual behaviour and inconsistent use of condoms. Increased

travel both within and between countries, recreational drug use, alcohol and more frequent partner change are also implicated. Multiple infections frequently coexist, some of which may be asymptomatic and facilitate spread.

Approach to the patient

Patients presenting with possible STIs are frequently anxious, embarrassed and concerned about confidentiality. Staff must be alert to these issues and respond sensitively. The clinical setting must ensure privacy and reinforce confidentiality.

History

The history of the presenting complaint frequently focuses on genital symptoms, the three most common being vaginal discharge (Table 2.46), urethral discharge (Table 2.47), and genital ulceration (Table 2.48). Details should be obtained of any associated fever, pain, itch, malodour, genital swelling, skin rash, joint pains and eye symptoms. All patients should be asked about dysuria, haematuria and loin pain. A full general medical, family and drug history, particularly of any recent antibacterial or antiviral treatment, allergies and use of oral contraceptives, must be obtained. In women, menstrual, contraception and obstetric history should be obtained. Any past or current history of drug misuse should be explored.

A detailed sexual history should be taken and include the number and types of sexual contacts (genital/genital, oral/genital, anal/genital, oral/anal) with dates, partner's sex, whether regular or casual partner, use of condoms and other forms of contraception, previous history of STIs including dates and treatment received, HIV testing and results and hepatitis B vaccination status.

Enquires should be made concerning travel abroad to areas where antibiotic resistance is known or where particular pathogens are endemic.

Examination

General examination must include the mouth, throat, skin and lymph nodes in all patients. Signs of HIV infection are covered on page 144. The inguinal, genital and perianal areas should be examined with a good light source. The groins should be palpated for lymphadenopathy and hernias. The pubic hair must be examined for nits and lice. The external genitalia must be examined for signs of erythema, fissures, ulcers, chancres, pigmented or hypopigmented areas and warts. Signs of trauma may be seen.

In men, the penile skin should be examined and the foreskin retracted to look for balanitis, ulceration, warts or tumours. The urethral meatus is located and the presence of discharge noted. Scrotal contents are palpated and the consistency of the testes and epididymis noted. A rectal examination/proctoscopy should be performed in patients with rectal symptoms, those who practise anoreceptive intercourse and patients with prostatic symptoms. A search for rectal warts is indicated in patients with perianal lesions.

Table 2.46 **Causes of vaginal discharge**

Infective	Non-infective
Candida albicans	Cervical polyps
Trichomonas vaginalis	Neoplasms
Bacterial vaginosis	Retained products (e.g. tampons)
Neisseria gonorrhoeae	Chemical irritation
Chlamydia trachomatis	
Herpes simplex	

Table 2.47 **Causes of urethral discharge**

Infective	Non-infective
Neisseria gonorrhoeae	Physical or chemical trauma
Chlamydia trachomatis	Urethral stricture Non-specific (aetiology unknown)
Mycoplasma genitilium	
Ureaplasma urealyticum	
Trichomonas vaginalis Herpes simplex virus Human papillomavirus (meatal warts) Urinary tract infection (rare)	
Treponema pallidum (meatal chancre)	

Table 2.48 **Causes of genital ulceration**

Infective	Non-infective
Syphilis:	Behget's syndrome Toxic epidermal necrolysis
Primary chancre	Stevens-Johnson syndrome
Secondary mucous patches	Carcinoma
Tertiary gumma Chancroid	Trauma
Lymphogranuloma venereum	
Donovanosis Herpes simplex:	
Primary	
Recurrent	
Herpes zoster	

In women, Bartholin's glands must be identified and examined. The cervix should be inspected for ulceration, discharge, bleeding and ectopy and the walls of the vagina for warts. A bimanual pelvic examination is performed to elicit adnexal tenderness or masses, cervical tenderness, and to assess the position, size and mobility of the uterus. Rectal examination and proctoscopy are performed if the patient has symptoms or practises anoreceptive intercourse.

Investigations

Although the history and examination will guide investigation, it must be remembered that multiple infections may coexist, some being asymptomatic. Full screening is indicated in any patient who may have been in contact with an STL

In men

- Urethral smears for Gram staining
- Urethral swabs for gonococcal culture and *Chlamydia* testing

- Two-glass urine test and urinalysis
- Rectal swabs for Gram staining and culture for *N. gonorrhoeae* and C. *trachomatis*
- Throat swab for culture for *N. gonorrhoeae*
- Blood for syphilis and HIV serology (with counselling).

In women

- Smears from the lateral vaginal wall for Gram staining
- Vaginal swab for culture of *Candida* and *Trichomonas*
- A wet preparation is made from the posterior fornix for *Trichomonas* and for the potassium hydroxide test for bacterial vaginosis
- The pH of vaginal secretions using narrow-range indicator paper
- Endocervical smears and swabs for Gram staining, gonococcal culture and *Chlamydia* tests
- Urethral smears and swabs for Gram staining and gonococcal culture
- Rectal and throat swabs for *N. gonorrhoeae* and C. *trachomatis,* if indicated
- Urinalysis
- Cervical cytology
- Blood for syphilis and HIV serology (with counselling).

Additional investigations when indicated

- Urine sample for nucleic acid amplification tests if available locally
- Blood for hepatitis B and C serology
- Swabs for HSV and *Haemophilus ducreyi* from clinically suspicious lesions into special media
- Smears and swabs from the subpreputial area in men with balanoposthitis (inflammation of glans penis and prepuce) for candidiasis
- Scrapings from lesions suspicious of early syphilis for immediate dark-ground microscopy
- Pregnancy testing
- Cervical cytology
- Stools for *Giardia, Shigella* or *Salmonella* from those practising oral/anal sex.

Treatment, prevention and control

The treatment of specific conditions is considered in the appropriate section. Many GUM clinics keep basic stocks of medication and dispense directly to the patient.

Tracing the sexual partners of patients is crucial in controlling spread of STIs. The aims are to prevent the spread of infection within the community and to ensure that people with asymptomatic infection are properly treated. Appropriate antibiotic therapy may be offered to those who have had recent intercourse with someone known to have an active infection (epidemiological treatment). Interviewing people about their sexual partners requires considerable tact and sensitivity, and specialist health advisors are available in GUM climes.

Prevention starts with education and information. People begin sexual activity at ever-younger ages and education programmes need to include school pupils as well as young adults. Education of health professionals is also crucial. Public health campaigns aimed at informing groups at particular risk are being implemented at a national level. Appropriate and accessible services must be well advertised. Avoiding multiple partners, correct and consistent use of condoms and avoiding sex with people who have symptoms of infection may reduce the risks of acquiring an STI. For those who change their sexual partners frequently, regular check-ups (approximately 3-monthly) are advisable. Once people develop symptoms they should be encouraged to seek medical advice as soon as possible to reduce complications and spread to others.

Sexual assault

The medical and psychological management of people who have been sexually assaulted requires particular sensitivity and should be undertaken by an experienced clinician in ways that reduce the risks of further trauma. Post-traumatic stress disorder is common. Although most frequently reported by women, both women and men may suffer sexual assault. Investigations for and treatment of sexually transmitted infections in people who have been raped can be carried out in GUM departments. Collection of material for use as evidence, however, should be carried out within 7 days of the assault by a physician trained in forensic medicine and must take place before any other medical examinations are performed.

History

In addition to the general medical, gynaecological and contraceptive history, full details of the assault, including the exact sites of penetration, ejaculation by the assailant and condom use should be obtained, together with details of the sexual history both before and after the event.

Examination

Any injuries requiring immediate attention must be dealt with prior to any other examination or investigations. Accurate documentation of any trauma is necessary. Forced oral penetration may result in small palatal haemorrhages. In cases of forced anal penetration, anal examination including proctoscopy should be carried out, noting any trauma.

Investigations

A full STI screen at presentation with a second examination 2 weeks later is recommended. Cultures for *Neisseria gonorrhoeae* and tests for *Chlamydia trachomatis* should be obtained from all sites of actual or attempted penetration. C. *trachomatis* culture is the only test currently accepted as evidence. Gram-stained slides of urethral, cervical and rectal specimens for microscopy for gonococci should be performed. Bacterial vaginosis, yeasts and *Trichomonas vaginalis* (TV) tests should be carried out on vaginal material. Syphilis serology should be requested and a serum saved. Hepatitis B, HIV and hepatitis C testing should be offered. Specimens should be identified as having potential medicolegal implications.

Management

Preventative therapy for gonorrhoea and chlamydia may be advised using a single dose combination of ciprofloxacin 500 mg and azithromycin 1 g. Hep B vaccine should be offered and may be of value up to 3 weeks after the event. HIV prophylaxis may be offered within 72 hours of the assault, based upon a specific risk assessment. Post-coital oral contraception may be given within 72 hours of assault. Psychological care provision and appropriate referral to support agencies should be arranged. Sexual partners should be screened and treated if necessary.

Initial follow-up at 2 weeks should be arranged to review the patient's needs and the prophylaxis regimens that are in place, with further follow-up as needed.

CLINICAL SYNDROMES

HIV and **AIDS**

These are discussed in the section starting on page 129.

Gonorrhoea (GC)

Neisseria gonorrhoeae is a Gram-negative intracellular diplococcus (Fig. 2.40), which infects epithelium particularly of the urogenital tract, rectum, pharynx and conjunctivae. Humans are the only host and the organism is spread by intimate physical contact. It is very intolerant to drying and although occasional reports of spread by fomites exist, this route of infection is extremely rare.

Clinical features

Up to 50% of women and 10% of men are asymptomatic. The incubation period is 2-14 days with most symptoms occurring between days 2 and 5. In men the most common syndrome is one of anterior urethritis causing dysuria and/or urethral discharge (Fig. 2.41). Complications include ascending infection involving the epididymis or prostate leading to acute or chronic infection. In homosexual men rectal infection may produce proctitis with pain, discharge and itch.

In women the primary site of infection is usually the endocervical canal. Symptoms include an increased or altered vaginal discharge, pelvic pain due to ascending infection, dysuria, and intermenstrual bleeding. Complications include Bartholin's abscesses and in rare cases a perihepatitis (Fitzhugh-Curtis syndrome) can develop. On a global basis GC is one of the most common causes of female infertility. Rectal infection, due to local spread, occurs in women and is usually asymptomatic, as is pharyngeal infection. Conjunctival infection is seen in neonates born to infected mothers and is one cause of ophthalmia neonatorum.

Disseminated GC leads to arthritis (usually monoarticular or pauciarticular) (see p. 572) and characteristic papular or pustular rash with an erythematous base in association with fever and malaise. It is more common in

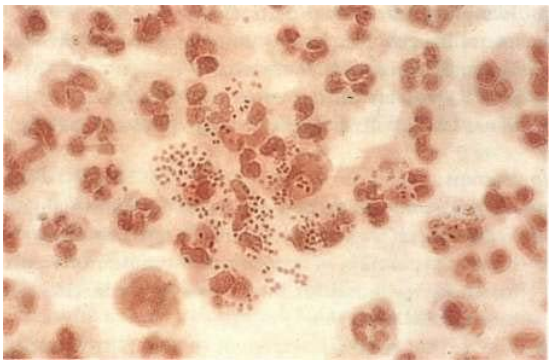

Fig. 2.40 ***Neisseria gonorrhoeae* - Gram-negative intracellular diplococci.** Courtesy of Dr B Goh.

Fig. 2.41 ***Neisseria gonorrhoeae* - purulent urethral discharge.** Courtesy of Dr B Goh.

Diagnosis

N. gonorrhoeae can be identified from infected areas by culture on selective media with a sensitivity of at least 95%. Microscopy of Gram-stained secretions may demonstrate intracellular, Gram-negative diplococci, allowing rapid diagnosis. The sensitivity ranges from 90% in urethral specimens from symptomatic men to 50% in endocervical specimens. Nucleic acid amplification tests (NAATs) using urine specimens are non-invasive and highly sensitive, although may give false positive results. Microscopy should not be used for pharyngeal specimens. Blood culture and synovial fluid investigations should be performed in cases of disseminated GC. Coexisting pathogens such as *Chlamydia, Trichomonas* and syphilis must be sought.

Treatment

Treatment is indicated in those patients who have a positive culture for GC, positive microscopy or a positive NAAT. Epidemiological treatment is given to patients

who have had recent sexual intercourse with someone with confirmed GC infection. Although *N. gonorrhoeae* is sensitive to a wide range of antimicrobial agents, antibiotic-resistant strains have shown a recent significant increase in the UK. Up to 10% of strains show resistance to penicillins and ciprofloxacin and over 40% resistance to tetracyclines. Immediate therapy based on Gram-stained slides is usually initiated in the clinic, prior to culture and sensitivity results. Antibiotic choice is influenced by travel history or details known from contacts.

Single-dose oral therapy with either cefixime (400 mg), ceftriaxone i.m. (250 mg) or spectinomycin 2 g i.m. (not generally available in the UK) successfully treats uncomplicated anogenital infection. Single-dose amoxicillin 3 g with probenecid 1 g, ciprofloxacin (500 mg) or ofloxacin (400 mg) are recommended for use in areas with low prevalence of antibiotic resistance.

Longer courses of antibiotics are required for complicated infections. There should be at least one follow-up assessment, and culture tests should be repeated at least 72 hours after treatment is complete. All sexual contacts should be examined and treated as necessary.

Chlamydia trachomatis (CT)

Genital infection with CT is common, with up to 5% of sexually active women in the UK infected. It is regularly found in association with other pathogens: 20% of men and 40% of women with gonorrhoea have been found to have coexisting chlamydial infections. In men 40% of non-gonococcal and post-gonococcal urethritis is due to *Chlamydia.* As CT is often asymptomatic much infection goes unrecognized and untreated, which sustains the infectious pool in the population. The long-term complications associated with *Chlamydia* infection, especially infertility, impose significant morbidity in the UK. The organism has a world-wide distribution.

Clinical features

In men CT gives rise to an anterior urethritis with dysuria and discharge; infection is asymptomatic in up to 50% and detected by contact tracing. Ascending infection leads to epididymitis. Rectal infection leading to proctitis occurs in men practising anoreceptive intercourse. *In women* the most common site of infection is the endocervix where it may go unnoticed; up to 80% of infection in women is asymptomatic. Symptoms include vaginal discharge, post-coital or intermenstrual bleeding and lower abdominal pain. Ascending infection causes acute salpingitis. Reiter's disease (see p. 568) has been related to infection with C. *trachomatis.* Neonatal infection, acquired from the birth canal, can result in mucopurulent conjunctivitis and pneumonia.

Diagnosis

CT is an obligate intracellular bacterium, which complicates diagnosis. Cell culture techniques provide the 'gold standard' but are expensive and require considerable expertise. Indirect diagnostic tests include direct fluorescent antibody (DIF) tests, enzyme immunoassays (EIA) and nucleic acid amplification techniques such as PCR or ligase chain reaction (LCR): none is diagnostic.

In men first-voided urine samples are tested, or urethral swabs obtained. In women endocervical swabs are the best specimens, and up to 20% additional positives will be detected if urethral swabs are also taken. Urine specimens are much less reliable than endocervical swabs in women and are not recommended. Specimen quality is critical and it must contain cellular material.

Treatment

Tetracyclines or macrolide antibiotics are most commonly used to treat *Chlamydia.* Doxycycline 100 mg 12-hourly for 7 days or azithromycin 1 g as a single dose are both effective for uncomplicated infection. Tetracyclines are contraindicated in pregnancy. Other effective regimens include erythromycin 500 mg four times daily. Routine test of cure is not necessary after treatment with doxycycline or azithromycin, although if symptoms persist or reinfection is suspected then further tests should be taken. Sexual contacts must be traced and treated, particularly as so many infections are clinically silent.

Urethritis

Urethritis is usually characterized in men by a discharge from the urethra, dysuria and varying degrees of discomfort within the penis. In 10-15% of cases there are no symptoms. A wide array of aetiologies can give rise to the clinical picture which are divided into two broad bands: gonococcal or non-gonococcal urethritis (NGU). NGU occurring shortly after infection with gonorrhoea is known as postgonococcal urethritis (PGU). Gonococcal urethritis and chlamydial urethritis (a major cause of NGU) are discussed above.

Trichomonas vaginalis, Mycoplasma genitilium, Ureaplasma urealyticum and *Bacteroides* spp. are responsible for a proportion of cases. HSV can cause urethritis in about 30% of cases of primary infection, considerably fewer in recurrent episodes. Other causes include syphilitic chancres and warts within the urethra. Non-sexually transmitted NGU may be due to urinary tract infections, prostatic infection, foreign bodies and strictures.

Clinical features

The urethral discharge is often mucoid and worse in the mornings. Crusting at the meatus or stains on underwear occur. Dysuria is common but not universal. Discomfort or itch within the penis may be present. The incubation period is 1—5 weeks with a mean of 2—3 weeks. Asymptomatic urethritis is a major reservoir of infection. Reiter's disease causing conjunctivitis and/or arthritis occurs, particularly in HLA B27-positive individuals.

Diagnosis

Smears should be taken from the urethra when the patient has not voided urine for at least 4 hours and should be Gram stained and examined under a high-power (xlOOO) oil-immersion lens. The presence of five or

more polymorphonuclear leucocytes per high-power field is diagnostic. Men who are symptomatic but have no objective evidence of urethritis should be re-examined and tested after holding urine overnight. Cultures for gonorrhoea must be taken together with specimens for *Chlamydia* testing.

Treatment

Therapy for NGU is with either doxycycline 100 mg 12-hourly or azithromycin 1 g orally as a single dose. Sexual intercourse should be avoided. The vast majority of patients will show partial or total response. Sexual partners must be traced and treated; *C. tmchomatis* can be isolated from the cervix in 50-60% of the female partners of men with PGU or NGU, many of whom are asymptomatic. This causes long-term morbidity in such women, acts as a reservoir of infection for the community, and may lead to reinfection in the index case if not treated.

Recurrent/persistent NGU

This is a common and difficult clinical problem, and can occur in 20-60% of men treated for acute NGU. The usual time for patients to re-present is 2-3 weeks following treatment. Tests for organisms, e.g. *Mycoplasma, Chlamydia* and *Ureaplasma* are usually negative. It is necessary to document objective evidence of urethritis, check adherence to treatment and establish any possible contact with untreated sexual partners. Investigations should include wet preparation and culture of urethral material for *Trichomonas vaginalis*. Cultures should be taken for HSV. A mid-stream urine sample should be examined and cultured. A further 1 week's treatment with erythromycin 500 mg four times a day for 2 weeks plus metronidazole 400 mg twice daily for 5 days may be given, and any specific additional infection treated appropriately. If symptoms are mild and all partners have been treated, patients should be reassured and further antibiotic therapy avoided. In cases of frequent recurrence and/ or florid unresponsive urethritis, the prostate should be investigated and urethroscopy or cystoscopy performed to investigate possible strictures, periurethral fistulae or foreign bodies.

Lymphogranuloma venereum (LGV)

Chlamydia tradiomatis types LGV 1, 2 and 3 are responsible for this sexually transmitted infection. It is endemic in the tropics, with the highest incidences in Africa, India and South East Asia.

Clinical features

The primary lesion is a painless ulcerating papule on the genitalia occurring 7-21 days following exposure. It is frequently unnoticed. A few days to weeks after this heals, regional lymphadenopathy develops. The lymph nodes are painful and fixed and the overlying skin develops a dusky erythematous appearance. Finally, nodes may become fluctuant (buboes) and can rupture. Acute LGV also presents as proctitis with perirectal abscesses, the appearances sometimes resembling anorectal Crohn's disease. The destruction of local lymph nodes can lead to lymphoedema of the genitalia.

Diagnosis

The diagnosis is often made on the basis of the characteristic clinical picture after other causes of genital ulceration or inguinal lymphadenopathy have been excluded. Syphilis and genital herpes must be excluded.

- Isolation of C. *tradiomatis* in tissue culture. The sensitivity is 75-85%.
- Antigen-detection methods with material from bubo aspirates or ulcer scrapes:
  - direct immunofluorescence using monoclonal antibodies
  - enzyme immunoassay (ElA).
- Sensitivity 70-80%.
- Positive C. *tradiomatis* serology (complement fixation tests, L-type immunofluorescence or micro-immunofluorescence test, IF). A fourfold rise in antibody titre in the course of the illness is diagnostic. NB: Micro-IF is the only serological means of distinguishing different serotypes of CT.

Treatment

Early treatment is critical to prevent the chronic phase. Doxycycline (100 mg twice daily for 21 days) or erythromycin (500 mg four times daily for 21 days) is efficacious. Follow-up should continue until signs and symptoms have resolved, usually 3-6 weeks. Chronic infection may result in extensive scarring and abscess and sinus formation. Surgical drainage or reconstructive surgery is sometimes required. Sexual partners in the 30 days prior to onset should be examined and treated if necessary.

Syphilis

Syphilis is a chronic systemic disease, which is acquired or congenital. In its early stages diagnosis and treatment are straightforward but untreated it can cause complex sequelae in many organs and eventually lead to death.

The causative organism, *Treponema pallidum* (TP), is a motile spirochaete that is acquired either by close sexual contact or can be transmitted transplacentally. The organism enters the new host through breaches in squamous or columnar epithelium. Primary infection of non-genital sites may occasionally occur but is rare.

Both acquired and congenital syphilis have early and late stages, each of which has classic clinical features (Table2.49).

Primary

Between 10-90 days (mean 21 days) after exposure to the pathogen a papule develops at the site of inoculation. This ulcerates to become a painless, firm chancre. There is usually painless regional lymphadenopathy in association. The primary lesion may go unnoticed, especially if it is on the cervix or within the rectum. Healing occurs spontaneously within 2-3 weeks.

Table 2.49 Clinical features of syphilis

Acquired	
Early stages	
Primary	Hard chancre Painless, regional lymphadenopathy
Secondary	*General:* Fever, malaise, arthralgia, sore throat and generalized lymphadenopathy *Skin:* Red/brown maculopapular non-itchy, sometimes scaly rash; condylomata lata *Mucous membranes:* Mucous patches, 'snail-track' ulcers in oropharynx and on genitalia
Late stages	
Tertiary	*Late benign:* Gummas (bone and viscera) *Cardiovascular:* Aortitis and aortic regurgitation *Neurosyphilis:* Meningovascular involvement, general paralysis of the insane (GPI) and tabes dorsalis
Congenital	Stillbirth or failure to thrive ***Early stages*** 'Snuffles' (nasal infection with discharge) Skin and mucous membrane lesions as in secondary syphilis ***Late stages*** *'Stigmata':* Hutchinson's teeth, 'sabre' tibia and abnormalities of long bones Keratitis, uveitis, facial gummas and CNS disease

Secondary

Between 4-10 weeks after the appearance of the primary lesion constitutional symptoms with fever, sore throat, malaise and arthralgia appear. Any organ may be affected - leading, for example, to hepatitis, nephritis, arthritis and meningitis. In a minority of cases the primary chancre may still be present and should be sought. Signs include:

- Generalized lymphadenopathy (50%)
- Generalized skin rashes involving the whole body including the palms and soles but excluding the face (75%) - the rash, which rarely itches, may take many different forms, ranging from pink macules, through coppery papules, to frank pustules (Fig. 2.42)
- Condylomata lata - warty, plaque-like lesions found in the perianal area and other moist body sites
- Superficial confluent ulceration of mucosal surfaces - found in the mouth and on the genitalia, described as 'snail track ulcers'
- Acute neurological signs in less than 10% of cases (e.g. aseptic meningitis).

Untreated early syphilis in pregnant women leads to fetal infection in at least 70% of cases and may result in stillbirth in up to 30%.

Latent

Without treatment, symptoms and signs abate over 3-12 weeks, but in up to 20% of individuals may recur during a period known as early latency, a 2-year period in the UK (1 year in USA). Late latency is based on reactive syphilis serology with no clinical manifestations for at least 2 years. This can continue for many years before the late stages of syphilis become apparent.

Fig. 2.42 **Rash of secondary syphilis on the palms.** Courtesy of Dr B Goh.

Tertiary

Late benign syphilis, so called because of its response to therapy rather than its clinical manifestations, generally involves the skin and the bones. The characteristic lesion, the gumma (granulomatous, sometimes ulcerating, lesions), can occur anywhere in the skin, frequently at **sites** of trauma. Gummas are commonly found in the skull, tibia, fibula and clavicle, although any bone may be involved. Visceral gummas occur mainly in the liver (hepar lobatum) and the testes.

Cardiovascular and neurosyphilis are discussed on pages 810 and 1240.

Congenital syphilis

Congenital syphilis usually becomes apparent between the second and sixth week after birth, early signs being nasal discharge, skin and mucous membrane lesions, and failure to thrive. Signs of late syphilis generally do not appear until after 2 years of age and take the form of 'stigmata' relating to early damage to developing structures, particularly teeth and long bones. Other late manifestations parallel those of adult tertiary syphilis.

Investigations for diagnosis

Treponema pallidum is not amenable to in vitro culture - the most sensitive and specific method is identification by dark-ground microscopy. Organisms may be found in variable numbers, from primary chancres and the mucous patches of secondary lesions. Individuals with either primary or secondary disease are highly infectious. Serological tests used in diagnosis are either treponemal-specific or non-specific (cardiolipin test) (Table 2.50):

- **Treponemal specific.** The *T. pallidum* enzyme immunoassay (EIA). *T. pallidum* haemagglutination or particle agglutination assay (TPHA/TPPA) and fluorescent treponemal antibodies absorbed (FTA-abs)

Table 2.50 **Syphilis serology**

Stage of infection	Results			
	EIA	FTA-abs	TPHA/TPPA	VDRL/RPR
Very early primary				
Early primary	+ (IgM) +			
Primary	(IgM)			
Secondary or latent				
Late latent				± ±
Treated				
Biological false-positive				

EIA, enzyme immunoassay; FTA-abs, fluorescent *Treponema* antibodies absorbed; TPHA/TPPA, *Treponema pallidum* haemagglutination/particle agglutination assay; VDRL, Venereal Disease Research Laboratory; RPR, rapid plasma reagin

test are both highly specific for treponemal disease but will not differentiate between syphilis and other treponemal infection such as yaws. These tests usually remain positive for life, even after treatment. ■ **Treponemal non-specific.** The Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests are non-specific, becoming positive within 3-4 weeks of the primary infection. They are quantifiable tests which can be used to monitor treatment efficacy and are helpful in assessing disease activity. They generally become negative by 6 months after treatment in early syphilis. The VDRL may also become negative in untreated patients (50% of patients with late-stage syphilis) or remain positive after treatment in late stage. False-positive results may occur in other conditions - particularly infectious mononucleosis, hepatitis, *Mycoplasma* infections, some protozoal infections, cirrhosis, malignancy, autoimmune disease and chronic infections.

The EIA is the screening test of choice and can detect both IgM and IgG antibodies. A positive test is then confirmed with the TPHA/TPPA and VDRL/RPR tests. All serological investigations may be negative in early primary syphilis; the EIA IgM and the FTA-abs being the earliest tests to be positive. The diagnosis will then hinge on positive dark-ground microscopy, and treatment should not be delayed if serological tests are negative in such situations.

In certain cases, examination of the CSF for evidence of neurosyphilis and a chest X-ray to determine the extent of cardiovascular disease will be indicated.

Treatment

Treponemocidal levels of antibiotic must be maintained in serum for at least 7 days in early syphilis to cover the slow division time of the organism (30 hours). In late syphilis treponemes may divide even more slowly requiring longer therapy.

Early syphilis (primary or secondary) should be treated with long-acting penicillin such as procaine benzyl-penicillin (procaine penicillin) (e.g. Jenacillin A which also contains benzylpenicillin) 600 mg intramuscularly daily for 10 days. For late-stage syphilis, particularly when there is cardiovascular or neurological involvement, the treatment course should be extended for a further week. For patients sensitive to penicillin, either doxycycline 200 mg daily or erythromycin 500 mg four times daily is given orally for 2-4 weeks depending on the stage of the infection. Non-compliant patients can be treated with a single dose of benzathine penicillin G 2.4 g intramuscularly. These long-acting penicillins are not generally available in the UK but are imported directly by GUM clinics.

The *Jarisch-Herxheimer reaction,* which is due to release of TNF-oc, IL-6 and IL-8, is seen in 50% of patients with primary syphilis and up to 90% of patients with secondary syphilis. It occurs about 8 hours after the first injection and usually consists of mild fever, malaise and headache lasting several hours. In cardiovascular or neurosyphilis the reaction, although rare, may be severe and exacerbate the clinical manifestations. Prednisolone given for 24 hours prior to therapy may ameliorate the reaction but there is little evidence to support its use. Penicillin should not be withheld because of the Jarisch-Herxheimer reaction; since it is not a dose-related phenomenon, there is no value in giving a smaller dose.

The prognosis depends on the stage at which the infection is treated. Early and early latent syphilis have an excellent outlook but once extensive tissue damage has occurred in the later stages the damage will not be reversed although the process may be halted. Symptoms in cardiovascular and neurosyphilis may therefore persist.

All patients treated for early syphilis must be followed up at regular intervals for the first year following treatment. Serological markers should be followed and a fall in titre of the VDRL/RPR of at least fourfold is consistent with adequate treatment for early syphilis. The sexual partners of all patients with syphilis and the parents and siblings of patients with congenital syphilis must be contacted and screened. Babies born to mothers who have been treated for syphilis in pregnancy are retreated at birth.

Chancroid

Chancroid or soft chancre is an acute STI caused by *Haemophilus ducreyi.* It is probably the commonest cause of genital ulceration world-wide, and is prevalent in parts of Africa and Asia. Epidemiological studies in Africa have shown an association between genital ulcer disease, frequently chancroid, and the acquisition of HIV infec-

tion. A new urgency to control chancroid has resulted from these observations.

Clinical features

The incubation period is 3-10 days. At the site of inoculation an erythematous papular lesion forms which then breaks down into an ulcer. The ulcer frequently has a necrotic base, a ragged edge, bleeds easily and is painful. Several ulcers may merge to form giant serpiginous lesions. Ulcers appear most commonly on the prepuce and frenulum in men and can erode through tissues. In women the most commonly affected site is the vaginal entrance and the perineum. The lesions in women sometimes go unnoticed.

At the same time, inguinal lymphadenopathy develops (usually unilateral) and can progress to form large buboes which suppurate.

Diagnosis and treatment

Chancroid must be differentiated from other genital ulcer diseases (see Table 2.48). Co-infection with syphilis and herpes simplex is common. Isolation of *H. ducreyi* in specialized culture media is definitive but difficult. Swabs should be taken from the ulcer and material aspirated from the local lymph nodes for culture. Polymerase chain reaction (PCR) techniques are available. Gram stains of clinical material may show characteristic coccobacilli.

Single-dose regimens include azithromycin 1 g orally or ceftriaxone 250 mg i.m. Other regimens include ciprofloxacin 500 mg twice daily for 3 days, erythromycin 500 mg four times daily for 7 days. Clinically significant plasmid-mediated antibiotic resistance in *H. ducreyi* is developing.

Patients should be followed up at 3-7 days, when if treatment is successful ulcers will be responding.

Sexual partners should be examined and treated epidemiologically, as asymptomatic carriage has been reported.

HIV-infected patients should be closely monitored, as healing may be slower. Multiple-dose regimens are needed in HIV patients since treatment failures have been reported with single-dose therapy.

Donovanosis

Donovanosis is the least common of all STIs in North America and Europe, but is endemic in the tropics and subtropics, particularly the Caribbean, South East Asia and South India. Infection is caused by *Klebsiella granulomatis,* a short, encapsulated Gram-negative bacillus. The infection was also known as granuloma inguinale. Although sexual contact appears to be the most usual mode of transmission, the infection rates are low, even between sexual partners of many years' standing.

Clinical features

In the vast majority of patients, the characteristic, heaped-up ulcerating lesion with prolific red granulation tissue appears on the external genitalia, perianal skin or the inguinal region within 1-4 weeks of exposure. It is rarely painful. Almost any cutaneous or mucous membrane site can be involved, including the mouth and anorectal regions. Extension of the primary infection from the external genitalia to the inguinal regions produces the characteristic lesion, the 'pseudo-bubo'.

Diagnosis and treatment

The clinical appearance usually strongly suggests the diagnosis but *K. granulomatis* (Donovan bodies) can be identified intracellularly in scrapings or biopsies of an ulcer. Successful culture has only recently been reported and PCR techniques and serological methods of diagnosis are being developed, but none is routinely available.

Antibiotic treatment should be given until the lesions have healed. A minimum of 3 weeks' treatment is recommended. Regimens include doxycycline 100 mg twice daily, co-trimoxazole 960 mg twice daily, azithromycin 500 mg daily or 1 g weekly, or ceftriaxone 1 g daily.

Sexual partners should be examined and treated if necessary.

Herpes simplex (p. 43)

Genital herpes is one of the most common STIs worldwide. Between 1997 and 2002 there has been a 17% increase in diagnoses of genital herpes in the UK. The peak incidence is in 16- to 24-year-olds of both sexes. Infection may be either primary or recurrent. Transmission occurs during close contact with a person who is shedding virus. Most genital herpes is due to type 2. Genital contact with oral lesions caused by HSV-1 can also produce genital infection.

Susceptible mucous membranes include the genital tract, rectum, mouth and oropharynx. The virus has the ability to establish latency in the dorsal root ganglia by ascending peripheral sensory nerves from the area of inoculation. It is this ability which allows for recurrent attacks.

Clinical features

Asymptomatic infection has been reported but is rare. Primary genital herpes is usually accompanied by systemic symptoms of varying severity including fever, myalgia and headache. Multiple painful shallow ulcers develop which may coalesce (Fig. 2.43). Atypical lesions are common. Tender inguinal lymphadenopathy is usual. Over a period of 10-14 days the lesions develop crusts and dry. In women with vulval lesions the cervix is almost always involved. Rectal infection may lead to a florid proctitis. Neurological complications can include aseptic encephalitis and/or involvement of the sacral autonomic plexus leading to retention of urine.

Recurrent attacks occur in a significant proportion of people following the initial episode. Precipitating factors vary, as does the frequency of recurrence. A symptom prodrome is present in some people prior to the appearance of lesions. Systemic symptoms are rare in recurrent attacks.

The clinical manifestations in immunosuppressed patients (including those with HIV) may be more severe,

Fig. 2.43
Dr B Goh.

Herpes simplex rash on the penis. Courtesy of

asymptomatic shedding increased, and recurrences occur with greater frequency. Systemic spread has been documented (see p. 139).

Diagnosis

Although the history and examination can be highly suggestive of HSV infection, a firm diagnosis can be made only on the basis of isolation of virus from lesions. Swabs should be taken from the base of lesions and placed in viral transport medium. Virus is most easily isolated from new lesions. Type-specific immune responses can be found 8-12 weeks following primary infection and may form the basis for newer serological assays, although these are not yet available in routine clinical practice.

Management

Primary

Saltwater bathing or sitting in a warm bath is soothing and may allow the patient to pass urine with some degree of comfort. Aciclovir 200 mg five times daily, famciclovir 250 mg three times daily or valaciclovir 500 mg twice daily, all for 5 days, are useful if patients are seen whilst new lesions are still forming. If lesions are already crusting, antiviral therapy will do little to change the clinical course. Secondary bacterial infection occasionally occurs and should be treated. Rest, analgesia and antipyretics should be advised. In rare instances patients may need to be admitted to hospital and aciclovir given intravenously, particularly if HSV encephalitis is suspected.

Recurrence

Recurrent attacks tend to be less severe and can be managed with simple measures such as saltwater bathing. Psychological morbidity is associated with recurrent genital herpes and frequent recurrences impose strains on relationships; patients need considerable support. Long-term suppressive therapy is given in patients with frequent recurrences. An initial course of aciclovir 400 mg twice daily or valaciclovir 250 mg twice daily for 6-12 months significantly reduces the frequency of attacks, although there may still be some breakthrough. Therapy should be discontinued after 12 months and the frequency of recurrent attacks reassessed.

HSV in pregnancy

The potential risk of infection to the neonate needs to be considered in addition to the health of the mother. Infection occurs either transplacentally or via the birth canal. If HSV is acquired for the first time during pregnancy, transplacental infection of the fetus may, rarely, occur. Management of primary HSV in the first or second trimester will depend on the woman's clinical condition and aciclovir can be prescribed in standard doses. Aciclovir therapy during the last 4 weeks of pregnancy may prevent recurrence at term.

Primary acquisition in the third trimester or at term with high levels of viral shedding usually leads to delivery by caesarean section.

For women with previous infection, concern focuses on the baby acquiring HSV from the birth canal. The risk is very low in recurrent attacks. For women with recurrent episodes, only those with genital lesions at the onset of labour are delivered by caesarean section. Sequential cultures during the last weeks of pregnancy to predict viral shedding at term are no longer indicated.

Prevention and control

Patients must be advised that they are infectious when lesions are present; sexual intercourse should be avoided during this time or during prodromal stages. Condoms may not be effective as lesions may occur outside the areas covered. Sexual partners should be examined and may need information on avoiding infection.

Warts

Anogenital warts are amongst the most common sexually acquired infections. The causative agent is human papillomavirus (HPV) especially types 6 and 11 (p. 48). HPV is acquired by direct sexual contact with a person with either clinical or subclinical infection. Genital HPV infection is common, with only a small proportion of those infected being symptomatic. Neonates may acquire HPV from an infected birth canal, which may result either in anogenital warts or in laryngeal papillomas. The incubation period ranges from 2 weeks to 8 months or even longer.

Clinical features

Warts develop around the external genitalia in women, usually starting at the fourchette, and involve the perianal region. The vagina may be infected. Flat warts may develop on the cervix and are not easily visible on routine examination. Such lesions are associated with cervical intraepithelial neoplasia. In men the penile shaft and subpreputial space are the most common sites, although warts involve the urethra and meatus. Perianal lesions are more common in men who practise anoreceptive intercourse but can be found in any patient. The rectum may become involved. Warts become more florid during pregnancy or in immunosuppressed patients.

Diagnosis

The diagnosis is essentially clinical. It is critical to differentiate condylomata lata of secondary syphilis.

Unusual lesions should be biopsied if the diagnosis is in doubt. Up to 30% of patients have coexisting infections with other STIs and a full screen must be performed.

Treatment

Significant failure and relapse rates are seen with current treatment modalities. Choice of treatment will depend on the number and distribution of lesions. Local agents, including podophyllin extract (15-25% solution, once or twice weekly), podophyllotoxin (0.5% solution or 1.5% cream in cycles), and trichloroacetic acid, are useful for non-keratinized lesions. Those that are keratinized respond better to physical therapy, e.g. cryotherapy, electrocautery or laser ablation. Imiquimod (5% cream used three times a week) is indicated in both types. Podophyllin, podophyllotoxin and imiquimod are not advised in pregnancy.

Sexual contacts should be examined and treated if necessary. In view of the difficulties of diagnosing subclinical HPV, condoms should be used for up to 8 months after treatment. Because of the association of HPV with cervical intraepithelial neoplasia, women with warts and female partners of men with warts are advised to have regular cervical screening, i.e. every 3 years. Colposcopy may be useful in women with vaginal and cervical warts.

Hepatitis B

This is discussed in Chapter 7. Sexual contacts should be screened and given vaccine if they are not immune (see p. 366).

Trichomoniasis

Trichomonas vaginalis (TV) is a flagellated protozoon which is predominantly sexually transmitted. It is able to attach to squamous epithelium and can infect the vagina and urethra. *Trichomonas* may be acquired perinatally in babies born to infected mothers.

Infected women may, unusually, be asymptomatic. Commonly the major complaints are of vaginal discharge which is offensive and of local irritation. Men usually present as the asymptomatic sexual partners of infected women, although they may complain of urethral discharge, irritation or urinary frequency.

Examination often reveals a frothy yellowish vaginal discharge and erythematous vaginal walls. The cervix may have multiple small haemorrhagic areas which lead to the description 'strawberry cervix'. *Trichomonas* infection in pregnancy has been associated with preterm delivery and low birth-weight.

Diagnosis and treatment

Phase-contrast, dark-ground microscopy of a drop of vaginal discharge shows TV swimming with a characteristic motion in 40-80% of female patients. Similar preparations from the male urethra will only be positive in about 30% of cases. Many polymorphonuclear leucocytes are also seen. Culture techniques are good and confirm the diagnosis. *Trichomonas* is sometimes observed on cervical cytology with a 60-80% accuracy in diagnosis. New, highly sensitive and specific tests based on polymerase chain reactions are in development.

Metronidazole is the treatment of choice, either 2 g orally as a single dose or 400 mg twice-daily for 7 days. There is some evidence of metronidazole resistance and nimorazole may be effective in these cases. Topical therapy with intravaginal tinidazole can be effective, but if extravaginal infection exists this may not be eradicated and vaginal infection reoccurs. Male partners should be treated, especially as they are likely to be asymptomatic and more difficult to detect.

Candidiasis

Vulvovaginal infection with *Candida albicans* is extremely common. The organism is also responsible for balanitis in men. *Candida* can be isolated from the vagina in a high proportion of women of childbearing age, many of whom will have no symptoms.

The role of *Candida* as pathogen or commensal is difficult to disentangle and it may be changes in host environment which allow the organism to produce pathological effects. Predisposing factors include pregnancy, diabetes, and the use of broad-spectrum antibiotics and corticosteroids. Immunosuppression can result in more florid infection.

Clinical features

In women, pruritus vulvae is the dominant symptom. Vaginal discharge is present in varying degree. Many women have only one or occasional isolated episodes. Recurrent candidiasis (four or more symptomatic episodes annually) occurs in up to 5% of healthy women of reproductive age. Examination reveals erythema and swelling of the vulva with broken skin in severe cases. The vagina may contain adherent curdy discharge. Men may have a florid balanoposthitis. More commonly, self-limiting burning penile irritation immediately after sexual intercourse with an infected partner is described. Diabetes must be excluded in men with balanoposthitis.

Diagnosis

Microscopic examination of a smear from the vaginal wall reveals the presence of spores and mycelia. Culture of swabs should be undertaken but may be positive in women with no symptoms. *Trichomonas* and bacterial vaginosis must be considered in women with itch and discharge.

Treatment

Topical. Pessaries or creams containing one of the imidazole antifungals such as clotrimazole 500 mg single dose used intravaginally are usually effective. Nystatin is also useful.

Oral. The triazole drugs such as fluconazole 150 mg as a single dose or itraconazole 200 mg twice in 1 day are

used systemically where topical therapy has failed or is inappropriate. Recurrent candidiasis may be treated with fluconazole 100 mg weekly for 6 months, or clotrimazole pessary 500 mg weekly for 6 months.

The evidence for sexual transmission of *Candida* is slight and there is no evidence that treatment of male partners reduces recurrences in women.

Bacterial vaginosis

Bacterial vaginosis (BV) is a disorder characterized by an offensive vaginal discharge. The aetiology and pathogenesis are unclear but a mixed flora of *Gardnerella vaginalis,* anaerobes including *Bacteroides, Mobiluncus* spp. and *Mycoplasma hominis,* replaces the normal lactobacilli of the vagina. Amines and their breakdown products from the abnormal vaginal flora are thought to be responsible for the characteristic odour associated with the condition. As vaginal inflammation is not part of the syndrome the term vaginosis is used rather than vaginitis. The condition has been shown to more common in black women than in white. It is not regarded as a sexually transmitted disease.

Clinical features

Vaginal discharge and odour are the most common complaints although a proportion of women are asymptomatic. A homogeneous, greyish white, adherent discharge is present in the vagina, the pH of which is raised (greater than 5). Associated complications are ill-defined but may include chorioamnionitis and an increased incidence of premature labour in pregnant women. Whether BV disposes non-pregnant women to upper genital tract infection is unclear.

Diagnosis

Different authors have differing criteria for making the diagnosis of BV. In general it is accepted that three of the following should be present for the diagnosis to be made:

- characteristic vaginal discharge
- the amine test: raised vaginal pH using narrow-range indicator paper (> 4.7)
- a fishy odour on mixing a drop of discharge with 10% potassium hydroxide
- the presence of clue cells on microscopic examination of the vaginal fluid.

Clue cells are squamous epithelial cells from the vagina which have bacteria adherent to their surface, giving a granular appearance to the cell. A Gram stain gives a typical reaction of partial stain uptake.

Treatment

Metronidazole given orally in doses of 400 mg twice daily for 5-7 days is usually recommended. A single dose of 2 g metronidazole is less effective. Topical 2% clindamycin cream 5 g intravaginally once daily for 7 days is effective. Recurrence is high, with some studies giving a rate of 80% within 9 months of completing metronidazole therapy. There is debate over the treatment of asymptomatic women who fulfil the diagnostic criteria for BV. The diagnosis should be fully discussed and treatment offered if the woman wishes. Until the relevance of BV to other pelvic infections is elucidated, the treatment of asymptomatic women with BV is not to be recommended. There is no convincing evidence that simultaneous treatment of the male partner influences the rate of recurrence of BV, and routine treatment of male partners is not indicated.

INFESTATIONS (see also p. 1326)

Pediculosis pubis

The pubic louse *(Phthirus pubis)* is a blood-sucking insect which attaches tightly to the pubic hair. They may also attach to eyelashes and eyebrows. It is relatively host-specific and is transferred only by close bodily contact. Eggs (nits) are laid at hair bases and usually hatch within a week. Although infestation may be asymptomatic the most common complaint is of itch.

Diagnosis

Lice may be seen on the skin at the base of pubic and other body hairs. They resemble small scabs or freckles but if they are picked up with forceps and placed on a microscope slide will move and walk away. Blue macules may be seen at the feeding sites. Nits are usually closely adherent to hairs. Both are highly characteristic under the low-power microscope.

As with all sexually transmitted infections, the patient must be screened for coexisting pathogens.

Treatment

Both lice and eggs must be killed with 0.5% malathion, 1% permethrin or 0.5% carbaryl. The preparation should be applied to all areas of the body from the neck down and washed off after 12 hours. In a few cases a further application after 1 week may be necessary. For severe infestations, antipruritics may be indicated for the first 48 hours. All sexual partners should be seen and screened.

Scabies

This is discussed on page 1325.

HUMAN IMMUNE DEFICIENCY VIRUS (HIV) AND AIDS

Epidemiology

HIV, the cause of the acquired immune deficiency syndrome (AIDS), continues to spread, being described as a global health emergency by the World Health Organization (WHO) in 2003. UNAIDS estimates for 2002 are that 41 million people are infected with HIV worldwide, over 70% of whom are in sub-Saharan Africa. Approximately 16 000 new infections occur daily, the majority in young adults. HIV is now the leading single cause of death in adults, causing 5 million deaths in 2003. In sub-Saharan Africa 5000 men and women and 1000 children die of HIV every 24 hours. Dramatic rises in infection have been seen in SE Asia with eastern Europe and Russia having the most rapidly expanding epidemic in 2003.

The human and economic costs are huge - 33% of 15-year-olds in high-prevalence countries in Africa will die of HIV, life expectancy in African countries is falling with an inevitable impact on the fabric of society and on economic growth and stability. The advent of more effective therapy for HIV has brought geographical differences in the impact of the epidemic into stark relief, with falling mortality and morbidity in resource-rich settings that are unmatched in poorer parts of the world. Although in the UK and other wealthy countries deaths from HIV have fallen, new diagnoses are rising sharply. At least 5000 new diagnoses were recorded in the UK in 2003, a 20% increase over the preceding year, and the highest annual number since surveillance began, with the result that prevalence is rising. Demographics have varied greatly within different regions influenced by social, behavioural, cultural and political factors. Despite the fact that HIV can be isolated from a wide range of body fluids and tissues, the majority of infections are transmitted via semen, cervical secretions and blood. The character of the epidemic in different regions of the world has been influenced by the relative frequency of each of the routes of transmission.

Sexual intercourse (vaginal and anal)

Globally, heterosexual intercourse accounts for the vast majority of infections, and coexistent STIs, especially those causing genital ulceration, enhance transmission. Passage of HIV appears to be more efficient from men to women, and to the passive partner in anal intercourse, than vice versa.

In the UK, sex between men still accounts for over half the infections reported, but there is an increasing rate of heterosexual transmission. Between 2000 and 2003 53% of new diagnoses were a result of heterosexual exposure, frequently in high-endemicity countries. Of these infections, 67% were in women compared to 5% in the late 1980s. In central and sub-Saharan Africa the epidemic has always been heterosexual and more than half the infected adults in these regions are women. South East Asia and the Indian subcontinent are experiencing an explosive epidemic, driven by heterosexual intercourse and a high incidence of other sexually transmitted diseases.

Mother to child (parentally, perinatally, breast-feeding)

Vertical transmission is the most common route of HIV infection in children. European studies suggest that, without intervention, 15% of babies born to HIV-infected mothers are likely to be infected, although rates of up to 40% have been reported from Africa and the USA. Increased vertical transmission is associated with advanced disease in the mother, maternal viral load, prolonged and premature rupture of membranes, and chorioamnionitis. Transmission can occur in utero although the majority of infections take place perinatally. Breast-feeding has been shown to increase the risk of vertical transmission by up to 20%. In the developed world interventions to reduce vertical transmission, including the use of antiretroviral agents, delivery by caesarean section and the avoidance of breast-feeding have led to a dramatic fall in the numbers of infected children. The lack of access to these interventions in resource-poor countries in which 90% of infections occur is a major issue.

Contaminated blood, blood products and organ donations

Screening of blood and blood products was introduced in 1985 in Europe and North America. Prior to this, HIV infection was associated with the use of clotting factors (for haemophilia) and with blood transfusions. In some developing countries where blood is not screened or treated, and in areas where the rate of new HIV infections is very high, transfusion-associated transmission remains significant.

Contaminated needles (intravenous drug misuse, injections, needle-stick injuries)

The practice of sharing needles and syringes for intravenous drug use continues to be a major route of transmission of HIV in both developed countries and parts of South East Asia, Latin America and the states of the former Soviet Union. In some areas, including the UK,

successful education and needle exchange schemes have reduced the rate of transmission by this route. Iatrogenic transmission from needles and syringes used in developing countries is reported. Healthcare workers have a risk of approximately 0.3% following a single needle-stick injury with known HIV infected blood.

There is no evidence that HIV is spread by social or household contact or by blood-sucking insects such as mosquitoes and bed bugs.

The virus

HIV belongs to the lentivirus group of the retrovirus family. There are at least two types, HIV-1 and HIV-2. HIV-2 is almost entirely confined to West Africa although there is evidence of some spread to the Indian subcontinent. HIV-2 is associated with an AIDS-type illness although it may be more indolent in nature. The structure of the virus is shown in Figure 2.44.

Retroviruses are characterized by the possession of the enzyme reverse transcriptase, which allows viral RNA to be transcribed into DNA, and thence incorporated into the host cell genome. Reverse transcription is an error-prone process with a significant rate of misincorporation of bases. This, combined with a high rate of viral turnover, leads to considerable genetic variation and a diversity of viral subtypes or clades. On the basis of DNA sequencing, HIV-1 is divided into two subtypes:

- *Group M (major) subtypes.* There are at least 10, which are denoted A-J. There is a predominance of subtype B in Europe, North America and Australia, but areas of central and sub-Saharan Africa have multiple M subtypes.
- *Group O (outlier) subtypes.* These are highly divergent from group M and are confined to small numbers centred on the Cameroons.

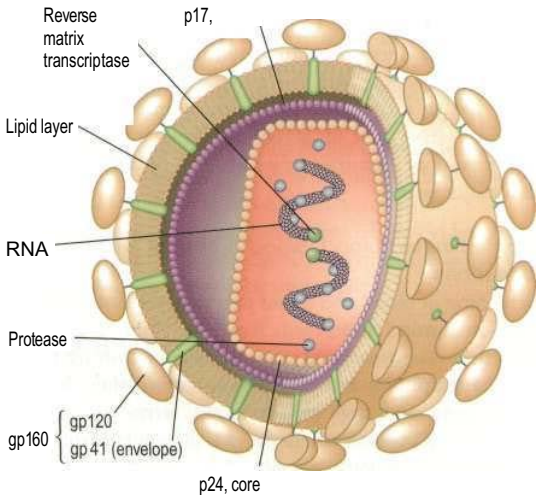

Fig. 2.44 **Structure of HIV.** Two molecules of single-stranded RNA are shown within the nucleus. The reverse transcriptase polymerase converts viral RNA into DNA (a characteristic of retroviruses). The protease includes integrase (p32 and p10). The p24 (core protein) levels can be used to monitor HIV disease. p17 is the matrix protein. gp120 is the outer envelope glycoprotein which binds to cell surface CD4 molecules. gp41, a transmembrane protein, influences infectivity and cell fusion capacity.

Recombination of viral material generates an array of circulating recombinant forms (CRFs), which increases the genetic diversity that may be encountered.

Connections between genetic diversity and biological effects, in particular pathogenicity, rates of transmission and response to therapy, are being sought.

Pathogenesis

The interrelationship between HIV and the host immune system is the basis of the pathogenesis of HIV disease. The host cellular receptor that is recognized by HIV surface glycoprotein is the CD4 molecule, which defines the cell populations that are susceptible to infection (Fig. 2.45). The interaction between CD4 and HIV surface glycoprotein together with chemokine co-receptors CCR5 and CXCR4 is responsible for HIV entry into cells. Mutations in the gene expressing the receptor for chemokine CCR5 may impair entry of HIV into cells and therefore confer some resistance to this infection. Auxiliary viral proteins such as those coded by the *Nef* gene have a role in influencing host cell membrane proteins and signal transduction pathways. CD4 receptors and HIV surface glycoprotein interactions mediate the process of syncytium formation, which is a cytopathic effect of HIV infection.

Studies of viral turnover in HIV-infected individuals have demonstrated a virus half-life in the circulation of about 6 hours. To maintain observed levels of plasma viraemia, 10^8-10^9 virus particles need to be released and cleared daily. Virus production by infected cells lasts for about 2 days and is probably limited by the death of the cell, owing to direct HIV effects, linking HIV replication to the process of CD4 destruction and depletion. Studies suggest that immunopathogenesis is a result of defective T cell homeostasis in HIV infection. The progressive and severe depletion of CD4 helper lymphocytes has profound repercussions for the functioning of the immune system (see p. 1218). Cell-mediated immunodeficiency, which is the major consequence, leaves the host open to infections with intracellular pathogens, whilst the co-existing antibody abnormalities predispose to infections with capsulated bacteria. HIV also has a direct effect on certain tissues, notably the nervous system.

Diagnosis and natural history (Fig 2 46)

HIV infection is diagnosed either by the detection of virus-specific antibodies (anti-HIV) or by direct identification of viral material.

Detection of IgG antibody to envelope components (gp!20 and its subunits). This is the most commonly used marker of infection. The routine tests used for screening are based on ELISA techniques, which may be confirmed with Western blot assays. Up to 3 months

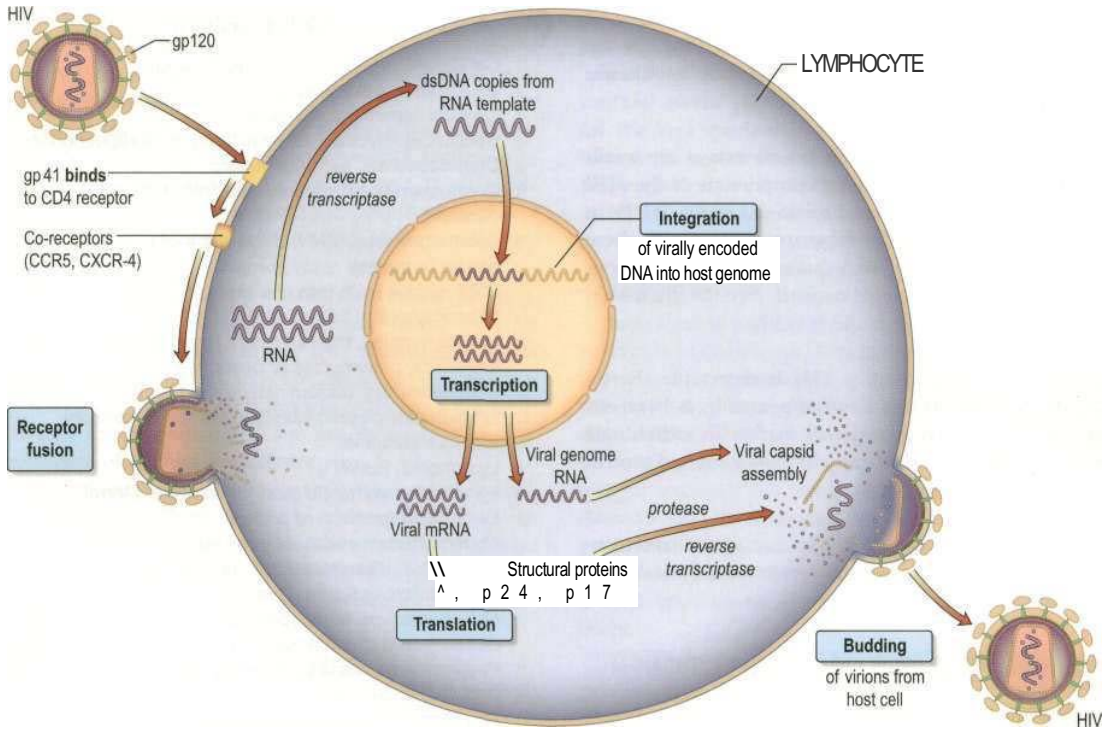

Fig. 2.45 **HIV entry and replication in CD4 T lymphocytes.** The human immune deficiency virus binds to the host CD4 inoculate via the envelope glycoprotein gp120. gp41 binds to the cell chemokine causing receptor fusion and uncoating of RNA. DNA copies are made from both RNA templates (reverse transcriptase). The enzyme polymerase from the host cell leads to formation of dsDNA. In the nucleus the virally encoded DNA is inserted into the host genome (integration). Regulatory proteins control transcription (a process in which an RNA molecule is synthesized from a DNA template). The virus is reassembled in the cytoplasm and budded out from the host cell.

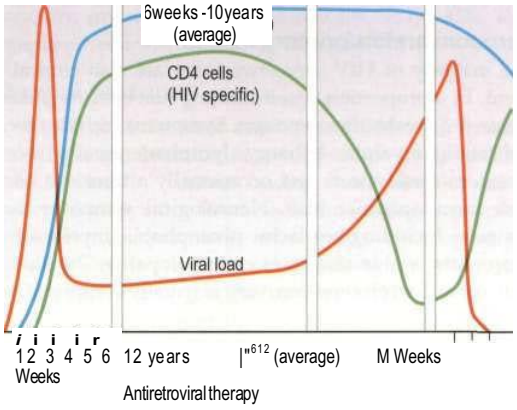

Fig. 2.46 **The immune response to HIV (seroconversion).**

may elapse from initial infection to antibody detection (serological latency, or window period). These antibodies to HIV have no protective function and persist for life. As with all IgG antibodies, anti-HIV will cross the placenta. All babies born to HIV-infected women will thus have the antibody at birth. In this situation, anti-HIV antibody is not a reliable marker of active infection, and in uninfected babies will be gradually lost over the first 18 months of life.

Other than in exceptional circumstances, HIV antibody testing should be carried out only after full discussion of the implications with the patient and with the patient's express consent.

Simple and rapid HIV antibody assays are increasingly available, giving results within hours. Such assays are easy to perform and require little or no additional equipment. They are designed for use with individual or a limited number of samples, Assays that can utilize alternative body fluids to serum/plasma such as saliva, whole blood and urine are becoming accessible.

A serologic testing algorithm for recent HIV seroconversions (STARHS) can be used to identify recently acquired infection. A highly sensitive ELISA that is able to detect HIV antibodies 6-8 weeks after infection is paired with a less sensitive (detuned) test that identifies later HIV antibodies within 130 days. A positive result on the sensitive test and a negative 'detuned' test are indicative of recent infection, whilst positive results on both tests point to an infection that is more than 130 days old. The major application of this is in epidemic surveillance and monitoring.

IgG antibody to p24 (anti-p24). This can be detected from the earliest weeks of infection and through the asymptomatic phase. It is frequently lost as disease progresses.

Antigen assays. Nucleic acid-based assays are available which amplify and test for components of the HIV genome. These assays are used to aid diagnosis of HIV in the babies of HIV-infected mothers or in situations where serological tests may be inadequate, such as subtyping HIV variants for medicolegal reasons. (See the discussion of viral load monitoring, p. 143.)

Viral p24 antigen (p24ag). This is detectable shortly after infection but has usually disappeared by 8-10 weeks after exposure. It can be a useful marker in individuals who have been infected recently but have not had time to mount an antibody response.

Isolation of Virus in culture. This is a specialized technique available in some laboratories to aid diagnosis and as a research tool.

CLINICAL FEATURES OF HIV INFECTION

The spectrum of illnesses associated with HIV infection is broad and is the result of both direct HIV effects and the associated immune dysfunction. Several classification systems exist, the most widely used being the 1993 Centers for Disease Control (CDC) classification (Box 2.16). This classification depends to a large extent on definitive diagnoses of infection, which makes it more difficult to use in those areas of the world without sophisticated laboratory support. As immunosuppression progresses the patient is susceptible to an increasing range of opportunistic infections and tumours, certain of which meet the criteria for the diagnosis of AIDS (Box 2.17).

Since 1993 the definition of AIDS has differed between the USA and Europe. The USA definition includes individuals with CD4 counts below 200 in addition to the clinical classification based on the presence of specific indicator diagnoses shown in Box 2.17. In Europe the definition remains based on the diagnosis of specific clinical conditions with no inclusion of CD4 lymphocyte counts.

***Box2.17* AIDS-defining conditions**

Candidiasis of bronchi, trachea or lungs
Candidiasis, oesophageal
Cervical carcinoma, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (1-month duration)
Cytomegalovirus (CMV) disease (other than liver, spleen or nodes)
CMV retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes simplex, chronic ulcers (1-month duration); or bronchitis, pneumonitis or oesophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis; chronic intestinal (1-month duration)
Kaposi's sarcoma
Lymphoma, Burkitt's
Lymphoma, immunoblastic (or equivalent term)
Lymphoma (primary) of brain
Mycobacterium avium-intracellulare complex or *M. kansasii,* disseminated or extrapulmonary
Mycobacterium tuberculosis, any site
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis carinii pneumonia
Pneumonia, recurrent
Progressive multifocal leucoencephalopathy
Salmonella septicaemia, recurrent
Toxoplasmosis of brain
Wasting syndrome, due to HIV

Incubation

The 2-4 weeks immediately following infection are usually silent both clinically and serologically.

Seroconversion/primary illness

The majority of HIV seroconversions are also clinically silent. In a proportion, a self-limiting non-specific illness occurs 6-8 weeks after exposure. Symptoms include fever, arthralgia, myalgia, lethargy, lymphadenopathy, sore throat, mucosal ulcers and occasionally a transient faint pink maculopapular rash. Neurological symptoms are common, including headache, photophobia, myelopathy, neuropathy and in rare cases encephalopathy. The illness lasts up to 3 weeks and recovery is usually complete.

Sox *2.16* Summary of CDC classification of HIV infection

Absolute CD4 count (/mm^3)	A: Asymptomatic OR persistent generalized lymphadenopathy OR acute seroconversion illness	B: HIV-related conditions,* not A or C	C: Clinical conditions listed in AIDS surveillance case definition (see Box 2.17)
>500	**A1**	**B1**	**C1**
200-499	**A2**	**B2**	**C2**
<200	**A3**	**B3**	C4

* Examples of category B conditions include: bacillary angiomatosis, candidiasis (oropharyngeal), constitutional symptoms, oral hairy leucoplakia, herpes zoster invoiving more than one dermatome, idiopathic thrombocytopenic purpura, listeriosis, pelvic inflammatory disease especially if complicated by tubo-ovarian abscess, peripheral neuropathy

Laboratory abnormalities include lymphopenia with atypical reactive lymphocytes noted on blood film, thrombocytopenia and raised liver enzymes. CD4 lymphocytes may be markedly depleted and the CD4 : CD8 ratio reversed. Antibodies to HIV may be absent during this early stage of infection, although the level of circulating viral RNA is high and p24 core protein may be detectable. Patients experiencing a seroconversion illness may have a more rapidly progressive course of infection.

Clinical latency

The majority of people with HIV infection are asymptomatic for a substantial but variable length of time. However, the virus continues to replicate and the person is infectious. Studies suggest a median time of 10 years from infection to development of AIDS, although some patients progress much more rapidly and others have remained symptom-free for up to 15 years. Older age is associated with more rapid progression, and the influence of putative protective genetic factors is under scrutiny. Gender and pregnancy per se do not appear to influence the rate of progression, although women may fare less well for a variety of reasons. A subgroup of patients with asymptomatic infection have persistent generalized lymphadenopathy (PGL), defined as lymphadenopathy (> 1 cm) at two or more extrainguinal sites for more than 3 months in the absence of causes other than HIV infection. The nodes are usually symmetrical, firm, mobile and non-tender. There may be associated splenomegaly. The architecture of the nodes shows hyperplasia of the follicles and proliferation of the capillary endothelium. Biopsy is rarely indicated. Similar disease progression has been noted in asymptomatic patients with or without PGL. Nodes may disappear with disease progression.

Symptomatic HIV infection

As HIV infection progresses the viral load rises, the CD4 count falls, and the patient develops an array of symptoms and signs. The clinical picture is the result of direct HIV effects and of the associated immunosuppression.

In an individual patient the clinical consequences of HIV-related immune dysfunction will depend on at least three factors:

- *The microbial exposure of the patient throughout life.* Many clinical episodes represent reactivation of previously acquired infection, which has been latent. Geographical factors determine the microbial repertoire of an individual patient. Those organisms requiring intact cell-mediated immunity for their control are most likely to cause clinical problems.
- *The pathogenicity of organisms encountered.* High-grade pathogens such as *Mycobacterium tuberculosis, Candida* and the herpesviruses are clinically relevant even when immunosuppression is mild, and will thus occur earlier in the course of the disease. Less virulent organisms occur at later stages of immunodeficiency.
- *The degree of immunosuppression of the host.* When patients are severely immunocompromised (CD4 count < 100/mm^3) disseminated infections with organisms of very low virulence such as *M. avium-intracellulare* (MAI) and *Cryptosporidium* are able to establish themselves. These infections are very resistant to treatment, mainly because there is no functioning immune response to clear organisms. This hierarchy of infection allows for appropriate intervention with prophylactic drugs.

EFFECTS OF HIV INFECTION

am

Neurological disease

Infection of the nervous tissue occurs at an early stage but clinical neurological involvement increases as HIV advances. This includes AIDS dementia complex (ADC), sensory polyneuropathy and aseptic meningitis (see p. 1241). These conditions are much less common since the introduction of HAART (highly active antiretroviral therapy). The pathogenesis is thought to be due both to the release of neurotoxic products by HIV itself and to cytokine abnormalities secondary to immune dysregulation.

ADC has varying degrees of severity, ranging from mild memory impairment and poor concentration through to severe cognitive deficit, personality change and psychomotor slowing. Changes in affect are common and depressive or psychotic features may be present. The spinal cord may show vacuolar myelopathy histologically. In severe cases brain CT scan shows atrophic change of varying degrees. MRI changes consist of white matter lesions of increased density on T2-weighted sections. EEG may show non-specific changes consistent with encephalopathy. The CSF is usually normal, although the protein concentration may be raised. Patients with mild neurological dysfunction may be unduly sensitive to the effects of other insults such as fever, metabolic disturbance or psychotropic medication, any of which may lead to a marked deterioration in cognitive functioning.

Sensory polyneuropathy is seen frequently in HIV infection, most commonly in the legs and feet, although hands may be affected in advanced disease. In its most severe form it causes intense pain, usually in the feet, which may disrupt sleep, impair mobility and generally reduce the quality of life.

Autonomic neuropathy may also occur with postural hypotension and diarrhoea. Autonomic nerve damage is found in the small bowel. Zalcitabine, didanosine and stavudine produce a similar neuropathy as a major toxic side-effect and must be used with caution in patients with HIV neuropathy.

HAART has a beneficial effect on HIV neurological disease, with startling improvement in cognitive function in many patients with ADC. It may also have a neuroprotective role.

Eye disease

Eye pathology is a regular finding in HIV infection, usually in the later stages. The most serious is cytomegalovirus retinitis (see p. 138), which is sight-threatening. Retinal cotton wool spots due to HIV per se

are rarely troublesome but they may be confused with CMV retinitis. Anterior uveitis can present as acute red eye associated with rifabutin therapy for mycobacterial infections in HIV. Steroids used topically are usually effective but modification of the dose of rifabutin is required to prevent relapse. Pneumocystis, toxoplasmosis, syphilis and lymphoma can all affect the retina and the eye may be the site of first presentation.

Mucocutaneous manifestations (see Table 2.52)

The skin is a common site for HIV-related pathology as the function of dendritic and Langerhans' cells, both target cells for HIV, is disrupted. Delayed-type hypersensitivity (p. 226), a good indicator of cell-mediated immunity, is frequently reduced or absent even before clinical signs of immunosuppression appear. Pruritus is a common complaint at all stages of HIV. Generalized dry, itchy, flaky skin is typical and the hair may become thin and dry. An intensely pruritic papular eruption favouring the extremities may be found, particularly in patients from sub-Saharan Africa. Eosinophilic folliculitis presents with urticarial lesions particularly on the face, arms and legs.

Drug reactions with cutaneous manifestations are extremely frequent, with rashes developing notably to sulphur-containing drugs amongst others (see Fig. 23.39, p. 1359). Recurrent aphthous ulceration, which is severe and slow to heal is common and can impair the patient's ability to eat. Biopsy may be indicated to exclude other causes of ulceration. Topical steroids are useful and resistant cases may respond to thalidomide.

In addition to the above the skin is a common site of opportunistic infections (see below).

Haematological complications

Anaemia, neutropenia and thrombocytopenia are all common in advanced HIV infection.

- *Lymphopenia* - this progresses as the CD4 count falls.
- *Anaemia of chronic HIV infection* is usually mild, normochromic and normocytic.
- *Neutropenia* is common and usually mild.
- *Isolated thrombocytopenia* may occur early in infection and be the only manifestation of HIV for some time. Platelet counts are often moderately reduced but can fall dramatically to 10-20 x 10^9/L producing easy bleeding and bruising. Circulating antiplatelet antibodies lead to peripheral destruction. Megakaryocytes are increased in the bone marrow but their function is impaired. Effective antiretroviral therapy usually produces a rise in platelet count. Thrombocytopenic patients undergoing dental, medical or surgical procedures may need therapy with human immunoglobulin, which gives a transient rise in platelet count, or be given platelet transfusion. Steroids are best avoided.
- *Pancytopenia* occurs because of underlying opportunistic infection or malignancies, in particular *Mycobacterium avium-intracellulare,* disseminated cytomegalovirus and lymphoma.
- *Other complications.* Myelotoxic drugs include zidovudine (megaloblastic anaemia, red cell aplasia, neutropenia), lamivudine (anaemia, neutropenia), ganciclovir (neutropenia), systemic chemotherapy (pancytopenia) and co-trimoxazole (agranulocytosis).

Gastrointestinal effects (see p. 335)

Weight loss and diarrhoea are extremely common in HIV-infected patients. Wasting is a common feature of advanced HIV infection, which although originally attributed to direct HIV effects on metabolism, is usually a consequence of anorexia. There is a small increase in resting energy expenditure in all stages of HIV, but weight and lean body mass usually remain normal during periods of clinical latency when the patient is eating normally.

HIV enteropathy is a term that has been used to describe a syndrome of diarrhoea, malabsorption and weight loss for which no other pathology has been found. HIV infection of the lymphocytes (in the lamina propria) which are distributed throughout both the large and small bowel, with disturbance of cytokine production, may be responsible. Villous atrophy is a common histological finding in the small bowel.

Hypochlorhydria is reported in patients with advanced HIV disease and may have consequences for drug absorption and bacterial overgrowth in the gut.

Rectal lymphoid tissue cells are the targets for HIV infection during penetrative anal sex and may be a reservoir for infection to spread through the body.

Renal complications

HIV-associated nephropathy (HIVAN) (see p. 635), although rare, can cause significant renal impairment, particularly in more advanced disease. It is most frequently seen in black male patients and can be exacerbated by heroin use.

Nephrotic syndrome subsequent to *focal glomerulosderosis* is the usual pathology, which may be a consequence of HIV cytopathic effects on renal tubular epithelium. The course is usually relentlessly progressive and dialysis may be required.

Many nephrotoxic drugs are used in the management of HIV-associated pathology, particularly foscarnet, amphotericin B, pentamidine, sulfadiazine and indinavir.

Respiratory complications

The upper airway and lungs serve as a physical barrier to airborne pathogens and any damage will decrease the efficiency of protection, leading to an increase in upper and lower respiratory tract infections. The sinus mucosa may also function abnormally in HIV infection and is frequently the site of chronic inflammation. Response to antibacterial therapy and topical steroids is usual but some patients require surgical intervention. A similar process is seen in the middle ear, which can lead to chronic otitis media.

Lymphoid interstitial pneumonitis (LIP) is well described in paediatric HIV infection but is uncommon in adults. There is an infiltration of lymphocytes, plasma cells and

lymphoblasts in alveolar tissue. Epstein-Barr virus may be present. The patient presents with dyspnoea, and a dry cough, which may be confused with pneumocystis infection (see p. 136). Reticular nodular shadowing is seen on chest X-ray. Therapy with steroids may produce clinical and histological benefit in some patients.

Endocrine complications

Various endocrine abnormalities have been reported, including reduced levels of testosterone and abnormal adrenal function. The latter assumes clinical significance in more advanced disease when intercurrent infection superimposed upon borderline adrenal function precipitates clear adrenal insufficiency requiring replacement doses of gluco- and mineralocorticoid. CMV is also implicated in adrenal-deficient states.

Cardiac complications

Cardiomyopathy, although rare associated with HIV, may lead to congestive cardiac failure. Lymphocytic and necrotic myocarditis have been described. Ventricular biopsy should be performed to ensure other treatable causes of myocarditis are excluded. Antiretrovirals therapy may be helpful.

CONDITIONS ASSOCIATED WITH IMMUNODEFICIENCY

Immunodeficiency allows the development of opportunistic infections (OI) (Table 2.51). These are diseases caused by organisms that are not usually considered pathogenic, unusual presentations of known pathogens, and the occurrence of tumours that may have an oncogenic viral aetiology. Susceptibility increases as the patient becomes more immunosuppressed. CD4 T lymphocyte numbers are used as markers to predict the risk of infection. Patients with CD4 counts above 200 are at low risk for the majority of AIDS-defining OIs. A hierarchy of thresholds for specific infectious risks can be constructed. Mechanisms include defective T cell function against protozoa, fungi and viruses, impaired macrophage function against intracellular bacteria such as mycobacteria and salmonella and defective B cell immunity against capsulated bacteria such as *Strep, pneumoniae* and *Haemophilus.* Many of the organisms causing clinical disease are ubiquitous in the environment or are already carried by the patient.

Diagnosis in an immunosuppressed patient may be complicated by a lack of typical signs, as the inflammatory response is impaired. Examples are lack of neck stiffness in cryptococcal meningitis or minimal clinical findings in early *Pneumocystis carinii* pneumonia (PCP). Multiple pathogens may coexist. Indirect serological tests are frequently unreliable. Specimens must be obtained from the appropriate site for examination and culture in order to make a diagnosis.

Table 2.51 **Major HIV-associated pathogens**

Protozoa
Toxoplasma gondii
Cryptosporidium parvum
Microsporidia spp.
Leishmania donovani

Haemophilus influenzae
Moraxella catarrhalis
Rhodococcus equii
Bartonella quintana
Nocardia

Opportunistic infections in the HAART era

In many developed countries the mortality and morbidity associated with HIV infection have declined dramatically since the introduction of potent antiretroviral therapy. In the USA the age-adjusted death rate from AIDS fell 48% between 1996 and 1997 and death rates across Europe fell fivefold between 1995 and 1998. European data showed a fall in AIDS defining illnesses (ADI) from 30.7 per 100 patient years of observation to 2.5 per 100 patient years between 1994 and 1998, with patients on HAART having a lower rate of ADIs than patients not on HAART. This trend has continued - recent data from Europe demonstrate a 50% lower incidence of AIDS in 1998-2001 than in 1996-1998, irrespective of CD4 count. Potential long-term adverse effects associated with HAART have not altered its effectiveness in treating AIDS. However the decline has been steeper for some OIs than others, suggesting that the immune reconstitution due to HAART may not be functionally equal against all HIV-associated complications. Importantly not all patients have adequate responses to these medications, even if they are available and tolerable. Immune reconstitution with HAART may produce unusual responses to opportunistic pathogens and confuse the clinical picture. Thus prevention and treatment of OIs remains an integral part of the management of HIV infection.

Prevention of opportunistic infection in HIV-infected patients

Avoid infection

Exposure to certain organisms can be avoided in those known to be HIV infected. Attention to food hygiene will reduce exposure to salmonella, toxoplasmosis and *Cryptosporidium,* and protected sexual intercourse will reduce exposure to herpes simplex virus (HSV), hepatitis B and papillomaviruses. Cytomegalovirus (CMV)-negative patients should be given CMV-negative blood products.

Immunization strategies

Immunization may not be as effective in HIV-infected individuals. Live virus vaccines should not be used (e.g. yellow fever, live polio).

Hepatitis A and B vaccines should be given for those without natural immunity who are at risk, particularly if there is coexisting liver pathology, e.g. hepatitis C.

Chemoprophylaxis

In the absence of a normal immune response, many OIs are hard to eradicate using antimicrobials, and the recurrence rate is high. Primary and secondary chemoprophylaxis has reduced the incidence of many OIs. Advantages must be balanced against the potential for toxicity, drug interactions and cost, with each medication added to what are often complex drug regimens.

Primary prophylaxis has been shown to be effective in reducing the risk of *Pneumocystis carinii,* toxoplasmosis and *Mycobacterium avium-intracellulare.*

Primary prophylaxis is not normally recommended against cytomegalovirus, herpesviruses or fungi.

With the introduction of HAART and immune reconstitution, ongoing chemoprophylaxis for previously life-threatening conditions (e.g. *Pneumocystis carinii,* cytomegalovirus retinitis, cryptococcus, toxoplasmosis, MAI) can be discontinued in those patients with CD4 counts that remain consistently above 200 and who have a low viral load. American guidelines for stopping and restarting prophylaxis have been published. It is necessary to review such decisions as clinical and laboratory parameters change. In developing countries unable to obtain HAART, long-term secondary prophylaxis is advocated. Other less severe but recurrent infections may also warrant prophylaxis (e.g. herpes simplex, candidiasis).

SPECIFIC CONDITIONS ASSOCIATED WITH HIV INFECTION

Fungal infections

Pneumocystis carinii (see p. 95) This organism most commonly causes pneumonia (PCP) but can cause disseminated infection. It is not usually seen until patients are severely immunocompromised with a CD4 count below 200. The infection remains common although the use of primary prophylaxis in patients with CD4 < 200 has reduced the incidence. The organism damages alveolar epithelium, which impedes gas exchange and reduces lung compliance.

The onset is often insidious over a period of weeks, with a prolonged period of increasing shortness of breath (usually on exertion), non-productive cough, fever and malaise. Clinical examination reveals tachypnoea, tachycardia, cyanosis and signs of hypoxia. Fine crackles are heard on auscultation, although in mild cases there may be no auscultatory abnormality. In early infection the chest X-ray is normal but the typical appearances are of bilateral perihilar interstitial infiltrates, which can progress to confluent alveolar shadows throughout the lungs. High-resolution CT scans of the chest demonstrate a characteristic ground-glass appearance even when there is little to see on the chest X-ray. The patient is usually hypoxic and desaturates on exercise. Definitive diagnosis rests on demonstrating the organisms in the lungs via bronchoalveolar lavage. As the organism cannot be cultured in vitro it must be directly observed either with silver staining or immunofluorescent techniques.

Treatment should be instituted as early as possible. First-line therapy is with intravenous co-trimoxazole (100 mg/kg per day sulfamethoxazole and 20mg/kg per day trimethoprim in divided doses) for 21 days. Up to 40% of patients receiving this regimen will develop some adverse drug reaction, including a typical allergic rash. Mutations in the gene for dihydropteroate synthetase in P. *carinii,* which may theoretically lead to co-trimoxazole resistance, have been reported. There is, however, no evidence that co-trimoxazole is becoming less efficacious clinically. If the patient is sensitive to co-trimoxazole, intravenous pentamidine (4 mg/kg per day) or dapsone and trimethoprim are given for the same duration. Atovaquone or a combination of clindamycin and primaquine is also used. In severe cases (P_aO_2 less than 9.5 kPa), systemic corticosteroids have been shown to reduce mortality and should be added. Continuous positive airways pressure (CPAP) or mechanical ventilation (see p. 982) may be required if the patient remains severely hypoxic or becomes too tired. Pneumothorax not uncommonly complicates the clinical course in an already severely hypoxic patient.

Long-term secondary prophylaxis is required in developing countries *without* HAART in patients whose CD4 count remains below 200, and to prevent relapse, the usual regimen being co-trimoxazole 960 mg three times a week. Patients sensitive to sulphonamide are given either dapsone or pyrimethamine or nebulized pentamidine. The latter only protects the lungs and does not penetrate the upper lobes particularly efficiently; hence if relapses occur on this regimen they may be either atypical or extrapulmonary.

Cryptococcus (see p. 93)

The most common presentation of cryptococcus in the context of HIV is meningitis, although pulmonary and disseminated infections can also occur. The organism, C. *neoformans,* is widely distributed - often in bird droppings - and is usually acquired by inhalation. The onset may be insidious with non-specific fever, nausea and headache. As the infection progresses the conscious level is impaired and changes in affect may be noted. Fits or focal neurological presentations are uncommon. Neck stiffness and photophobia may be absent as these signs depend on the inflammatory response of the host, which in this setting is abnormal.

The diagnosis is made on examination of the CSF (a CT scan must be carried out before lumbar puncture to exclude space-occupying pathology). Indian ink staining shows the organisms directly and CSF cryptococcal

antigen is positive at variable titre. It is unusual for the cryptococcal antigen to become negative after treatment, although the levels should fall substantially. Cryptococci can also be cultured from CSF and/or blood.

Factors associated with a poor prognosis include a high organism count in the CSF, a low white cell count in the CSF, and an impaired consciousness level at presentation.

Treatment. Initial treatment is usually with intravenous amphotericin B (0.7 mg/kg per day), although intravenous fluconazole (400 mg daily) is useful if renal function is impaired or if amphotericin side-effects are troublesome. Oral fluconazole can be substituted if the organism is shown to be fully sensitive and the patient is responding. The mortality from a first episode of cryptococcal meningitis is up to 20%. Relapse is very common, possibly from a prostatic reservoir in men. Lifelong secondary prophylaxis is required in the absence of HAART.

Candida (see p. 91)

Mucosal infection with *Candida* is very common in HIV-infected patients. Oral *Candida* is one of the most common conditions. C. *albicans* is the usual organism, although C. *krusei* and C. *glabrata* occur. Pseudomembranous candidiasis consisting of creamy plaques in the mouth and pharynx is the best recognized. *Erythematous Candida* is more subtle and appears as reddened areas on the hard palate or as atypical areas on the tongue. Angular cheilitis can occur in association with either form or more rarely alone. Vulvovaginal *Candida* is often problematic.

Oesophageal Candida infection produces dysphagia with retrosternal discomfort (see p. 279). Barium swallow or endoscopy shows multiple areas of ulceration throughout the length of the oesophagus. Fluconazole or itraconazole are the agents of choice. With prolonged exposure to these agents in HIV-infected patients, azole-resistant C. *albicans* is becoming an increasing problem. Switching azoles may produce a response. Symptom relief may require intravenous amphotericin. *Disseminated Candida* is uncommon in the context of HIV infection. C. *krusei* may colonize patients who have been treated with fluconazole, as it is fluconazole-resistant. Amphotericin is useful in the treatment of this infection and an attempt to type *Candida* from clinically azole-resistant patients should be made.

Aspergillus (see p. 93)

Infection with *Aspergillus fumigatus* occurs in advanced HIV disease. *Aspergillus* is controlled by functioning neutrophils, and patients with long-standing neutropenia (often due to chemotherapy) and those on ganciclovir therapy for CMV and myelotoxic antiretrovirals, are prone to this infection. Spores are airborne and ubiquitous. Following inhalation, lung infection proceeds to haematogenous spread to other organs. Sinus infection occurs.

The prognosis is very poor, with amphotericin B being the mainstay of therapy. Itraconazole is also effective. It is almost impossible to deal effectively with *Aspergillus* unless the neutrophil count can be sustained, and neutropenic patients should be supported with granulocyte colony-stimulating factors.

Table 2.52 **Some mucocutaneous manifestations of HIV infection (see also Ch. 23)**

Skin	Mucous membranes
Dry skin and scalp	Candidiasis:
Onychomycosis	oral
Seborrhoeic dermatitis	vulvovaginal
Tinea:	Oral hairy leucoplakia
cruris	Aphthous ulcers
pedis	Herpes simplex:
Pityriasis:	genital
versicolor	oral
rosea	labial
Folliculitis	Periodontal disease
Acne	Warts:
Molluscum contagiosum	oral
Warts	genital
Herpes zoster:	
mutidermatomal	
disseminated	
Papular pruritic eruption	
Scabies	
Icthyosis	
Kaposi's sarcoma	

Histoplasmosis (see p. 92)

This infection is a well-recognized complication of HIV in the USA where it is endemic in soil. The most common manifestation is with pneumonia, which may be confused with *Pneumocystis carinii* in its presentation (see above).

Superficial dermatophyte infections

These are common. Nail infection with *Tricophyton rubrum* causes onychomycosis (see p. 1323 and Table 2.52).

Protozoal infections

Toxoplasmosis (see p. 103)

Toxoplasma gondii most commonly causes encephalitis and cerebral abscess in the context of AIDS, usually as a result of reactivation of previously acquired infection. The incidence depends on the rate of seropositivity to toxoplasmosis in the particular population. High levels are found in France where up to 90% of the adult population is seropositive. About 25% of the adult UK population is toxoplasmosis seropositive. AIDS patients who have these antibodies may develop cerebral toxoplasmosis.

The clinical presentation is of a focal neurological lesion with convulsions, fever, headache and possible confusion. Examination reveals focal neurological signs in more than 50% of cases. Eye involvement with chorioretinitis may also be present. In most but not all cases toxoplasmosis serology is positive. Typically CT scan of the brain shows multiple ring-enhancing lesions. A single lesion on CT may be found to be one of several

on MRI. A solitary lesion on MRI, however, makes a diagnosis of toxoplasmosis unlikely.

The definitive method of diagnosis is brain biopsy, but in most cases an empirical trial of anti-toxoplasmosis therapy is instituted and if this leads to radiological improvement within 3 weeks this is considered diagnostic. The differential diagnosis includes cerebral lymphoma, tuberculoma or focal cryptococcal infection.

Treatment is with pyrimethamine for at least 6 weeks (loading dose 200 mg, then 50 mg daily) combined with sulfadiazine and folinic acid. Clindamycin and pyrimethamine may be used in patients allergic to sulphonamide. Anticonvulsants should be given. Lifelong maintenance is required to prevent relapse unless the CD4 count can be restored by HAART. There is some evidence to suggest that co-trimoxazole as PCP prophylaxis has some ability to reduce the incidence of toxoplasmosis.

Cryptosporidiosis (see p. 105)

Cryptosporidium parvum can cause a self-limiting acute diarrhoea in an immunocompetent individual. In HIV infection it can cause severe and progressive watery diarrhoea which may be associated with anorexia, abdominal pain, nausea and vomiting. Cysts attach to the epithelium of the small bowel wall, causing secretion of fluid into the gut lumen and failure of fluid absorption. It is associated with sclerosing cholangitis (see p. 404). The cysts are seen on stool specimen microscopy using Kinyoun acid-fast stain. The organism is readily identified in small bowel biopsy specimens.

Treatment is largely supportive, as there are no effective antimicrobial agents available other than a non-absorbable aminoglycoside, paromamycin, which may have a limited effect on diarrhoea.

Microsporidiosis

Enterocytozoon bieneusi and *Septata intestinalis* are associated with diarrhoeal illness in HIV infection. Spores can be detected in stools using a trichrome or fluorescent stain that attaches to the chitin of the spore surface. Albendazole eradicates the infection with amelioration of symptoms.

Leishmaniasis (see p. 101)

This is a cause of illness in immunosuppressed HIV-infected individuals who have been in endemic areas, which include South America, tropical Africa and much of the Mediterranean. Symptoms are frequently non-specific with fever, malaise, diarrhoea and weight loss. Splenomegaly, anaemia and thrombocytopenia are significant findings. Amastigotes may be seen on bone marrow biopsy or from splenic aspirates. Serological tests exist for *Leishmania* but they are not reliable in this setting.

Treatment is based on sodium stibogluconate (pentavalent antimony) but in HIV infection the response may be better to liposomal amphotericin. Relapse without HAART is common unless long-term secondary prophylaxis is given.

Viral infections

Hepatitis virus B and C (see pp. 364 and 367) Because of the comparable routes of transmission of hepatitis viruses and HIV, co-infection is common, particularly in drug users and those infected by blood products. A higher prevalence of hepatitis viruses is found in those with HIV infection than in the general population. With the striking improvement in prognosis in HIV since the introduction of HAART, morbidity and mortality of hepatitis co-infection has become increasingly significant and may limit life expectancy in HIV. In co-infected patients the hepatotoxicity associated with certain antiretroviral agents may be potentiated.

Hepatitis B infection does not appear to influence the natural history of HIV; however, in HIV co-infected patients there is a significantly reduced rate of hepatitis B e antigen (HBeAg) clearance, and the risk of developing chronic infection is increased. HBV reactivation and reinfection is also seen. Liver disease occurs most commonly in those with high HBV DNA levels indicative of continuing replication.

It has been suggested that hepatitis C is associated with more rapid progression of HIV infection, and the CD4 responses to HAART in co-infected patients may be blunted. Hepatitis C progression is both more likely and more rapid in the presence of HIV infection, and the levels of hepatitis C viral activity tend to be elevated. The hepatotoxicity associated with HAART is worse in those with HCV co-infection.

Assessment of co-infected patients requires full clinical and laboratory evaluation and staging of both infections. For HCV both viral load and genotype will influence therapeutic decision-making. In HBV infection, detection and quantification of HBV DNA acts as a marker of viral activity, whilst the significance of viral genotype is still uncertain. Liver biopsy is useful to obtain a histological staging of disease.

There are limited treatment options for HBV. The ideal time to start treatment is not clear; however, response rates for co-infected patients may be better at higher CD4 counts. Treatments for HBV include some agents with concomitant anti-HIV activity, including lamivudine and tenofovir. These must be used within an effective anti-HIV regimen.

In HCV co-infection, criteria for treatment are similar for those infected with HCV alone, depending on stage of disease and HCV genotype. Pegylated interferon has greater efficacy than standard interferon in this situation and is combined with ribavirin. In HIV/HCV co-infected patients those with a CD4 count above 200 have a better chance of success. In general it is preferable to treat HCV first if HIV infection is stable, as this minimizes hepatotoxicity associated with HAART. However, if the CD4 count is low or the patient is at risk of HIV progression, HIV therapy should be instituted first.

Cytomegalovirus (see p. 46)

CMV can be a cause of considerable morbidity in HIV-infected individuals, especially in the later stages of

disease. The major problems encountered are retinitis, colitis, oesophageal ulceration, encephalitis and pneumonitis. CMV infection is associated with an arteritis, which may be the major pathogenic mechanism. CMV also causes polyradiculopathy and adrenalitis.

CMV retinitis

This tends to occur once the CD4 count is below 100 and is found in up to 30% of AIDS cases. It is the most common cause of eye disease and blindness. Although usually unilateral to begin with, the infection frequently progresses to involve both eyes. Presenting features depend on the area of retina involved (loss of vision being most common with macular involvement) and include floaters, loss of visual acuity, field loss and scotomata, orbital pain and headache.

Examination of the fundus (Fig. 2.47) reveals haemorrhages and exudates, which follow the vasculature of the retina (so called 'pizza pie' appearances). The features are highly characteristic and the diagnosis is made clinically. Retinal detachment and papillitis may occasionally occur. If untreated, retinitis spreads within the eye, destroying the retina within its path. Routine fundoscopy should be carried out on all HIV-infected patients to look for evidence of early infection. Any patient with symptoms of visual disturbance should have a thorough examination with pupils dilated, and if no evident pathology is seen a specialist ophthalmologic opinion should be sought.

TrBatment for CMV should be started as soon as possible with either ganciclovir (lOmg/kg daily) or foscarnet (60mg/kg 8-hourly) given intravenously for at least 3 weeks, or until retinitis is quiescent. Reactivation is common, leading to blindness. The major side-effect of ganciclovir is myelosuppression, and foscarnet is nephrotoxic. Maintenance therapy requires long-term vascular access through either a Hickman line or subcutaneous reservoir device. An oral form of ganciclovir is available which has some long-term benefit when used as maintenance therapy, but has a lower efficacy than intravenous ganciclovir. Ganciclovir can be given directly into the vitreous cavity but regular injections are required. A sustained-release implant of ganciclovir can be surgically inserted into the affected eye. Cidofovir is available for use when the above drugs are contraindicated. It has renal toxicity.

Fig. 2.47 Untreated CMV retinitis.

CMV colitis

The usual presenting features include abdominal pain, often generalized or left iliac, diarrhoea which may be bloody, generalized abdominal tenderness with rebound in some cases, and a low-grade fever. Loops of dilated large bowel may be seen on abdominal X-ray. Sigmoidoscopy shows a friable or ulcerated mucosa, which should be biopsied. The diagnosis is made on the histological appearances with characteristic 'owls eye' cytoplasmic inclusion bodies (see Fig. 2.16).

Treatment with either intravenous ganciclovir or foscarnet for 3 weeks improves symptoms and the histological changes are reversed. However, relapse is common once therapy is stopped, unless HAART is available. The issue of long-term maintenance therapy in this situation is controversial since, unlike CMV retinitis, repeated attacks of colitis do not necessarily have significant long-term sequelae of the sort associated with retinitis. Given the complications associated with maintenance anti-CMV therapy there may be no overall benefit.

Other sites along the gastrointestinal tract also are prone to CMV infection. Solitary ulceration of the oesophagus, usually in the lower third, causes painful dysphagia. CMV can also cause hepatitis.

CMV neurological conditions

CMV polyradiculopathy usually affects the lumbosacral roots, leading to paraparesis and sphincter disturbance. The CSF has an increase in white cells, which surprisingly are almost all neutrophils. Although progression may be arrested by anti-CMV medication, functional recovery may not occur. The encephalopathy of CMV has clinical similarities to that caused by HIV itself. It tends to respond poorly to therapy.

Herpesviruses (see pp. 43 and 1321) *Herpes simplex* infection occurs with greater frequency and severity, presenting in an ulcerative rather than vesicle form in profoundly immunosuppressed individuals. Genital, oral and occasionally disseminated infection is seen. Viral shedding may be prolonged in comparison with immunocompetent patients.

Varicella zoster can occur at any stage of HIV but tends to be more aggressive and longer-lasting in the more immunosuppressed patient. Multidermatomal zoster may occur.

Therapy with aciclovir is usually effective. Frequent recurrences need suppressive therapy. Aciclovir-resistant strains (usually due to thymidine kinase-deficient mutants) in HIV-infected patients have become more common. Such strains may respond to foscarnet.

Herpesvirus 8 (HHV-8) is associated with Kaposi's sarcoma (see p. 48).

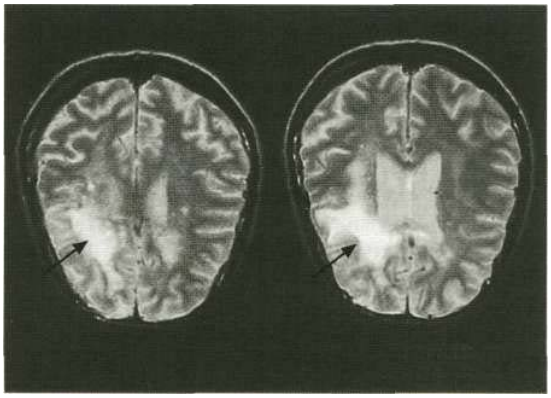
Epstein-Barr virus (see p. 47)

Patients with HIV have been shown to have high levels of EBV colonization. There are increased EBV titres in oropharyngeal secretions and high levels of EBV-infected B cells. The normal T cell response to EBV is depressed in HIV. EBV is strongly associated with primary cerebral lymphoma and non-Hodgkin's lymphoma (see below). Oral hairy leucoplakia caused by EBV is a sign of immunosuppression first noted in HIV but now also recognized in other conditions. It appears intermittently on the lateral borders of the tongue or the buccal mucosa as a pale ridged lesion. Although usually asymptomatic, patients may find it unsightly and occasionally painful. The virus can be identified histologically and on electron-microscopy. There is a variable response to aciclovir.

Human papillomavirus (see **p. 48)** HPV produces genital, plantar and occasionally oral warts, which may be slow to respond to therapy and recur repeatedly. HPV is associated with the more rapid development of cervical and anal intraepithelial neoplasia, which in time may progress to squamous cell carcinoma of the cervix or rectum in HIV-infected individuals.

Papovavirus (see p. 48)

JC virus, a member of the papovavirus family, which infects oligodendrocytes, causes progressive multifocal leucoencephalopathy (PML). This leads to demyelination particularly within the white matter of the brain. The features are of progressive neurological and/ or intellectual impairment, often including hemiparesis or aphasia. The course is usually inexorably progressive but a stuttering course may be seen. Radiologically the lesions are usually multiple and confined to the white matter. They do not enhance with contrast and do not produce a mass effect. MRI (Fig. 2.48) is more sensitive than CT and reveals enhanced signal on T2-weighted images of the lesions. Definitive diagnosis is made on histological and viral examination of brain tissue obtained at biopsy. There is no specific therapy. HAART which enhances the immune response has, however, produced both clinical and radiological remission in a number of cases. Addition of cidofovir to HAART may improve outcome in some patients.



Fig, 2.48 MRI scans showing progressive multifocal leucoencephalopathy.

Bacterial infections

Bacterial infection in HIV is common and frequently disseminated. Cell-mediated immune responses normally control infection against intracellular bacteria, e.g. *Mycobacterium*. The abnormalities of B cell function associated with HIV lead to infections with encapsulated bacteria, as reduced production of IgG_2 cannot protect against the polysaccharide coat of such organisms. These functional abnormalities may be present well before there is a significant decline in CD4 numbers and so bacterial sepsis may be seen at early stages of HIV infection. *Streptococcus pneumoniae, Haemophilus influenzae* and *Moraxella catarrhalis* infections are examples. Bacterial infection is often disseminated and, although usually amenable to standard antibiotic therapy, may reoccur. Long-term prophylaxis is required if recurrent infection is frequent.

Skin conditions such as folliculitis, abscesses and cellulitis are common and are usually caused by *Staph. aureus*. Periodontal disease, which may be necrotizing, causes pain and damage to the gums. It is more common in smokers, but no specific causative agent has been identified. Therapy is with local debridement and systemic antibiotics.

Salmonella (non-typhoidal) (see p. 68) is a frequent pathogen in HIV infection. Salmonellas are able to survive within macrophages, this being a major factor in their pathogenicity. Organisms are usually acquired orally and frequently result in disseminated infection. Gastrointestinal disturbance may be disproportionate to the degree of dissemination, and once the pathogen is in the bloodstream any organ may be infected. Salmonella osteomyelitis and cystitis have been reported. Diagnosis is from blood and stool cultures.

Response to standard antibiotic therapy, depending on laboratory sensitivities, is usually good. Recurrent infection is, however, common and long-term prophylaxis may be required.

Education on food hygiene should be provided.

Mycobacteria

Mycobacterium tuberculosis (see p. 86) The interaction between HIV and TB has several particular characteristics. Many parts of the world with a high prevalence of TB also have high rates of HIV infection. The respiratory transmission of TB means both HIV-positive and negative people are being infected. Although more common in immunosuppressed patients, TB can cause disease when there is only minimal immunosuppression and thus often appears early in the course of HIV infection. In many countries where HIV is spreading and TB is endemic there has been a substantial

increase in the incidence of tuberculosis. HIV-related TB frequently represents reactivation of latent TB, but there is also clear evidence of newly acquired infection and nosocomial spread in HIV-infected populations.

The pattern of disease differs with immunosuppression. Patients with relatively well preserved CD4 counts have a clinical picture similar to that seen in HIV-negative patients with pulmonary infection.

In more advanced HIV disease, atypical pulmonary presentations without cavitation and prominent hilar lymphadenopathy, or extrapulmonary TB affecting lymph nodes, bone marrow or liver occur. Bacteraemia may be present.

The diagnosis depends on demonstrating the organisms in appropriate tissue specimens. The response to tuberculin testing is blunted in HIV-positive individuals and is unreliable. Sputum microscopy may be negative even in pulmonary infection and culture techniques are the best diagnostic tool.

M. *tuberculosis* infection usually responds well to standard treatment regimens, although the duration of therapy may be extended, especially in extrapulmonary infection. Multidrug resistance is becoming a problem, particularly in the USA where it is becoming a nosocomial danger. Cases from HIV units in the UK have been reported. Compliance with antituberculous therapy needs to be emphasized. Treatment of TB in the HIV-infected individual is not curative and long-term isoniazid prophylaxis may be given. In patients from TB endemic areas, primary prophylaxis may prevent emergence of infection. Immune reconstitution phenomenon as a result of HAART occurs (p. 149).

Mycobacterium avium-intracellulare

Atypical mycobacteria, particularly *M. avium-intracelluhre* (MAI), generally appear only in the later stages of HIV infection when patients are profoundly immunosuppressed. It is a saprophytic organism of low pathogenicity that is ubiquitous in soil and water. Entry may be via the gastrointestinal tract or lungs with dissemination via infected macrophages.

The major clinical features are fevers, malaise, weight loss, anorexia and sweats. Dissemination to the bone marrow causes anaemia. Gastrointestinal symptoms may be prominent with diarrhoea and malabsorption. At this stage of disease patients frequently have other concurrent infections, so differentiating MAI is difficult on clinical grounds. Direct examination and culture of blood, lymph node, bone marrow or liver give the diagnosis most reliably.

MAI is typically resistant to standard antituberculous therapies, although ethambutol may be useful. Drugs such as rifabutin in combination with clarithromycin or azithromycin reduce the burden of organisms and in some ameliorate symptoms. A common combination is ethambutol, rifabutin and clarithromycin. Addition of amikacin to a drug regimen may produce a good symptomatic response. Primary prophylaxis with rifabutin or azithromycin may delay the appearance of MAI, but no corresponding increase in survival has been shown.

Treatment of mycobacteria in the age of HAART (see pp. 144 and 149)

Treatment of TB in HIV co-infected patients presents specific challenges and requires input from a specialist physician. Treatment is similar to that for HIV-negative patients, although intermittent and short-course regimens are not advised. Therapy should be initiated with four drugs, isoniazid, rifampicin, pyrazinamide and ethambutol for 2 months. Once sensitivities are confirmed, pyrazinamide and ethambutol may be withdrawn and the other two drugs continued for 4 months, although this may be extended in some circumstances. The drug-drug interactions between antiretroviral and antituberculous medications are complex and are a consequence of enzyme induction or inhibition. Rifampicin is a potent inducer of cytochrome P450, which is also the route for metabolism of HIV protease inhibitors. Using both drugs together results in a reduction in circulating protease inhibitor with reduced efficacy and increased potential for drug resistance. Some protease inhibitors themselves block cytochrome P450, which leads to potentially toxic levels of rifampicin and problems such as uveitis and hepatotoxicity. The non-nucleoside reverse transcriptase class also interacts variably with rif amycins, requiring dose alterations. Additionally, there are overlapping toxicities between HAART regimens and antituberculous drugs, in particular hepatotoxicity, peripheral neuropathy and gastrointestinal side-effects. Rifabutin has a weaker effect on cytochrome P450 and may be substituted for rifampicin. Dose adjustments must be made for drugs used in this situation to take account of these interactions.

Paradoxical inflammatory reactions (immune reconsti tution inflammatory syndrome, IRIS) which can include exacerbation of symptoms, new or worsening clinical signs and deteriorating radiological appearances have been associated with the improvement of immune function seen in HIV-infected patients starting HAART in the face of M. *tuberculosis* infection. They are most commonly seen in the first few weeks after initiation of HAART in patients recovering from TB and can last several weeks or months. The syndrome does not reflect inadequate TB therapy and is not confined to any parti cular combination of antiretroviral agents. It is vital to exclude new pathology in this situation. Given these complexities, in certain circumstances it may be prefer able to delay the initiation of HAART until TB is under control. .,

Infections due to other organisms

Strongyloides (see p. Ill), a nematode found in tropical areas, may produce a hyperinfection syndrome in HIV-infected patients. Larvae are produced which invade through the bowel wall and migrate to the lung and occasionally to the brain. Albendazole or ivermectin may be used to control infection. Gram-negative septicaemia can develop (see p. 967).

Scabies (see p. 1325) may be much more severe in HIV infection. It may be widely disseminated over the body

and appear as atypical, crusted papular lesions known as 'Norwegian scabies', from which mites are readily demonstrated. Superadded staphylococcal infection may occur. Treatment with conventional agents such as lindane may fail, and ivermectin has been used to good effect in some patients.

Neoplasms

The mortality and morbidity associated with neoplasia in HIV is substantial, non-Hodgkin's lymphoma being the most significant tumour now, ahead of Kaposi's sarcoma.

Kaposi's sarcoma (see p. 1353)

Kaposi's sarcoma (KS) in association with HIV (epidemic KS) behaves more aggressively than that associated with HIV-negative populations (endemic KS). The incidence has fallen significantly since the introduction of HAART. The tumour is most common in homosexual men and others who have acquired HIV sexually, particularly from a partner who has KS, implicating a sexually transmitted cofactor in the pathogenesis. Human herpesvirus 8 (HHV-8) is involved in pathogenesis. KS skin lesions are characteristically pigmented, well circumscribed and occur in multiple sites. It is a multicentric tumour consisting of spindle cells and vascular endothelial cells, which together form slit-like spaces in which red blood cells become trapped. This process is responsible for the characteristic purple hue of the tumour. In addition to the skin lesions, KS affects lymphatics and lymph nodes, the lung and gastrointestinal tract, giving rise to a wide range of symptoms and signs. Most patients with visceral involvement also have skin or mucous membrane lesions. Visceral KS carries a worse prognosis than that confined to the skin. Kaposi's sarcoma is seen around the eye (Fig. 2.49), particularly in the conjunctivae, which can lead to periorbital oedema.

Treatment with local radiotherapy gives good results in skin lesions and is helpful in lymph node disease. Initiation of HAART may cause regression of lesions and prevent new ones emerging. For patients with aggressive disease, systemic chemotherapy is indicated using combinations of vincristine and bleomycin or the newer liposomal preparations of doxorubicin. Response is often very good although of uncertain duration. Alpha-interferon is also effective.

Fig. ***2.49*** Kaposi's sarcoma of the eyelid.

Lymphoma

A significant proportion of patients with HIV develop lymphoma, mostly of the non-Hodgkin's, large B cell type. These are frequently extranodal, often affecting the brain, lung and gastrointestinal tract. Many of these tumours are strongly associated with Epstein- Barr virus (EBV), with evidence of expression of latent gene nuclear antigens such as EBNA 1-6, some of which are involved in the immortalization of B cells and drive a neoplastic pathway.

HIV-associated lymphomas are frequently very aggressive. Patients often present with systemic 'B' syndromes and progress rapidly despite chemotherapy. Primary cerebral lymphoma is variably responsive to radiotherapy but overall carries a poor prognosis. Lymphomas occurring early in the course of HIV infection tend to respond better to therapy and carry a better prognosis, occasionally going into complete remission.

Squamous cell carcinoma

Squamous cell carcinoma, especially of the cervix and anus, is associated with HIV. Human papillomavirus may have a role in the pathogenesis of these malignancies. Women with HIV infection should have yearly cervical cytology for detection of premalignant change.

INVESTIGATIONS AND MONITORING

Initial assessment

A full history should be taken, followed by examination. Baseline investigations will depend on the clinical setting, but those for an asymptomatic person in the UK are shown in Box 2.18.

Monitoring

Patients are regularly monitored to assess the progression of the infection. Clinical examination will identify signs of immunosuppression (such as oral hairy leucoplakia) and detect early evidence of major opportunistic events. Decisions about appropriate intervention can be made.

Immunological monitoring

CD4 lymphocytes. The absolute CD4 count and the percentage of total lymphocytes that this represents falls as HIV progresses. These figures bear a relationship to the risk of the occurrence of HIV-related pathology, with patients with counts below 200 cells at greatest risk. Rapidly falling CD4 counts and those below 350 are an indication to consider HAART. Routine assays measure numbers of circulating CD4 lymphocytes but are unable to assess cellular function, which may be abnormal, even when numbers are relatively well preserved. Factors

other than HIV (e.g. smoking, exercise, intercurrent infections and diurnal variation) also affect CD4 numbers. CD4 counts are performed at approximately 3-monthly intervals unless values are approaching critical levels for intervention, in which case they are performed more frequently.

Virological monitoring

Viral load (HIV RNA)

The replication of HIV continues at a high rate throughout the course of infection, with many billion new virus particles being produced daily. The rate of viral clearance is relatively constant in any individual and thus the level of viraemia is a reflection of the rate of virus replication. This has both prognostic and therapeutic value.

The commonly used term 'viral load' has been coined to encompass viraemia and HIV RNA levels. Three HIV RNA assays for viral load are in current use:

- branched-chain DNA (bDNA)
- reverse transcription polymerase chain reaction (RT-PCR)
- nucleic acid sequence-based amplification (NASBA).

Results are given in copies of viral RNA per millilitre of plasma, or converted to a logarithmic scale, and there is good correlation between tests. The most sensitive test is able to detect as few as 20 copies of viral RNA per millilitre. Transient increases in viral load are seen following immunizations (e.g. for influenza and *Pneumococcus)* or during episodes of acute intercurrent infection (e.g. tuberculosis); and viral load measurements should not be carried out within a month of these events.

By about 6 months after seroconversion to HIV, the viral set-point for an individual is established and there is a correlation between HIV RNA levels and long-term prognosis, independent of the CD4 count. Those patients with a viral load consistently greater than 10 000 copies/mL have a 10 times higher risk of progression to AIDS over the ensuing 5 years than those consistently below 10 000 copies/mL. Although a correlation exists between viral load and CD4 cell numbers, the viral load appears to be the best predictor of the long-term prognosis, whilst the CD4 count will give warning of the risks of immediate or shorter-term problems.

HIV RNA is the standard marker of treatment efficacy, with levels falling in response to the introduction of effective antiretroviral medication (see below). Both duration and magnitude of virus suppression are pointers to clinical outcome. None of the currently available therapies is able to suppress viral replication indefinitely, and a rising viral load indicates drug failure.

Various guidelines exist for viral load monitoring in clinical practice. Baseline measurements are followed by repeat estimations at intervals of 3-4 months, ideally in conjunction with CD4 counts to allow both pieces of evidence to be used together in decision-making. Following initiation of antiretroviral therapy or changes in therapy, effects on viral load should be seen by 4 weeks, reaching a maximum at 10-12 weeks, when repeat viral load testing should be carried out (see Fig. 2.46).

Phenotype determination

Two phenotypes of HIV, syncytium-inducing (SI) and non-syncytium-inducing (NSI), exist and appear to correlate with disease progression. This is a specialized technique that is currently available only as a research tool.

Genotype determination

Clear genotype variations exist within HIV and there are increasing numbers of well-identified point mutations associated with antiretroviral drugs. Viral genotype has now entered routine practice to guide therapy, particularly in treatment-experienced patients and women who are pregnant.

MANAGEMENT OF THE HIV-INFECTED PATIENT (Box 2.19)

The possibility of understanding HIV as a chronic controllable condition came with the advent of highly active antiretroviral therapy (HAART). Since then management in the resource-rich world has moved away from treating opportunistic conditions in immunosuppressed patients towards delivering long-term, effective suppressive therapy. The emphasis on using treatments to sustain life has shifted in favour of managing life with the current therapies.

Nonetheless there is still no cure for HIV and patients must live with a chronic, infectious and unpredictable condition. Limitations to efficacy include the inability of current drugs to clear HIV from certain intracellular pools, the occurrence of serious side-effects, strict adherence

Box 2.19 **An approach to sick HIV-positive patients**

Potential problems include

Adverse drug reactions Acute opportunistic infections Presentation or complication of malignancy Immune reconstitution phenomenon Infection in an immunocompromised host Organic or functional brain disorders Non-HIV-related pathology must not be forgotten

Full medical history

Remember:

Antiretroviral drugs, prophylaxis, travel, previous HIV-related pathology, potential source of infectious agents (food hygiene, pets, contacts with acute infections, contact with TB, sexually transmitted infections) Secure confidentiality. Check with patient who is aware of HIV diagnosis.

Full physical examination

Remember:

Signs of adverse drug reactions, e.g. skin rashes, oral ulceration

Signs of disseminated sepsis

Clinical evidence of immunosuppression, e.g. oral Candida, oral hairy leucoplakia

Focal neurological signs and/or meningism

Evidence of altered mental state - organic or functional

Examine:

- the genitalia, e.g. herpes simplex, syphilis, gonorrhoea
- the fundi, e.g. CMV retinitis
- the mouth

*• Lymphadenopathy.

Immediate investigations

Full blood count and differential count

Liver and renal function tests

Plasma glucose

Blood gases including acid-base balance

Blood cultures, including specimens for mycobacterial culture Microscopy and culture of available/appropriate specimens: stool, sputum, urine, CSF Malaria screen in recent travellers from malaria areas Serological tests for cryptococcal antigen, toxoplasmosis: save serum for viral studies Chest X-ray CT/MR scan of brain if focal neurological signs, and ALWAYS before lumbar puncture

A/6: Lymphocyte subsets and HIV viral load assays may yield misleading results during intercurrent illness.

requirements, complex drug-drug interactions, and the ongoing emergence of resistant viral strains.

The aims of management in HIV infection are to maintain physical and mental health, to avoid transmission of the virus, and to provide appropriate palliative support as needed. The complexity of HIV infection means that it is best managed via a multidisciplinary team approach. Confidentiality must be strictly observed and care taken over establishing who is aware of the patient's diagnosis and who is excluded from that knowledge. Psychological support is needed not only for the patient but also for family, friends and carers. Dietary assessment and advice should be freely accessible. Clear advice on reducing the risk of HIV transmission must be provided and future sexual practices discussed. Information must be available to allow people to make informed choices about child-bearing. The implications for existing family members should be considered. General health promotion advice on smoking, alcohol, diet, drug misuse and exercise should be given, particularly in the light of the emerging cardiovascular, metabolic and hepatotoxicity risks associated with HAART (see p. 149).

Antiretroviral drugs (ARVs)

The complexity of treatment regimens against HIV infection increases with the rising number of available compounds and the growth in new information about their use. Drugs of five different classes (Table 2.53) are currently available in the UK, with several others close to release. Various events in the HIV life cycle have been identified as potential targets for antiretroviral therapy. Inhibitors of HIV reverse transcriptase and of HIV protease are so far the most developed. Newer agents of these classes with improved pharmacokinetic, side-effect and resistance profiles are coming into production.

Reverse transcriptase inhibitors are of three types: nucleoside analogues (nucleoside reverse transcription inhibitors, NRTIs), nucleotide analogues (nucleotide reverse transcriptase inhibitors, NtRTIs) and non-nucleoside analogues (non-nucleoside reverse transcriptase inhibitors NNRTIs).

- *Nucleoside analogues (NRTIs)* inhibit reverse transcription by binding to viral DNA and also act as DNA chain terminators. NRTIs need to be phosphorylated intracellularly for activity to occur. These were the first group of agents to be used against HIV, initially as monotherapy and later as dual drug combinations. Usually two drugs of this class are combined to provide the 'backbone' of a HAART regimen. Zidovudine and lamivudine have been combined into a single tablet, (Combivir), and zidovudine, lamivudine and abacavir into Trizivir, which helps reduce the pill burden. NRTIs have been associated with mitochondrial toxicity, a consequence of their effect on the human mitochondrial DNA polymerase. Lactic acidosis is a recognized complication of this group of drugs.
- *Nucleotide analogues (NtRTIs)* have a similar mechanism of action but do not require intracellular phosphorylation for activity. Tenofovir, a monophosphorylated thymidine derivative, is the only licensed compound of this group.
- *Non-nucleoside analogues (NNRTIs)* interfere with reverse transcriptase by direct binding to the enzyme.

Table 2.53 **Antiretroviral drugs available in the UK**

Drug	Daily dose and pill burden	Metabolism/food	Side-effects
Nucleoside reverse transcriptase inhibitors (NRTIs) (nucleoside analogues)			
Abacavir	300 mg x 2 tablets/day	No food restrictions	Hypersensitivity reaction, fever, rash, vomiting. Association with mitochondrial dysfunction and lactic acidosis
Didanosine/DDI	400 mg o.d. (> 60 kg), 250 mg o.d. (< 60 kg) 1 capsule/day	30-60 minutes before food	Nausea, diarrhoea, peripheral neuropathy, pancreatitis. Association with mitochondrial dysfunction and lactic acidosis
Emtricitabine (PTC)	200 mg o.d.		Headache, nausea, skin pigmentation
		No food effects Renal excretion Modify dose if creatinine clearance is < 50 mLYmin	
Lamivudine/3TC	150 mg x 2 2 tablets/day	No food effects, well absorbed with high bioavailability	Nausea, headache, rash, peripheral neuropathy, myelosuppression. Association with mitochondrial dysfunction and lactic acidosis
Stavudine/D4T	40 mg x 2 2 capsules/day x 3 Reduce to 30 mg x 2 for persons less than 60 kg	High bioavailability. Competes with zidovudine for phosphorylation so do not use together	Polyneuropathy. May be able to tolerate reduced dosage. Megaloblastic changes. Association with mitochondrial dysfunction and lactic acidosis
Zalcitabine/DDC	0.75 mg x 3 3 tablets/day	No food effects	Polyneuropathy, aphthous ulceration. Association with mitochondrial dysfunction and lactic acidosis
Zidovudine/AZT	250-300 mg x 2 2 capsules/day	Well absorbed with good bioavailability. No food effects	Nausea, headache, insomnia, skin and nail pigmentation, myelosuppression, megaloblastic changes. Myelopathy with extended use. Association with mitochondrial dysfunction and lactic acidosis
Combivir (AZT plus 3TC)	1 tablet twice daily		As for component drugs
Kivexa abacavir/3TC	1 tablet daily o.d.		As for component drugs
Triizivir (abacavir/AZT/3TC)	1 tablet twice daily		
Nucleotide reverse transcriptase inhibitor (NtRTI)			
Tenofovir	245 mg o.d. 1 tablet daily	After food	Hypophosphataemia, renal toxicity
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)			
Efavirenz	600 mg o.d. 1 capsule at night	Metabolized by cytochrome P450 (3A mixed inducer and inhibitor). Do not take with high-fat foods	Rash, Stevens-Johnson syndrome, central nervous system effects (vivid dreams, agitation, hallucinations, and depression amongst others). Contraindicated in pregnancy
Nevirapine	200 mg o.d. for first 14 days then 200 mg x 2 2 tablets/day	High bioavailability, long half-life, wide tissue distribution. Induces its own metabolism, hence dose escalation. No food effects	Rash, Stevens-Johnson syndrome, hepatic toxicity
Protease inhibitors (single drugs)			
Amprenavir	1200 mg x 2 16 capsules/day May be used in lower doses boosted with ritonavir	Cytochrome P450 inhibitor High-fat meals lead to reduced plasma drug levels	Diarrhoea, nausea, rash, oral paraesthesia, abnormal liver function, body fat redistribution and abnormal plasma lipids
Atazanavir*	400 mg o.d. 2 tablets/day Can boost with ritonavir	Fewer lipid abnormalities than other protease inhibitors	Hyperbilirubinaemia

Cont'd

Table 2.53 (Cont'd) **Antiretroviral drugs available in the UK**

Drug	Daily dose and pill burden	Metabolism/food	Side-effects
Protease inhibitors (single drugs)			
Indinavir	800 mg x 3 6 capsules/day	Take 1 hour before or 2 hours after food. Drink additional 1.5 L water/day Food reduces plasma levels.	nail dystrophy, alopecia, Nephrolithiasis and crystalluria, dry skin, hyperbilirubinaemia, fat redistribution, raised plasma lipids, hyperglycaemia
Nelfinavir	1250 mg x2 10 tablets/day	Take with food. Cytochrome P450 3A inhibitor	Diarrhoea, fat redistribution, raised plasma lipids, hyperglycaemia
Ritonavir	600 mg x 2 12 capsules/day Most commonly taken at lower doses to boost other compounds	Take with meals. Potent cytochrome P450 3A4 inhibitor	Nausea/vomiting, diarrhoea, taste distortion, perioral paraesthesia, fat redistribution, hepatotoxicity, hyperglycaemia, pancreatitis
Saquinavir (soft gel)	1200 mgx3 or 1800 mg x2 18 capsules/day	Take with food	Nausea, diarrhoea, abdominal pain, fat redistribution, abnormal plasma lipids, hyperglycaemia
Protease inhibitors boosted with ritonavir			
Lopinavir R	3 capsules x 2 6 capsules/day	Take with food	Diarrhoea, nausea, fat redistribution, abnormal plasma lipids
Fosamprenavir	700 mg plus ritonavir 100 mg x 2 100	Pro-drug of amprenavir No food effect	Similar to amprenavir As
Ritonavir/indinavir	mg/800 mg x 2 6 capsules/day 400	With a light meal/snack	ritonavir and indinavir As
Ritonavir/saquinavir	mg/400 mg x 2 12 capsules/day 500	With a light meal	ritonavir and saquinavir
TipranavirVritonavir	mg/200 mg x 2		Nausea, abnormal LFT
Fusion inhibitors			
Enfurvitide (T20)	90 mg x 2 - subcutaneous injection		Reaction at the injection site

* Not yet licensed in the UK

They are generally small molecules that are widely disseminated throughout the body and have a long half-life. NNRTIs affect cytochrome P450. They are ineffective against HIV-2. The level of cross-resistance across the class is very high. All have been associated with rashes and elevation of liver enzymes.

Protease inhibitors (Pis) act competitively on the HIV aspartyl protease enzyme, which is involved in the production of functional viral proteins, and enzymes. In consequence, viral maturation is impaired and immature dysfunctional viral particles are produced. Most of the protease inhibitors are active at very low concentrations and in vitro are found to have synergy with reverse-transcriptase inhibitors. However there are marked differences in toxicity, pharmacokinetics and resistance patterns which influence prescribing. Cross-resistance is common across the PI group, which makes it difficult to use the drugs sequentially. There appears to be no activity against human aspartyl proteases (e.g. renin), although there are clinically significant interactions with the cytochrome P450 system. This is used to therapeutic advantage, boosting blood levels of PI by blocking drug metabolism with small doses of ritonavir. Pis have been linked with abnormalities of fat metabolism and control of blood sugar, and some have been associated with deterioration in clotting function in haemophiliacs.

Fusion inhibitors. Enfurvitide (T20) is the only licensed compound in this class of agents. It is a peptide derived from HIV GP41 that inhibits GP41-mediated fusion of HIV with the target cell. It is synergistic with NRTIs and Pis. Although resistance to enfurvitide has been described, there is no evidence of cross-resistance with other drug classes Because it has an extracellular mode of action there are few drug-drug interactions. Side-effects relate to the subcutaneous route of administration in the form of injection site reactions.

Newer drugs NRTIs include alovudine (MIV-310) and SPD-756 which appear to have activity against NRTI-resistant strains. New NNRTIs include capravirine in

phase III trials. New PIs include tipranavir with activity against PI-resistant viral isolates and TMC 114, also with a good activity against resistant isolates. Entry inhibitors in development include compounds that block CD4 attachment and inhibitors of chemokine co-receptors CXCR4 and CCR5. Early studies of HIV integrase and maturation inhibitors are now in progress.

Starting therapy

Treatment regimens for HIV infection are complicated and require a long-term commitment to high levels of adherence. Risks of therapy include serious side-effects, drug interactions and the potential for development of resistant viral strains. The full involvement of patients in therapeutic decision-making is essential for success. Various national guidelines and treatment frameworks exist (e.g. BHIVA Guidelines, DHHS Guidelines, and IAS Recommendations). A combination of clinical assessment and laboratory marker data, including viral load and CD4 counts, together with individual circumstances, should guide therapeutic decision-making. The current UK recommendations are shown in Table 2.54. In situations where therapy is recommended but the patient elects not to start, then more intensive clinical and laboratory monitoring is advisable.

Clear clinical benefit has been demonstrated with the use of antiretroviral drugs in advanced HIV disease. Treatment should be recommended for all patients with symptomatic HIV disease, AIDS or a CD4 count that is consistently below 200 cells/mm^3. In such situations there is a significant risk of serious HIV-associated morbidity and mortality.

In asymptomatic patients the absolute CD4 count is the key investigation used to guide treatment decisions. A count below 200 cells/mm^3 is associated with disease progression and death. The outcome for patients initiating therapy below 200 CD4 cells/mm^3 is less good than for those who start at higher counts. *The UK recommendation* is that therapy should be started before the count falls below200.

The risk of disease progression for individuals with a count greater than 350 is low, and treatment may be deferred. Therapy should be considered for people with a CD4 count between 350 and 201 cells/mm^3. Those who may have a higher risk of disease progression, e.g. those with high viral loads (> 60 000 copies/mL) or rapidly falling CD4 count (losing more than > 80 cells/year) may consider earlier intervention. Co-infection with hepatitis C virus may call for earlier intervention (see p. 372).

Treatment for primary HIV infection is only recommended either within a clinical trial or to alleviate symptoms.

Special situations (seroconversion, pregnancy, post-exposure prophylaxis) in which antiretrovirals may be used are described on page 151.

Table 2.54 UK recommendations for starting therapy*

Clinical presentation	Laboratory markers	Treatment recommendation
Symptomatic HIV infection, AIDS	Any CD4 count or viral load	Treat
Established, asymptomatic infection	CD4 < 200, any viral load	Treat
	CD4 201-350	Consider treatment based on viral load, rate of CD4 decline, coexisting clinical conditions, patient preference
	CD4 > 350	Defer treatment
Primary HIV infection		Treatment only recommended in a clinical trial or for severe symptoms.

* After British HIV Association (BHIVA) guidelines for the treatment of HIV-infected adults with antiretroviral therapy, 2003

Choice of drugs

The drug regimen used for starting therapy must be individualized to suit each patient's needs. Treatment is initiated with three drugs, two NRTIs in combination, with either a boosted protease inhibitor or NNRTI (Tables 2.53 and 2.55).

The choice of which drugs to include in initial therapy is governed by effectiveness, adherence issues, side-effect profile, potential drug reactions, availability and the resistance and cross-resistance patterns of the drugs. Given that long-term patient adherence is essential to gain the most enduring viral suppression and to impede the emergence of drug resistance, it is crucial that patients be fully involved in therapeutic decision-making throughout and be treated with drug regimens that are manageable as part of their day-to-day lives. Current UK guidance (BHIVA 2003) prioritises ease of adherence and minimization of toxicity over the likely development of resistant mutations following failure of therapy.

Selection of the two NRTIs to form a backbone is increasingly influenced by ease of administration as no conclusive comparative efficacy data exist. Abacavir, didanosine, lamivudine, tenofovir and zidovudine are all licensed for use in naive patients. Stavudine has become associated with lipodystrophy and is not recommended.

Of the NNRTIs, efavirenz and nevirapine are both recommended options and comparable in potency. Efavirenz has the advantage of once-daily dosing but is associated with CNS side-effects such as dysphoria and insomnia. Nevirapine is taken twice daily and has a higher incidence of rash and hepatotoxicity.

The protease inhibitor class have demonstrated excellent efficacy in clinical practice. PIs combined with a low dose of ritonavir to provide a pharmacokinetic advantage are now most commonly used in naive patients. Using this approach, the half-life of the active drug is increased, which may allow simplification of dosing regimens, potency may be enhanced and the risk of resistance minimized.

Table 2.55 **Initial HAART regimens - choice of initial therapy***

Regimen	Recommendation	Advantages	Disadvantages
2 NRTIs + NNRTI	Recommended	Equivalent/superior surrogate marker trials compared with PI-based regimens at 104 weeks of follow-up Easier adherence	No randomized clinical trial (RCT) end-point data Shorter follow-up Single mutations may lead to cross class resistance No RCT clinical end-point data Possible increased toxicity and drug interactions
2 NRTIs + boosted PI	Recommended	Evidence of improved surrogate end-point efficacy for lopinavir/ritonavir compared to a single PI Better PK Easier adherence	
3 NRTIs	Not usually recommended except for patients with low viral load and major adherence concerns	Less resistance at virological failure Spares PI and NNRTI classes	No RCT clinical end-point data Short-term surrogate marker data suggest less potent than NNRTI or PI Less effective at high viral loads

* After British HIV Association (BHIVA) guidelines for the treatment of HIV-infected adults with antiretroviral therapy, 2003

Although previous studies have suggested that three NRTIs were able to produce good levels of viral suppression in ARV-naive patients, more recent comparative data show this approach to be less efficacious than combining two NRTIs with either an NNRTI or a PI. The combination is no longer recommended unless there are other pressing individual issues. Recent clinical trail data have shown early virological failure of the combinations of tenofovir + abacavir + lamivudine and tenofovir + didanosine + lamivudine. These combinations should not be offered.

Monitoring therapy (Box 2.20)

Virological success of HAART is a viral load of less than 50 copies/ mL within 3-6 months of therapy. This is feasible for those starting therapy for the first time but may not be a realistic objective for heavily pretreated patients. Once ARV has been initiated the viral load should be measured at 4 weeks to assess efficacy. A viral load of 1000 copies/mL should be achievable by this stage if treatment is to be considered adequate. The durability of the virological response is linked both to the rate of viral load fall and the absolute nadir attained. Viral load and CD4 count should be measured at 12 weeks and then at 3-monthly intervals. Regular clinical assessment should include weight, blood pressure and urinalysis.

Box 2.20 **Monitoring patients on highly active antiretroviral therapy (HAART)**

Clinical history and examination
Weight
HIV viral load
Lymphocyte subsets
Full blood count
Liver and renal function
Fasting lipid profile
Blood glucose

Patients should be monitored for drug toxicity, including full blood count, liver and renal function and fasting lipids and glucose levels.

Drug resistance

Resistance to ARVs results from mutations in the protease and reverse transcriptase genes of the virus. HIV has a rapid turnover with 10^8 replications occurring per day. The error rate is high, resulting in genetic diversity within the population of virus in an individual. This mixture will include drug-resistant mutants. When drugs only partially inhibit virus replication there will be a selection pressure for the emergence of drug-resistant strains. The rate at which resistance develops depends on the frequency of pre-existing variants and the number of mutations required. Resistance to zidovudine occurs with an accumulation of mutations, whilst a single-point mutation will confer high-level resistance to all three NNRTIs.

HIV antiretroviral drug resistance testing has become routine clinical management of the HIV patient. Genotypic assays to determine the genetic structure of the RT and protease genes of HIV are available. The tests are based on PCR amplification of virus and give an indirect measure of drug susceptibility in the predominant variants. Such assays are limited both by the starting concentration of virus, most assays requiring at least 1000 copies/mL of blood, and by their poor ability to detect minority strains. For results to be useful, samples must be analysed when the patient is on therapy, as once the selection pressure of therapy is withdrawn, wild type virus becomes the predominant strain and resistance mutations present earlier may no longer be detectable.

The use of genotypic assays with appropriate interpretation in patients for whom therapy is failing has shown significant virological benefits. Phenotypic assays provide a more direct measure of susceptibility but the complexity of the assays limits availability and no

additional advantage has been demonstrated. In the UK, increasing numbers of patients are infected with viral strains originating in sub-Saharan Africa, which may require modification of the assay and the interpretation of the results.

There is evidence for the transmission of HIV strains that are resistant to all or some classes of drugs. Studies of primary HIV infection have shown prevalence rates between 2-20%. Prevalence of primary mutations associated with drug resistance in chronically infected patients not on treatment ranges from 3% to 10% in various studies. Advantages exist for genotypic analysis prior to initiating treatment.

Drug interactions

Drug therapy in HIV is highly complex and the potential for clinically relevant drug interactions is substantial. Both Pis and NNRTIs are metabolized through cytochrome P450 dependent pathways. However both classes of drug are able to variably inhibit and induce cytochrome P450, influencing both their own and other drug metabolic rates. Situations occur where both inducers and inhibitors of cytochrome P450 are prescribed simultaneously. Induction of metabolism may result in sub-therapeutic antiretroviral drug levels with the risk of treatment failure and development of viral resistance, whilst inhibition can raise drug levels to toxic values and precipitate adverse reactions. Additionally, conventional (e.g. rifamycins) and complementary therapies (e.g. St John's Wort) affect cytochrome P450 activity and may precipitate substantial drug interactions. Therapeutic drug monitoring (TDM) indicating peak and trough plasma levels may be useful in certain settings.

Complications of antiretroviral therapy

Side-effects are a common problem in HAART (see Table 2.53). Some are acute and associated with initiation of medication, whilst others emerge after longer-term exposure to drugs. As increasing numbers of patients start antiretroviral therapy, adverse drug events are an important clinical presentation.

Allergic reactions

Allergic reactions occur with greater frequency in HIV infection and have been documented to all the antiretroviral drugs. Abacavir is associated with a hypersensitivity reaction, usually within the first 6 weeks of treatment, in up to 4% of patients, which can be fatal. There may be a discrete rash and often a fever coupled with general malaise and gastrointestinal and respiratory symptoms. The diagnosis is clinical and symptoms resolve when abacavir is withdrawn. Rechallenge with abacavir can be fatal and is contraindicated. Allergies to NNRTIs (often in the second or third week of treatment) usually present with a widespread maculopapular pruritic rash, often with a fever and disordered liver function tests. Reactions may resolve in the face of continuing therapy but drugs should be stopped immediately in any patient with mucous membrane involvement or severe hepatic dysfunction.

Lipodystrophy

A syndrome of lipodystrophy in patients with HIV on HAART comprising characteristic morphological changes and metabolic abnormalities is now well described. It is a major complication for patients, being highly stigmatizing, and is a cause of drug discontinuation. The main characteristics, which may be found individually or in combination, are a loss of subcutaneous fat in the arms, legs and face (lipoatrophy), deposition of visceral, breast and local fat, raised total cholesterol, HDL cholesterol and triglycerides, and insulin resistance with hyperglycaemia. The syndrome is potentially associated with increased cardiovascular morbidity. A clinical case definition has been developed to attempt to standardize the definition of the syndrome. The aetiology is still unclear although Pis and NRTIs have been implicated. The highest incidence occurs in those taking combinations of NRTIs and Pis. Stavudine seems to be associated with the lipoatrophy component of the process. The syndrome is difficult to treat, and switching or stopping therapy may not always reverse the processes, although switching away from a stavudine and/or Pi-based therapy is recommended. Dietary advice and increasing exercise may improve some of the metabolic problems and help body shape. The introduction of glitazones, metformin and growth hormone has been investigated with variable outcomes. Statins and fibrates are recommended to reduce circulating lipids. Pravastatin has a low likelihood of interactions with protease inhibitors. On the other hand, simvastatin is contraindicated as it has high levels of drug interactions with Pis. Surgical approaches are useful in improving facial appearance following lipoatrophy. Polylactic acid injections (New-Fill) have provided improvement in some patients.

Mitochondrial toxicity and lactic acidosis

Mitochondrial toxicity, mostly involving the nucleoside analogue class leads to raised lactate and lactic acidosis, which has in some cases been fatal. NRTIs inhibit gamma DNA polymerase, and other enzymes that are important for normal mitochondrial function. Different NRTIs affect different cell lines and so a variety of clinical syndromes may be observed. Lactic acidosis, occasionally fatal, has been seen. Symptoms are often vague and insidious and may include anorexia, nausea, abdominal pain and general malaise. Venous lactate is raised, and the anion gap is typically widened. This is a serious condition requiring immediate cessation of antiretroviral therapy and provision of appropriate supportive measures until normal biochemistry is restored. All patients should be alerted to possible symptoms and encouraged to attend hospital promptly.

Reports of osteopenia, osteoporosis and avascular necrosis of bone have also been described.

IRIS

Paradoxical inflammatory reactions (immune reconstitution inflammatory syndrome, IRIS) may occur on initiating HAART. This occurs usually in people who have been profoundly immunosuppressed and begin therapy. As

their immune system recovers, they are able to mount an inflammatory response to a range of pathogens, which can include exacerbation of symptoms, new or worsening of clinical signs. Examples include unusual mass lesions or lymphadenopathy associated with mycobacteria, including deteriorating radiological appearances associated with MTB infection. Inflammatory retinal lesions in association with cytomegalovirus, deterioration in liver function in chronic hepatitis B carriers and vigorous vesicular eruptions with herpes zoster have also been described.

Adherence

Adherence to treatment is pivotal to success. Levels of adherence below 95% have been associated with poor virological and immunological responses. Many of the drugs used have a short half-life and require frequent dosing. Poor absorption and low bioavailability mean that for some compounds trough levels are barely adequate to suppress viral replication. For some regimens missing even a single dose will result in plasma drug levels falling dangerously low. Patchy adherence facilitates the emergence of drug-resistant variants, which in time will lead to virological treatment failure. Even with the development of more potent and sophisticated antiretroviral compounds, success will only be possible if patients adhere adequately to the dosing schedules.

Factors implicated in poor adherence may be associated with the medication, with the patient or with the provider. The former include side-effects associated with medications, the degree of complexity and pill burden and inconvenience of the regimen. Patient factors include the level of motivation and commitment to the therapy, psychological well-being, the level of available family and social support, and health beliefs. Supporting adherence is a key part of clinical care and specific guidelines are available (BHIVA 2004). Education of patients about their condition and treatment is a fundamental requirement for good adherence, as is education of clinicians in adherence support techniques. Provision of acute and ongoing multidisciplinary support for adherence within clinical settings should be universal. Medication-alert devices may be useful for some patients.

Treatment failure

Failure of antiretroviral treatment, i.e. persistent viral replication causing immunological deterioration and eventual clinical evidence of disease progression, is caused by a variety of factors. HAART drug regimens have limited potency. Food or other medication may compromise drug absorption. Drug interactions may interfere with metabolism and elimination of medication. There may be limited penetration of drug into sanctuary sites such as the CNS, permitting viral replication. Side-effects and other patient-related elements might contribute to poor adherence.

Changing therapy

A rise in viral load, a falling CD4 count or new clinical events that imply progression of HIV disease are all reasons to review therapy. Intolerance or adverse drug reactions may occur. Reasons for treatment failure include the emergence of resistant viral strains or poor patient adherence. New data in this rapidly changing field may lead to therapeutic changes.

Virological failure, i.e. two consecutive viral loads of greater than 400 copies/mL in a previously fully suppressed patient requires investigation. All possible factors including adherence, drug interactions affecting ARV metabolism or absorption and the viral genotype must be considered before therapy is changed. Following failure of initial therapy, viral genotype should be used to help select future therapy. If a new treatment option is available that is likely to lead to complete viral suppression then treatment should be switched as soon as possible. At least one or two different classes of drug should be used wherever practical. Failure consequent upon poor adherence may require simplification of the regimen as well as a change of drug class.

In a situation where a patient has been exposed to a wide variety of drugs, the likelihood of complete inhibition of viral replication is small and the CD4 count is stable there may be a rationale to continue with the current therapy.

Treatment failure in highly treatment-experienced patients poses considerable challenges. The term salvage therapy may be applied in this situation. Reasons for treatment failure should be investigated and adherence optimized. As many drugs as possible should be changed, including new agents if there is a realistic chance of success. In some situations it may be better to hold back a new drug and await development of another new agent to give the maximum chance of success. In this situation, success may be better estimated by a rise in CD4 count or an improvement in clinical condition than by complete suppression of viral replication. However, even modest reductions in viral load have been shown to correlate with improved clinical outcome.

If the patient has a viral load below the limit of detection and a change needs to be made because of intolerance of a particular drug, then a switch to another drug within the same class may resolve the problem. Simplification of complex regimens may be considered if adherence is problematic.

Stopping therapy

Stopping antiretroviral drugs may be the proper course of action in a number of circumstances. Examples are cumulative toxicity, or potential drug interactions with medications needed to deal with another more pressing problem. In situations where adherence is poor, stopping completely may be preferable to continuing with inadequate dosing, in order to reduce the risk of the development of viral resistance. Poor quality of life and the view of the patient on the matter must be considered. NNRTIs efavirenz and nevirapine have long half-lives. If all drugs in an NNRTI-containing regimen are stopped at the same time, there will be a period of time when only sub-therapeutic levels of NNRTI monotherapy are in the bloodstream. Even this period may be enough to allow

drug-resistant mutations to emerge. The NNRTI component should be stopped approximately 1 week before the other drugs in the mixture to reduce this risk.

Structured treatment interruptions (STIs) have been studied as a means of enhancing HIV-specific immune responses to HIV or to reduce the exposure to drugs and limit adverse events. Treatment interruption leads to rapid viral rebound. The adverse effects of viral rebound on the immune system, the CD4 count falling within weeks of stopping, give cause for concern in already immunosuppressed patients, although there may be more room to manoeuvre in patients with higher CD4 counts. 'Drug holidays' in those who are virologically failing therapy and have multidrug-resistant viral strains may be considered. There is a suggestion that wild type virus may re-emerge in such patients. Current British guidance does not support treatment interruption as a standard of care.

Specific therapeutic situations

Acute seroconversion

Antiretroviral therapy in patients presenting with an acute seroconversion illness is controversial. This stage of disease may represent a unique opportunity for therapy as there is less viral diversity, and the host immune capacity is still intact. There is evidence to show that the viral load can be reduced substantially by aggressive therapy at this stage, although it rises when treatment is withdrawn. The longer-term clinical sequelae of treatment at this stage remain uncertain. People with severe symptoms during primary HIV infection may gain a clinical improvement on antiretrovirals. If treatment is contemplated in this situation, entry into a clinical trial may be considered. If patients are treated outside a clinical trial then a standard regimen is likely to be most appropriate, although the risk of limiting future options must be assessed.

Pregnancy

Management of HIV-infected pregnant women requires close collaboration between obstetric, medical and paediatric teams. The aim of HIV management is to deliver a healthy, uninfected baby to a healthy mother without prejudicing the future treatment options of the mother. Although considerations of pregnancy must be factored into clinical decision-making, pregnancy per se should not be considered a contraindication to providing optimum HIV-related care for the woman. HIV-positive women should be advised against breast-feeding, which doubles the risk of vertical transmission. Delivery by caesarean section reduces the risk of transmission. For women who would be eligible for treatment of their own HIV disease, whether pregnant or not, triple therapy is the regimen of choice. The specific drug choices will be based on both maternal and fetal considerations. Risk of vertical transmission increases with viral load. Although the fetus will be exposed to more drugs, the chances of reducing the viral load and hence preventing infection are greatest with a potent triple therapy regimen in the mother. The regimen should contain zidovudine, as this is the only agent shown to have an effect on vertical transmission. Treatment may start from 12-14 weeks of pregnancy and continue during delivery. The baby should receive zidovudine for 6 weeks postpartum. The woman should remain on treatment with appropriate monitoring and support. Women who do not need treatment for themselves may consider short-course triple therapy or zidovudine monotherapy to reduce vertical transmission. Treatment of the mother with zidovudine monotherapy is at variance with the data on combination therapy for adults as described above. This may have longer-term implications for the course of the mother's HIV infection, particularly with regard to the possible emergence of zidovudine-resistant virus.

Post-exposure prophylaxis

Healthcare workers following occupational exposure to HIV may need antiretroviral therapy. The British recommendation is zidovudine, lamivudine and either indinavir or nelfinavir for 4 weeks. Prophylaxis after sexual exposure may be appropriate in certain situations, in particular rape or in HIV-discordant relationships. The choice of drugs will depend on the clinical setting and what is known of the HIV source.

PREVENTION AND CONTROL

Antiretroviral drugs are not a cure and are accessible only to a privileged minority of the world's population. Vaccine development has been hampered by the genetic variability of the virus and the complex immune response that is required from the host. Prevention of new infection is fundamental to the control of the epidemic. Strategies that have been shown to be effective include treatment of sexually transmitted infections, consistent use of condoms, use of clean needles and syringes for drug users and antiretroviral drugs to reduce mother-to-child transmission. Topical microbicides for intravaginal use are in development.

Screening of blood products has reduced iatrogenic infection in developed countries but is expensive and not globally available.

Partner notification schemes are developing but are sensitive and controversial. Availability and accessibility of confidential HIV testing provides an opportunity for individual health education and risk reduction to be discussed.

Understanding and changing behaviour is crucial but notoriously difficult, especially in areas that carry as many taboos as sex, HIV and AIDS. Poverty, social unrest and war all contribute to the spread of HIV. Political will, not always readily available, is required if progress in these areas is to occur.

THE CELL AND CELL BIOLOGY

The cell (Fig. 3.1) is a highly organized structure and radiates from the nuclear membrane to the cell plasma consists of various common organelles held by an membrane. The number and finer detail of these common adaptive internal scaffolding (the cytoskeleton), which organelles varies according to the specialized function a

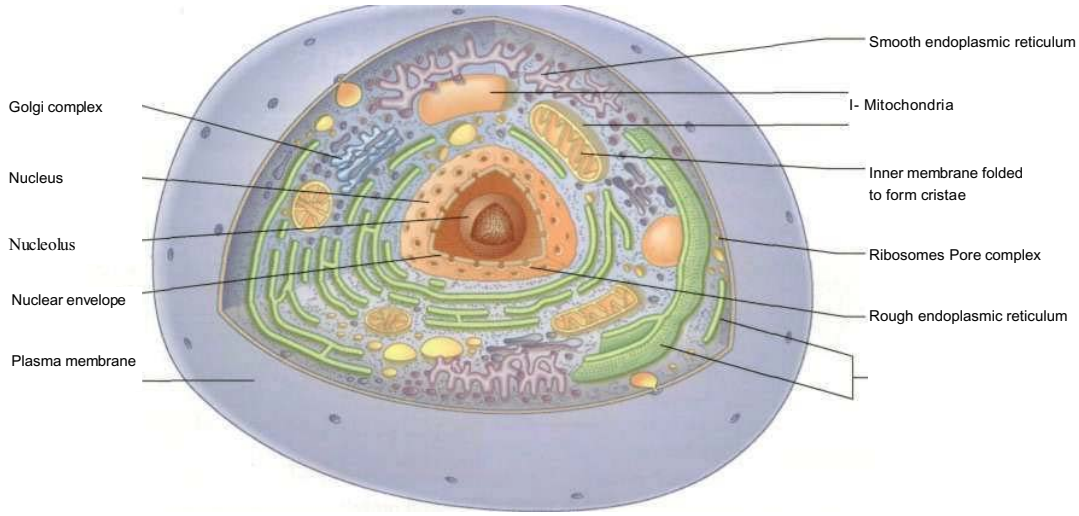

Fig. 3.1 Diagrammatic representation of the cell, illustrating the major organelles.

«

153

cell might perform. For example, the mitochondria of muscle cells contain many infolded cristae; they produce large amounts of ATP (from the electron transport chain that sits on the inner membrane), whereas the mitochondria of liver cells are smaller and rounded as they produce low levels of ATP, but many products from the inner matrix feed other metabolic pathways. Each cell is a component unit but can 'talk' to an adjacent cell via specific channels and receptors. Within a cell there is a constant flow of traffic between the organelles.

THE CELL MEMBRANE

The plasma cell membrane interfaces between the cell's internal mechanisms and the extracellular environment. It is a bilayer of amphipathic phospholipids that consist of a polar hydrophilic head (e.g. phosphatidyl choline) and an insoluble non-polar lipid hydrophobic tail (commonly two long-chain fatty acids). The phospholipids spontaneously form bilayers (as complete circular structures) that form an effective barrier that is impermeable to most water-soluble molecules. This barrier defines the interior environment of the cell. The exchanges across the plasma membrane are regulated by various proteins that are embedded in the lipid bilayer (Fig. 3.2). The lipids' hydrophobic structure means that relatively weak bonds hold the plasma membrane together. However, this strongly opposes the transverse movement of hydrophilic molecules but allows considerable freedom for lateral 'fluid' movement by molecules such as membrane proteins that are embedded in it. The plasma membrane is thus a very dynamic structure. Cell-to-cell communication is the key to many diseases and chemotherapeutic interventions.

The membrane proteins embedded in the lipid bilayer either traverse the whole membrane or are associated only with the outer or inner leaflet of the bilayer (Fig. 3.2). These proteins are responsible for the cell's interaction with its external environment. The molecules involved are either *channels, receptors* or *cell adhesion molecules* (see below).

Cell dynamics

Like all systems, the component proteins - and even organelles - of the cell are continually being formed and degraded. Most of the degradation steps involve ATP-dependent multienzyme complexes. Old cellular proteins are mopped up by a small cofactor molecule called *'ubiquitiri*, which interacts with these worn proteins via their exposed hydrophobic residues. Ubiquitin acts as a signal for destruction or repair, and a complex containing more than five ubiquitin molecules is rapidly degraded by a large proteolytic multienzyme array termed '26S proteasome'. The failure to remove worn proteins can result in the development of chronic debilitating disorders. Alzheimer and frontotemporal dementias are associated with the accumulation of ubiquinated proteins (prion-like proteins), which are resistant to ubiquitin-mediated proteolysis. Similar proteolytic-resistant ubiquinated proteins give rise to inclusion bodies found in myositis and myopathies. This resistance can be due to point mutation in the target protein itself (e.g. mutant p53 in cancer; see p. 189) or as a result of an external factor altering the conformation of the normal protein to create a proteolytic-resistant shape, as in the prion protein of variant Creutzfeldt-Jakob disease (vCJD). Nuclear factor kappa B (NFκB) is bound by inhibitory factor IκB. Upon phosphorylation, NFκB, is released and IκB is degraded by the proteasome. Failure to do so results in an accumulation of IκB.

Phagocytosis, pinocytosis and exocytosis

Specialized cells such as macrophages and neutrophils can engulf about 20% of their surface area in the pursuit of large particles such as bacteria. Lysosomes rapidly fuse with phagosomes, giving equally rapid digestion of the contents, and recycling as much of the internalized membrane as possible. *Phagocytosis* is only triggered when specific cell surface receptors - such as the macrophage Fc receptor - are occupied by their ligand. *Pinocytosis* is a much smaller-scale model of phagocytosis

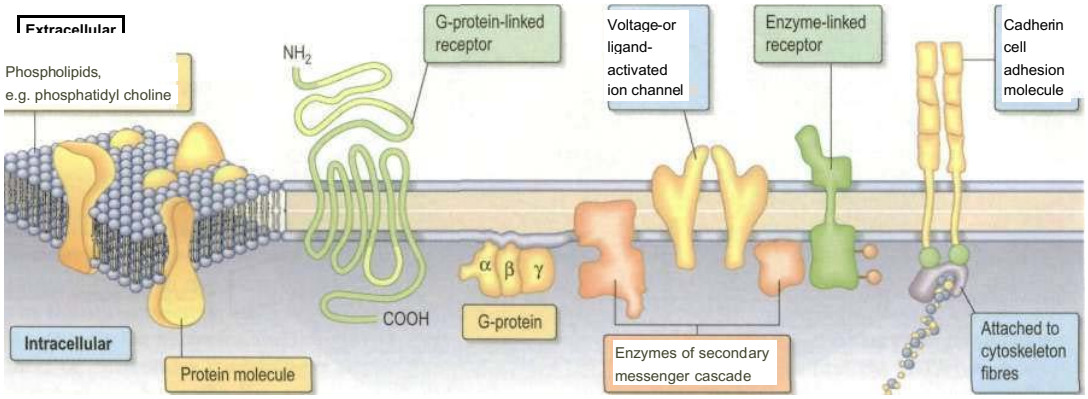

Fig. 3.2 **Cell membrane showing lipid structures and main types of integral proteins** such as receptors, G-proteins, channels, secondary messenger enzyme complexes and cell adhesion molecules.

and is continually occurring in all cells. In contrast to phagocytosis, receptors for smaller molecular complexes, such as low-density lipoprotein (LDL) (Fig. 3.3) result in surface clumping and the internal accumulation of a protein called *clathrin.* Clathrin-coated pits pinch inwards as clathrin-coated vesicles. Clathrin prevents fusion of lysosomes, and thus its removal will result in lysosomal fusion and degradation of the contents. Maintenance of a clathrin coat can result in transcellular transit of the contents and their *exocytosis* at another side of the plasma membrane, i.e. apical-to-basal surface transcytosis. Similarly, cell organelles bud off vesicles coated in clathrin to prevent lysosomal fusion and degradation. Some of these vesicles rapidly fuse with the plasma membrane and exocytose their contents. Other vesicles do not immediately fuse with the plasma membrane (or indeed any other organelle). The clathrin-coated vesicles have additional lipid bilayer-embedded proteins called v-SNAREs (signal and response elements), which interact with target organelle membrane proteins called t-SNAREs. Vesicle fusion is therefore specific, comprising fusion in the correct place (at a particular organelle or part of the plasma membrane) at the correct time (e.g. the fusion of neuronal transmitter vesicles and release of the transmitter at the synaptic membrane when stimulated).

Membrane transport and ion channels

The plasma membrane is freely permeable to gases such as O_2, CO_2 and N_2, and to small uncharged molecules such as H_2O *(not* H^+ and OH) and urea. Whilst larger hydrophobic lipid-soluble molecules - like steroids - also pass freely through the membrane, large uncharged molecules (glucose, amino acids and nucleotides) and small charged ions (K^+, Na^+, Ca^{2+}, Cr, Mg^{2+} and HCO3-) cannot pass unless via a specific transport protein embedded in the plasma membrane. Two structural types of transport molecules/complexes exist (Fig. 19.2):

- *Channel proteins* literally open a channel in the lipid membrane to allow a specific solute to pass through.
- *Carrier proteins* are slower in action, shuttling the solute across and either facilitating diffusion down a gradient across the membrane, or actively pumping solutes against the gradient using ATP as an energy source.

Active carrier pumps and gated ion channels work together in neural transmission (see Fig. 21.1). These carrier proteins pump Na^+ and K^+ across the neuronal cell membrane to create a differential gradient, but ion channels open in response to stimuli to cause a rapid depolarization, allowing the ions to flow back. At synaptic junctions these ion channels open in response to chemical signals such as the release of glutamate, epinephrine (adrenaline) or acetylcholine.

ATP-dependent transport molecules (ATPases) belong to a superfamily called the *'ABC transporter superfamily'.* These include the multidrug-resistance protein (MDR), which pumps out hydrophobic drugs and is overexpressed by tumour cells, and the chloride ion pump coded by the

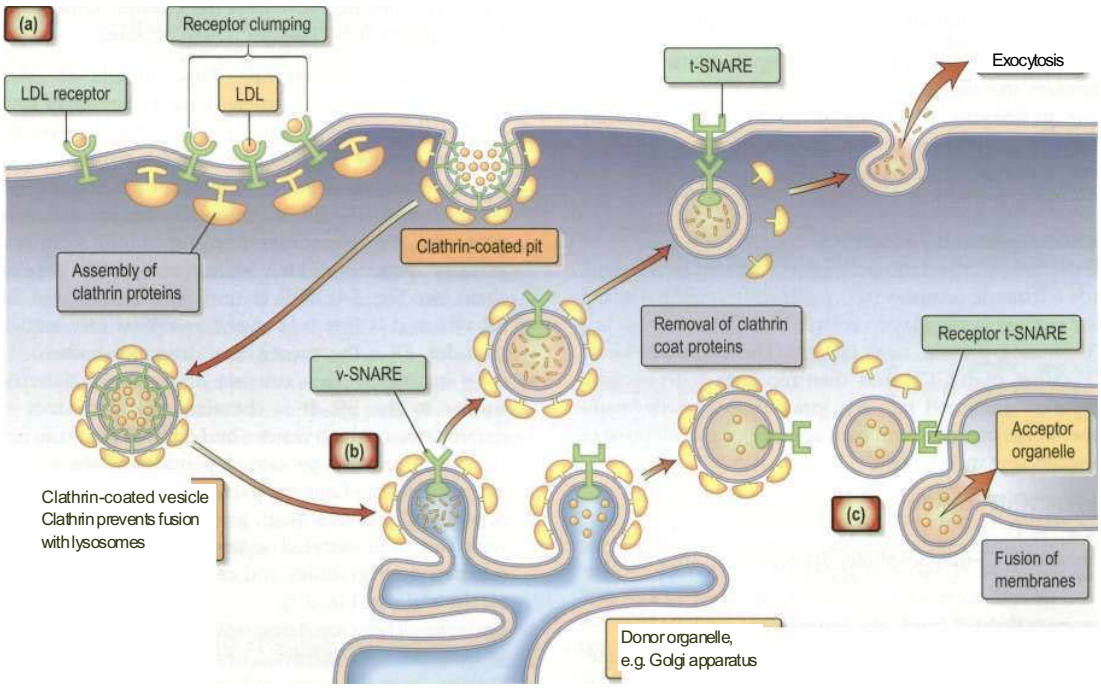

Fig. 3.3 **Intracellular transport, (a)** Receptor-mediated pinocytosis. (b) Trafficking of vesicles containing synthesized proteins to the cell surface (e.g. hormones), (c) Traffic between organelles is also mediated by v- and t-SNARE-containing organelles. v-SNARE, vesicle-specific SNARE; t-SNARE, target-specific SNARE.

cystic fibrosis gene (see Fig. 3.23). All share a common structure of six transmembrane domains interrupted by a cytoplasmic ATPase domain, followed by a further six transmembrane domains and another cytoplasmic ATPase. The cystic fibrosis chloride ion channel is unusual in that it requires the binding and hydrolysis of both ATP and cAMP for activation.

Receptors

Membrane surface receptors pass their extracellular signal across the plasma membrane to cytoplasmic secondary signalling molecules. Examples of these receptors include the non-lipid-soluble ligands such as growth hormone (GH), insulin, insulin-like growth factor (IGF) and luteinizing hormone (LH). These membrane-bound receptors can be subclassified according to the mechanism by which they activate signalling molecules:

- ion channel linked (see above)
- G-protein linked
- enzyme linked.

Structurally these plasma membrane receptors can be:

- serpentine (seven transmembrane domains, e.g. the LH receptor)
- transmembrane with large extra- and intracellular domains (e.g. the epidermal growth factor (EGF) receptor)
- transmembrane with a large extracellular domain only
- entirely linked onto the outer membrane leaflet by a lipid moiety known as a GPI (glycan phosphatidylinositol) anchor (e.g. T-cell receptor).

The function of these membrane receptors is to initiate a secondary message that ultimately results in activation of a specific enzyme or a DNA-binding protein. This may involve translocation to the nucleus and initiation of transcription of a specific set of genes.

G-protein-linked receptors

The G-protein-linked receptor, once activated by a ligand, binds a trimeric complex (a,(3,y) which is anchored to the inner surface of the plasma membrane. This complex is a GTP-binding protein, or G-protein. The G-protein binds GTP rather than GDP, and then interacts with enzyme complexes anchored into the inner leaflet of the membrane. These complexes in turn activate one or all three of the secondary messengers:

- cyclic AMP (cAMP) '■ "
- Ca^{2+} ions
- inositol 1,4,5-trisphosphate/diacylglycerol (IP_3/DAG).

Enzyme-linked surface receptors

These receptors usually have a single transmembrane-spanning region, and a cytoplasmic domain that has intrinsic enzyme activity or will bind and activate other membrane-bound or cytoplasmic enzyme complexes. Four classes of enzymes have been designated:

- *Guanylyl cydase-linked receptors* (e.g. the atrial natriuretic peptide receptor), which produce cyclic GMP. This in turn activates a cGMP-dependent kinase (G-kinase), which binds to and phosphorylates serine and threonine residues of specific secondary messengers.
- *Tyrosine kinase receptors* (e.g. the platelet-derived growth factor (PDGF) receptor), which either specifically phosphorylate kinases on a small set of intracellular signalling proteins, or associate with proteins that have tyrosine kinase activity.
- *Tyrosine phosphatase receptors* (e.g. CD45), which remove phosphates from tyrosine residues of specific intracellular signalling proteins.
- *Serine/threonine kinase receptors* (e.g. the transforming growth factor-beta (TGF-(3) receptor), which phos phorylate specific serine and threonine residues of intracellular signalling proteins.

There are many intracellular receptors that bind lipid-soluble ligands such as steroid hormones (e.g. progesterone, cortisol, T_3 and T_4). These cytoplasmic receptors often change shape in response to binding their ligands, form dimers, enter the nucleus and interact directly with specific DNA sequences (see DNA-binding proteins, p. 167).

CYTOPLASM

This is the fluid component inside the cell membrane and contains many specialized organelles (see Fig. 3.1). It contains a scaffolding or cytoskeleton that regulates the passage and direction in which the interior solutes and storage granules flow. The cytoplasm contains:

- *Endoplasmic reticulum (ER).* This consists of inter connecting tubules or flattened sacs (cisternae) of lipid bilayer membrane. It may contain ribosomes on the surface (termed rough endoplasmic reticulum (RER) when present, or smooth endoplasmic reticulum (SER) when absent). The ER is involved in the processing of proteins: the ribosomes translate mRNA into a primary sequence of amino acids of a protein peptide chain (see Fig. 3.4). This chain is synthesized into the ER where it is first folded and modified into mature peptides. ER is the major site of drug metabolism.
- *Golgi apparatus.* This consists of flattened cisternae similar to the ER. It is characterized as a stack of cisternae from which vesicles bud off from the thickened ends. The primary processed peptides of the ER are exported to the Golgi apparatus for maturation into functional proteins (e.g. glycosylation of proteins which are to be excreted occurs here) before packaging into secretory granules and cellular vesicles that bud off the end (see Fig. 3.3).
- *Lysosomes.* These are dense cellular vesicles containing acidic digestive enzymes. They fuse with phagocytotic vesicles from the outer cell membrane, digesting the contents into small biomolecules that can cross the lysosomal lipid bilayer into the cell cytoplasm. Lysosomal enzymes can also be released outside the

cell by fusion of the lysosome with the plasma membrane. Lysosomal action is crucial to the function of macrophages and polymorphs in killing and digesting infective agents, tissue remodelling during development and osteoclast remodelling of bone. Not surprisingly, many metabolic disorders result from impaired lysosomal function (p. 1146).

- *Peroxisomes.* These are dense cellular vesicles so named because they contain enzymes that catalyse the break down of hydrogen peroxide. They are involved in the metabolism of bile and fatty acids, and are primarily concerned with detoxification, e.g. D-amino acid oxidase and H_2O_2 catalase. The inability of the peroxisomes to function correctly can lead to rare metabolic disorders such as Zellweger's syndrome and rhizomelic dwarfism.
- *Mitochondria.* These organelles are the powerhouse of the cell. Each mitochondrion comprises two lipid bilayer membranes and a central matrix. It also possesses several copies of its own DNA in a circular genome. The *outer membrane* contains many gated receptors responsible for the import of raw materials like pyruvate and ADP, and the export of products such as oxaloacetate (precursor of amino acids and sugars) and ATP. An interesting caveat to our symbiotic relationship is that proteins of the *Bd-2/Bax* family are incorporated in this outer membrane and can release mitochondrial enzymes that trigger apoptosis (see p. 162). The *inner membrane* is often highly infolded to form cristae to increase its effective surface area. It contains transmembrane enzyme complexes of the electron transport chain, which generate an H^+ ion gradient. This gradient then drives the adjacent transmembrane ATPase complex to form ATP from ADP and P_r *The inner matrix* contains the enzymes of the Krebs cycle that generate the substrates of both the electron transport chain ($FADH_2$ and NADH) and central metabolism (e.g. succinyl CoA, oc-oxoglutarate, oxaloacetate).

SECONDARY MESSENGERS

Secondary messengers are molecules that transduce a signal from a bound receptor to its site of action (e.g. the nucleus). There are essentially four mechanisms by which secondary messengers act but they cross talk and are rarely activated independently of each other (Fig. 3.4). These mechanisms are cyclic AMP, IP_3/DAG, Ca^{2+} ions and protein phosphorylation.

Cyclic AMP, IP3/DAG and Ca^{2+} ions

The generation of cAMP by G-protein-linked receptors results in an increase in cellular cAMP (Fig. 3.4(ia)), which binds and activates specific cAMP-binding proteins. These dimerize and enter the cell nucleus to interact with set DNA sequences (the cAMP response elements). In addition, cofactors in the cAMP-binding proteins are co-activated and interact with the phosphorylation pathway. Other G-protein complexes activate inner membrane-bound phospholipase complexes. These in turn cleave membrane phospholipid-polyphosphoinositide (PIP_2) into two components (Fig. 3.4(ib)). The first is the water-soluble molecule inositol trisphosphate, IP_3. This floats off into the cytoplasm and interacts with gated ion channels in the endoplasmic reticulum (or sarcoplasmic reticulum in muscle cells), causing a rapid release of Ca^{2+}. The lipid-soluble component diacylglycerol (DAG) (Fig. 3.4(ic)) remains at the membrane, but activates a serine/threonine kinase, protein kinase C (see phosphorylation section below).

Although the cellular calcium-binding proteins and ion pumps rapidly remove Ca^{2+} from the cytoplasm back into a storage compartment (such as the endoplasmic reticulum), free Ca^{2+} interacts with target proteins in the cytoplasm, inducing a phosphorylation/dephosphorylation cascade, resulting in activated DNA-binding proteins entering the nucleus.

Protein phosphorylation

Although phosphorylation of the cytoplasmic secondary messengers is often a consequence of secondary activation of cAMP, Ca^{2+} and DAG, the principal route for the protein phosphorylation cascades is from the dimerization of surface protein kinase receptors, which have bound their ligands. The tyrosine kinase receptors phosphorylate each other when ligand binding brings the intracellular receptor components into close proximity (see Fig. 3.4(ii)). The inner membrane and cytoplasmic targets of these activated receptor complexes are ras, protein kinase C and ultimately the MAP (mitogen activated protein) kinase, Janus-Stat pathways or phosphorylation of IκB causing it to release its DNA-binding protein, nuclear factor kappa B (NFκB). These intracellular signalling proteins usually contain conserved non-catalytic regions called SH2 and SH3 (sere homology regions 2 and 3). The SH2 region binds to phosphorylated tyrosine. The SH3 domain has been implicated in the recruitment of intermediates that activate ras proteins. Like G-proteins, ras (and its homologous family members *rho* and *rac)* switches between an inactive GDP-binding state and an active GTP-binding state. This starts a phosphorylation cascade of the MAP kinase, Janus-Stat protein pathways, which ultimately activate a DNA-binding protein (NFκB). NFκB undergoes a conformational change, enters the nucleus and initiates transcription of specific genes.

Lipid-soluble ligands (e.g. steroids) do not need secondary messengers; their cytoplasmic receptors, once activated, enter the nucleus as DNA-binding proteins and alter gene expression directly.

THE CYTOSKELETON

This is a complex network of structural proteins which regulates not only the shape of the cell, but also its ability to traffic internal cell organelles and even move in response to external stimuli (see Fig. 3.2). The major components are microtubules, intermediate filaments and microfilaments. '. .. ■

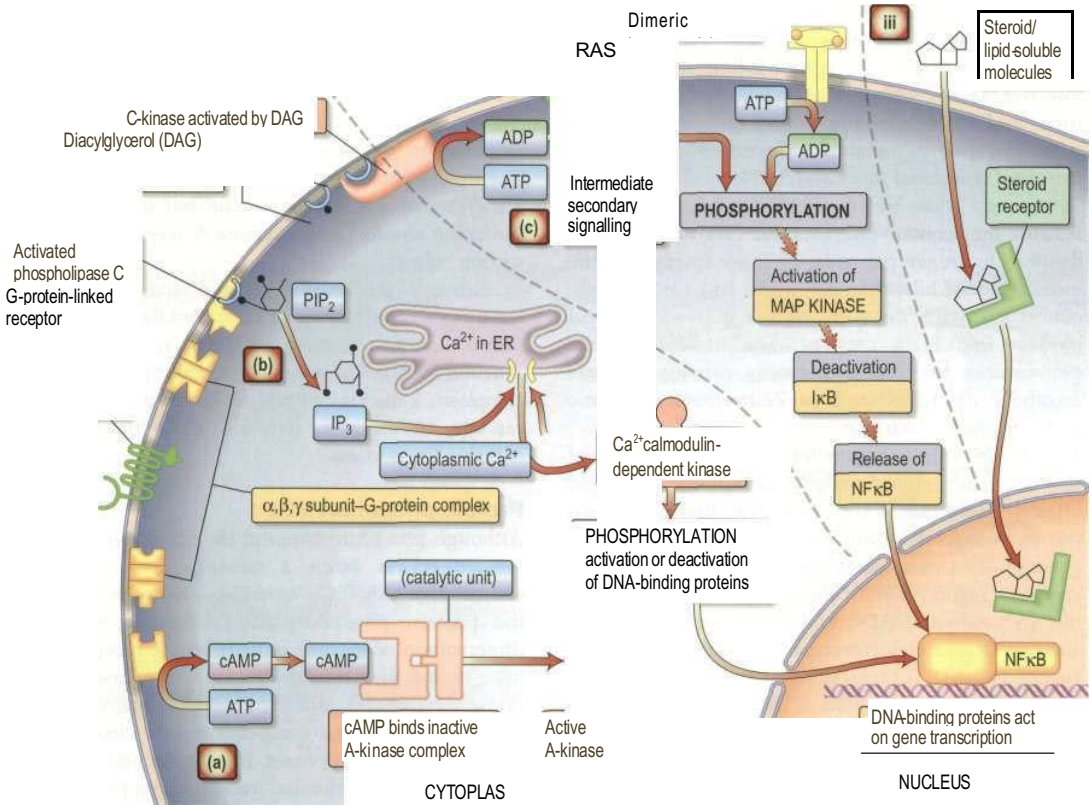

Fig. 3.4 **Receptor and secondary messengers, (i) G-protein receptor** binds ligand (e.g. hormone) and activates G-protein complex. The G-protein complex can activate three different secondary messengers: (a) cAMP generation; (b) inositol 1,4,5-trisphosphate (IP3) and release of Ca^{2+}; (c) diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation. **(ii) Dimeric hormone** binds receptor subunits bringing them into close association. Intracellular domains cross-phosphorylate and link to the phosphorylation cascades via molecules such as RAS. **(iii) Lipid-soluble molecules,** e.g. steroids, pass through the cell membrane and bind to cytoplasmic receptors, which enter the nucleus and bind directly to DNA. ER, endoplasmic reticulum; IκB, inhibitory factor kappa B; NFκB, nuclear factor kappa B.

Microtubules (Fig. 3.5). These are made up of two protein subunits, a and fi tubulin (50 kDa), and are continuously changing length. They form a 'highway', transporting organelles through the cytoplasm. There are two motor microtubule-associated proteins - dynein and kinesin - allowing antegrade and retrograde movement. Dynein is also responsible for the beating of cilia. During interphase the microtubules are rearranged by the microtubule-organizing centre (MTOC), which consists of centrosomes containing tubulin and provides a structure on which the daughter chromosomes can separate. Another protein involved in the binding of organelles to microtubules is the cytoplasmic linker protein (CLIP). Drugs that disrupt the microtubule assembly (e.g. colchicine and vinblastine) affect the positioning and morphology of the organelles. The anticancer drug paclitaxel causes cell death by binding to microtubules and stabilizing them so much that organelles cannot move, and thus mitotic spindles cannot form.

Intermediate filaments. These form a network around the nucleus and extend to the periphery of the cell. They make cell-to-cell contacts with the adjacent cells via desmosomes, and with basement matrix via hemidesmosomes (Fig. 3.6). Their function appears to be in structural integrity; they are prominent in cellular tissues under stress. The intermediate filament fibre proteins are specific to the embryonic lineage of the cell concerned, for example keratin intermediate fibres are only found in epithelial cells whilst vimentin is only found in mesothelial (fibroblastic) cells.

Microfilaments. Muscle cells contain a highly ordered structure of actin (a globular protein, 42-44 kDa) and myosin filaments, which form the contractile system. These filaments are also present throughout the non-muscle cells as truncated myosins (e.g. myosin 1), in the cytosol (forming a contractile actomyosin gel), and beneath the plasma membrane. Cell movement is mediated by the anchorage of actin filaments to the plasma membrane at adherent junctions between cells (Fig. 3.6). This allows a non-stressed coordination of contraction between adjacent cells of a tissue. Similarly, vertical contraction of tissues is anchored across the cell membrane to the basement matrix at focal adhesion

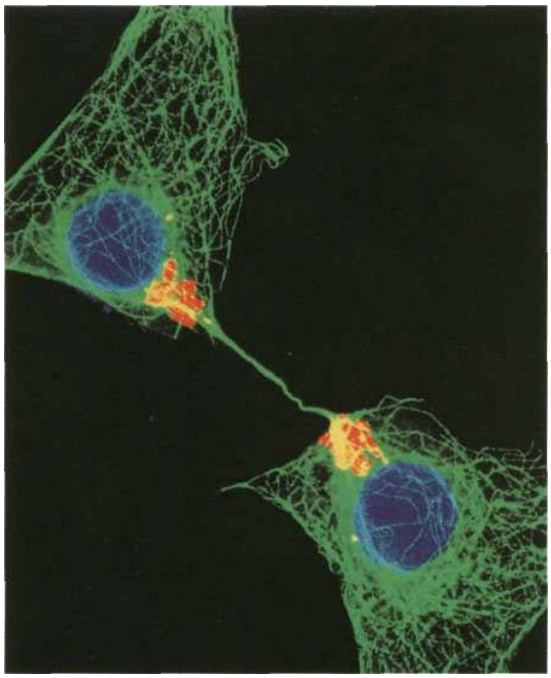

Fig. 3.5 **Immunofluorescent micrograph of dividing fibroblasts showing the cytoskeleton.** Microtubules are shown in green, Golgi apparatus in yellow and the nuclei in blue. Reproduced with permission of Dr Philip Huie, Stanford University, from *Biotechniques* July/August 1995.

junctions where actin fibres converge (Fig. 3.6). Actin-binding proteins (e.g. fimbria) modulate the behaviour of microfilaments, and their effects are often calcium-dependent. The actin-associated proteins can be tissue type specific, for example actin-binding troponin is a complex of three subunits and two of these have isomers which are only found in cardiac muscle. " Cardiac troponin I and T are released into the blood circulation after the onset of a myocardial infarction (p. 809).

Alterations in the cell's actin architecture are also controlled by the activation of small ras-like GTP-binding proteins *rho* and *rac*. These are involved in rearrangement of the cell during division, and thus dysfunctions of these proteins are associated with malignancy.

INTERCELLULAR CONNECTIONS

The cytoskeleton and plasma membrane interconnect, and extracellular domains form junctions between cells to form tissues. There are three types of junction between cells: tight junctions, adherent junctions and gap junctions (Fig. 3.6).

Tight junctions

Tight junctions (zonula occludens) hold cells together. They are situated at the ends of margins adjacent to epithelial cells (e.g. intestinal and renal cells) and form a barrier to the movement of ions and solutes across the epithelium, although they can be variably 'leaky' to certain solutes. The proteins responsible for the intercellular tight junction closure are called *daudins*. They show selective expression within tissue and regulate what small ions may pass through the gaps between cells. For example, the kidney displays a differential expression of these claudin proteins. Mutations of claudin-16 (which is expressed in the distal convoluted tubule in the kidney, where magnesium is reabsorbed) are responsible for some forms of Gitelman's syndrome (p. 706). Since magnesium reabsorption is paracellular, tight junctions (which contain claudin-16) prevent these divalent ions rapidly diffusing back between the cells into renal tubules.

Adherent junctions

Adherent junctions (zonula adherens) are continuous on the basal side of cells. They contain cadherins and are the major site of attachment of intracellular microfilaments. Intermediate filaments attach to *desmosomes,* which are apposed areas of thickened membranes of two adjacent cells. *Hemidesmosomes* attach cells to the basal lamina and are also connected to intermediate filaments. Transmembrane *integrins* link the extracellular matrix to microfilaments at focal areas where cells also attach to their basal laminae. In blistering dermatological disorders autoantibodies cause damage by attacking tight junction desmosomal proteins such as desmoglein-3 in *pemphigus vulgaris* and desmoglein-1 in *pemphigus foliaceus* (p. 1347).

Gap junctions

Gap junctions allow substances to pass directly between cells without entering the extracellular fluids. Protein channels *(connexons)* are lined up between two adjacent cells and allow the passage of solutes up to molecular weight 1000 kDa (e.g. amino acids and sugars), as well as ions, chemical messengers and other factors. The diameter of these channels is regulated by intracellular Ca^{2+}, pH and voltage. Connexons are made up of six subunits surrounding a channel and their isoforms in tissues are encoded by different genes. Mutant connexons can cause disorders, such as the X-linked form of Charcot-Marie-Tooth disease (p. 1263).

CELL ADHESION MOLECULES (see also p. 198)

Adhesion molecules and adhesion receptors are essential for tissue structural organization. Differential expression of such molecules is implicit in the processes of cell growth and differentiation, such as wound repair and embryogenesis. There are four major families of cell adhesion molecules: cadherins, integrins, the immunoglobulin superfamily and selectins (Fig. 3.6).

Cadherins

The cadherins establish molecular links between adjacent cells. They form zipper-like structures at 'adherens junctions', areas of the plasma membrane where cells make

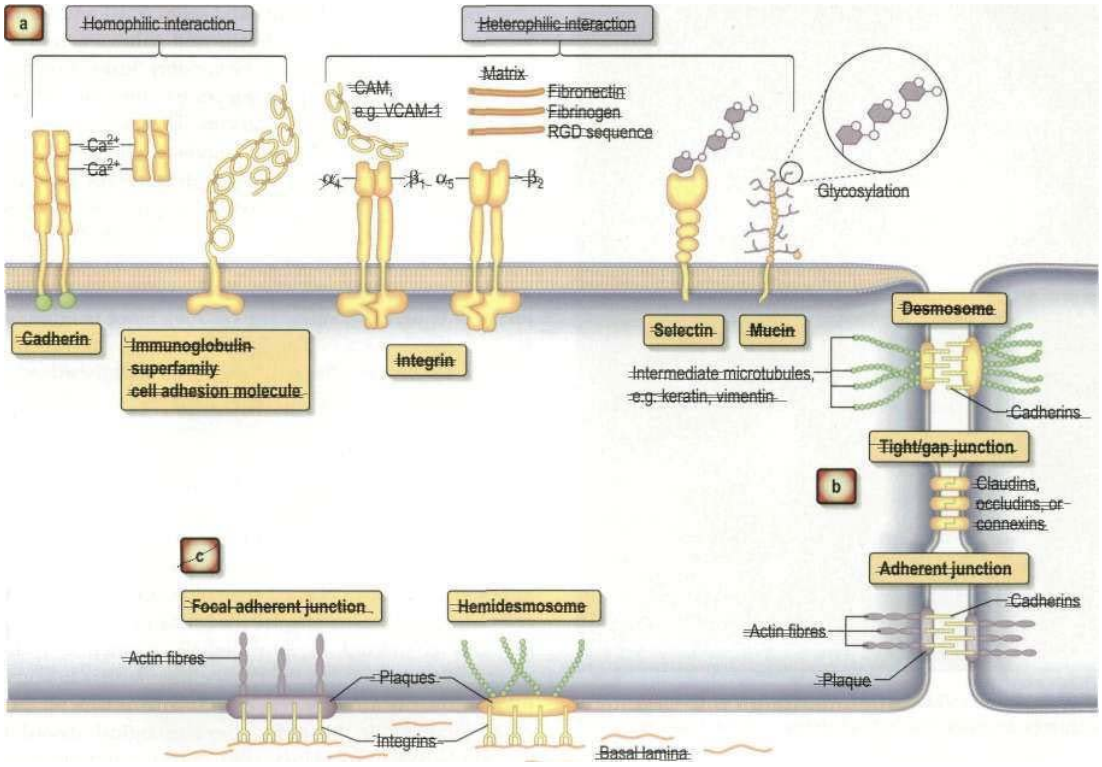

Fig. 3.6 **Cell adhesion molecules and cellular junctions, (a) Five main groups of adhesion molecules.** The cadherins have a Ca^{2+}-dependent homodimer homophilic interaction and their intracellular domains link to the cytoskeleton. Immunoglobulin superfamily cell adhesion molecules (CAMs) have both homophilic and heterophilic (integrin) interactions. Binding is Ca^{2+} independent and the intracellular domains are cell signalling. Integrins have heterophilic interactions mostly with basement matrix components. They have an a-p chain structure and their intracellular domains are predominantly cell signalling but can directly interact with cytoskeletal complexes. Selectins have a weak binding affinity for specific sugar molecules found on mucins. Mucins are long tandem-repeat peptides which protrude from the cell membrane and are covered in glycosylation moieties, **(b) Adjacent cells form focal adhesion junctions.** *Desmosomes are* where the membrane forms a proteinaceous plaque containing molecules like desmoglein, from which cadherins protrude and bind cadherins of the adjacent cell. Intracellularly the plaque binds loops of cytoskeleton intermediate filaments, e.g. keratin in epithelial cells and vimentin in fibroblasts. *Tight junctions* are mediated by integral membrane proteins, claudins and diclaudins, which associate to form subunits bridging the intercellular gap. *Gap junctions* consists of connexin subunits that form a regulated hollow tube. *Adherent junctions* are similar to desmosomes in that cell-to-cell adhesion is mediated by cadherins but the membrane proteinaceous plaque components are different and bind contractile cytoskeletal fibres like actin at the terminus, **(c) Basement membrane adhesion.** This is similar to desmosomes and adherent junctions in that membrane plaques link intercellular intermediate filaments (e.g. keratin or vimentin) in *hemidesmosomes* and contractile cytoskeleton actin in *focal adherent junctions* to the basement matrix. However, integrins replace cadherins as the surface adhesion molecules.

contact with other cells. Through these junctions, bundles of actin filaments run from cell to cell. Related molecules such as desmogleins form the main constituents of desmosomes, the intercellular contacts found abundantly between epithelial cells. Desmosomes serve as anchoring sites for intermediate filaments of the cytoskeleton. When dissociated embryonic cells are grown in a dish, they tend to cluster according to their tissue of origin. The homophilic (like with like) interaction of cadherins is the basis of this separation, and has a key role in segregating embryonic tissues. The expression of specific adhesion molecules in the embryo is crucial for the migration of cells and the differentiation of tissues. For example, when neural crest cells stop producing N-CAM (see below) and N-cadherin and start to display integrin receptors they can separate, and begin to migrate on the extracellular matrix. Changes in cadherin expression are often associated with tumour metastatic potential.

Integrins

These are membrane glycoproteins with a and fJ subunits which exist in active and inactive forms. The integrins principally bind to extracellular matrix components such as fibrinogen, elastase and laminin. The amino acid sequence arginine-glycine-aspartic acid (RGD) is a potent recognition sequence for integrin binding, and

integrins replace cadherins in the focal membrane anchorage of hemidesmosomes and focal adhesion junctions (Fig. 3.6). A feature of integrins is that the active form can come about as a result of a cytoplasmic signal that causes a conformational change in the extracellular domain, increasing affinity for its ligand. This 'inside-out' signalling occurs when leucocytes are stimulated by bacterial peptides, rapidly increasing leukocyte integrin affinity for immunoglobulin superfamilies structures such as the Fc portion of immunoglobulin. The 'outside-in' signalling follows the binding of the ligand to the integrin and stimulates secondary signals resulting in diverse events such as endocytosis, proliferation and apoptosis. Defective integrins are associated with many immunological and clotting disorders such as Bernard-Soulier syndrome and Glanzmann's thrombasthenia (p. 472).

Immunoglobulin superfamily cell adhesion molecules (CAMs)

These molecules contain domain sequences which are immunoglobulin-like structures. The neural-cell adhesion molecule (N-CAM) is found predominantly in the nervous system. It mediates a homophilic (like with like) adhesion. When bound to an identical molecule on another cell, N-CAM can also associate laterally with a fibroblast growth factor receptor and stimulate the tyrosine kinase activity of that receptor to induce the growth of neurites. Thus adhesion molecules can trigger cellular responses by indirect activation of other types of receptors. The placenta and gastrointestinal tract also express immunoglobulin superfamily members, but their function is not completely understood.

Selectins

Unlike most adhesion molecules (which bind to other proteins), the selectins interact with carbohydrate-ligands or *mucin* complexes on leucocytes and endothelial cells (vascular and haematological systems). Selectins were named after the tissues in which they were first identified. *L-selectin* is found on leucocytes and mediates the homing of lymphocytes to lymph nodes. *E-selectin* appears on endothelial cells after they have been activated by inflammatory cytokines; the small basal amount of E-selectin in many vascular beds appears to be necessary for the migration of leucocytes. *P-selectin* is stored in the alpha granules of platelets and the Weibel-Palade bodies of endothelial cells, but it moves rapidly to the plasma membrane upon stimulation of these cells. All three selectins play a part in leucocyte rolling (p. 199).

THE NUCLEUS AND ITS RESPONSES ^

A nucleus is present in all eukaryotic cells that divide. It contains the human genome and is bound by two bilayer lipid membranes. The outer of the two is continuous with the endoplasmic reticulum. Nuclear pores are present in the membranes, allowing the passage of nucleotides and DNA interacting proteins in, and mRNA out (see Fig. 3.4). The genome consists of DNA and all the apparatus for replication and transcription into RNA (see p. 164). There are two types of cell division - meiosis and mitosis. In *meiosis,* which occurs only in germ cells, the chromosome complement is halved (haploid) and, at fertilization, the union of two cells restores the full complement of 46 chromosomes. *Mitosis* occurs in dividing cells after fertilization, and results in two identical daughter cells. It is only during cell division that chromosomes (see p. 171) become visible.

A nucleolus is a dense area within the nucleus. It is rich in proteins and RNA and is chiefly concerned with the synthesis of ribosomal RNA (rRNA) and ribosomes.

The cell cycle (Fig. 3.7)

Cells in the quiescent GO phase (G, gap) of the cycle are stimulated by the receptor-mediated actions of growth factors (e.g. EGF, epithelial growth factor; PDGF, platelet-derived growth factor; IGF, insulin-like growth factor) via intracellular second messengers. Stimuli are transmitted to the nucleus (see below) where they activate transcription factors and lead to the initiation of DNA synthesis, followed by mitosis and cell division. Cell cycling is modified by the cyclin family of proteins that activate or deactivate proteins involved in DNA replication by phosphorylation (via kinases and phosphatase domains). Thus from GO the cell moves on to Gl (gap 1) when the chromosomes are prepared for replication. This is followed by the synthetic (S) phase, when the 46

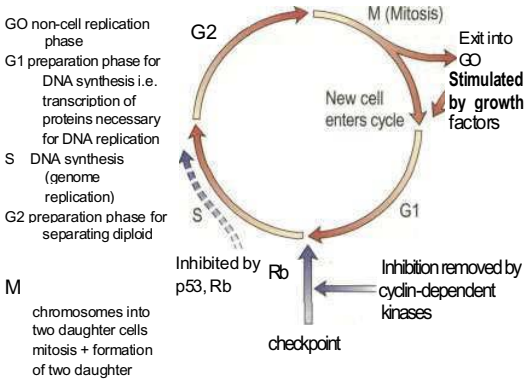

Fig. 3.7 **The cell cycle.** Cells are stimulated to leave non-cycle GO to enter G1 phase by growth factors. During G1, transcription of the DNA synthesis molecules occurs. Rb is a 'checkpoint' (inhibition molecule) between G1 and S phases and must be removed for the cycle to continue. This is achieved by the action of the cyclin-dependent kinase produced during G1. During the **S phase** any DNA defects will be detected and p53 will halt the cycle (see p. 189). Following DNA synthesis (S phase) cells enter G2, a preparation phase for cell division. Mitosis takes place in the M **phase.** The new daughter cells can now either enter GO and differentiate into specialized cells, or re-enter the cell cycle.

cells

chromosomes are duplicated into chromatids, followed by another gap phase (G2), which eventually leads to mitosis (M).

Apoptosis (programmed cell death)

Apoptosis or physiological cell death occurs through the deliberate activation of constituent genes whose function is to cause their own demise.

Necrotic cell death, in contrast is where some external factor (e.g. hypoxia, chemical toxins) damages the cell's physiology and results in the disintegration of the cell. Characteristically there is an influx of water and ions, after which cellular organelles swell and rupture. Cell lysis induces acute inflammatory responses in vivo owing to the release of lysosomal enzymes into the extracellular environment.

Apoptotic cell death has characteristic morphological features:

- chromatin aggregation, with nuclear and cytoplasmic condensation into distinct membrane-bound vesicles which are termed apoptotic bodies
- organelles remain intact
- cell 'blebs' (which are intact membrane vesicles)
- there is no inflammatory response
- cellular 'blebs' and remains are phagocytosed by adjacent cells and macrophages.

This process requires energy (ATP), and several Ca^{2+}- and Mg^{2+}-dependent nuclease systems are activated which specifically cleave nuclear DNA at the inter-histone residues. An endonuclease destroys DNA following apoptosis. This involves the enzyme caspase (cysteine-containing aspartase-specific protease) which activates the CAD (caspase-activated DNase)/ICAD (inhibitor of CAD) system which can destroy DNA. Regulated apoptosis is essential for many life processes, from tissue structure formation in embryogenesis and wound healing to normal metabolic processes such as autodestruction of the thickened endometrium to cause menstruation in a non-conception cycle. In oncology, chemotherapy and radiotherapy regimens only work if they can trigger the tumour cells' own apoptotic pathways. Failure to do so in resistant tumours can result in the accumulation of further genetic damage to the surviving cells. Several factors initiate apoptosis but in general there are two signalling pathways: the extrinsic apoptotic pathway triggered by death receptors on the cell surface and the intrinsic pathway initiated at the mitochondrial level. Death receptors are all members of the TNF receptor superfamily and include CD95 (APO-1/Fas), TRAIL (TNF-related apoptosis ligand)-Rl, TRAIL-R2, TNF-R1, DR3 and DR6.

The *extrinsic pathway* is involved in processes such as tissue remodelling and induction of immune self-tolerance. Activated receptors with internal death domain complexes multiply pro-caspase 8 molecules whose autocatalytic activity results in release of the initiator caspase 8 (Fig. 3.8). In turn caspase 8 cleaves pro-caspase 3 and caspase 3, in combination with the other effector caspases, activating DNA cleavage, cell condensation and fragmentation.

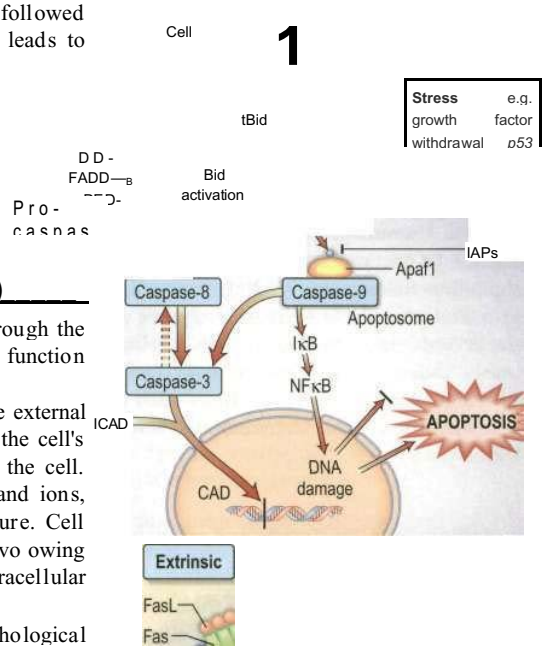

Fig. 3.8 **Diagrammatic representation of the extrinsic and intrinsic apoptotic signalling network.** The Fas protein and Fas ligand (FasL) are two proteins that interact to activate one of the best-defined apoptotic pathways.

Fas and **FasL** are both members of the TNF (tumour necrosis factor) family - Fas is part of the transmembrane receptor family and FasL is part of the membrane-associated cytokine family. When the homotrimer of FasL binds to Fas, it causes Fas to trimerize and brings together the **death domains (DD)** on the cytoplasmic tails of the protein. The adaptor protein, **FADD (Fas-associating protein with death domain),** binds to these activated death domains and they bind to pro-caspase 8 through a set of **death effector domains (DED).** When pro-caspase 8s are brought together, they transactivate and cleave themselves to release **caspase** 8, a protease that cleaves protein chains after aspartic acid residues. Caspase 8 then cleaves and activates other caspases which eventually leads to activation of caspase 3. **Caspase** 3 cleaves **ICAD,** the inhibitor of CAD (caspase activated DNase), which frees **CAD** to enter the nucleus and cleave DNA. Although caspase 3 is the pivotal execution caspase for apoptosis, the processes can be initiated by intrinsic signalling which always involves mitchondrial release of cytochrome C and activation of **caspase** 9.
The release of **cytochrome C** and mitochondrial inhibitor of IAPs is mediated via Bcl-2 family proteins (including Bax, Bak) forming pores in the mitochondrial membrane. Interestingly, the extrinsic apoptotic signal is aided and amplified by activation of **tBid** which recruits Bcl-2 family members and hence also activates the intrinsic pathway. Apafl, apoptotic protease activating factor 1; Bid, family member of Bcl-2 protein; IAPs, inhibitor of apoptosis proteins.

The *intrinsic pathway* centres on the release of cytochrome C from the mitochondria. Cellular stress, such as growth factor withdrawal and p53 cell cycle arrest induces the expression of the pro-apoptotic Bcl-2 family of proteins, Bax and Bak. These form tetrameric complexes,

which imbed into the outer mitochondrial membrane forming permissive pores. Cytochrome C, released from the mitochondria, binds Apafl, forming a complex known as the apoptosome, which then activates an initiator caspase, in this case caspase 9. Caspase 9, then activates the effector caspase, caspase 3. Other proteins released from damaged mitochondria, Smac/DIABLO and Omi/HtrA2, counteract the effect of IAPs (inhibitor of apoptosis proteins), which normally bind and prevent activation of pro-caspase 3. Anti-apoptotic Bcl-2 protein, when incorporated as a member of the Bak/Bax pore complex, renders the mitochondrial pore non-permissive to release of cytochrome C and the anti-IAPs.

There is an amplification link between the extrinsic and intrinsic apoptotic pathways in that caspase 8 cleaves a Bcl-2 family member, tBid, which then aids formation of the Bcl-2/Bax/Bak pore complexes. If this complex is predominately formed from pro-apoptotic members of the Bcl-2 family of proteins then apoptosome/caspase 9, along with mitochondrial anti-IAPs, amplifies the apoptotic activation of effector caspases 3 (Fig. 3.8). Conversely, overexpression of anti-apoptotic Bcl-2 will not only inhibit intrinsic, but also dampen down extrinsic apoptotic signalling.

MOLECULAR BIOLOGY AND GENETIC DISORDERS

Over 200 genetic disorders have been identified, and the role of molecular biology in the diagnosis of monogenic disease is clear cut. The interaction of 'at risk' genes in multifactorial diseases has also increased the role of genetics in rheumatology, cancer and schizophrenia.

DNA STRUCTURE AND FUNCTION

Genetic information is stored in the form of double-stranded deoxyribonucleic acid (DNA). Each strand of DNA is made up of a deoxyribose-phosphate backbone and a series of purine (adenine (A) and guanine (G)) and pyrimidine (thymine (T) and cytosine (C)) bases of the nucleic acid. For practical purposes the length of DNA is generally measured in numbers of base-pairs (bp).

The monomeric unit in DNA (and in RNA) is the nucleotide, which is a base joined to a sugar-phosphate unit (Fig. 3.9a). The two strands of DNA are held together by hydrogen bonds between the bases. There are only four possible pairs of nucleotides - TA, AT, GC and CG (Fig. 3.9b). The two strands twist to form a double helix with major and minor grooves, and the large stretches of helical DNA are coiled around histone proteins to form nucleosomes and further condensed into the chromosomes that are seen at metaphase (Fig. 3.9c, d).

GENES

A gene is a portion of DNA that contains the codes for a polypeptide sequence. Three adjacent nucleotides (a codon) code for a particular amino acid, such as AGA for arginine, and TTC for phenylalanine. There are only 20 common amino acids, but 64 possible codon combinations that make up the genetic code. This means that most amino acids are encoded for by more than one triplet; other codons are used as signals for 'initiating' or 'terminating' polypeptide-chain synthesis.

Genes consist of lengths of DNA that contain sufficient nucleotide triplets to code for the appropriate number of amino acids in the polypeptide chains of a particular protein. Genes vary greatly in size: most extend over 20^0 kbp, but a few (such as the gene for the muscle protein dystrophin) can extend over millions of base-pairs. In bacteria the coding sequences are continuous, but in higher organisms these coding sequences (exons) are interrupted by intervening sequences that are non-coding (introns) at various positions (see Fig. 3.10). Some genes code for RNA molecules which will not be further translated into proteins. These code for functional

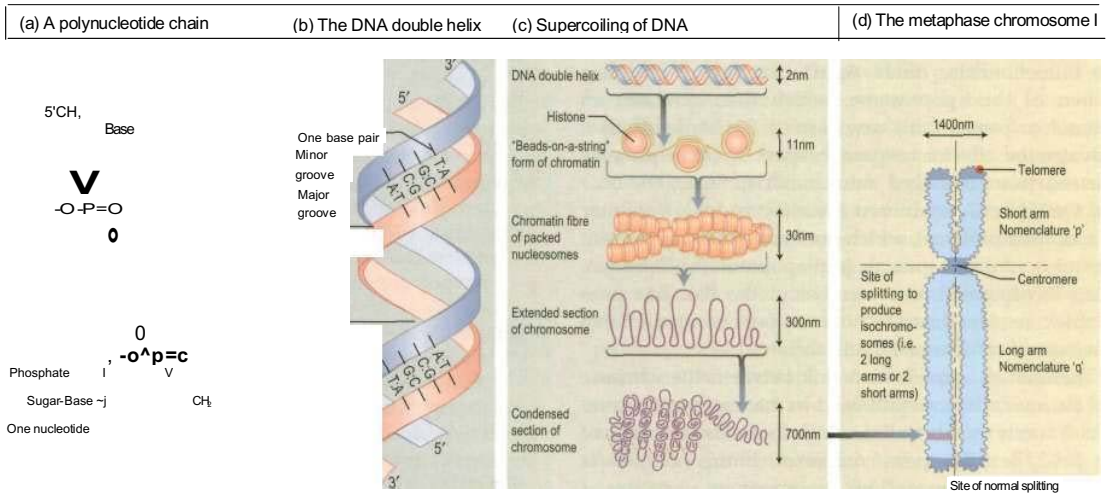

Fig. 3.9 **DNA and its structural relationship to human chromosomes.**
(a) A polynucleotide strand with the position of the nucleic bases indicated. Individual nucleotides form a polymer linked via the deoxyribose sugars. The 5' carbon of the heterocyclic sugar structure links to the 3' carbon of the next via a phosphate molecule forming the sugar-phosphate backbone of the nucleic acid. The 5'-3' linkage gives an orientation to a sequence of DNA.
(b) Double-stranded DNA. The two strands of DNA are held together by hydrogen bonds between the bases. As T always pairs with A, and G with C, there are only four possible pairs of nucleotides - TA, AT, GC and CG. The orientation of the complementary single strands of DNA (ssDNA) is always opposite; i.e. one will be 5'-3' whilst the partner will be 3'-5'. CG base-pairs form three hydrogen bonds whilst the AT bonds form only two. Thus, CG bonds are stronger than AT bonds, which affects the biophysical nature of different sequences of DNA. In a random sequence of DNA with equal proportions of CG and AT base-pairs, complementary strands form a helical 3D structure. This helix will have major and minor grooves and a complete turn of the helix will contain 12 base-pairs. These grooves are structurally important, as DNA-binding proteins predominantly interact with the major grooves. DNA sequences rich in repetitive CG base-pairs distort the helical shape whereby the minor grooves become more equal in size to the major grooves, giving a Z-like structure. These CG-rich regions are sites were DNA-binding proteins are likely to bind.
(c) Supercoiling of DNA. In humans, and other higher organisms, the large stretches of helical DNA are coiled to form nucleosomes and further condensed into the chromosomes that can be seen at metaphase. DNA is first packaged by winding around nuclear proteins - histones - every 180 bp. This can then be coiled and supercoiled to compact nucleosomes and eventually visible chromosomes.
(d) At the end of the metaphase DNA replication will result in a twin chromosome joined at the centromere. This picture shows the chromosome, its relationship to supercoiling, and the positions of structural regions: centromeres, telomeres and sites where the double chromosome can split.
Nomenclature of chromosomes. This is the assigned number or X or Y, plus short arm (p) or long arm (q). The region or subregion is defined by the transverse light and dark bands observed when staining with Giemsa (hence G-banding) or quinacrine and numbered from the centromere outwards.
Chromosome constitution = chromosome number + sex chromosomes + abnormality; e.g.
46XX = normal female
47XX+21 = Down's syndrome (trisomy 21)
46XYt (2;19) (p21;p12) = male with a normal number of chromosomes but a translocation between chromosome 2 and 19 with breakages at short-arm bands 21 and 12 of the respective chromosomes.

ribosomal RNA (rRNA) and transfer RNA (tRNA), which play vital roles in polypeptide synthesis.

TRANSCRIPTION AND TRANSLATION
(Fig. 3.10)

The conversion of genetic information to polypeptides and proteins relies on the transcription of sequences of bases in DNA to messenger RNA molecules; mRNAs are found mainly in the nucleolus and the cytoplasm, and are polymers of nucleotides containing a ribose-phosphate unit attached to a base. The bases are adenine, guanine, cytosine and uracil (U) (which replaces the thymine found in DNA). RNA is a single-stranded molecule but it can hybridize with a complementary sequence of single-stranded DNA (ssDNA). Genetic information is carried from the nucleus to the cytoplasm by mRNA, which in turn acts as a template for protein synthesis.

Each base in the mRNA molecule is lined up opposite to the corresponding base in the DNA: C to G, G to C, U to A and A to T. A gene is always read in the 5'-3' orientation and at 5' promoter sites which specifically bind the enzyme RNA polymerase and so indicate where transcription is to commence. Eukaryotic genes have two AT-rich promoter sites. The first, the TATA box, is located about 25 bp upstream of (or before) the transcription start site, while the second, the CAAT box, is 75 bp upstream of the start site. The initial or primary mRNA is a

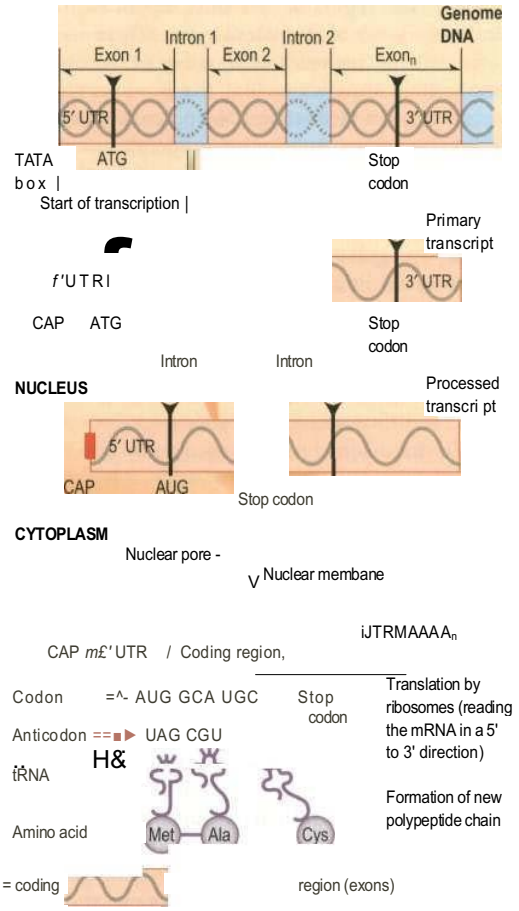

Fig. 3.10 **Transcription and translation (DNA to RNA to protein).**

RNA polymerase creates an **RNA copy** of the DNA gene sequence. This **primary transcript** is processed: capping of the 5' free end of the mRNA precursor involves the addition of an inverted guanine residue to the 5' terminal which is subsequently methylated, forming a 7-methylguanosine residue. (The corresponding position on the gene is thus called the CAP site.)

The 3' end of an mRNA defined by the sequence AAUAAA acts as a cleavage signal for an endonuclease, which cleaves the growing transcript about 20 bp downstream from the signal. The 3' end is further processed by a Poly A polymerase which adds about 250 adenosine residues to the 3' end, forming a Poly A tail (polyadenylation). Without these additions, the mRNA sequence will be rapidly degraded 5'-3' but the inverted cap nucleotide prevents nuclease attachment. The activity of specific 5' mRNA nucleases to remove the cap is further regulated by the Poly A tail which must first be removed by other degradation enzymes. **Splicing** out of the introns then produces the mature mRNA (prokaryote genes do not contain introns). This then moves out of the nucleus via nuclear pores and aligns on endoplasmic reticulum.

Ribosomal subunits assemble on the mRNA moving along 5' to 3'. With the transport of amino acids to their active sites by specific tRNAs, the complex translates the code, producing the peptide sequence. Once formed, the peptide is released into the cytoplasmic reticulum for post-translational modification into a mature protein.

complete copy of one strand of DNA and therefore contains both introns and exons. While still in the nucleus, the mRNA undergoes post-transcriptional modification whereby the 5' and 3' ends are protected by the addition of an inverted guanidine nucleotide (CAP) and a chain of adenine nucleotides (Poly A) (see Fig. 3.10). In higher organisms, the primary transcript mRNA is further processed inside the nucleus whereby the introns are spliced out. Splicing is achieved by small nuclear RNA in association with specific proteins. Furthermore, alternative splicing is possible whereby an entire exon can be omitted. Thus more than one protein can be coded from the same gene. The processed mRNA then migrates out of the nucleus into the cytoplasm. Polysomes (groups of ribosomes) become attached to the mRNA; the ribosomes consist of subunits composed of small RNA molecules (rRNA) and proteins. The rRNA components are key to the binding and translation of the genetic code. Held by the ribosomes, triplets of adjacent bases on the mRNA called codons are exposed and recognized by complementary sequences, or anti-codons, in transfer RNA (tRNA) molecules. Each tRNA molecule carries an amino acid that is specific to the anti-codon. As the ribosome passes along the mRNA in the 5'-3' direction, amino acids are transferred from tRNA molecules and sequentially linked by the ribosome in the order dictated by the order of codons. The ribosome, in effect, moves along the mRNA like a 'zipper', linking the assembled amino acids to form a polypeptide chain. The first 20 or more nucleotides are recognition and regulatory sequences and are untranslated but necessary for translation and possibly earlier transcription. Translation begins when the triplet AUG (methionine) is encountered. All proteins start with methionine but this is often lost as the leading sequence of amino acids of the native peptides are removed during protein folding and post-translational modification into a mature protein. Similarly the Poly A tail is not translated (3' untranslated region) and is preceded by a stop codon, UAA, UAG or UGA.

THE CONTROL OF GENE EXPRESSION

Gene expression can be controlled at many points in the steps between the translation of DNA to proteins. Proteins and RNA molecules are in a constant state of turnover; as soon as they are produced, processes for their destruction are at work. For many genes, transcriptional control is the key point of regulation. Deleterious, even oncogenic, changes to a cell's biology may arise through no fault in the expression of a particular gene. Apparent overexpression may be due to non-breakdown of mRNA or protein product. Conversely, a recent paper suggests the existence of a pathway that stops gene expression by promoting degradation of RNA (RNA interference, RNA$_{(}$).

Transcriptional control

Gene transcription (DNA to mRNA) is not a spontaneous event and is possible only as a result of the interaction of a number of DNA-binding proteins with genomic DNA.

Regulation of a gene's expression must first start with the opening up of the double helix of DNA in the correct region of the chromosome. In order to do this, a class of protein molecules that recognize the outside of the DNA helix have evolved. These DNA-binding proteins preferentially interact with the major groove of the DNA double helix (see Fig. 3.9). The base-pair composition of the DNA sequence can change the geometry of a DNA helix to facilitate the fit of a DNA-binding protein with its target region: CG-rich areas form the Z-structure DNA helix; sequences such as AAAANNN cause a slight bend, and if this is repeated every 10 nucleotides it produces pronounced curves. DNA-binding proteins that recognize these distorted helices result either in the opening up of the helix so that the gene may be transcribed, or in the prevention of the helix being opened.

Structural classes of DNA-binding proteins

There are four basic classes of DNA-binding protein, classified according to their structural motifs (see Fig. 3.11 and Table 3.1).

Control regions and proteins

DNA-binding proteins act as regulators of gene expression in three different ways. They are the promoters, the operators and the enhancers. The primary gene expression regulators are the *promoters*. The RNA polymerases bind to a promoter region, normally adjacent to the transcribed sequence of DNA. In eukaryotes active transcription is possible only when a number of DNA-binding and associated proteins come together and interact. Known as 'general transcription factors', these proteins are thought to assemble at promoter sites used by RNA polymerases (e.g. Pol II) that are characterized by specific motifs such as the TATA sequence.

Other DNA regulator proteins operate in close proximity to the site of promoter binding. These are called operator proteins/regions and act either as repressors by binding to DNA sequences within the promoter site or as positive regulators facilitating RNA polymerase binding. The third class of regulator proteins operate as enhancer sequences which are at least 200 bp away from the site of transcription initiation. Binding of regulator proteins to enhancer regions, several hundred bases from the promoter site, upregulates the expression. This turns out to be a distance favourable for DNA to loop back on itself without straining the backbone bonds of the DNA double helix.

The GAL4 enhancer of yeast physically aids the binding of transcription factors to the TATA region of the promoter, and thus acts like a catalyst for general transcription factor assembly, and consequently also the rate of RNA polymerase activity. In mammals, it is frequently a region termed the 'cyclic AMP response element' (CRE) that acts in this manner. Increasing intracellular cAMP levels cause activation and release of CRE-binding protein (CREB). This binds to the CRE sequence and enhances the transcription rate.

These relatively remote regulatory regions need not just enhance gene expression but may also repress transcription. Indeed, loops can be formed from regulatory regions downstream as well as upstream of the gene's coding sequence. Repressors can inhibit the transcription of a given gene by binding to the regulatory sequence and blocking positive regulators, binding and thus inactivating the positive regulator, or by interfering with the promoter protein assembly. Multiple regulatory regions and DNA-binding proteins can surround a given gene and precisely control its expression at a basal level and in response to a cellular stimulus (Table 3.1).

Table 3.1 **Examples of DNA-binding proteins**

Class of DNA-binding protein	Examples
Helix-turn-helix	CREB (cAMP response element binding protein) Steroid and thyroid hormone receptors Retinoic acid and vitamin D receptors *Bcl-6* oncogene product (lymphoma) *WT1* oncogene product (Wilms' tumour) GATA-1 erythrocyte differentiation and Hb expression factor *c-jun* cell replication

Leucine zippers	oncogene *c-fos* cell replication oncogene *myc oncogene mad*
Helix-loop-helix	*oncogene max oncogene*

CHROMOSOMES, INTRONS AND THE SIZE OF THE HUMAN GENOME

Human genetics differs from that of bacteria in structural components of the genetic code and in the way DNA is packaged. The fact that humans have chromosomes and introns affects how much DNA we require to code for all our proteins in an unusual way. We have far more DNA (3×10^9 bp) than protein-coding genes (32 000), whereas simple bacteria appear to have a much more economical DNA to gene ratio. Simple organisms like bacteria that have circular genomes, that are not contained within a membrane-bound organelle (the nucleus), are termed 'prokaryotes'. Higher eukaryotic organisms have their linear genomic packages - chromosomes - separated from the general cytoplasm by the nuclear envelope. In eukaryotes, genomic DNA is associated with nuclear proteins called histones.

Coiling around histones and structural regions such as the cetromeres and telomeres, requires regions of DNA devoted specifically to the purpose of packaging (see Fig. 3.9c). Ten per cent of human DNA is highly repetitive (or 'satellite' DNA), consisting of long arrays of tandem

repeats. These regions tend to be supercoiled around histones in condensed regions termed *heterochromatin,* even when the cell is not undergoing division. In contrast, most other DNA regions are relatively uncondensed and constitute the euchromatin. This remaining DNA is either moderately repetitive, accounting for about 30% of the genome, or codes for unique genes and gene families, occupying some 2% of the genome.

Although supercoiling of DNA around histones, intronic spacing (all giving tighter control of specific gene expression) and packaging into functional chromosomes accounts for some 40% of our total DNA, at least 60% is random and has no apparent function. However, life

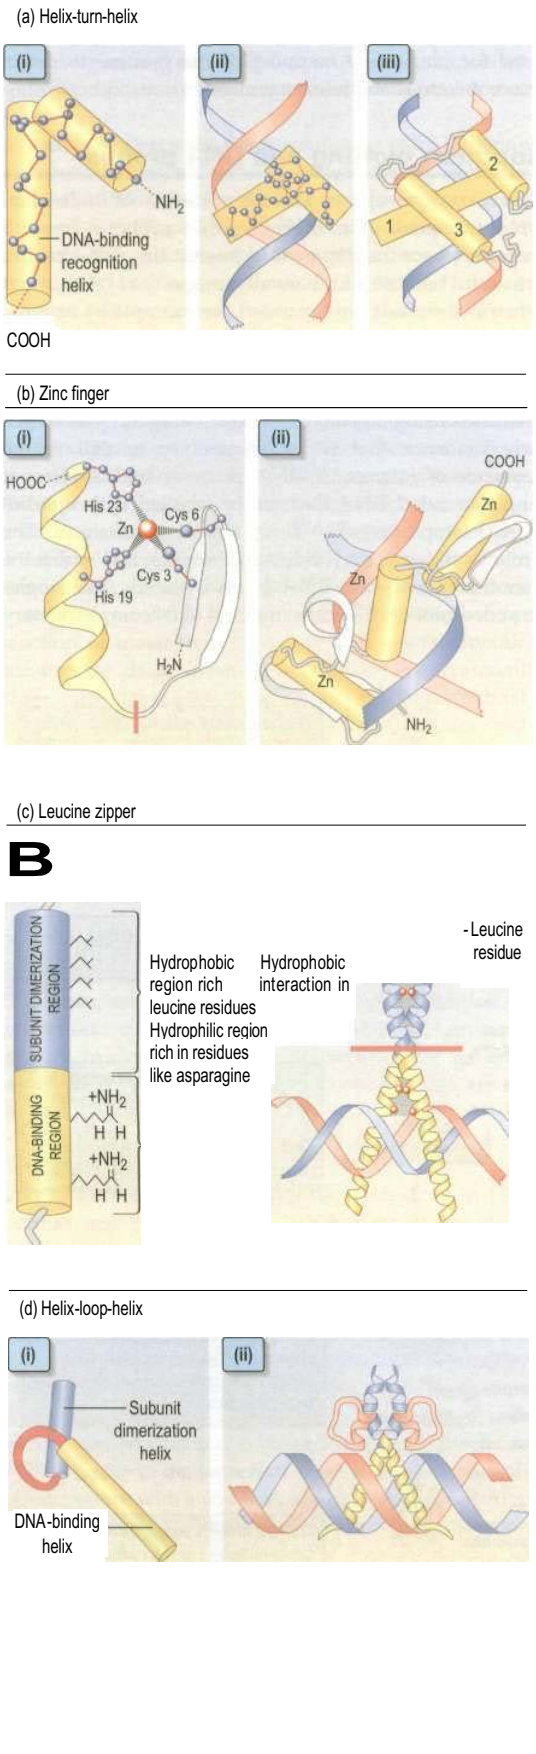

Fig. 3.11 **The four classes of DNA-binding proteins.**
(a) Helix-turn-helix (HTH) motifs. The simplest and most common, it consists of a helix connected by a fixed angle to a second helix, (i) This represents the 'core' motif of HTH DNA-binding proteins but considerable modifications occur, (ii) Like all DNA-binding proteins they interact as dimers, binding at exactly one turn of the double helix (3.4 nm or 12 bp) apart. The homeodomain HLH DNA-binding proteins are a special class of HTH proteins. Discovered in the 1980s during investigation of the gene controlling *Drosophila* development, they contain an almost identical stretch of 60 amino acids. They have a third helix which holds the DNA-binding region in a fixed orientation. Indeed, all homeodomain proteins appear to have specific conserved amino acid positions and residues which interact with DNA. **(iii)** Furthermore, random orientation extension chains at the N-terminal can interact with the minor groove.
(b) Zinc finger motifs, characterized by the incorporation of zinc, in some form, into the protein's quartenary structure. (i) The term originated from the structural model of a *Xenopus laevis* protein which uses a zinc ion to hold a loop in a 'finger'-shape by cross-linking two histidine residues with two cysteine residues. The Cys-Cys-His-His family of zinc finger DNA regulator proteins typically consists of an anti-parallel sheet forming a tight tertiary association with its own helix by zinc interaction with Cys and His residues within each of the two secondary structures, (ii) Several clusters of zinc fingers are found together and form a repeating structure which can interact with repetitive sequences in DNA.
(c) Leucine zipper motif, (i) This consists of a long ex-helix which has many hydrophobic leucine residues at one end, responsible for dimer formation, whilst the opposite hydrophilic ends interact with DNA across the major groove of the double helix, (ii) The quaternary structure of the leucine zippers need not be homodimeric, and indeed heterodimers are extremely common. Thus multiple sequences may be recognized by two or three DNA leucine zipper proteins depending on the type of dimer formed.
(d) Helix-loop-helix (HLH) motifs, (i) These consist of a DNA-binding a-helix joined to a protein dimerization secondary a-helix via a loop, (ii) These combine leucine zipper properties with those of helix motif DNA-binding proteins. A helix interacting with DNA is linked via a loop to a large second helix which non-covalently binds to a similar HLH protein. Homo- and heterodimers can form, but the loop gives flexibility in the orientation of the given DNA-binding a-helix domain.

outside of the sea is exposed to increased DNA damage by radiations and chemicals. This additional genomic mass of terrestrial animals, compared to deep-sea creatures, may be there to absorb the increased risk of DNA damage.

TOOLS FOR MOLECULAR BIOLOGY

Preparation of genomic DNA

The first step in studying the DNA of an individual involves preparation of genomic DNA. This is a simple procedure in which any cellular tissue including blood (the nucleated cells are isolated from the erythrocytes) can be used. The cells are lysed in order to open their cell and nuclear membranes, releasing chromosomal DNA. Following digestion of all cellular protein by the addition of proteolytic enzymes, the genomic DNA is isolated by chemical extraction with phenol. DNA is stable and can be stored for years.

Restriction enzymes and gel electrophoresis

Genomic DNA can be cut into a number of fragments by enzymes called 'restriction enzymes', which are obtained from bacteria. Restriction enzymes recognize specific DNA sequences and cut double-stranded DNA at these sites. For example, the enzyme EcoRI will cut DNA wherever it reads the sequence GAATTC, and so human genomic DNA is cut into hundreds of thousands of fragments. Whenever the genomic DNA from an individual is cut with EcoRI, the same 'restriction fragments' are produced. As DNA is a negatively charged molecule, the genomic DNA that has been digested with a restriction enzyme can be separated according to its size and charge, by electrophoresing the DNA through a gel matrix. The DNA sample is loaded at one end of the gel, a voltage is applied across the gel, and the DNA migrates towards the positive anode. The small fragments move more quickly than the large fragments, and so the DNA fragments separate out. Fragment size can be determined by running fragments of known size on the same gel.

Pulsed-field gel electrophoresis (PFGE) can be used to separate very long pieces of DNA (hundreds of kilobases) which have been cut by restriction enzymes that cut at rare sites in the genome. In this technique, DNA molecules are subjected to two perpendicular electric fields that are switched on alternately. The DNA molecules are separated on the basis of molecular size, and this technique can be used for long-range mapping of the genome to detect major deletions and rearrangements.

Southern blotting and DNA probes

This technique allows the visualization of individual DNA fragments (Fig. 3.12). A DNA probe is used to indicate where the fragment of interest lies. DNA probes are useful because a fundamental property of DNA is that when two strands are separated, for example by heating, they will always reassociate and stick together again because of their complementary base sequences. Therefore the presence or position of a particular gene can be identified using a gene 'probe' consisting of DNA with a base sequence that is complementary to that of the sequence of interest. A DNA probe is thus a piece of single-stranded DNA that can be labelled with a radioactive isotope (usually ^{32}P) or a fluorescent signal. The probe is added to a hybridization solution into which the membrane with the DNA is also placed. The single-stranded probe will locate and bind to its complementary

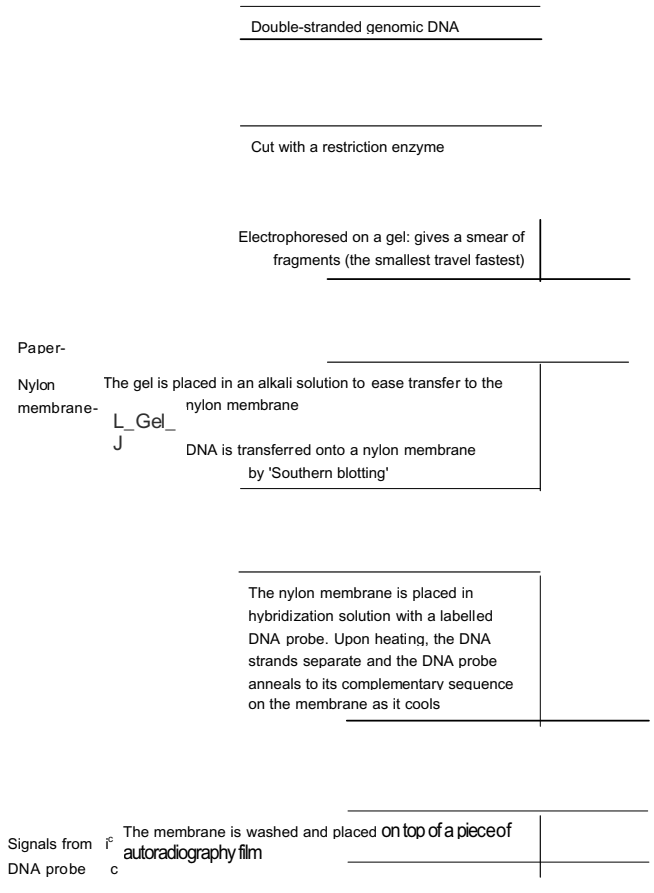

Fig. 3.12 Southern blotting and DNA probes.

sequence on the blot and can be identified by auto-radiography or fluorescence.

A similar technique for blotting RNA fragments (which are not cut by restriction enzymes, but which are blotted as full-length mRNAs) on to membranes is called Northern blotting, and one for blotting proteins is called Western blotting.

The polymerase chain-reaction (PCR)

Minute amounts of DNA can be amplified over a million times within a few hours using this in vitro technique (Fig. 3.13). The exact DNA sequence to be amplified needs to be known because the DNA is amplified between two short (generally 17-25 bp) single-stranded DNA fragments ('oligonucleotide primers') which are complementary to the sequences at each end of the DNA of interest.

The technique has three steps. First, the double-stranded genomic DNA is denatured by heat into single-stranded DNA. The reaction is then cooled to favour DNA annealing, and the primers bind to their target DNA. Finally, a DNA polymerase is used to extend the primers in opposite directions using the target DNA as a template. After one cycle there are two copies of double-stranded DNA, after two cycles there are four copies, and this number rises exponentially with the number of cycles. Typically a polymerase chain-reaction is set for 25-30 cycles, allowing millions of amplifications, i.e. 2^n where n = number of cycles.

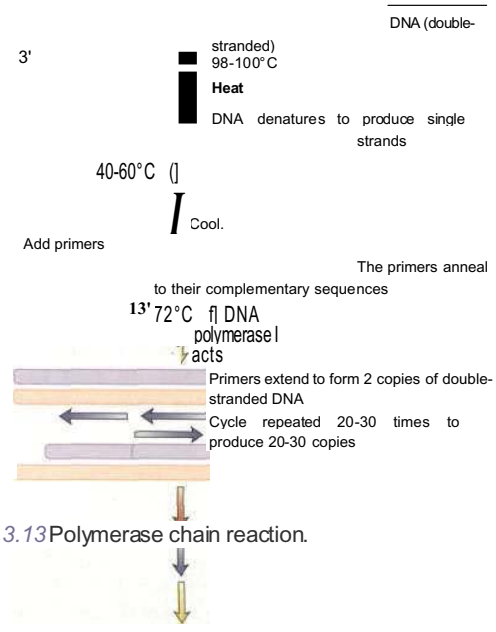

Fig. 3.13 Polymerase chain reaction.

This technique has revolutionized genetic research because minute amounts of DNA not previously amenable to analysis can be amplified, such as from buccal cell scrapings, blood spots, or single embryonic cells.

DNA cloning

A particular DNA fragment of interest can be isolated and inserted into the genome of simple self-replicating organisms or organelles such as viruses and plasmids. When used for this purpose they are referred to as vectors. Replication by the million of the vector results in multiple copies or clones of the inserted sequence. Thus, after removal from the host vector, cloned gene sequences can be prepared in large quantities independently of other sequences. Vectors include: bacteriophage viruses; plasmids, which are self-replicating episomal circular DNA molecules found in bacteria that carry antibody resistance genes; and 'yeast artificial chromosomes' (YACs), which are derived from centromeric and telomeric DNA sequences found in yeast. Each vector takes an optimum size of cloned DNA insert. Typically, viruses can accommodate only small sequences up to a maximum of a kilobase, larger fragments of 2-10 kilobases can be inserted into a plasmid, and sequences of several hundred kilobases can be inserted into a YAC. Each has its relative merits - viruses being very efficient, but the vectors which take large clones being considerably less so. A hybrid between a plasmid and a bacteriophage (called a cosmid) has been constructed artificially. This has the ability to clone reasonably large sequences as plasmids within a host bacteria. However, cosmids trick bacteriophages into packaging them into a viral body, and this viral body is then able to infect the target bacteria, giving efficient transfection rates.

The DNA fragment of interest is inserted into the vector DNA sequence using an enzyme called a ligase. This takes place in vitro. The next step, cloning, creates many copies of the 'recombinant DNA molecule' and takes place in vivo when the plasmid or other vector is placed back into the bacterial (or yeast) host. Bacteria that have successfully taken up the recombinant plasmid can be selected if the plasmid also carries an antibiotic resistance gene (so bacteria without the plasmid die in the presence of antibiotic) (Fig. 3.14).

The DNA fragment of interest to be cloned may be a restriction fragment. Alternatively it could be cDNA which has been copied from an mRNA sequence. mRNA provides the template from which a viral enzyme called reverse transcriptase (RT) can synthesize a complementary single-stranded DNA copy (cDNA). A DNA polymerase may then be used to produce a double-stranded copy by PCR. A cDNA molecule contains all the sequences necessary for a functional gene, but unlike genomic DNA it lacks introns.

DNA libraries

These are pools of isolated and cloned DNA sequences that form a permanent resource for further experiments. Two types of library are used:

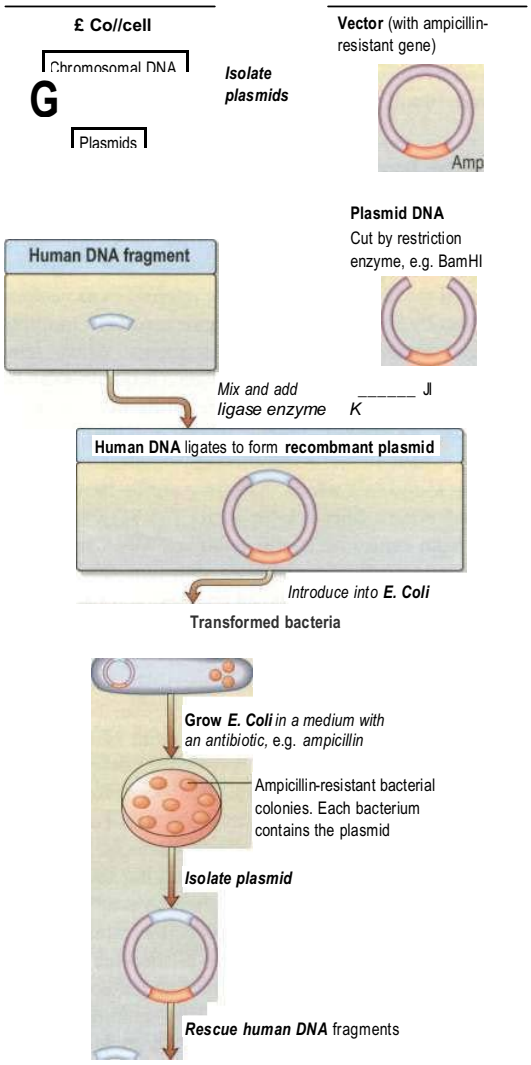

***Fig. 3.14* DNA cloning.** Recombinant DNA technique, showing incorporation of foreign DNA into a plasmid. The ampicillin-resistant genes can be used to distinguish transformed *Escherichia coli* cells.

Genomic libraries are prepared from genomic DNA that has been digested with restriction enzymes, ligated into a vector and each individual clone passed into a bacterial (plasmid, bacteriophage, cosmid) or yeast (YAC) host. A genomic library usually contains almost every sequence in the genome. cDNA libraries are prepared from the total mRNA of a tissue, which is copied into cDNA by reverse trans-criptase. The cDNA is ligated into a vector and passed into a host as above. A cDNA library should contain sequences derived from all the mRNAs expressed in that tissue type.

DNA sequencing

A chemical process known as dideoxy-sequencing allows the identification of the exact nucleotide sequence of a piece of DNA. As in PCR an oligonucleotide primer is annealed adjacent to the region of interest. This primer acts as the starting point for a DNA polymerase to build a new DNA chain that is complementary to the sequence under investigation. Chain extension can be prematurely interrupted when a dideoxynucleotide becomes incorporated (because they lack the necessary 3'-hydroxyl group). As the dideoxynucleotides are present at a low concentration, not all the chains in a reaction tube will incorporate a dideoxynucleotide in the same place; so the tubes contain sequences of different lengths but which all terminate with a particular dideoxynucleotide. Each base dideoxynucleotide (G, C, T, A) has a different fluorochrome attached, and thus each termination base can be identified by its fluorescent colour. As each strand can be separated efficiently by capillary electrophoresis according to its size/length, simply monitoring the fluorescence as the reaction products elute from the capillary will give the gene sequence (see Fig. 3.15).

Expression microarrays/gene chips

This is a methodology developed to examine the relative abundance of mRNA for thousands of genes present in cells/tissue of different types or conditions. For example, to examine the changes in gene expression from normal colonic tissue to that of malignant colonic polyps. The basic technology is the ability to immobilize sequences of DNA complementary to specific genes or different regions of known genes, onto a solid surface in precise microdot arrays. Total mRNA is extracted from one tissue and labelled with fluorescent tag Cy3-green, and the mRNA from the second tissue with fluorescent tag Cy5-red. The two fluorescent-tagged total mRNA samples are mixed in a 1:1 ratio and washed over the DNA gene chips. The mRNA for specific genes will bind to their complementary microdot and can be detected by laser-induced excitation of the fluorescent tag and the position and light wavelength and intensity recorded by a scanning confocal microscope. The relative intensity of Cy5-red : Cy3-green is a reliable measure of the relative abundance of specific mRNAs in each sample. Yellow results from equal binding of both fluorescent-tagged mRNAs. If no hybridization occurs on a dot then the area is black. The power of the system is that many thousands of genes can be screened for not only their expression but relative expression in normal and diseased tissue. A considerable amount of computing power and analysis is

required to interpret the thousands of dots on a microarray chip (Fig. 3.16).

THE BIOLOGY OF CHROMOSOMES

HUMAN CHROMOSOMES

The nucleus of each diploid cell contains 6 x 10^9 bp of DNA in long molecules called *chromosomes*. Chromosomes are massive structures containing one linear molecule of DNA that is wound around histone proteins into small units called nucleosomes, and these are further wound to make up the structure of the chromosome itself. Diploid human cells have 46 chromosomes, 23 inherited from each parent; thus there are 23 'homologous' pairs of chromosomes (22 pairs of 'autosomes' and two 'sex chromosomes'). The sex chromosomes, called X and Y, are not homologous but are different in size and shape. Males have an X and a Y chromosome; females have two X chromosomes. (Primary male sexual characteristics are determined by the *SRY* gene — sex determining region, Y chromosome).

The chromosomes can be classified according to their size and shape, the largest being chromosome 1. The constriction in the chromosome is the centromere, which can be in the middle of the chromosome (metacentric) or at one extreme end (acrocentric). The centromere divides the chromosome into a short arm and a long arm, which are referred to as the p arm and the q arm respectively (see Fig. 3.9d). In addition, chromosomes can be stained when they are in the metaphase stage of the cell cycle and are very condensed. The stain gives a different pattern of light and dark bands that is diagnostic for each chromosome. Each band is given a number, and gene mapping techniques allow genes to be positioned within a band within an arm of a chromosome. For example, the *CFTR* gene (in which a defect gives rise to cystic fibrosis) maps to 7q21; that is, on chromosome 7 in the long arm in band 21.

During cell division (mitosis), each chromosome divides into two so that each daughter nucleus has the same number of chromosomes as its parent cell. During gametogenesis, however, the number of chromosomes is halved by meiosis, so that after conception the number of chromosomes remains the same and is not doubled. In the female, each ovum contains one or other X chromosome but, in the male, the sperm bears either an X or a Y chromosome.

Chromosomes can only be seen easily in actively dividing cells. Typically, lymphocytes from the peripheral blood are stimulated to divide and are processed to allow the chromosomes to be examined. Cells from other tissues can also be used - for example amniotic fluid, placental cells from chorionic villus sampling, bone marrow and skin (see Box 3.1).

THE X CHROMOSOME AND INACTIVATION

Although female chromosomes are XX, females do not have two doses of X-linked genes (compared with just one dose for a male XY), because of the phenomenon of

Box 3.1 **Indications for chromosomal analysis**

Chromosome studies may be indicated in the following circumstances.

Antenatal

Pregnancies in women over 35 years
Positive maternal serum screening test for aneuploid pregnancy » Ultrasound features consistent with an aneuploid fetus *m* Severe fetal growth retardation
- Sexing of fetus in X-linked disorders

In the neonate

Congenital malformations Suspicion of trisomy or monosomy s Ambiguous genitalia

In the adolescent

- Primary amenorrhoea or failure of pubertal development
- Growth retardation

In the adult

» Screening parents of a child with a chromosomal abnormality for further genetic counselling *m*
Infertility or recurrent miscarriages
- Learning difficulties
- Certain malignant disorders (e.g. leukaemias and Wilms' tumour)

X inactivation or Lyonization (after its discoverer, Dr Mary Lyon). In this process, one of the two X chromosomes in the cells of females becomes transcriptionally inactive, so the cell has only one dose of the X-linked genes. Inactivation is random and can affect either X chromosome.

TELOMERES AND IMMORTALITY

The ends of chromosomes, telomeres (see Fig. 3.9d) do not contain genes but many repeats of a hexameric sequence TTAGGG. Replication of linear chromosomes starts at coding sites (origins of replication) within the main body of chromosomes and not at the two extreme ends. The extreme ends are therefore susceptible to single-stranded DNA degradation back to double-stranded DNA. Thus cellular ageing can be measured as a genetic consequence of multiple rounds of replication with consequential telomere shortening. This leads to chromosome instability and cell death.

Stem cells have longer telomeres than their terminally differentiated daughters. However, germ cells replicate without shortening of their telomeres. This is because they express an enzyme called telomerase, which protects against telomere shortening by acting as a template primer at the extreme ends of the chromosomes. Most somatic cells (unlike germ and embryonic cells) switch off the activity of telomerase after birth and die as a result of apoptosis. Many cancer cells, however, reactivate telomerase, contributing to their immortality. Conversely, cells from patients with progeria (premature ageing syndrome) have extremely short telomeres. Recent research has shown transient expression of telomerase in various stem and daughter cells as part of their normal biology. The inability to activate telomerase in cells such as those of the immune system can produce disease pathologies, in addition to overexpression.

THE MITOCHONDRIA!. CHROMOSOM

In addition to the 23 pairs of chromosomes in the nucleus of every diploid cell, the mitochondria in the cytoplasm of the cell also have their own genome. The mitochondrial chromosome is a circular DNA (mtDNA) molecule of approximately 16 500 bp, and every base-pair makes up part of the coding sequence. These genes principally encode proteins or RNA molecules involved in mitochondrial function. These proteins are components of the mitochondrial respiratory chain involved in oxidative phosphorylation (OXPHOS) producing ATR They also have a critical role in apoptotic cell death. Every cell contains several hundred mitochondria, and therefore several hundred mitochondrial chromosomes. Virtually all mitochondria are inherited from the mother as the sperm head contains no (or very few) mitochondria. Disorders are shown in Figure 3.17 (p. 176).

HUMAN GENETIC DISORDERS

The spectrum of inherited or congenital genetic disorders can be classified as the chromosomal disorders, including mitochondrial chromosome disorders, the Mendelian and sex-linked single-gene disorders, a variety of non-Mendelian disorders, and the multifactorial and polygenic disorders (Table 3.2 and Box 3.2). All are a result of a mutation in the genetic code. This may be a change of a single base-pair of a gene, resulting in functional change in the product protein (e.g. thalassaemia) or gross rearrangement of the gene within a genome (e.g. chronic myeloid leukaemia). These mutations can be congenital (inherited at birth) or somatic (arising during a person's life). The latter are responsible for the collective disease known as cancer, and the principles underlying Mendelian inheritance act in a similar manner to produce dominant and recessive traits. Both gross chromosomal and point mutations occur in somatic genetic disease.

CHROMOSOMAL DISORDERS

Chromosomal abnormalities are much more common than is generally appreciated. Over half of spontaneous abortions have chromosomal abnormalities, compared with only 4-6 abnormalities per 1000 live births. Specific chromosomal abnormalities can lead to well-recognized and severe clinical syndromes, although autosomal aneuploidy (a differing from the normal diploid number)

Box 3.2 **Genetic disorders**

Mendelian
Inherited or new mutation
.- Mutant allele or pair of mutant alleles at single locus Clear pattern of inheritance (autosomal or sex-linked) dominant or recessive High risk to relatives

Chromosomal
Loss, gain or abnormal rearrangement of one or more of 46 chromosomes in diploid cell No clear pattern of inheritance Low risk to relatives

Multifactorial
Common
v Interaction between genes and environmental factors ■ Low risk to relatives

Mitochondrial
'■■ Due to mutations in mitochondrial genome *m*
Transmitted through maternal line •' Different pattern of inheritance from Mendelian disorders

Somatic cell
• Mutations in somatic cells >
Somatic event is not inherited Often give rise to tumours

is usually more severe than the sex-chromosome aneuploidies. Abnormalities may occur in either the number or the structure of the chromosomes.

Abnormal chromosome numbers

If a chromosome or chromatids fail to separate ('non-disjunction') either in meiosis or mitosis, one daughter cell will receive two copies of that chromosome and one daughter cell will receive no copies of the chromosome. If this non-disjunction occurs during meiosis it can lead to an ovum or sperm having either (i) an extra chromosome, so resulting in a fetus that is 'trisomic' and has three instead of two copies of the chromosome; or (ii) no chromosome, so the fetus is 'monosomic' and has one instead of two copies of the chromosome. Non-disjunction can occur with autosomes or sex chromosomes. However, only individuals with trisomy 13, 18 and 21 survive to birth, and most children with trisomy 13 and trisomy 18 die in early childhood. Trisomy 21 (Down's syndrome) is observed with a frequency of 1 in 650 live births regardless of geography or ethnic background. This should be reduced with widespread screening (p. 191). Full autosomal monosomies are extremely rare and very deleterious. Sex-chromosome trisomies (e.g. Klinefelter's syndrome, XXY) are relatively common. The sex-chromosome monosomy in which the individual has an X chromosome only and no second X or Y chromosome is known as Turner's syndrome and is estimated to occur in 1 in 2500 live-born girls.

Occasionally, non-disjunction can occur during mitosis shortly after two gametes have fused. It will then result in the formation of two cell lines, each with a different chromosome complement. This occurs more often with the sex chromosome, and results in a 'mosaic' individual.

Very rarely the entire chromosome set will be present in more than two copies, so the individual may be triploid rather than diploid and have a chromosome number of 69. Triploidy and tetraploidy (four sets) result in spontaneous abortion.

Table 3.2 **Prevalence of genetic disease**

Genetic disease	Congenital malformation
0.5% of all newborns have a chromosomal abnormality 7% of all stillborns have a chromosomal abnormality 20-30% of all infant deaths are due to genetic disorders	3-5% of all births result in congenital malformations
11 % of paediatric hospital admissions are for children with genetic disorders	30-50% of post-neonatal deaths are due to congenital malformations 18% of paediatric hospital admissions are for children with congenital malformations
12% of adult hospital admissions are for genetic causes 15% of all cancers have an inherited susceptibility 10% of chronic diseases of the adult population (heart, diabetes, arthritis) have a significant genetic component	

European incidences per 1000 births			
Single gene disorders:	**10**	Congenital malformations:	31
Dominant	7.0	Genetically determined	0.6
Recessive	1.66	Multifactorial	30
X-linked	1.33	Non-genetic	-0.4
Chromosomal disorders:	3.5		
Autosomes	1.69		
Sex chromosomes 10	1.80		

Although individual genetic diseases are rare, regional variation is enormous - the incidence of Down's syndrome varies from 1/1000 to 1/100 world-wide. Single gene diseases collectively comprise over 15 500 recognized genetic disorders. The global prevalence of all single gene diseases at birth is approximately 10/1000

Abnormal chromosome structures

As well as abnormal numbers of chromosomes, chromosomes can have abnormal structures, and the disruption to the DNA and gene sequences may give rise to a genetic disease.

- *Deletions.* Deletions of a portion of a chromosome may give rise to a disease syndrome if two copies of the genes in the deleted region are necessary, and the individual will not be normal with just the one copy remaining on the non-deleted homologous chromosome. Many deletion syndromes have been well described. For example, Prader-Willi syndrome (p. 252) is the result of cytogenetic events resulting in deletion of part of the long arm of chromosome 15, Wilms' tumour is characterized by deletion of part of the short arm of chromosome 11, and microdeletions in the long arm of chromosome 22 give rise to the DiGeorge syndrome.
- *Duplications.* Duplications occur when a portion of the chromosome is present on the chromosome in two copies, so the genes in that chromosome portion are present in an extra dose. A form of the neuropathy, Charcot-Marie-Tooth disease (p. 1263), is due to a small duplication of a region of chromosome 17.
- *Inversion.* Inversions involve an end-to-end reversal of a segment within a chromosome; e.g. abcdefgh becomes abcfedgh, for example, haemophilia (p. 472).
- *Translocations.* Translocations occur when two chromosome regions join together, when they would not normally. Chromosome translocations in somatic cells may be associated with tumorigenesis (see p. 485).

Translocations can be very complex, involving more than two chromosomes, but most are simple and fall into one of two categories. Reciprocal translocations occur when any two non-homologous chromosomes break simultaneously and rejoin, swapping ends. In this case the cell still has 46 chromosomes but two of them are rearranged. Someone with a balanced translocation is likely to be normal (unless a translocation breakpoint interrupts a gene); but at meiosis, when the chromosomes separate into different daughter cells, the translocated chromosomes will enter the gametes and any resulting fetus may inherit one abnormal chromosome and have an unbalanced translocation, with physical manifestations.

Robertsonian translocations occur when two acrocentric chromosomes join and the short arm is lost, leaving only 45 chromosomes. This translocation is balanced as no genetic material is lost and the individual is healthy. However, any offspring have a risk of inheriting an unbalanced arrangement. This risk depends on which acrocentric chromosome is involved. Clinically relevant is the 14/21 Robertsonian translocation. A woman with this karyotype has a 1 in 8 risk of delivering a baby with Down's syndrome (a male carrier has a 1 in 50 risk). However, they have a 50% risk of producing a carrier like themselves, hence the necessity for genetic family studies. Relatives should be alerted to the increased risk of Down's syndrome in their offspring, and should have their chromosomes checked.

Table 3.3 shows some of the syndromes resulting from chromosomal abnormalities.

Mitochondrial chromosome disorders (Fig. 3.17)

The mitochondrial chromosome (p. 172) carries its genetic information in a very compact form; for example there are no introns in the genes. Therefore any mutation has a high chance of having an effect. However, as every cell contains hundreds of mitochondria, a single altered mitochondrial genome will not be noticed. As mitochondria divide there is a statistical likelihood that there will be more mutated mitochondria, and at some point this will give rise to a mitochondrial disease.

Most mitochondrial diseases are myopathies and neuropathies with a maternal pattern of inheritance. Other abnormalities include retinal degeneration, diabetes mellitus and hearing loss. Many syndromes have been described. Myopathies include chronic progressive external ophthalmoplegia (CPEO); encephalomyopathies include myoclonic epilepsy with ragged red fibres (MERRF) and mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) (see p. 1271). Kearus-Sayre syndrome includes ophthalmoplegia, heart block, cerebellar ataxia, deafness and mental deficiency due to long deletions and rearrangements. Leber's hereditary optic neuropathy (LHON) is the commonest cause of blindness in young men, with bilateral loss of central vision and cardiac arrhythmias, and is an example of a mitochondrial disease caused by a point mutation in one gene. Multisystem disorders include Pearson's syndrome (sideroblastic anaemia, pancytopenia, exocrine pancreatic failure, subtotal villous atrophy, diabetes mellitus and renal tubular dysfunction). In some families, hearing loss is the only symptom, and one of the mitochondrial genes implicated may predispose patients to aminoglycoside ototoxicity.

Analysis of chromosome disorders

The cell cycle can be arrested at mitosis with colchicines and, following staining, the chromosomes with their characteristic banding can be seen and any abnormalities identified (Fig. 3.18).

YAC-cloned probes are also available and cover large genetic regions of individual chromosomes. These probes can be labelled with fluorescently tagged nucleotides and used in in situ hybridization of the nucleus of isolated tissue from patients. These tagged probes allow rapid and relatively unskilled identification of metaphase chromosomes, and allow the identification of chromosomes dispersed within the nucleus. Furthermore, tagging two chromosome regions with different fluorescent tags allows easy identification of chromosomal translocations (Fig. 3.19).

GENE DEFECTS

Mendelian and sex-linked single-gene disorders are the result of mutations in coding sequences and their control elements. These mutations can have various effects on the

Table 3.3 **Chromosomal abnormalities: examples of a few syndromes**

Syndrome	Chromosome karyotype	Incidence and risks	Clinical features	Mortality
Autosomal abnormalities				
Trisomy 21 (Down's syndrome)	47, +21 (95%) Mosaicism Translocation 5%	**1** : 650 (overall) (risk with 20- to 29-year-old mother 1 : 1000; > 45-year-old mother 1 : 30)	Flat face, slanting eyes, epicanthic folds, small ears, simian crease, short stubby fingers, hypotonia, variable learning difficulties, congenital heart disease (up to 50%)	High in first year, but many survive to adulthood
Trisomy 13 (Patau's syndrome)	47, +13	1 : 5000	Low-set ears, cleft lip and palate, polydactyly, micro-ophthalmia, learning difficulties	Rarely survive for more than a few weeks
Trisomy 18 (Edward's syndrome)	47,+18	1 : 3000	Low-set ears, micrognathia, rocker-bottom feet, learning difficulties	Rarely survive for more than a few weeks
Sex chromosome abnormalities				
Fragile X syndrome	46, XX, fra (X) 46, XY, fra (X)	1 : 2000	Most common inherited cause of learning difficulties predominantly in male Macro-orchidism	
Female				
Turner's syndrome	45, XO	1 : 2500	Infantilism, primary amenorrhoea, short stature, webbed neck, cubitus valgus, normal IQ	
Triple X syndrome	47, XXX	1 : 1000	No distinctive somatic features, learning difficulties	
Others	48, XXXX 49, XXXXX	Rare	Amenorrhoea, infertility, learning difficulties	
Male				
Klinefelter's syndrome	47, XXY (or XXYY)	1 : 1000 (more in sons of older mothers)	Decreased crown-pubis : pubis-heel ratio, eunuchoid, testicular atrophy, infertility, gynaecomastia, learning difficulties (20%; related to number of X chromosomes)	
Double Y syndrome	47, XYY	**1 :800**	Tall, fertile, minor mental and psychiatric illness, high incidence in tall criminals	
Others	48, XXXY 49, XXXXY		Learning difficulties, testicular atrophy	

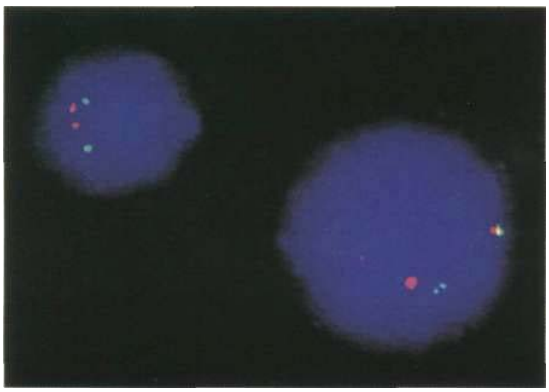

Fig. 3.19 **Fluorescence in situ hybridization (FISH).** Two-coloured FISH using a red paint for the *ABL* gene on chromosome 9 and a green paint for the SCR gene on chromosome 22 in the anaphase cell nucleus. Where a translocation has occurred the two genes become juxtaposed on the Philadelphia chromosome and a hybrid yellow fluorescence can be seen only in the affected cell nucleus on the right. Courtesy of D Lillington, Medical Oncology Unit, St. Bartholomew's Hospital.

producing a clinical disorder. Many different types of mutation occur.

Point mutation
This is the simplest type of change and involves the substitution of one nucleotide for another, so changing the codon in a coding sequence. For example, the triplet AAA, which codes for lysine, may be mutated to AGA, which codes for arginine. Whether a substitution produces a clinical disorder depends on whether it changes a critical part of the protein molecule produced. Fortunately, many substitutions have no effect on the function or stability of the proteins produced as several codons code for the same amino acid. However, some mutations may have a severe effect; for example, in sickle cell disease a mutation within the globin gene changes one codon from GAG to GTG, so that instead of glutamic acid, valine is incorporated into the polypeptide chain, which radically alters its properties.

Insertion or deletion
Insertion or deletion of one or more bases is a more serious change, as it results in the alteration of the rest of the following sequence to give a frame-shift mutation. For example, if the original code was:

TAAGGAGAGTTT

and an extra nucleotide (A) is inserted, the sequence becomes:

TAAAGGAGAGTTT

Alternatively, if the third nucleotide (A) is deleted, the sequence becomes:

TAG GAG AGT TT

In both cases, different amino acids are incorporated into the polypeptide chain. This type of change is responsible for some forms of thalassaemia (p. 440). Insertions and deletions can involve many hundreds of base-pairs of DNA. For example, some large deletions in the dystrophin gene remove coding sequences and this results in Duchenne muscular dystrophy. Insertion/deletion (ID) polymorphism in the angiotensin-converting enzyme (ACE) gene has been shown to result in the genotypes II, ID and DD. The deletion is of a 287 bp repeat sequence, and DD is associated with higher concentrations of circulating ACE and possibly cardiac disease (see p. 802).

Splicing mutations
If the DNA sequences which direct the splicing of introns from mRNA are mutated, then abnormal splicing may occur. In this case the processed mRNA which is translated into protein by the ribosomes may carry intron sequences, so altering which amino acids are incorporated into the polypeptide chain.

Termination mutations
Normal polypeptide chain termination occurs when the ribosomes processing the mRNA reach one of the chain termination or 'stop' codons (see above). Mutations involving these codons will result in either late or premature termination. For example, Haemoglobin Constant Spring is a haemoglobin variant where instead of the 'stop' sequence, a single base change allows the insertion of an extra amino acid (see p. 442).

Single-gene disease

Monogenetic disorders involving single genes can be inherited as dominant, recessive or sex-linked characteristics. Although classically divided into autosomal dominant, recessive or X-linked disorders (see Tables 3.5-3.7), many syndromes show multiple forms of inheritance pattern. This is predominately because multiple defects can occur within a given disease-associated gene or in separate genes which all contribute to a particular molecular/cellular pathway and thus give rise to the same phenotype. For example in Ehlers-Danlos syndrome we find autosomal dominant, recessive and X-linked inheritance. In addition there is a spectrum between autosomal recessive and autosomal dominance in that having just one defective allele gives a mild form of the disease whilst having both alleles with the mutation results in a more severe form of the syndrome. In some cases, such as factor V Leiden disease, the boundary between dominant and recessive forms is very blurred.

Tables 3.4 and 3.5 list some autosomal dominant and autosomal recessive genetic diseases with their chromosomal localization. Some diseases show a racial or geographical prevalence. Thalassaemia (see p. 440) is seen mainly in Greeks, South East Asians and Italians, porphyria variegata occurs more frequently in the South African white population, and Tay-Sachs (p. 1147) disease particularly occurs in Ashkenazi Jews. The most common

Table 3.4 **Examples of autosomal dominant disorders with chromosome location and gene defect**

Syndrome	Disease prevalence	Gene (Product)	Gene location	Genetic test detection rate
Achondroplasia	1/15 000-1/40 000	*FGFR3* (Fibroblast growth factor receptor-3)	4p16.3	99%
Alexander disease	Very rare	*GFAPP* (Glial fibrillary acidic protein)	17q21	95%
Alagille syndrome (AGS)	1/70 000	*JAG1* (Jagged 1 protein)	20p12	77%
Alzheimer's disease (early onset)	41/10 000 at risk	*PSEN1* (Presenilin 1)	14q24.3	30-70%
		PSEN11 (Presenilin 2)	1q31-q42	<5%
		APP (Amyloid beta A4 protein)	21q21	10-15%
Aniridia	1-2/100 000	*PAX6* (Paired box protein Pax-6)	11p13	90%
Breast cancer (familial early onset)	1/300-1/800	*BRAC-1* (Breast cancer type 1 susceptibility protein)	17q21	50-75%
		BRAC-2 (Breast cancer type 2 susceptibility protein)	13q12.3	15-30%
Charcot-Marie-Tooth disease subtypes:	(30/100 000)			
CMT1	15/100 000	*PMP22* (Peripheral myelin protein 22)	17p11.2	-50%

recessive disease in the UK is cystic fibrosis (see pp. 192 and 909). Thus the worldwide prevalence of a disease may be low (as detailed in Tables 3.4-3.6) but much higher in specific populations. Some disorders are rare to the extent that the prevalence is counted in the total number of cases ever reported. Molecular biology has enabled the subclassification of some syndromes according to which gene is giving rise to the disease (e.g. polycystic kidney disease) and the proportion of cases arising from defects in that particular gene can be estimated from linkage analysis. However, this may not be reflected in the detection rate of a given clinical genetic test, since a single test cannot detect all the possible mutations arising at a particular locus.

Autosomal dominant disorders (Fig. 3.20 and Table 3.4)

Each diploid cell contains two copies of all the autosomes. An autosomal dominant disorder occurs when one of the two copies has a mutation and the protein produced by the normal form of the gene cannot compensate. In this case a heterozygous individual who has two different forms (or alleles) of the same gene will manifest the disease. The offspring of heterozygotes have a 50% chance of inheriting the chromosome carrying the disease allele, and therefore also of having the disease. However, estimation of risk to offspring for counselling families can be difficult because of three factors:

- These disorders have a great variability in their manifestation. 'Incomplete penetrance' may occur if patients have a dominant disorder but it does not manifest itself clinically in them. This gives the appearance of the gene having 'skipped' a generation.
- Dominant traits are extremely variable in severity (variable expression) and a mildly affected parent may have a severely affected child.
- New cases in a previously unaffected family may be the result of a new mutation. If it is a mutation, the risk of a further affected child is negligible. Most cases of achondroplasia are due to new mutations.

The overall incidence of autosomal dominant disorders is 7 per 1000 live births.

Autosomal recessive disorders (Fig. 3.20 and Table 3.5)

These disorders manifest themselves only when an individual is homozygous for the disease allele, i.e. both chromosomes carry the mutated gene. In this case the parents are generally unaffected, healthy carriers (heterozygous for the disease allele). There is usually no family history, although the defective gene is passed from

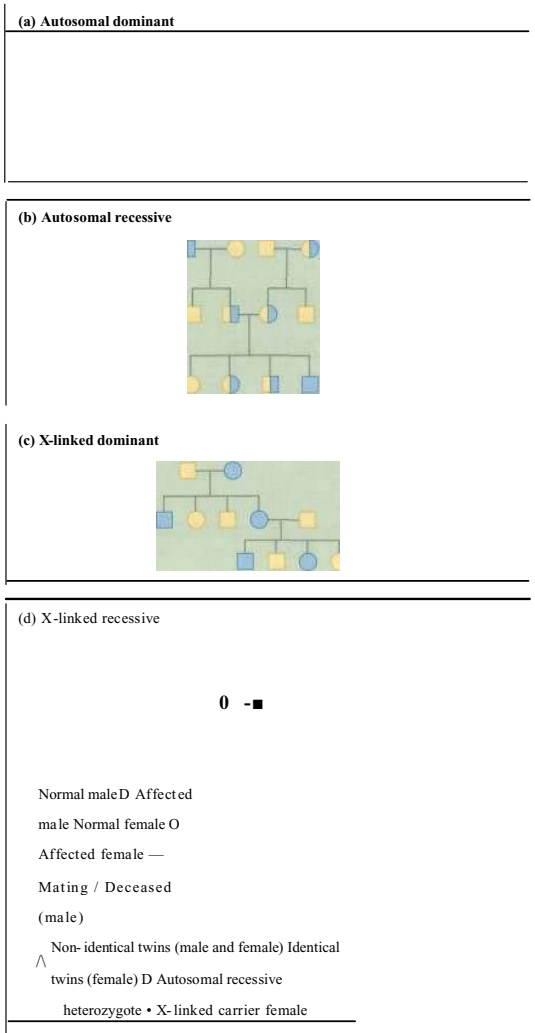

Fig. 3.20 Modes of inheritance of simple gene disorders, with a key to the standard pedigree symbols.

generation to generation. The offspring of an affected person will be healthy heterozygotes unless the other parent is also a carrier. If carriers marry, the offspring have a 1 in 4 chance of being homozygous and affected, a 1 in 2 chance of being a carrier, and a 1 in 4 chance of being genetically normal. Consanguinity increases the risk. The clinical features of autosomal recessive disorders are usually severe; patients often present in the first few years of life and have a high mortality. The overall incidence of autosomal recessive disorders is about 2.5 per 1000 live births.

Sex-linked disorders (Fig. 3.20 and Table 3.6) Genes carried on the X chromosome are said to be 'X-linked', and can be dominant or recessive in the same way as autosomal genes. As females have two X chromosomes they will be unaffected carriers of X-linked recessive diseases. However, since males have just one X chromosome, any deleterious mutation in an X-linked gene will manifest itself because no second copy of the gene is present.

X-linked dominant disorders
These are rare. Vitamin D-resistant rickets is the best-known example. Females who are heterozygous for the mutant gene and males who have one copy of the mutant gene on their single X chromosome will manifest the disease. Half the male or female offspring of an affected mother and all the female offspring of an affected man will have the disease. Affected males tend to have the disease more severely than the heterozygous female.

X-linked recessive disorders
These disorders present in males and present only in homozygous females (usually rare). X-linked recessive diseases are transmitted by healthy female carriers or affected males if they survive to reproduce. An example of an X-linked recessive disorder is haemophilia A (see p. 472), which is caused by a mutation in the X-linked gene for factor VIII. It has been shown that in 50% of cases there is an intrachromosomal rearrangement (inversion) of the tip of the long arm of the X chromosome (one break point being within intron 22 of the factor VIII gene).

Of the offspring from a carrier female and a normal male:

- 50% of the girls will be carriers as they inherit a mutant allele from their mother and the normal allele from their father; the other 50% of the girls inherit two normal alleles and are themselves normal
- 50% of the boys will have haemophilia as they inherit the mutant allele from their mother (and the Y chromosome from their father); the other 50% of the boys will be normal as they inherit the normal allele from their mother (and the Y chromosome from their father).

The male offspring of a male with haemophilia and a normal female will not have the disease as they do not inherit his X chromosome. However, all the female offspring will be carriers as they all inherit his X chromosome.

Y-linked genes
Genes carried on the Y chromosome are said to be Y-linked and only males can be affected. However, there are no known examples of Y-linked single-gene disorders which are transmitted.

Sex-limited inheritance
Occasionally a gene can be carried on an autosome but manifests itself only in one sex. For example, frontal baldness is an autosomal dominant disorder in males but behaves as a recessive disorder in females.

Other single-gene disorders
These are disorders which may be due to mutations in

Table 3.6 **Examples of X-linked disorders with chromosome location and gene defects**

Syndrome	Disease prevalence	Gene (Product)	Gene location	Genetic test detection rate
Recessive				
Alport's syndrome	1/50 000	*COL4A5* (Collagen alpha 5(IV) chain)	Xq22	60%
Adrenal hypoplasia (congenital) - X-linked	1/13 000	*NR0B1* (Orphan nuclear receptor DAX-1)	Xp21.3-21.2	70-100%
Adrenoleucodystrophy - X-linked	1-3/50 000	ABCD1 (Adrenoleucodystrophy protein)	Xq28	98%
Agammaglobulinaemia - X-linked	3-6/million	*BTK* (Tyrosine-protein kinase BTK)	Xq21.3-22	98-99%
Androgen insensitivity syndrome	2-5/100 000	*AR* (Androgen receptor)	Xq11-q12	90%
Dystrophinopathies (Becker's and Duchenne muscular dystrophies)	1^1/20 000 (UK)	*DMD* (Dystrophin)	Xp21.2	65-85%
Charcot-Marie-Tooth disease subtype CMX	3-6/100 000	*GJB1* (Gap junction beta-1 protein)	Xq13.1	90%
Fabry's disease	1-2/100 000	*GLA* (a-galactosidase A)	Xq22	100%
Haemophilia A	1/4000	FS (Factor VIII)	Xq28	98%
Haemophilia B	1/20 000	*F9* (Factor IX)	Xq27.1-27.2	99%
Myotubular myopathy - X-linked	1/50 000	*MTM1* (Myotubularin)	Xq28 8	0-85%
Nephrogenic diabetes insipidus	Rare	*AVPR2* (Vasopressin V2 receptor)	Xq28	97%
a-Thalassaemia - X-linked (mental retardation syndrome)	**Rare**	*ATRX* (Transcriptional regulator ATRX)	Xq13	90%
X-linked severe combined immunodeficiency (X-SCID)	1-2/100 000	*IL2RG* (Cytokine receptor common gamma chain)	Xq13.1	99%
Dominant				
Coffin-Lowry syndrome	1/50 000	*RPS6KA3* (Ribosomal protein S6 kinase alpha 3)	Xp22.2-22.1	35-40%
Incontinentia pigmenti	Rare	*IKBKG* (NF-kappaB essential modulator)	Xq28	80%
Oral-facial-digital syndrome type-1	1-5/250 000	*OFD1* (Oral-facial-digital syndrome 1 protein)	Xp22.3-p22.2	Unknown
Periventricular heterotopia - X-linked	Unknown	*FLNA* (Filamin 1)	Xq28	83%
Retinitis pigmentosa - X-linked	1-4/100 000 (70% of cases)	*RPGR* (Retinitis pigmentosa GTPase regulator)	Xp21.1	Unknown
	(8% of cases)	*RP2* (XRP2 protein)	Xp11.2	Unknown
Rett syndrome	1/10 000	*MECP2* (Methyl-CpG-binding protein 2)	Xq28	80%

single genes but which do not manifest as simple monogenic disorders. They can arise from a variety of mechanisms, including the following.

Triplet repeat mutations (Table 3.7) In the gene responsible for dystrophia myotonica(p. 1270), the mutated allele was found to have an expanded 3'UTR region in which three nucleotides, CTG, were repeated up to about 200 times. In families with dystrophia myotonica, people with the late-onset form of the disease had 20^0 copies of the repeat, but their children and grandchildren who presented with the disease from birth had vast increases in the number of repeats, up to 2000 copies. It is thought that some mechanism during meiosis causes this 'triplet repeat expansion' so that the offspring inherit an increased number of triplets. The number of triplets affects mRNA and protein function. See also page 191 for the phenomenon of 'anticipation'.

Table 3.7 **Examples of trinucleotide repeat genetic disorders**

Syndrome inheritance pattern	Disease prevalence	Gene, product, location and disorder	Genetic test detection rate
Friedreich's ataxia - AR	2-4/100 000	*FRDA* (Frataxin) 9q13 - GAA trinucleotide repeat expansion disorder in intron 1 of *FRDA*	96%
Fragile X syndrome - X-linked	16-25/100 000	*FMRI* (Fragile X mental retardation 1 protein) Xq27.3 - CGG trinucleotide repeat expansion and methylation changes in the 5' untranslated region of *FMRI* exon 1	99%
Huntington's disease - AD	**3-15/**100 000	*HD* (Huntingtin protein) 4p16.3 - CAG trinucleotide repeat expansion within the translated protein giving rise to long tracts of repeat glutamine residues in HD	98%
Dystrophia myotonica - AD	1/20 000	*DMPK* (Myotonin-protein kinase) 19q13.2-13.3 100% - CTG trinucleotide repeat expansion in the 3' untranslated region of the *DMPK* gene	

AD, autsomal dominant; AR, autsomal recessive

Mitochondria! disease (Fig. 3.17)
As discussed on pages 74 and 76 various mitochondrial gene mutations can give rise to complex disease syndromes with incomplete penetrance maternal inheritance.

Imprinting
It is known that normal humans need a diploid number of chromosomes of 46. However, the maternal and paternal contributions are different and, in some way which is not yet clear, the fetus can distinguish between the chromosomes inherited from the mother and the chromosomes inherited from the father, although both give 23 chromosomes. In some way the chromosomes are 'imprinted' so that the maternal and paternal contributions are different. Imprinting is relevant to human genetic disease because different phenotypes may result depending on whether the mutant chromosome is maternally or paternally inherited. A deletion of part of the long arm of chromosome 15 (15qll-ql3) will give rise to the Prader-Willi syndrome (PWS) if it is paternally inherited. A deletion of a similar region of the chromosome gives rise to Angelman's syndrome (AS) if it is maternally inherited. Recently the affected gene has been identified as ubiquitin *(UBE3A).* Significantly, maternal chromosome 15 *UBE3A* is expressed in the brain and hypothalamus. Defective maternal ubiquitin in Angelman's syndrome is thus responsible for accumulation of undegraded protein, and hence neuronal damage.

Complex traits: multifactorial and polygenic inheritance

Characteristics resulting from a combination of genetic and environmental factors are said to be multifactorial; those involving multiple genes can also be said to be polygenic.

Measurements of most biological traits (e.g. height) show a variation between individuals in a population, and a unimodal, symmetrical (Gaussian) frequency distribution curve can be drawn. This variability is due to variation in genetic factors and environmental factors. Environmental factors may play a part in determining some characteristics, such as weight, whilst other characteristics such as height may be largely genetically determined. This genetic component is thought to be due to the additive effects of a number of alleles at a number of loci, many of which can be individually identified using molecular biological techniques, for example studying identical twins in different environments.

A common genetic variation in the 3' untranslated region of the prothrombin gene is associated with elevated prothrombin (up to fourfold) and an increased risk of venous thrombosis (thrombophilia, see p. 477), and myocardial infarction. Presumably the 3' mutation induces overexpression of the prothrombin gene by increasing mRNA stability. In some pedigree studies those homozygous for this mutation and heterozygous for factor V Leiden mutation have an even greater risk of thrombotic events (p. 477). Conversely, downregulation of the a,-antitrypsin gene (due to similar mutation in the 3' and 5' untranslated regions) is associated with emphysema and cirrhosis (p. 388). There are sex differences. Congenital pyloric stenosis is most common in boys, but if it occurs in girls the latter have a larger number of affected relatives. This difference suggests that a larger number of the relevant genes are required to produce the disease in girls than in boys. Most human diseases, such as heart disease, diabetes and common mental disorders, are multifactorial traits (Table 3.8).

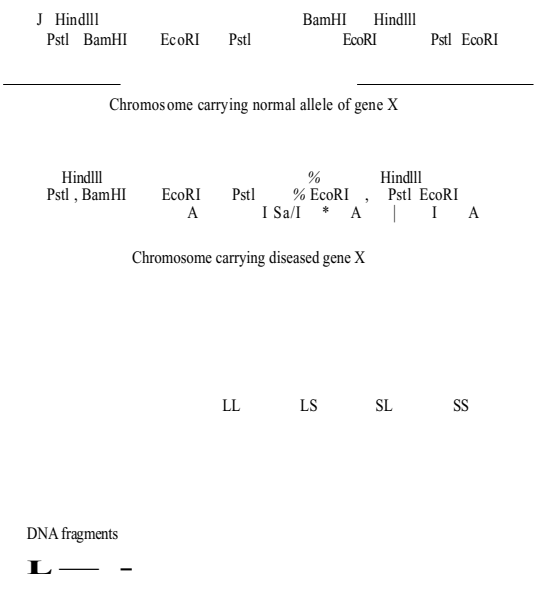

Fig. 3.21 **(a) Restriction fragment length polymorphism.** Diagrammatic representation of two allelic sections of DNA from a chromosome pair. The restriction site map of the two is identical except for a BamHI sequence which has been mutated by environmental radiation, resulting in a restriction fragment length polymorphism (RFLP). The blue area represents a cloned sequence which acts as a marker probe or tag for the polymorphism. This polymorphism is within one million base pairs of a disease gene and co-segregates with the disease, **(b) RFLP and disease tracking.** A family with four children whose parents are heterozygous for the polymorphism shown in (a). The bands below show DNA fragments (large, L, and small, S) on a Southern blot of DNA. If the RLFP which gives the L fragment is on the chromosome carrying the defective gene then only the fetus which is homozygous for the large fragment (LL) will be affected. The fetus homozygous for the small fragment (SS) will not be a sufferer. The heterozygous fetuses (LS and SL) will also be unaffected but will be carriers.

ANALYSIS OF MUTATIONS AND GENETIC DISEASE

Tracking a disease gene

Of the estimated 3400 inherited genetic disorders, only a small number have been characterized in terms of their biochemistry and genetics. Their clinical phenotype may have been described extensively but the identity of the culpable gene is still unknown. However, it is not necessary to identify the gene because two genes that are situated close together on a chromosome are nearly always co-inherited. Only on rare occasions do they segregate during meiosis when the two chromosomes of a diploid pair crossover and exchange parts (recombination) - even then the crossover point must be between the two genes. The closer the genes, the less chance of a segregating crossover, such that two genes that are one million base-pairs apart will only have a 1 % chance of being separated by recombination. This might be an enormous distance in molecular terms, but for clinical genetic analysis this is acceptable for diagnosis. If a known gene or non-coding repetitive DNA sequence is within this one million base-pairs of the disease gene, it will act as the tag or marker probe for the disease.

The large amount of non-coding DNA between genes, like all DNA, accumulates random base-pair changes throughout many generations. If these changes occur within genes, then they cause inherited disorders. The rate of mutation in some genes is quite low as there is a strong genetic selection against variants, but this is not true of non-coding DNA where a base-pair change has no deleterious effect. The frequency of change can approach 1 in 100 base-pairs. These changes occur randomly throughout the non-coding DNA, as do restriction enzyme sites. Sometimes a base-pair change will create or destroy a particular restriction site. Generally two members of a chromosome pair (homologues) will have broadly the same restriction patterns at any one point (Fig. 3.21a). However, owing to a random base-pair change, one chromosome will show a different restriction pattern for one enzyme (BamHI in Fig. 3.21a) compared with its homologue. These differences in restriction pattern are inherited, and are known as polymorphisms. Because they are observable as differences in length of particular restriction fragments, they are known as *restriction fragment length polymorphisms* (RFLPs).

The inheritance of RFLPs

The blue area in Figure 3.21a shows a cloned area of DNA from two chromosomes. If this is used as a probe, it will detect any restriction fragment that contains an identical piece of DNA sequence, and thus it can be used to detect the BamHI polymorphism shown. A person with these two chromosomes will be heterozygous for the BamHI polymorphism, as the two chromosomes are different. The person will produce gametes that have only one *of*

these chromosomes: 50% of the cells will have one type, 50% the other. If the mate of this person is also heterozygous for the same polymorphism, he or she will produce gametes that are 50% of one type and 50% the other. At fertilization there is a random chance that any one gamete will fuse with any gamete from the other parent, and thus four types of progeny will be produced. Two will be heterozygous for the polymorphism (Fig. 3.21b), one will be homozygous for the large BamHI fragment, the other will be homozygous for the small BamHI fragment.

If the chromosome carrying the BamHI polymorphism has a closely linked gene that when defective causes an inherited disorder, then by studying the family pedigree, the inheritance of both the disorder and the RFLP can be monitored. Generally, inherited disorders are caused by recessive genes. Both parents can therefore be carriers without being affected. If both parents come from families that have affected relatives, or they themselves have produced affected children, then they may wish to know if any subsequent children will also be sufferers. Suppose that the large BamHI fragment of the polymorphism is on the same chromosome as the defective gene, the small fragment being on the same chromosome as the normal allele. This can be checked by showing that any sufferers of the condition must be homozygous for the defective gene and thereby homozygous for the large BamHI fragment. To determine if any subsequent children are likely sufferers, DNA from a chorionic villus or amniocentesis sample can be digested with BamHI and electrophoresed on an agarose gel. It can then be probed with a cloned fragment using a Southern blot.

DNA can be amplified from very small tissue samples using PCR. If a polymorphism is reasonably well characterized, PCR across the RFLP will yield a suitable fragment to test for its presence. Other markers used to trace disease genes are simple sequence repeats. More common and more polymorphic (i.e. having greater variability) than RFLPs, these are short di-, tri-, tetra- or pentanucleotide repeats (such as (CA)n) which are present throughout the genome and have highly variable lengths. By designing primers to the sequence either side of one of these repeats, the repeat can be amplified by PCR. The amplified product is electrophoresed on a gel and different-sized products are produced from different people. If the mutant gene is close by, then a particular size repeat in that region will always segregate with the disease allele.

The likelihood of recombination between the marker under study and the disease allele must be taken into account. This measure of likelihood is known as the 'lod score' (the logarithm of the odds) and is a measure of the statistical significance of the observed co-segregation of the marker and the disease gene, compared with what would be expected by chance alone. Positive lod scores make linkage more likely; negative lod scores make it less likely. By convention a lod score of +3 is taken to be definite evidence of linkage because this indicates 1000 to 1 odds that the co-segregation of the DNA marker and the disease did not occur by chance alone.

Linkage analysis has provided many breakthroughs in mapping the positions of genes that cause genetic diseases, such as the gene for cystic fibrosis which was found to be tightly linked to a marker on chromosome 7, or the gene for Friedreich's ataxia which is tightly linked to a marker on chromosome 9.

Gene hunting

Two approaches to the identification of a disease gene are possible - functional or positional cloning (Fig. 3.22).

Functional cloning

Extracted mRNA from tissue expressing the disease gene (from both normal and affected individuals) is cloned into a vector. The clones are engineered such that the gene product is expressed by the host organism (i.e. bacteria) which may then be screened by antibodies or functional (enzyme-substrate) assay for those clones producing the desired gene product. The selected clones are isolated, propagated and the insert sequenced. The isolated cDNA insert can then be used as a probe to identify the location of the gene on a chromosome by in situ hybridization and to identify the genomic sequence from genome libraries. As already stated, the biochemistry of most genetic disease is unknown and positional cloning is required.

Positional cloning

The first step in this cloning approach is to study the pattern of inheritance. This may provide valuable clues about whether a single gene is affected, and whether this gene is likely to be autosomal or on the sex chromosomes or the mitochondrial chromosome. Gross chromosome analysis can be useful and geneticists look for chromosomal

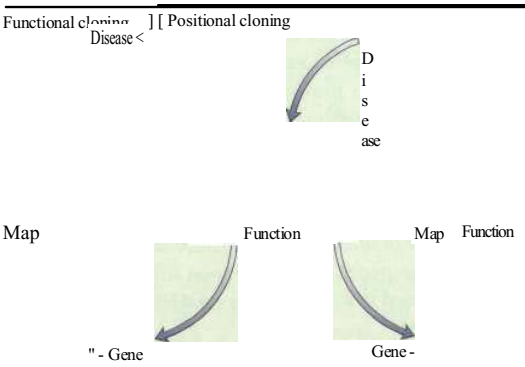

Fig. 3.22 **Diagrammatic representation of two classic approaches to gene cloning.**

Functional cloning requires a working knowledge of the biochemistry of the disease such that the defective protein/enzyme has previously been characterized in some way. From this the gene can be isolated and then its chromosomal location found.

Positional cloning is used to isolate genes whose protein products are not known, but whose existence can be inferred from a disease phenotype. The process involves narrowing the search to a chromosome, then to a region of the chromosome, and finally to a gene in which a mutation is always present in affected individuals and absent in normal individuals.

aberrations (for example deletions), which are present at an unusually high frequency in individuals affected with the disease, compared with the normal population. If there are no further clues, often the next stage in locating the gene that is mutated in the disease is to look for genetic markers as described earlier. Once polymorphic markers from across the genome have been tested, it should be possible by linkage analysis to see if any segregate with the disease allele in a family. If the position of the polymorphic marker is known, then the affected gene is likely to be close by and is therefore mapped to a region of the genome (i.e. a specific band on a chromosome arm).

Isolating the gene

Once linkage analysis has established which chromosome and which region of the chromosome contains the disease gene, the next step is to identify the gene. The region of DNA which contains the gene may span several million base-pairs, and a variety of techniques exist for cloning cDNAs and gene sequences from such regions. Genes which have been cloned and are very tightly linked to a genetic disease may be 'candidate genes' for that disease, and researchers have to show that a mutation in the gene is likely to give rise to the disease.

However, most are unknown and markers which span the disease gene's physical location on the chromosome are traced through the affected families' genetic samples. These markers define the target interval of genetic code - often several million base-pairs - within which the disease gene lies. Essentially the whole target interval is cloned and partially or entirely sequenced by 'chromosome walking' or searching cDNA libraries for uncharacterized sequences which hybridize to regions of the target interval. Sequencing approaches require searching for motif sequences, such as areas rich in repetitive cytosine and guanidine base-pairs, which are characteristic of a gene. A further criterion for candidacy is that the gene is expressed in the affected tissues. It is unlikely that a gene giving rise to a liver disease might give the instructions for making protein purely in neuronal tissue. Probably the most useful criterion is to find a mutation in the gene in affected and not in unaffected individuals.

When candidate genes have been identified, they are cloned and expressed in order to establish the function of the protein product.

THE GENETIC BASIS OF CANCER

Cancers are genetic diseases and involve changes to the normal function of cellular genes. However, multiple genes interact during oncogenesis and an almost stepwise progression of defects leads from an overproliferation of a particular cell to the breakdown of control mechanisms such as apoptosis (programmed cell death). This would be triggered if a cell were to attempt to survive in an organ other than its tissue of origin. For the vast majority of cancer cases (especially those in older people) the multiple genetic changes which occur are somatic. However, it is clear that susceptibility to the development of a particular form of cancer can be inherited. Indeed for some rare cancers a dominant single-gene defect can give rise to an almost Mendelian trend. In some other cancers (e.g. forms of breast cancer) the mode of inheritance is much more complex. In these cases close relatives may have an increased susceptibility to cancer (Table 9.3), and the genetics are clearly those of a multifactorial trait.

- Cancer tissues are clonal, and tumours arise from changes in only one cell, which then proliferates in the body.
- The genes that are primarily damaged by the genetic changes which lead to cancer fall into two categories: oncogenes and tumour suppressor genes.
- Oncogenesis is a multistep process in that a number of mutations or alterations to key genes are required before a malignant phenotype is expressed.
- Once mutations have begun to cause unchecked clonal expansion of the primary tumour cells, further mutations occur within the subsequent generations of daughter cells that give rise to clones which are invasive and/or form metastases.

ONCOGENES (see p. 485)

The genes coding for proteins which are either growth factors, growth factor receptors, secondary messengers or even DNA-binding proteins would act as promoters of abnormal cell growth if mutated. This concept was verified when viruses were found to carry genes which, when integrated into the host cell, promoted oncogenesis. These were originally termed viral or 'v-oncogenes', and later their normal cellular counterparts, c-oncogenes, were found. Thus, oncogenes encode proteins that are known to participate in the regulation of normal cellular proliferation e.g. *erb-A* on chromosome 17qll-ql2 encodes for the thyroid hormone receptor. See also Table 9.4.

Activation of oncogenes

Non-activated oncogenes which are functioning normally have been referred to as 'proto-oncogenes'. Their transformation to oncogenes can occur by three routes.

Mutation

Carcinogens such as those found in cigarette smoke, ionizing radiation and ultraviolet light can cause point mutations in genomic DNA. By chance some of these point mutations will occur in regions of the oncogene which lead to activation of that gene. Not all bases in an oncogene cause cancer if mutated, but some (e.g. those in the coding region) do.

Chromosomal translocation

If during cell division an error occurs and two chromosomes translocate, so that a portion swaps over, the translocation breakpoint may occur in the middle of two genes. If this happens then the end of one gene is

translocated on to the beginning of another gene, giving rise to a 'fusion gene'. Therefore sequences of one part of the fusion gene are inappropriately expressed because they are under the control of the other part of the gene.

An example of such a fusion gene (the Philadelphia chromosome) occurs in chronic myeloid leukaemia (CML, see p. 501). Similarly in Burkitt's lymphoma a translocation causes the regulatory segment of the *myc* oncogene to be replaced by a regulatory segment of an unrelated immunoglobulin.

Viral stimulation

When viral RNA is transcribed by reverse transcriptase into viral cDNA and in turn is spliced into the cellular DNA, the viral DNA may integrate within an oncogene and activate it. Alternatively the virus may pick up cellular oncogene DNA and incorporate it into its own viral genome. Subsequent infection of another host cell might result in expression of this viral oncogene. For example, the Rous sarcoma virus of chickens was found to induce cancer because it carried the ras oncogene.

After the initial activation event other changes occur within the DNA. A striking example of this is amplification of gene sequences, which can affect the *myc* gene for example. Instead of the normal two copies of a gene, multiple copies of the gene appear either within the chromosomes (these can be seen on stained chromosomes as homogeneously staining regions) or as extrachromosomal particles (double minutes). *N-myc* sequences are amplified in neuroblastomas as are *N-myc* or *L-myc* in some lung small-cell carcinomas.

TUMOUR SUPPRESSOR GENES

These genes restrict undue cell proliferation (in contrast to oncogenes), and induce the repair or self-destruction (apoptosis) of cells containing damaged DNA. Therefore mutations in these genes which disable their function lead to uncontrolled cell growth in cells with active oncogenes. An example is the germline mutations in genes found in non-polyposis colorectal cancer which are responsible for repairing DNA mismatches (p. 328).

The first tumour suppressor gene to be described was the *RB* gene. Mutations in *RB* lead to retinoblastoma which occurs in 1 in 20000 young children and can be sporadic or familial. In the familial variety, the first mutation is inherited and by chance a second somatic mutation occurs with the formation of a tumour. In the sporadic variety, by chance both mutations occur in both the *RB* genes in a single cell. Since the finding of KB, other tumour suppressor genes have been described, including the gene *p53.* Mutations in *p53* have been found in almost all human tumours, including sporadic colorectal carcinomas, carcinomas of breast and lung, brain tumours, osteosarcomas and leukaemias. The protein, encoded by *p53,* is a cellular 53 kDa nuclear phosphoprotein that plays a role in DNA repair and synthesis, in the control of the cell cycle and cell differentiation and programmed cell death - apoptosis. p53 is a DNA-binding protein which activates many gene expression pathways but it is normally only short-lived. In many tumours, mutations that disable p53 function also prevent its cellular catabolism. Although in some cancers there is a loss of *p53* from both chromosomes, in most cancers (particularly colorectal carcinomas; see Fig. 6.40) such long-lived mutant *p53* alleles can disrupt the normal alleles' protein. As a DNA-binding protein, p53 is likely to act as a tetramer. Thus, a mutation in a single copy of the gene can promote tumour formation because a hetero-tetramer of mutated and normal p53 subunits would still be dysfunctional.

How tumour suppressor genes work

Tumour suppressor gene products are intimately involved in control of the cell cycle (see Fig. 3.7). Progression through the cell cycle is controlled by many molecular gateways, which are opened or blocked by the cyclin group of proteins that are specifically expressed at various stages of the cycle. The RB and p53 proteins control the cell cycle and interact specifically within many cyclin proteins. The latter are affected by INK 4a acting on pl6 proteins. The general principle is that being held at one of these gateways will ultimately lead to programmed cell death. p53 is a DNA-binding protein which induces the expression of other genes and is a major player in the induction of cell death. Its own expression is induced by broken DNA. The induction of p53 by damage initially causes the expression of DNA repair enzymes. If DNA repair is too slow or cannot be effected, then other proteins that are induced by p53 will effect programmed cell death.

One gateway event that has been largely elucidated is that between the Gl and the S phase of the cell cycle. The transcription factor dimer E2F-DP1 causes progression from the Gl to the S phase. However, the RB protein binds to the E2F transcription factor, preventing its induction of DNA synthesis. Other, cyclin D-related molecules inactivate the RB protein, thus allowing DNA synthesis to proceed. This period of rapid DNA synthesis is susceptible to mutation events and will propagate a pre-existing DNA mistake. Damaged DNA-induced p53 expression rapidly results in the expression of a variety of closely related (and possibly tissue-specific) proteins WAF-l/p21, pl6, p27. These inhibit the inactivation of RB by cyclin D-related molecules. As a result RB, the normal gate which stops the cell cycle, binds to the E2F-DP1 transcription factor complex, halting S phase DNA synthesis. If the DNA damage is not repaired apoptosis ensues.

Viral inactivation of tumour suppressors

The suppression of normal tumour suppressor gene function can be achieved by disabling the normal protein once it has been transcribed, rather than by mutating the gene. Viruses have developed their own genes which pro duce proteins to do precisely this. The main targets of these proteins are RB and p53 to which they bind and thus disable. The best understood are the adenovirus El A and human papillomavirus (HPV) E7 gene products which bind RB, whilst the adenovirus E1B and HPV E6 gene products bind p53. The SV40 virus large T antigen binds both RB and p53.

Microsatellite instability

Microsatellites are short (50-300 bp) sequences composed of tandemly repeated segments of DNA two to five nucleotides in length (dinucleotide/trinucleotide/tetranucleotide repeats). Scattered throughout the genome in the non-coding regions between genes or within genes (introns), many of these microsatellites are highly polymorphic. Often used as markers for linkage analysis because of high variability in repeat number between individuals, these regions are inherently unstable and susceptible to mutations. Somatic microsatellite instability (MSI) has been detected in a number of tumours. Detecting MSI involves comparing the length of microsatellite alletes amplified from tumour DNA with the corresponding allele in normal tissue from the same individual. Recent studies indicate that MSI can be detected in approximately 90% of tumours from individuals with hereditary non-polyposis colorectal cancer (HNPCC). The presence of these additional microsatellite alleles (repeated segments) in tumour cells, results from the inherent susceptibility of these areas to such alterations and from mutations in the DNA mismatch repair mechanism that would normally correct these errors.

Tumour angiogenesis

Once a nest of cancer cells reaches 1-2 mm in diameter, it must develop a blood supply in order to survive and grow larger, as diffusion is no longer adequate to supply the cells with oxygen and nutrients. As with all tissues, solid tumour cancer cells secrete substances that promote the formation of new blood vessels - a process called angiogenesis. Over a dozen substances have been identified that promote angiogenesis (e.g. angiopoietin-1, basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF)). This has led to the discovery of a number of inhibitors of angiogenesis and some have already advanced to clinical trials as part of a cancer treatment strategy such as:

- angiostatin - a polypeptide of approximately 200 amino acids, produced by the cleavage of plasminogen; it binds to subunits of ATP synthase exposed at the surface of the cell embedded in the plasma membrane
- endostatin - a polypeptide of 184 amino acids which is derived from the globular domain found at the C-terminal of type XVIII collagen (a specific collagen of blood vessels) cleaved from the parent molecule.

Several therapeutic vaccine preparations are under development to produce a range of host immunity responses (humoral, cellular) against pro-angiogenic factors and their receptors in tumours. One approach has been directed at cell adhesion molecules found in tumour blood vessels. It turns out that the new blood vessels in tumours express a vascular integrin - designated alpha-v/beta-3 - that is not found on the old blood vessels of normal tissues. Vitaxin, a monoclonal antibody directed against the alpha-v/beta-3 vascular integrin, shrinks tumours in mice without harming them. In Phase II clinical trials in humans, Vitaxin has shown some promise in shrinking solid tumours without harmful side-effects.

CANCER AETIOLOGY: INHERITANCE OR ENVIRONMENT?

It is clear that a mutation causing the dysfunction of a single oncogene or tumour suppressor gene is not sufficient to induce unregulated clonal expansion. The Knudson multi-hit hypothesis elegantly unites the genetics of familial and sporadic tumour development: an inherited mutation in one gene allele may be insufficient to cause a tumour but will cause a significant susceptibility to the development of a particular cancer. Subsequent lifetime exposure to environmental carcinogens (viral, chemical, radiation), along with simple mistakes during cell division, may deregulate the normal allele. Other mutations which accumulate in a similar manner then lead to tumour development. Research has clearly shown that germline mutations in particular genes, such as *p53* and *RB,* have a much stronger influence on the chance of subsequent tumour development than others.

POPULATIONGENETICS

The genetic constitution of a population depends on many factors. The Hardy-Weinberg equilibrium is a concept, based on a mathematical equation, that describes the outcome of random mating within populations. It states that 'in the absence of mutation, non-random mating, selection and genetic drift, the genetic constitution of the population remains the same from one generation to the next'.

This genetic principle has clinical significance in terms of the number of abnormal genes in the total gene pool of a population. The Hardy-Weinberg equation states that:

$$f + Ipq + q^2 = 1$$

where p is the frequency of the normal gene in the population, q is the frequency of the abnormal gene, p^2 is the frequency of the normal homozygote, q^2 is the frequency of the affected abnormal homozygote, $2pq$ is the carrier frequency, and $p + q = 1$.

./

Example. The equation can be used, for example, to find the frequency of heterozygous carriers in cystic fibrosis. The incidence of cystic fibrosis is 1 in 2000 live births. Thus $q^2 = 1/2000$, and therefore $q = 1/44$. Since $p = 1 - q$, then $p = 43/44$. The carrier frequency is represented by $2pq$, which in this case is 1/22. Thus 1 in 22 individuals in the whole population is a heterozygous carrier for cystic fibrosis.

CLINICAL GENETICS AND GENETIC COUNSELLU ~

Genetic disorders pose considerable health and economic problems because often there is no effective therapy. In any pregnancy the risk of a serious developmental abnormality is approximately 1 in 30 pregnancies; approximately 15% of paediatric inpatients have a multifactorial disorder with a predominantly genetic element.

People with a history of a congenital abnormality in a member of their family often seek advice as to why it happened and about the risks of producing further abnormal offspring. Interviews must be conducted with great sensitivity and psychological insight, as parents may feel a sense of guilt and blame themselves for the abnormality in their child.

Genetic counselling should have the following aims:

- *Obtaining a full history.* The pregnancy history, drug and alcohol ingestion during pregnancy and maternal illnesses (e.g. diabetes) should be detailed.
- *Establishing an accurate diagnosis.* Examination of the child may help in diagnosing a genetically abnormal child with characteristic features (e.g. trisomy 21) or whether a genetically normal fetus was damaged in utero.
- *Drawing a family tree is essential.* Questions should be asked about abortions, stillbirths, deaths, marriages, consanguinity and medical history of family members. Diagnoses may need verification from other hospital reports.
- *Estimating the risk of a future pregnancy being affected or carrying a disorder.* Estimation of risk should be based on the pattern of inheritance. Mendelian disorders (see earlier) carry a high risk; chromosomal abnormalities carry a low risk. Empirical risks may be obtained from population or family studies.
- *Information giving.* On prognosis and management.
- *Continued support and follow-up.* Explanation of the implications for other siblings and family members.
- *Genetic screening.* This includes prenatal diagnosis if requested, carrier detection and data storage in genetic registers. A growing number of molecular genetic tests are now available (http://www.geneclinics.org).

Genetic counselling should be non-directive, with the couple making their own decisions on the basis of an accurate presentation of the facts and risks in a way they can understand.

GENETIC ANTICIPATION

It has been noted that successive generations of patients with, for example, dystrophia myotonica and Huntington's chorea, present earlier and with progressively worse symptoms. This 'anticipation' is due to unstable mutations occurring within the disease gene. Trinucleotide repeats such as CTG (dystrophia myotonica) and CAG (Huntington's chorea) expand within the disease gene with each generation, and somatic expansion with cellular replication is also observed. This novel type of genetic mutation can occur within the translated region or untranslated (and presumably regulatory) regions of the target genes. This genetic distinction has been used to subclassify a number of genetic diseases which have now been shown to be caused by trinucleotide repeat expansion and display phenotypic 'anticipation' (Table 3.7).

PRENATAL DIAGNOSIS

This is offered to all pregnant women in the UK. Practice varies in different maternity units, with some only offering screening to high-risk mothers. Prediction factors for high-risk include women who are older than 35 years and those with a history or family history of chromosomal abnormalities.

Investigations

First trimester

- m Ultrasound (high resolution) for nuchal translucency to exclude major chromosomal abnormalities (e.g. trisomies and Turner's syndrome).
- Maternal serum for pregnancy-associated plasma protein-A (PAPP-A from the syncytial trophoblast) for trisomy 21. This is more accurate than the triple test at 16 weeks.

Second trimester

- m Ultrasound for structural abnormalities (e.g. neural tube defects, congenital heart defects). Serum screening has been superseded by high-resolution ultrasound (above) in specialist centres.
- Triple test (used by some) for chromosomal abnormalities. This consists of a serum oc-fetoprotein (low), unconjugated oestradiol (low) and human chorionic gonadotrophin (high). cc-Fetoprotein (high for neural tube defects).

All markers are corrected for gestational ages, a multiple of the mean (MOM) value for the appropriate week of gestation. If abnormalities are detected, it is necessary to continue investigations with chorionic villus sampling (CVS) at 11-13 weeks, or amniocentesis at 15 weeks, under ultrasound control to sample amniotic fluid and fetal cells necessary for cytogenetic testing.

These tests may well be superseded by salvage of fetal cells from the maternal blood sample at 12 weeks.

APPLICATIONS OF MOLECULAR GENETICS

The use of molecular biological techniques in genetics is having a massive impact on the investigation, diagnosis, treatment and control of genetic disorders.

The avoidance and control of genetic disease

Some genetic disorders, such as phenylketonuria or haemophilia, can be managed by diet or replacement therapy, but most have no effective treatment. By understanding what causes genetic damage, potential mutagens such as radiation, environmental chemicals, viruses or drugs (e.g. thalidomide) can be avoided.

GENE THERAPY

There are many technical problems to overcome in gene therapy, particularly in finding delivery systems to introduce DNA into a mammalian cell. Very careful control and supervision of gene manipulation will be necessary because of its potential hazards and the ethical issues.

Gene therapy entails placing a normal copy of a gene into the cells of a patient who has a defective copy of the gene.

Experiments have concentrated on recessive disorders, such as cystic fibrosis where the disease is due to the absence of a normal gene product. In dominant disorders the pathogenic potential of the mutant allele is normally expressed in the presence of a normal allele. This requires gene correction, whereby the mutant sequence is replaced by an equivalent sequence from a normal allele, or the mutant allele is inactivated. Such procedures are more difficult.

Two major factors are involved in gene therapy:

- the introduction of the functional gene sequence into target cells
- the expression and permanent integration of the transfected gene into the host cell genome.

Suitable diseases for current gene therapy experiments include cystic fibrosis, adenosine deaminase deficiency, and familial hypercholesterolaemia.

Cystic fibrosis (see also p. 909 and p. 413) The gene responsible for cystic fibrosis was first localized to chromosome 7 by linkage analysis. The cystic fibrosis transmembrane regulator gene *(CFTR)* was then isolated by chromosome-mediated gene transfer, chromosome walking and jumping. The *CFTR* gene spans about 250 kbp and contains 27 exons. The DNA sequence analysis predicts a polypeptide sequence of 1480 amino acids. The *CFTR* gene also encodes a simple chloride ion channel within the cystic fibrosis transmembrane regulator (Fig. 3.23). The commonest is a single mutation with a 3 bp deletion in exon 10 resulting in the removal of a codon specifying phenylalanine (F508del). There are also over 1000 different minor mutations of the *CFTR* gene with most mapping to the ATP-binding domains.

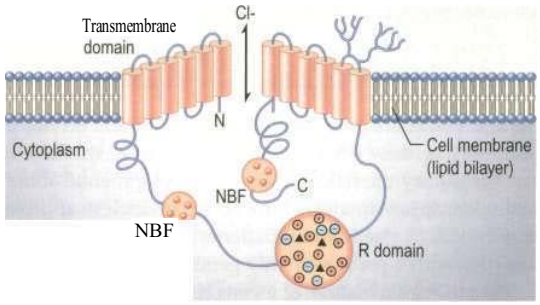

Fig. 3.23 **Model of cystic fibrosis transmembrane regulator (CFTR).** This is an integral membrane glycoprotein, consisting of two repeated elements. The cylindrical structures represent six membrane-spanning helices in each half of the molecule. The nucleotide-binding folds (NBFs) are in the cytoplasm, and the dots in these shaded areas represent the means of entry by the nucleotide. The regulatory (R) domain links the two halves and contains charged individual amino acids and protein kinase phosphorylation sites (black triangles). N and C are the N and C terminals. The branched structure on the right half represents potential glycosylation sites. The chloride channel is shown.

Gene therapy experiments are still under way in trying to restore *CFTR* function by transfection of cells with wild type receptor. Two different routes have been tried, either placing the *CFTR* gene in an adenovirus vector (Fig. 14.30) or into a liposome. The latter can be conveyed to the lung using ah aerosol spray, and the fatty surface of the liposome fuses with the cell membrane to deliver the *CFTR* DNA into the cell, where the gene should function normally. However, neither is yet a treatment option. An alternative method is to suppress premature termination codons and thus permit translation to continue; topical nasal gentamicin (an aminoglycoside antibiotic) has been shown to result in the expression of functional *CFTR* channels.

Adenosine deaminase (ADA) deficiency

Gene therapy for this rare immunodeficiency disease entails introducing a normal human *ADA* gene into the patient's lymphocytes to reconstitute the function of the cellular and humoral immune system in severe combined immunodeficiency (SCID). Lymphocytes have been tried for short-term therapy, but for longer-term treatment bone marrow transplantation would be the definitive approach (seep. 496).

Familial hypercholesterolaemia

This disorder is a result of a defective low-density lipoprotein (LDL) receptor gene. In therapy, a receptor gene is inserted into hepatocytes, removed by liver biopsy from the patient. Gene-corrected hepatocytes are then reinjected into the portal circulation of the patient. These cells migrate back to the liver where they are reincorporated and should start to produce LDL receptor protein, which would dramatically lower the patient's cholesterol level.

Muscle-cell-mediated gene therapy

Much of the problem associated with gene therapy of chronic genetic disease is how long the transfected cells will survive. Isolated myoblasts transfected with a retrovirus have been shown to function and live for the lifetime of mouse models (2 years). The myoblasts fuse with the animal's muscle fibres and express the transfected protein. The long life of the muscle fibres and their rich blood supply make them an ideal site for treatment of diseases in which functional serum-born factors are missing (e.g. human growth hormone, coagulation factors and erythropoietin).

Obviously, myoblast transfection would appear to be the best option for the treatment of Duchenne muscular dystrophy. However, the Duchenne gene is far too large to fit into any current viral vector, and reimplanted myoblasts do not colonize muscles fibres distant from the site of injection.

Treatment of somatic disease

Gene therapy which requires only a transient expression of the transfected genetic material circumvents the problems currently plaguing gene therapy of inherited disorders. This may also prove to be the front-line of gene therapy.

Vascular disease

The ideal therapy in heart disease would be neovascularization to increase blood flow and the repair of cardiac tissue after a myocardial infarction. In fact, any vascular disease might require regeneration or new blood vessel growth. Temporary expression of angiogenic factors at the site of a blockage would induce new blood vessels. Alternatively, local temporary expression of clot-disintegrating enzymes such as streptokinase and lipases may repair damaged and diseased arteries. It is quite possible to deliver liposomes loaded with DNA or, in fact, directly inject DNA plasmids into the tissue, and the protein will be expressed by the cells which take it up. Only 1-3% will do so, but this is sufficient for the local effect required and it is a transient expression. This gives a controllable gene therapy.

Neuronal disease

Neurotrophic factors can be transiently expressed as described above for vascular diseases. The local expression of neurotrophins is essential for nerve cell regeneration and maintenance. It is possible to extend the expression period of the neurotrophin by injecting transfected myocytes into the damaged area. They will fuse with any adjacent muscle tissue to give a prolonged expression of the factor gene.

Cancer

Cancer is a genetic disease and many genes are deregulated. *p53* is a tumour suppressor gene; the reintroduction and overexpression of a functional *p53* in tumours is being investigated with some success. Since *p53* will induce apoptosis in cells with damaged genetic material, the transient expression of high levels in a tumour cell with *p53* pathway defects should induce its own (apoptotic) demise. Since this is only likely to occur in rapidly dividing cells, this is a perfect target for cancer gene therapy. Transient expression induced by repeat exposure to vectors such as retroviruses, liposomes and naked DNA plasmids is all relatively straightforward. Trials using aerosols of these vectors in patients with lung cancer are being performed.

Tumour growth depends on the development of new blood vessels (angiogenesis), and inhibitors of this process are also being used in trials.

Creating and using animal models

There is a need for model systems in which to test gene therapies prior to use in patients. To some extent gene 'knock-out' experiments in mice are providing new animal models of disease. In these experiments the normal gene of interest in a mouse is targeted using recombinant DNA techniques so that gene function is impaired, in analogy to the situation in the particular gene of a human patient. However, mice and humans are different and it will not be possible to mimic some human genetic diseases in mice. Transgenic mice are created when exogenous DNA carrying a gene of interest is injected into a mouse egg. If this egg is fertilized then all the cells of the resulting animal will carry the extra gene sequences. Transgenic mice have also been used as animal models of human diseases in which new therapies may be tested.

Other animal models have paved the way for gene therapy techniques. For example, some of the first experiments in the transfer of globin genes (which will be useful for gene therapy for sickle cell disease and thalassaemia) have taken place in mice. These include transplanting normal donor cells with normal genes into lethally irradiated mice, which results in engraftment of the donor cells.

The human genome project (HGP)

On 14 April 1983 the entire human genome, all 3×10^9 bp on the 24 different chromosomes was sequenced (www.genome.gov 11006929). Now that the entire genome has been sequenced to an accuracy of 99.99%, finding genes that are co-located with a genetic disease marker takes a matter of hours instead of years and is in fact a database or adapted 'in silico' cloning exercise.

Only 2% of the genome codes for actual proteins; some 30 000 genes in the human genome of 300 million bases. However, many genetic disorders are the result of deregulation of expression, and it is the control elements surrounding the coding that are deregulated. The complete sequence also gives rise to an understanding of how genes are packaged as euchromatin or heterochromatin and why the genome is organized in the way it is.

The human proteome project

A more direct route to understanding genetic and somatic disease is by studying the protein expression character-

istics of normal and diseased cells - the proteome. This relies on the separation of proteins expressed by a given tissue by molecular size and charge on a simple two-dimensional display and is achieved by using two-dimensional gel electrophoresis. The pattern of dots corresponds to the different proteins expressed. With the improvement in technology, the patterns are reproducible and can be stored as electronic images. Non-, over- and underexpression of a given protein can be detected by a corresponding change on the proteome two-dimensional electrophoresis image. As can be seen in Figure 3.24, the protein profile of synovial fluid from a diseased joint shows a new protein arising with disease. Such proteins have been identified as inflammatory cytokines. Furthermore, post-translational modifications of the protein show up as a change in either size or charge on the proteome picture. In order to positively identify the altered protein and the post-translational modification it may contain, these protein spots are eluted and subjected to modern mass spectrometry techniques such matrix-assisted laser desorption (MALDI) and electrospray ionization (ESI) time of flight (TOF), which not only give the precise mass of the protein, up to ~ 500 000 Da, but can also sequence its amino acid, phosphorylation **and** glycosylation structure. This cannot be detected by genome analysis. Looking for such changes has already led to the discovery of new protein markers for the diagnosis of Creutzfeldt-Jakob disease, multiple sclerosis, schizophrenia, Parkinson's disease (spinal fluid protein) and Alzheimer's disease (blood and brain proteins). In 2000, the Swiss Institute of Bioinformatics (SIB) and the European Bioinformatics Institute (EBI) announced a major effort to annotate, describe and provide highly accurate information concerning human protein sequences, effectively launching the Human Proteomics Initiative (HPI).

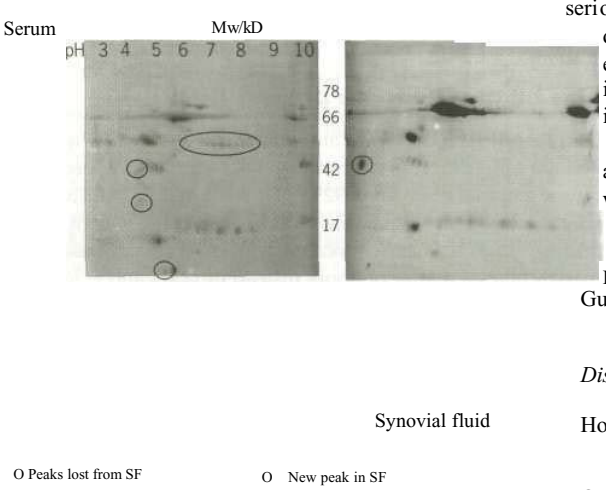

Fig. 3.24 **Two-dimensional gel electrophoresis comparing paired serum and synovial fluid in a patient with rheumatoid arthritis.** Biofluids were first separated according to isoelectric point on a linear immobilized pH gradient followed by SDS-PAGE in a 10% gel. The circled proteins indicate major proteins which differ between the two biofluids. Although serum contained many proteins not found in synovial fluid, one major protein was found to be present in the synovial fluid electropherogram but not in the serum electropherogram. This indicates that synovial fluid is not a simple transudate of serum. Courtesy of Prof. D Perrett and Dr R Bevan, Department of Medicine, Barts and The London School of Medicine.

Metabolomics

In the post-genomic era, computing **power, statistical** software, separation science and modern mass spectrometry have allowed the analysis of a complex mixture as a complete entity, and not merely the fluctuation in concentration of one analyte within it. Metabolomics is the study of the repertoire of non-proteinaceous, endogenously synthesized small molecules present in an organism. Such small molecules include well-known compounds like glucose, cholesterol, ATP and lipid signalling molecules. These molecules are the ultimate product of cellular metabolism, and the metabolome refers to the catalogue of those molecules in a specific organism, e.g. the human metabolome. In terms of clinical biochemistry, the analysis of the pattern of change of such molecules in urine samples of individuals with and without a particular disease and those treated with specific drugs represents a change in the metabolome. It is very likely that, in the future, medicine-regulating authorities will require metabolomic studies on all new drugs.

Ethical considerations

Ethical considerations must be taken into account in any discussion of clinical genetics. For example, prenatal diagnosis with the option of termination may be unacceptable on moral or religious grounds. With diseases for which there is no cure and currently no treatment (e.g. Huntington's), genetic tests can predict accurately which family members will be affected; however, many people would rather not know this information. One very serious outcome of the new genetic information is that disease susceptibility may be predictable, for example in Alzheimer's disease, so the medical insurance companies can decline to give policies for individuals at high risk.

Society has not yet decided who should have access to an individual's genetic information and to what extent privacy should be preserved.

Clinical immundogy

4

THE IMMUNE SYSTEM IN HEALTH

HOST

Throughout life we are exposed to millions of organisms which are inhaled, swallowed or in contact with our skin or mucous membranes. Whether these organisms invade and cause disease is determined by the balance of the pathogenicity of the organism (i.e. the virulence factors that it has at its disposal) and the integrity of the host defence mechanisms. Immunity is often divided into two types termed innate and adaptive (acquired or specific), although in practice these overlap and interlink.

INNATE IMMUNITY

Innate immunity provides the immediately active, first line, non-specific host defence mechanisms. It includes physical (e.g. epithelial cells) and chemical (e.g. 'natural' antimicrobial substances like defensins at surface barriers) as well as immune mechanisms (Table 4.1). The latter consist of cells such as phagocytic cells (neutrophils, and monocytes in the blood; macrophages including dendritic cells in tissues), eosinophils, mast cells and basophils, as well as humoral components (e.g. complement, acute-phase reactants, cytokines). These are directly activated by infectious agents, tissue damage or tumours via surface receptors, e.g. for complement factors when antibody molecules bind through immunoglobulin fc receptors (p. 206). Cells also possess pattern recognition receptors (PRRs) (p. 202) which can recognize structures on micro-organisms collectively. These 'structures' recognized by PRRs are called pathogen-associated molecular patterns (PAMPs) (p. 204). PAMPs include, for example, bacterial lipopolysaccharides, bacterial DNA, double-stranded RNA, peptidoglycans.

Despite the lack of specificity, innate immunity is very effective. Stimulation of either innate or adaptive immunity can also enhance each other's responses.

These non-specific immune responses illustrate normal mechanisms of cell production, recruitment and activation used by all cells of the immune system. The

Table 4.1 **Non-immunological host defence mechanisms**

Normal barriers	Examples of defects leading to infection
Physical barriers Skin and mucous membranes	Breach, e.g. trauma, burns, eczema, cannulae
Cough reflex	Suppression, e.g. by opiates, neurological disease
Mucociliary escalator	Ciliary paralysis (smoking, primary ciliary dyskinesis syndromes) Increased mucus production (asthma) Abnormally viscid secretions (cystic fibrosis) Decreased
Washing, tears, saliva, urine	fluid, e.g. sicca syndromes, drugs Urinary stasis, e.g. prostatic hypertrophy Gastric

Colonization resistance provided by non-pathogenic commensal organisms of skin and gut	broad-spectrum antibiotics

mechanisms that lead to protective inflammation are the same as those which cause extensive damage if not regulated.

Initiation of the inflammatory response

The neutrophil (polymorphonuclear, or PMN cell) is a specialized microbicidal (microbe-killing) phagocyte. The human body contains over 10^{11} polymorphonuclear leucocytes/kg, most of which are in the bone marrow. A series of events leads to the recruitment and activation of these cells at the site of tissue damage.

Adhesion molecules (Table 4.2)

Neutrophils, like most of the cells involved in immune responses, are not static within a particular tissue. Neutrophils travel within the blood, either flowing freely as part of the circulating pool or rolling along the vascular endothelium as the marginating pool (see below).

Table 4.2 **Adhesion molecules**

Adhesion molecule	Tissue distribution	Ligand
Immunoglobulin superfamily		
ICAM-1 (CD54)	Endothelial cells, monocytes, T and B cells, dendritic cells, keratinocytes, chondrocytes, epithelial cells	LFA-1
ICAM-2 (CD102)	Endothelial cells, monocytes, dendritic cells, subpopulations of lymphocytes	LFA-1
ICAM-3	Lymphocytes	LFA-1, Mac-1
VCAM-1 (CD106)	Endothelial cells, kidney epithelium, macrophages, dendritic cells, myoblasts, bone marrow fibroblasts	VLA-4
PECAM-1	Platelets, T cells, endothelial cells, monocytes, granulocytes	Unknown
MAdCAM-1	Endothelial venules in mucosal lymph nodes	a4p7 integrin and L-selectin
Selectin family		
E-selectin (CD62EJ/ELAM-1	Endothelial cells	Unknown
L-selectin (CD62L)	Lymphocytes, neutrophils, monocytes	CD34
P-selectin (CD62P)	Megakaryocytes, platelets and endothelial cells	Unknown
Integrin family		
VLA subfamily		
VLA-1 to VLA-4	Endothelial cells, resting T cells, monocytes, platelets and epithelial cells	Various molecules including laminin, fibronectin, collagen and VCAM-1
VLA-5 (fibronectin receptor)	Endothelial cells, monocytes and platelets	Laminin
VLA-6 (laminin receptor)	Endothelial cells, monocytes and platelets	Laminin
	Endothelial cells	Laminin
	Endothelial cells	Unknown
	Platelets and megakaryocytes	Fibronectin
p1a P2	Widely distributed	Collagen, laminin, vitronectin
Leucam subfamily		
LFA-1	Lymphocytes	ICAMs 1 to 3
Mac-1	Endothelial cells	ICAM-1, fibrinogen, C3bi
Cytoadhesin subfamily		
Vitronectin receptor	Platelets and megakaryocytes	Vitronectin, fibrinogen, laminin, fibronectin, von Willebrand factor, thrombospondin
		Laminin
P4a6	Endothelial cells, thymocytes and platelets	Vitronectin, fibronectin
P5a	Platelets and megakaryocytes	Fibronectin
P6a	Platelets and megakaryocytes	Fibronectin, VCAM-1
P7a4/LPAM-1	Endothelial cells, thymocytes, monocytes	Unknown
p8a	Platelets and megakaryocytes	

E-selectin or ELAM, endothelial leucocyte adhesion molecule; ICAM, intercellular adhesion molecule; LFA, leucocyte function antigen; LPAM, lymphocyte Peyer's patch adhesion molecule; MAdCAM-1, mucosal addressin; PECAM, platelet/endothelial cell adhesion molecule; VCAM vascular cell adhesion molecule; VLA, very late antigen

Recruitment of cells of the immune system (phagocytes and lymphocytes) to tissue sites involves cellular adhesion molecules (CAM) (p. 160, Fig. 3.6). The main ones are the intercellular adhesion molecules (ICAM), integrins, selectins and cadherins (calcium-dependent adherins). Adhesion molecules associate with cytoskeletal components to cause cytoskeletal reorganization, resulting in migration and spreading, allowing the cells to move. The binding of adhesion molecules to their ligand also causes signal transduction with increased expression of other receptors, altered gene expression and effects on protein synthesis and cell survival. This often leads to cell activation.

Cell recruitment

Cells move towards the site of inflammation in response to chemoattractants (chemicals which attract cells) at sites of infection or tissue damage. The main chemoattractants for neutrophils in vivo are N-formyl-methionyl-leucylphenylalanine (FMLP) from bacterial cell walls, which in turn causes the release of another chemoattractant, leukotriene B_4 (LTB_4) from tissue mast cells; the chemokine (chemoattractant cytokine) interleukin-8 (from macrophages); and C5a from the activation of complement. These substances cause migration of neutrophils by three mechanisms:

- *Upregulation of neutrophil adhesion molecules,* L-selectin and the integrin LFA-1 (leucocyte function antigen), which increases the stickiness of the cells.
- *Increase in local vascular endothelial cell expression of the adhesion molecules* E-selectin and ICAM-1, which causes increased stickiness of the endothelium. The selectin expression causes the circulating neutrophil to be tethered and roll along the endothelium slowly (margination), whereas the reaction between the integrins LFA-1 and ICAM-1 is much stronger, causing the cells to stop moving.
- *Stimulation of neutrophil chemotaxis* (directed movement along the chemoattractant gradient towards the stimulus).

The cells pass between endothelial cells into the tissues by the formation of foot-like processes (pseudopodia) that push through the intercellular spaces; this is called diapedesis. The cells continue to move along the chemoattractant gradient to the site of infection (Fig. 4.1). When the cells reach the highest concentration of chemoattractant, the receptor on the cell surface is downregulated, ensuring that the phagocytes remain at the site of inflammation.

The exodus of neutrophils leads to the inflammatory response and if it involves large numbers causes the formation of pus, the characteristic yellow colour being due to the cytochromes within the cells. Patients with congenital deficiencies of adhesion molecules or those on systemic corticosteroids who have acquired adhesion molecule defects (steroids reduce ICAM-1 expression on endothelial cells) cannot target their neutrophils to sites of infection. As a result of this they suffer recurrent infections. The peripheral blood characteristically shows a leucocytosis as the cells cannot leave the circulation.

Similar mechanisms of cell recruitment and trafficking by the use of adhesion molecules are described for other cells within the immune system, for example L-selectin facilitates 'homing' of lymphocytes to lymph nodes.

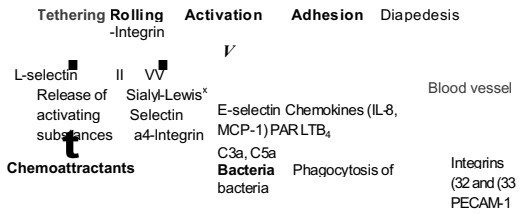

Fig. 4.1 **Neutrophil migration.** Neutrophils arrive at the site of the inflammation, attracted by chemoattractants. They *roll* along the blood-vessel wall and their progress is halted by L-selectin, on their surface, binding to a carbohydrate structure, e.g. sialyl-Lewis^x, an adhesion molecule. On *activation,* the L-selectin is replaced by another cell surface adhesion molecule, e.g. integrin which binds to E-selectin. Various other chemokines, e.g. interleukin-8 (IL-8), macrophage chemoattractant factor (MCP), TNF-a and other inflammatory mediators are involved. These inflammatory markers attract the activated neutrophil into the tissue where it phagocytoses and destroys C3b-coated bacteria. The inflammation releases activating substances, attracting more neutrophils. LFA, leucocyte function antigen; PAF, platelet-activating factor, LTB4, leukotriene B4; ICAM, intracellular adhesion molecule; VCAM, vascular cell adhesion molecule; PECAM, platelet/endothelial cell adhesion molecule.

Phagocytosis and intracellular killing

Once the neutrophils have been recruited, phagocytosis (ingestion) and intracellular killing of microbes begins. Phagocytosis occurs by the formation of pseudopodia (projections of cytoplasmic membrane) around the organism or particle to be ingested (see Fig. 4.11a). Owing to the fluidity of the cell membrane, the tips eventually fuse to form a membrane-bound vesicle called a phagosome. This fuses with the neutrophil cytoplasmic granules (Table 4.3) to form a phagolysosome. Within this localized environment, killing occurs, the cytoplasm being protected. There are two major mechanisms:

- *O_2-dependent response* or 'respiratory burst', in which there is production of reactive oxygen metabolites, such as hydrogen peroxide, hydroxyl radicals and singlet oxygen, via the reduction of oxygen by a cytochrome-dependent NADPH oxidase.
- *Ox-independent response,* due to the toxic action of preformed cationic proteins and enzymes contained within the cytoplasmic granules.

Ingestion and killing of organisms is much more effective if the particle is first coated or opsonized ('made ready to

Table 4.3 Neutrophil granule proteins (there are two types distinguished by staining characteristics)

eat') with specific antibody and complement. This is because neutrophils have receptors for the Fc portion of antibody molecules (FcR), and complement (CR). Binding of cell-surface receptors to complement and antibody on the particle both increases the strength of adhesion and causes transduction of intracellular signals, which activate the cell to promote phagocytic and killing activity.

Granulocyte and granulocyte-macrophage colony-stimulating factors (G-CSF and GM-CSF) are cytokines released by activated endothelial cells and macrophages and act on the bone marrow to release more neutrophils into the circulation. This causes the characteristic neutrophil leucocytosis observed in infectious or inflammatory disease. Interleukin-6 is also produced and induces the liver synthesis of the acute-phase reactants, particularly complement components, C-reactive protein (CRP), mannan-binding lectin and fibrinogen (Table 4.4). Many of these are opsonins. CRP and fibrinogen (the main factor which affects the ESR reading) are measured diagnostically to monitor infection and inflammatory conditions.

Neutrophils can only ingest particles smaller than themselves and are only able to detect extracellular infections, particularly bacteria and some fungi. Monocytes and macrophages act in the same way using similar types of receptors. Phagocytes also remove particles of foreign material and tissue debris. Once the stimulus is controlled, the neutrophils undergo apoptosis (programmed cell death) and are themselves phagocytosed by macrophages, limiting the inflammatory reaction.

Eosinophils in host defence

In developed countries eosinophils are most commonly associated with allergic disease, but their physiological function is in parasite control. Eosinophils have receptors for IgE which is the major antiparasite antibody, particularly against nematodes. Eosinophils bind IgE via the FceR, and toxic metabolites are released from the eosinophil granules directly onto the parasite surface. Examples are major basic protein (MBP), which produces ballooning and detachment of the helminth tegumental membrane, and eosinophil cationic protein (ECP), which is present in smaller amounts but is eight to ten times more toxic than MBP, producing complete fragmentation and disruption of the parasites.

Mast cells and basophils

Mast cells consist of two populations, which are distinguished by their enzyme content. The T mast cells contain trypsin alone (also termed mucosal mast cells owing to their location). The TC mast cells contain both trypsin and chymotrypsin and are called connective tissue mast cells. Mast cell function appears to be in the initiation of inflammatory responses (increased vascular permeability, bronchoconstriction) by the release (following degranulation) of pro-inflammatory mediators such as histamine, leukotrienes, platelet-activating factor (PAF), prostaglandins and some cytokines (e.g. IL-4). Basophils are morphologically similar to mast cells but are found in very small numbers in the blood. These cells bear high-affinity IgE receptors FceRl (CD23) which rapidly absorb any local IgE and participate in immediate-type hypersensitivity reactions (see p. 220).

Dendritic cells/Langerhans' cells

These are derived from the lymphoid and myeloid cell lines; dendritic cells in the skin are called Langerhans' cells. Their major function is to present antigen to T cells when stimulated. Dendritic cells link innate immunity to the adaptive immune system (p. 204) by being the only cell that can activate naive T cells to initiate an adaptive immune response. They are activated by signals from PAMP, heat shock proteins and TNF-a, and IFN-a (secreted from host cells) reacting to injury. When activated, dendritic cells can change their expression of chemokine receptors and migrate from tissue to the T cell zones of lymph nodes.

Complement

The complement system comprises a series of at least 20 glycoproteins that are activated in a cascade sequence, with proenzymes that undergo sequential proteolytic cleavage to their active forms. It is a major part of the innate immune system.

Three main pathways of complement activation exist, termed the classical, alternative and mannan-binding lectin (MBL) pathways (Fig. 4.2). The terminology of the

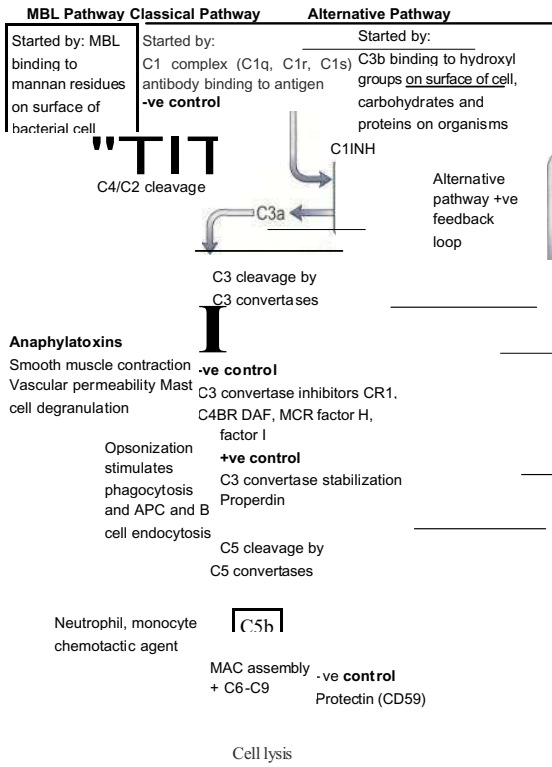

Fig. 4.2 **Complement pathway.** The three activation pathways (mannan-binding lectin (MBL), classical and alternative) converge at the central C3 component. This leads to a final common pathway with the assembly of C5 to C9 forming a transmembrane pore (membrane attack complex MAC) in the cell surface and death by osmotic lysis. C1INH, C1 esterase inhibitor; factors H and I, regulatory factors; DAF (CD55), decay-accelerating factor; MCP, macrophage chemoattractant protein; APC, antigen-presenting cell; CR1, complement receptor 1; C4BP, C4 binding protein.

complement proteins is that components of the classical pathway are named by 'C followed by a number (the numbering sequence is in order of their discovery not position in the sequence). Alternative pathway components are called factors followed by a specific letter. During activation some components are initially cleaved into fragments. The smaller fragment, designated 'a', is released; the larger 'b' fragment is usually deposited on the surface of the activating cell. Further fragmentation may occur to V, 'd' and 'g' fragments.

The complement pathways are triggered by different factors:

- *Classical pathway* by antigen-antibody immune complexes, apoptotic cells, C-reactive protein bound to ligand and certain viruses and bacteria.
- *Alternative pathway* by bacterial endotoxin, fungal cell walls, viruses and tumour cells.
- *Mannan-binding lectin (MBL) pathway* is activated by microbes with terminal mannose groups. MBL has a similar structure to Clq and activates through the classical pathway without the requirement for antibody.

The pathways converge in the activation of C3 (by the formation of either classical or alternative C3 convertase). This leads into a final common pathway with the assembly of components C5-C9 to form the membrane attack complex (MAC) which assembles into a 'doughnut-like' transmembrane channel leading to cell lysis by osmotic shock.

Complement activation is focused at cell membranes. Host cells are protected from complement-mediated lysis by inhibitory surface molecules, for example decay accelerating factor (DAF). Most organisms lack any protective molecules and are therefore susceptible to complement.

Functions of complement

- *Anti-infective function:*
  - opsonization by C3b and C4b
  - chemotaxis - attraction of phagocytes by chemo attractant activation products
  - activation of leucocytes by anaphylatoxins (C5a, C3a and C4a); via receptors on leucocytes
  - lysis of bacteria and cells (C5b-C9).
- *Interplay between innate and adaptive immune system.* Immunomodulation of B-cell responses to specific antigen through binding of complement receptors on B-cell surface, thus augmenting antibody responses and immunological memory.
- *Clearance of:*
  - immune complexes (Clq, C3 and C4)
  - apoptotic cells (Clq, C3 and C4).

Other cells or factors active in non-specific immunity

Natural killer (NK) cells

These non-phagocytic cells have the morphology of lymphocytes but do not bear the markers for T or B cells. They are distinguished by the presence of numerous cytoplasmic granules. They have non-specific antiviral and antitumour activity, causing lysis of cells with which they react.

NK cells recognize abnormal cells in two ways. Firstly, they bear immunoglobulin receptors (FcR) and bind antibody-coated targets leading to antibody-dependent cellular cytotoxicity (ADCC). Secondly, they have surface receptors for MHC (major histocompatibility complex) class I. If these MHC receptors are not bound on interaction with a cell, the NK cell is programmed to lyse this target cell. It does this by making holes in its cell membrane by secreting 'performs'; granzymes are injected through these pores and cause the induction of apoptosis. As normal host cells are MHC class I positive, the 'death pathway' is inhibited by the NK cell binding to this receptor. However, tumours on affected cells and viruses

often cause downregulation of class I and thus it leaves them open to NK cell attack.

NK cells may also shape the adaptive T cell responses to Thl or Th2 type depending on the balance of the NK receptor activation during the early stage of an immune response.

Cytokines

Cytokines are small soluble intercellular messengers that exert their effect by binding to specific receptors on target cells. They act as autocrine, paracrine or endocrine messengers. Cytokines are produced by any cell. Their biological effect varies according to the cytokine and the cell involved (Table 4.5), but typically these molecules will signal certain cell populations to activate, divide or home in on a particular site in the body. Cytokines include:

- *Interleukins* produced by and signal between white cells.
- *Chemokines* have a chemoattractant function.
- *Colony-stimulating factors* cause differentiation and proliferation of stem cells.
- *Interferons* (see below).
- *Tumour necrosis factors.* TFN-a increases phagocyte function.

Interferons (IFN) are a major class of cytokine. They are divided into type I (alpha and beta) and type II (gamma or 'immune' interferon). Type I interferons are antiviral agents produced mainly by fibroblasts, monocytes and infected cells as a reaction to viral infection. *Alpha* and *beta IFN* bind the same cellular receptor and protect uninfected cells by inducing the inrracellular production of molecules that inhibit viral RNA and DNA production. They also increase the expression of MHC class I molecules, leading to enhanced lysis of virally infected cells by specific cytotoxic T lymphocytes. Type I interferons also have antiproliferative function. IFN-a is used in the treatment of chronic hepatitis B and C infections as well as in some forms of leukaemia. IFN-P reduces the relapse rate in some forms of multiple sclerosis.

Gamma-interferon has different functions, acting mainly on the immune response. It activates macrophage and neutrophil intracellular killing, stimulates natural killer cells and enhances T-cell responses by increasing MHC class II expression on antigen-presenting cells. IFN-yuses a separate receptor from the type I interferons. It is used therapeutically in the congenital neutrophil defect (chronic granulomatous disease), in patients with defects in IFN-y production or receptor expression, and in the adjunct therapy of some infections (leishmaniasis, atypical mycobacterial disease).

Other cytokines are also involved in innate immunity. Interleukin-6 mediates the acute-phase reaction through hepatic induction. Interleukin-8 is a powerful chemoattractant. Granulocyte and macrophage- granulocyte colony-stimulating factors (G- and GM-CSF) increase phagocyte numbers.

Heat-shock proteins (HSP)

Heat-shock proteins are a family of highly conserved proteins which act as immunodominant antigens in many infections. They are molecular chaperones, housekeeping proteins within cells, preserving the cell's protein structure. They are similar in configuration to antigens found on certain microorganisms and may induce autoimmunity through molecular mimicry.

HSPs are also released and may act on cells to modulate function by inducing cytokines, adhesion molecules and maturation signals.

Pattern recognition receptors (PRRs) (Fig. 4.3) The innate immune response is essential for host survival as it is immediately active. It is not antigen specific but can detect tissue damage and discriminate foreign molecules from 'self (sometimes called 'danger-stranger' recognition). Phagocytic cells (macrophages, dendritic and B cells - antigen-presenting cells) bear pattern-recognition receptors with lectin-like activity which recognize *pathogen-associated molecular patterns* (PAMPs) present on microbes but not host cells. PRRs include:

- Mannan-binding lectin, which initiates complement activity inducing *opsonization* (p. 201).
- *Endocytic pattern recognition receptors,* which act by enhancing antigen presentation on macrophages, by recognizing microorganisms with mannose-rich carbo hydrates on their surface or by binding to bacterial cell walls and scavenging bacteria from the circulation. All lead to *phagocytosis.*

m *Signalling receptors* that initiate nuclear factor kappa B induction (e.g. toll-like receptors) and immune response genes leading to *cell activation.* These may have some specificity, e.g. TLR4 binds Gram-negative bacterial endotoxin and TLR2 binds Gram-positive bacterial lipoteichoic acid. TLR3 and TLR9 detect nucleic acid. TLR5 recognizes a protein on bacterial flagella. Innate immunity critically depends on toll-like receptor signalling. These receptors act through a critical adaptor molecule, myeloid differentiation factor 88 (MyD88), to regulate the activity of NFκB pathways and the expression of many of the cytokines necessary to mount an innate defence response.

- *TREM-1* (triggering receptor expressed on myeloid cells), a member of the aminoglobulin superfamily, is a cell surface receptor which, when bound to its ligand, triggers secretion of proinflammatory cytokines. It is upregulated by bacterial lipopolysaccharides (e.g. pseudomonas), but not in non-infective disorders. It is a mechanism that links bacteria on the outside of the cell membrane with gene transcription of cytokines in the cell nucleus.

Nuclear factor kappa B (NFκB)

NFκB is a pivotal transcription factor in chronic inflammatory diseases. It is a heterodimer of two proteins (p. 157) and is found in the cytoplasm bound to an inhibitor (IκB), which prevents it from entering the nucleus. It is released from IκB on stimulation of the cell and passes

Table 4.5 **Origins and biological functions of cytokines (including chemokines)**

gCytokine	Source	Mode of action
Haemopoietins		
IL-1	Macrophages/monocytes	Immune activation: induces an inflammatory response
IL-2	Primarily Th1 cells	Activates T (and NK) cells and supports their growth
IL-3	T cells	Primarily promotes growth of haemopoietic cells
IL-4	Th2 cells	Lymphocyte growth factor; involved in IgE responses
IL-5	Th2 cells	Promotes growth of B cells and acute phase response
IL-6	Th2 cells and macrophages	eosinophils Promotes B-cell growth and antibody production
IL-7	Stromal cells	Lymphocyte growth factor, important in the growth of
IL-10	CD4 cells, activated monocytes	immature cells Inhibits the production of IFN-y, IL-1, IL-6, TNF-a and
IL-11	Macrophage	antigen presentation Maintains epithelial integrity of gastrointestinal tract and
IL-12	Monocytes/macrophages	megakaryocyte differentiation Augments Th1 responses and induces IFN-y Stimulates B cells
IL-13	Activated T cells	Similar action to IL-2 Promotes growth of
IL-15	Many tissues, not T cells	myeloid cells Promotes growth of macrophages
G-CSF	Primarily monocytes	Promotes growth of monomyelocytic cells
M-CSF	Primarily monocytes	
GM-CSF	Primarily T cells	
Interferons		Immune activation and modulation (following viral infection)
IFN-a	Leucocytes	Immune activation and modulation (following viral infection)
IFN-p	Fibroblasts	Immune activation and modulation (inhibits Th2 cells,
IFN-v	Th1 and NK cells	activates macrophages)
Tumour necrosis factors		
TNF-a	Macrophages, NK, T, B and mast cells	Stimulates generalized immune activation as well as tumour necrosis; formerly known as cachectin
TNF-p	T and B cells, macrophages, mast cells Platelets	Stimulates immune activation and generalized vascular effects; also known as lymphotoxin
TGF-P		Immunoinhibitory but stimulates tumorigenesis, angiogenesis and fibrosis
Chemokines* *'CC chemokines'*		
MCP1-MCPS	Monocytes, macrophages, fibroblasts, keratinocytes Macrophages	Attracts monocytes and memory T cells to inflammatory sites Attracts monocytes
MIP-1a	Monocytes, macrophages, endothelial	and T cells Attracts monocytes and $CD8^+$
MIP-1P	cells, T and B cells Macrophages, activated leucocytes,	T cells
Eotaxin	endothelial cells Platelets and T cells	Attracts eosinophils, basophils Attracts
RANTES		monocytes, T cells, eosinophils
'CXC chemokines'	Macrophages	
IL-8	Macrophages	Attracts neutrophils, naive T cells
CINC	Kupffer cells	Attracts neutrophils Attracts
MIP2	Epithelial cells, Kupffer cells	neutrophils Activates neutrophils
ENA78	Macrophages, hepatocytes,	Unknown
GROa	endothelial cells Hepatocytes, endothelium Monocytes/macrophages,	Unknown
IP10 MIG	hepatocytes	Attracts lymphocytes

* Refers to a double cysteine amino acid structure (-CC-) within the cytokine; in some cases this is interspersed with another amino acid (-CXC-)
CINC, cytokine-induced neutrophil chemoattractant; ENA78, epithelial neutrophil activating protein 78; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GROa, growth-related oncogene; IFN, interferon; IL, interleukin; IP10, interferon-gamma-inducible protein 10; MCP, monocyte chemoattractant protein; M-CSF, monocyte colony-stimulating factor; MIG, monokine induced by interferon gamma; MIR macrophage inflammatory protein; MIP2, macrophage inflammatory protein; RANTES, regulated on activation, normal T-cell expressed and secreted; TGF, transforming growth factor; TNF, tumour necrosis factor

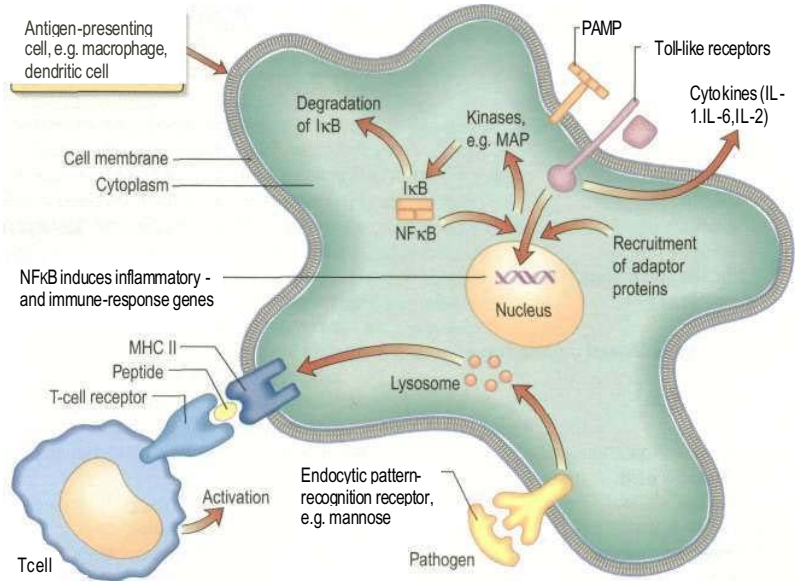

Fig. 4.3 **Pattern recognition receptors in the innate and adaptive immune systems.** The innate immune system has pattern-recognition receptors, e.g. toll-like receptors, which recognize microbial products by their pathogen-associated molecular pattern (PAMP). This leads to activation of kinases (e.g. mitogen-activated protein - MAP), which in turn leads to degradation of inhibitory κB (IκB) and release of NFκB. NFκB induces inflammatory and immune-response genes in the nucleus and is activated by the recognition of PAMP. An antigen-presenting cell, e.g. macrophage, dendritic cell, has endocytic pattern-recognition receptors (e.g. macrophage mannose receptor) through which it binds to and phagocytoses pathogens. These are processed by lysosomes to produce peptides which form a complex with the major histocompatibiiity complex (MHC) on the surface. These are recognized by T-cell receptors leading to activation of this cell. NF, nuclear factor.

into the nucleus where it binds to specific sequences in the promoter regions of target genes. It is stimulated by, for example, cytokines, protein C activators and viruses, and itself regulates various proteins (e.g. pro-inflammatory cytokines, chemokines, adhesion molecules, inflammatory enzymes and receptors).

The importance of regulation of the inflammatory response is demonstrated in sepsis when overwhelming activation, by for example, endotoxin, leads to induction of a 'cytokine storm' with organ failure, shock and death as a result. Proteosome inhibitors are being developed which inhibit the degradation of ubiquinated proteins including the cell cycle regulating proteins like cyclins and cyclin-dependent kinases. For example, bortezomib, a proteosome inhibitor (p. 518) inhibits activation of NFκB.

Dysregulated chronic inflammation is also associated with clinical disease, in particular an increased risk of cardiovascular complication in conditions with chronically elevated CRP such as rheumatoid arthritis. The inflam matory process is thought to contribute to the atheromatous lesions.

ADAPTIVE (SPECIFIC OR ACQUIRED) IMMUNITY

Specific or 'adaptive' immunity is the hallmark of the immune system of higher animals. Innate immunity is a rapid non-specific response whereas adaptive immunity gives a targetted attack against, for example, a pathogen. The characteristic of this response is the use of antigen-specific receptors on T lymphocytes (T-cell receptor, TCR) and B lymphocytes (surface and secreted antibody) to direct the response. Specificity is achieved by an unusual mechanism involving multiple rearrangements of original (germline) DNA in T and B lymphocytes. The altered DNA codes for proteins with hypervariable regions and creates the specific antigen-binding T-cell receptor and antibody sites. This diversity allows the production, for example, of over 10^8 different antibodies and 10^7 distinct TCRs, enough to cover the spectrum of pathogenic antigens encountered by man. T and B cells do not recognize exactly the same part of any antigen. T-cell receptors recognize peptide fragments, whereas antibody identifies the shape of epitopes. This increases the ability of the immune system to recognize a wider range of antigens and provides back-up for each system. The response takes time to develop so that although specific immunity has the benefit of being very focused it cannot provide immediate protection on first meeting an antigen. However, another characteristic is the development of memory so that subsequent exposure leads to a more rapid response. The role of T and B lymphocytes in specific immunity is shown in Figure 4.4.

T and B cell immunity extends the ability to combat infection and tumours. Phagocytes only recognize extra-

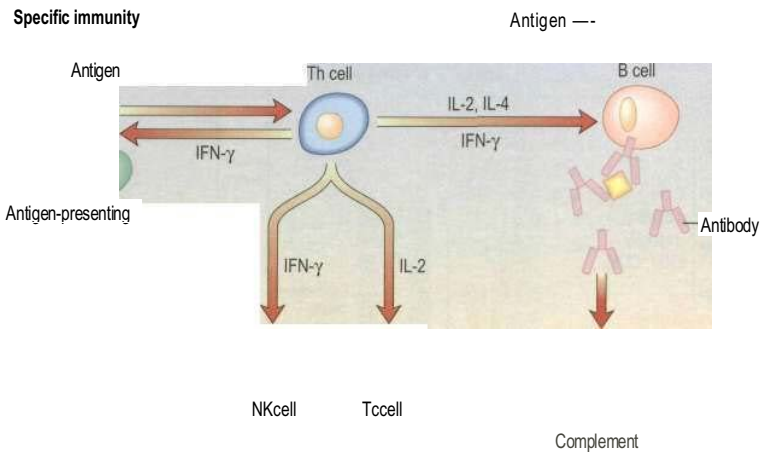

Fig. 4.4 Components of the **immune response.** Antigen is presented to T-helper cells (Th cells) by an antigen-presenting cell. Th cells secrete lymphokines, which activate cytotoxic T cells (Tc cells) that are involved in antiviral and anti-tumour activity. The lymphokines also activate NK cells, which are involved in tumour surveillance. B cells are activated when the antigen binds to the surface immunoglobulins in the presence of cytokines. This leads to secretion of antibodies. Antibody and complement coat the antigen (opsonize), leading to phagocytosis by phagocytes via binding to the complement receptor and Fc receptor (FcR). NK, natural killer cell.

cellular organisms, mostly bacteria. In contrast, T cells are able to combat intracellular infections, such as viruses, as well as the organisms that parasitize macrophages such as facultative intracellular bacteria (mycobacteria, legionella, listeria, brucella, salmonella), many fungi and protozoa. Such intracellular infections are controlled by two separate T-cell mechanisms.

- *Cytotoxic T cells* recognize tiny fragments of foreign antigen (virus or tumour antigen) that are expressed on the surface of affected cells and are able to destroy the cell and pathogen within it. Cytotoxic cells usually bear CD8.
- *Helper T cells* are unable to destroy pathogens or cells directly, but through cytokine production are able to activate macrophages to kill organisms within them and further activate cytotoxic T cells and NK cells. Helper T-cells are usually CD4 positive.

Antibody enhances the innate response by opsonizing foreign particles, neutralizing viruses and toxins, and plays a part in antigen presentation.

ORGANIZATION OF THE LYMPHOID SYSTEM

Most lymphocyte maturation and activation occurs within the lymphoid tissue/organs located throughout the body. Populations of lymphoid cells of different types originate from pluripotent stem cells in the bone marrow (Fig. 4.5). Immature B lymphocytes remain in the bone marrow to mature. Lymphoid precursors destined to be T cells move to the thymus for maturation. These are termed the primary lymphoid tissues. Once cells have matured, they are released into the circulation and populate secondary lymphoid tissue such as lymph nodes, tonsils and spleen where they are ready to respond to foreign antigens.

Mucosa-associated lymphoid tissue (MALT)

Lymphoid tissue is frequently found in mucosal surfaces in non-encapsulated patches. This is termed mucosa-associated lymphoid tissue (MALT), consisting of genito-urinary and gut-associated lymphoid tissue (GALT, mainly Peyer's patches), bronchus-associated lymphoid tissue (BALT, found in the lobes of the lungs along the main bronchi) and skin-associated lymphoid tissue (SALT).

B cells

These cells comprise approximately 25% of lymphocytes. In response to antigen binding to the B-cell receptor (BCR) and usually with T-cell help, B cells divide and are activated to become plasma cells which secrete large amounts of antibody (Fig. 4.5).

Antibody molecules (immunoglobulins)

Antibodies are glycoproteins. They consist of two heavy chains and two light chains (either κ or *X* polypeptides) (Fig. 4.6). The heavy chain determines the antibody *isotype* or class, i.e. IgG, A, M, D or E. The major regions of immunoglobulin are as follows:

Variable 'V domains have variation in the amino acid sequence between immunoglobulins, with short segments of hypervariable regions. Antigen binding occurs in the area where the loops bearing the hypervariable regions of the light and heavy chains come together, called the *Fab (fragment antigen binding)* region. The shape of the binding site determines the 'goodness of fit' or affinity/avidity of any particular antibody for an antigen.

Idiotypes are markers found in the hypervariable region and are associated with the antigen-binding site. The idiotype is antigenic, and idiotypes and anti-idiotypes are

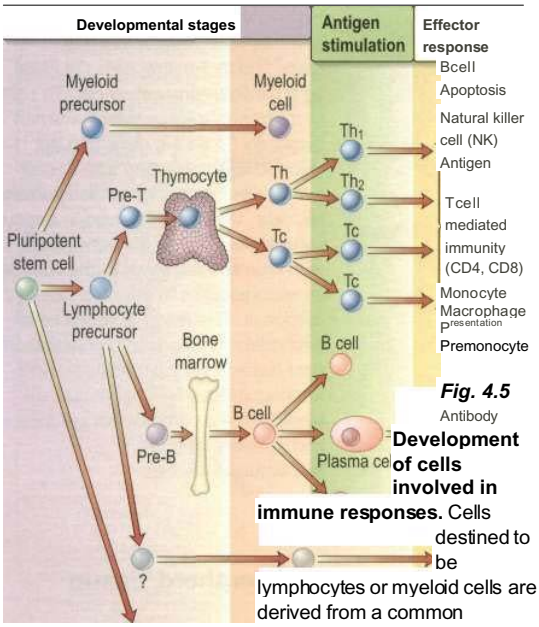

Fig. 4.5 **Development of cells involved in immune responses.** Cells destined to be lymphocytes or myeloid cells are derived from a common pluripotent stem cell in the bone marrow.

Immature T cells leave the bone marrow to enter the thymus as thymocytes. Gene rearrangement takes place to form the antigen-specific T-cell receptor; positive and negative selection occur to ensure that functional cells that are non-autoreactive survive and differentiate to $CD4^+$ or $CD8^+$ cells. These antigen-naive T cells leave the thymus to populate peripheral lymphoid tissue. On encountering their specific antigen, proliferation and activation occur, having either helper ($CD4^+$ cell) or cytotoxic ($CD8^+$ cell) function.

B cells undergo development to maturity within the bone marrow, including gene rearrangement for production of antigen-specific antibody molecules. The mature cells are released and populate the follicles of lymph nodes. On meeting their specific antigen, B cells proliferate and differentiate to antibody-secreting plasma cells. **Cells of the myeloid lineage** develop within the marrow under the influence of colony-stimulating factors to become monocytes, neutrophils, eosinophils and basophils (Fig. 8.1).

thought to make a network regulating the production of antibody.

The Fc (fragment crystalline) region is formed from the constant domains in which the amino acid sequences are relatively conserved. This is the part that binds to cell-surface immunoglobulin receptors (FcR) or causes complement fixation; hence it controls the effects of the antibody molecule after it has bound its antigen.

Genetics of antibody production

Rearrangement of **the germline DNA occurs within**

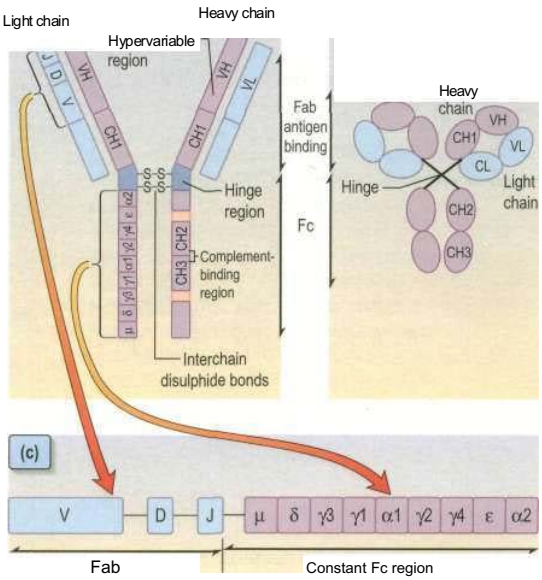

Fig. 4.6 **Immunoglobulin structure, (a) Basic subunit** consisting of two heavy and two light chains, **(b) Schematic diagram of the same molecule.** C and V, constant and variable domains; H and L, heavy and light chains; Fab, fragment antigen binding; Fc fragment crystalline, **(c) Genes on the Fab and Fc regions of an immunoglobulin.** The chain is made up of a V (variable) gene which is translocated to the J (joining) chain. The VJ segment is then spliced to the C (constant) gene. Heavy chains have an additional D (diversity) segment which forms the VDJ segment that bears the antigen-binding site determinants.

immature B cells in the bone marrow, leading to production of antibodies with many different antigen-binding sites or *clonal diversity* (Fig. 4.6). There are three main areas of the gene called the variable (V), diversity (D) and joining (J) regions which need to be spliced together to form the final sequence from which protein will be transcribed to form the antibody molecule. It is during this splicing that much of the variability occurs. Firstly, there is a multiplicity of all these regions within the DNA (V = 25-100 genes, D = 10 genes and J = 5-6 genes). Any one of the multiple genes within a region can join any other (called *combinational freedom)* to form the final VDJ sequence. Secondly, splicing of the genes together is frequently inaccurate and 'frame-shift' in base-pairs leads to misreading and production of the 'wrong' amino acid (junctional diversity). Thirdly, somatic mutation in the genes may occur during cell division.

Once the VDJ region is spliced it combines successively to the IgM, IgD, IgG, IgA, and IgE constant genes to cause progressive switching in the isotype of the antibody. However, as the Fab gene is not further altered the same antigen-binding region is maintained. Thus, a mature but naive B cell that has rearranged its VDJ gene will initially make an IgM response on antigen stimulation, as this is the first to be translocated. The primary

immune response is therefore of the IgM isotype with IgG and other isotype responses developing later and usually requiring additional T-cell help (T-independent responses are restricted to polysaccharide antigens and usually do not progress from the IgM isotype). However, once the 'switch' from IgM to another isotype has occurred, memory B cells remain in the body for many years. These react rapidly to any re-challenge with the same antigen, and the characteristic IgG production of the secondary or late primary response occurs. Knowledge of the timing of primary and secondary antibody responses is used in the serological diagnosis of infections, the presence of IgM suggesting acute infection.

Immunoglobulin isotypes and their functions

The main biological features of the human antibodies are summarized in Table 4.6. Different classes of antibody tend to predominate at different sites. The major functions of antibody are:

- elimination of infective organisms by:
  - binding to prevent adhesion and invasion of organisms (e.g. preventing the entry of poliovirus and other enteroviruses)
  - opsonization of particles for phagocytosis
  - lysis (in combination with complement)
- antitoxin activity (e.g. in prevention of tetanus)
- sensitization of cells for antibody-dependent cell cytotoxicity (ADCC)
- immune regulation, acting as the antigen receptor on B cells and presenting the antigen to helper T cells.

IgM

The antibody is confined mainly to the intravascular pool. It is a large pentameric molecule, bound together by the joining 'J' chain. It does not cross the placenta, and is not normally produced in the child until after birth. Therefore, if present in the newborn infant, antigen-specific IgM is a good marker for intrauterine infection. It is usually a sign of acute infections.

IgG

This is the most abundant immunoglobulin in serum, present as a monomer. IgG is the antibody of secondary response, and has high antigen affinity. It is the only antibody to cross the placenta in significant quantities. There are four subclasses: IgG!, IgG_2, IgG_3 and IgG_4. IgG] and IgG_3 are produced mainly in response to protein antigens, such as viruses. These subclasses are good opsonins, binding *Fc* receptors on neutrophils and activating complement. IgG_2 and IgG_4 are produced in response to polysaccharide antigen (e.g. the capsule of bacteria such as pneumococcus and *Haemophilus influenzae)* and are the major opsonins for such organisms. IgG antibody is involved in resistance to infection, as patients who are lacking in IgG suffer with recurrent, even life-threatening bacterial infections. Those with isolated IgA or IgM deficiency have much less severe problems.

IgA

This is mainly the antibody of secretions, being present in the respiratory, gastrointestinal and urinary tracts. There are two subclasses, IgAj and IgA_2; their functions appear to be similar. IgA is mainly monomeric in the serum, but dimeric in secretions, the two molecules being complexed

Table 4.6 Characteristics of the immunoglobulins

	IgG Dominant class of antibody	IgM Produced first in immune response	IgA Found in mucous membrane secretions	Responsible for symptoms of allergy; used in defence against nematode parasites	igD Found almost solely on lymphocyte membrane
Heavy chain	Y	H	a	e	8
Mean adult serum levels (mg/mL):	IgG (total) = 8-16 G, = 6.5 G_2 = 2.5 G_3 = 0.7 G_4 = 0.3	0.5-2	IgA (total) = 1.4-4 A, = 1.5 A_2 = 0.2	17-450 ng/mL	0-0.4
Half-life (days)	21	10	6	2	3
Complement fixation Classical Alternative	++	+++	+	-	-
Binding to mast cells	-	-	-	+	-
Crosses placenta	+	-	-	-	-

by a joining (J) chain. The mechanism for transport from serum to intestinal mucosal surface is well established. IgA in serum binds to a poly-Fc receptor for IgA and IgM on the basal surface of enterocytes and hepatocytes. Transcellular transport delivers the immunoglobulin to the luminal surface where it is secreted still bound to the receptor, which is termed the *secretory component* (SC). For IgA responses, localized antigen exposure gives rise to generalized mucosal immunity, which is of importance in vaccination. This is because after encountering antigen, IgA precursor B cells in the mucosal lymphoid follicles journey to regional lymph nodes. After clonal expansion the cells return to the systemic circulation via the thoracic duct and circulate to settle widely in the mucosa-associated lymphoid tissue (MALT; see p. 205), not just the area where antigen exposure occurred.

igD

Serum levels are very low and its function at this site is uncertain. IgD is present on the surface of B lymphocytes, and may have an immunoregulatory role. Levels are high in conditions with B-cell activation such as systemic lupus erythematosus (SLE), HIV infection and Hodgkin's disease.

IgE is a monomer that is normally present in very low levels in serum, as most is membrane-bound to the high-affinity receptors on mast cells and basophils. Its main physiological role is its antinematode activity, but its most common clinical relevance is in the pathogenesis of type 1 hypersensitivity (atopic or allergic) disease.

T lymphocytes

T cells are classified into CD4 (mainly cytokine-secreting helper cells, making up about 75% of peripheral blood T cells) and CD8 (mainly cytotoxic suppressor cells, which account for the remainder). These cell types are indistinguishable morphologically, but can be separated by the presence of cell-surface molecules detected by monoclonal antibodies detecting cluster of differentiation or CD molecules.

Cytotoxic/suppressor cells

The cytotoxic/suppresser lymphocyte can be recognized by the presence of the $CD8^+$ cell surface molecule and its ability to recognize antigen only when presented with MHC class I molecules. Cytotoxic T cells kill other cells, either by inserting perforins into target cell membranes, producing pores through which granzyme is inserted and causing the action of granule-associated osmotic lysis of the cell (similar to the membrane attack complex of complement) or via activation of caspases to induce apoptosis (programmed cell death, p. 162) in the target. This kind of response is used in controlling viral infections and possibly malignancies. The suppressor cell down-regulates immune responses. It may function by releasing soluble factors which act on B lymphocytes to reduce their output of antibodies. CD8 cells can also mount a non-cytotoxic antiviral response (NCAR) that blocks viral replication through the secretion of CD8 antiviral factor (CAF); this has been demonstrated in HIV infection.

Helper/inducer cells

T-helper cells can be distinguished by the presence of the CD4 protein on their surface and the ability to recognize antigen only when expressed with MHC class II on antigen-presenting cells. Whereas the cytotoxic response is a simple recognition system for foreign invasion, the CD4-cell system is more elaborate, involving a limited number of cells to produce an even more specific series of reactions. T-helper cells are viewed as orchestrating the immune response. They cannot directly destroy their target, but recognize specific foreign antigen and proceed to activate other parts of the system which can eradicate it (Fig. 4.7).

T-helper cells have been categorized into two major functional subpopulations based on their pattern of cytokine production. A single clone of T cells can differentiate to either type, depending on antigen route, dose, the cytokine environment in which the response occurs and hereditary tendency. The *T-helper 1 (Thl)* class produces IL-2, IL-3 and gamma-interferon. These cytokines will promote immune responses that are primarily cell-mediated/inflammatory by activating cytotoxic T cells, NK cells and macrophages. Cells in the *T-helper 2 (Thl)* category produce cytokines that favour induction of antibody responses by B cells, i.e. IL-4, IL-5, IL-6, IL-10, and are thought to be involved in the development of allergic disease.

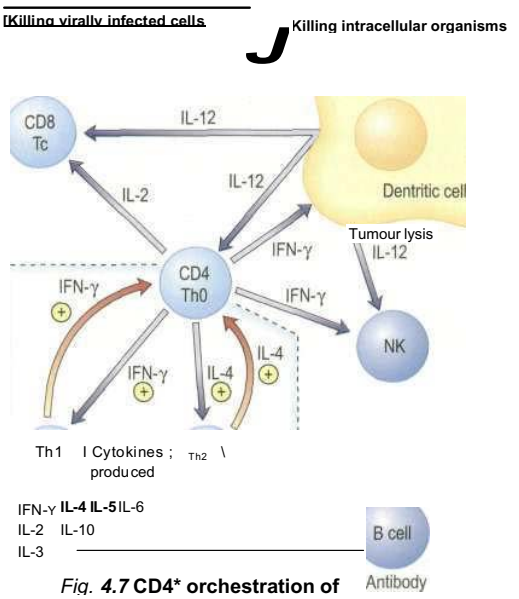

Fig. 4.7 **CD4* orchestration of the immune response.**
CD4 T helper cells (ThO) differentiate into either Th1 or Th2. The type of cell produced depends on the cytokine environment. The presence of IFN-y leads to production of Th1 cells; IL-4 leads to Th2 predominance. Stimulation of B cells leads to antibody production and NK cells to tumour lysis.

Cluster of differentiation (CD) classification

The CD nomenclature classifies over 300 molecules both within and outside the immune system, using monoclonal antibodies. As the surface molecule has many different epitopes (antibody-binding sites), several different antibodies may react (a cluster). As initially most of the surface molecules defined the stage of development of the cell, they were termed 'differentiation' molecules. The term CD therefore refers to a specific target molecule on a cell that is recognized by one or more antibodies and defines a particular cell type or function. A list of CD molecules that are commonly mentioned is given in Table 4.7.

Antigen recognition - the T-cell receptor complex

Antigen recognition by T cells is accomplished by a mechanism similar to that employed by immunoglobulin. Essentially, a limited set of gene segments can recombine to encode a highly diverse set of receptor specificities; however, unlike B cells, the receptor is not released. The T-cell receptor (TCR) is on the surface of all thymus-derived lymphocytes. It comprises two transmembrane glycoprotein chains, termed a and (3 (af5 cells) (although analogous structures named y and 5 (y8 cells) can be found on some immature T cells). The a(3 cells play a role in adaptive immune responses, whereas the y5 cells are

Table 4.7 Major CD antigens and their cellular distribution*

Cluster designation	Tissue distribution	Function
CD1	Cortical thymocytes	All T cells and NK cells
CD2	Found on all mature T cells	Intimately associated with the T cell receptor
CD3		
CD4	T-helper/inducer lymphocytes comprise {2/3} circulating T cells	
CD5		
CD8	T cells; also B cells	
	Cytotoxic/suppressor T cells	
CD11a	Lymphocytes (especially memory T cells), granulocytes, monocytes and macrophages	
CD14	Macrophages	
CD15 (also known as Lewis X)	Granulocytes	
CD16	Natural killer cells and macrophag<	
CD18	Leucocytes	
CD19	All mature B cells	
CD20	All mature B cells	
CD21	Mature B cells, follicular dendritic cells, pharyngeal and cervical epithelial cells	
CD23	B cells, macrophages, eosinophils	
CD25	T, B cells, macrophages	
CD28	Activated T cells and some B cells	
CD34	Precursors of haemopoietic cells	
CD36	Monocytes, platelets	
CD40	B cells	
CD44	Leucocytes, RBCs, endothelium	
CD45	All cells of a haemopoietic origin; also called leucocyte common antigen	
CD56	NK cell marker	
CD62	Endothelial cells, leucocytes and platelets (E-, L-, P-selectin)	
CD72	All mature B cells	
CD80/86	Antigen-presenting cells	
CD95(FasAg, APO-1)	Multiple cells	
CD103	Intraepithelial lymphocytes	

Ligand for CD58; pair (e.g. between T cell and antigen-presenting cell) Signal transduction following antigen presentation

Interacts with class II MHC molecules associated with processed antigen fragments Ligand for CD72

Interacts with class I MHC molecules associated with processed antigen fragments

Part of adhesion molecule LFA-1

Receptor for bacterial lipopolysaccharide

Ligand for selectins

CD16 is a low-affinity Fc receptor involved in signal transduction

Common p-chain of LFA family (beta integrins)

Signal transduction

Involved in cell activation; may be a calcium channel

Complement C3d receptor

Low-affinity receptor for IgE

IL-2 receptor

Activation of naive T cells

Unknown

GPIIIb

B-cell activation, induced by T-cell interaction

Cell adhesion and migration, removal of apoptotic neutrophils by macrophages

Two isoforms, RO and RA. RO is associated with memory. Functions by cell signalling through the T-cell receptor; RA identifies naive cell

Mediates cell adhesion

Adhesion

Ligand for CD5; involved in signalling

Costimulatory ligands for CD28

Induction of programmed cell death

Binds to E-cadherin

This list is far from exhaustive and has been confined to CD types most commonly encountered in a clinical immunology setting

involved in epithelial defence (see p. 302). As with antibody, the polypetide chains have both a variable (V) and a constant region (C) of amino acid residues. In the (B chain the variable region is encoded by V-, D- and J-like elements. The a chain is made up of V- and J-like elements (Fig. 4.6). The polypeptide chains of the receptor are linked by disulphide bridges. The molecule is arranged on the T-cell membrane as a complex with another structure known as CD3. This association is necessary for the antigen receptor to be expressed at the cell surface. The receptor also has a transmembrane tail. When an antigenic peptide is received by the receptor, either in association with MHC class 1 for cytotoxic T cell activation or MHC class II for T-helper cell activation, a signal, manifesting as a series of enzyme phosphorylation reactions, is transmitted to the nucleus and the cell then responds accordingly by becoming activated, releasing cytokines and/or proliferating.

Antigen presentation

The term antigen means any structure that can be recognized by the specific immune response and is not restricted to microbial pathogens and toxins but includes antigens from foreign tissues (i.e. following organ transplantation) and certain tumour-associated structures. The immune system has the ability to discriminate between 'self and 'non-self antigens. This process is facilitated by a recognition system called the *major histocompatibility complex* (MHC) which dictates the way antigen is processed and recognized as foreign. In man, the products of MHC are termed human leucocyte antigens (HLA).

HUMAN LEUCOCYTE ANTIGENS
(Fig. 4.8)

The HLA cluster of genes is located on the short arm of chromosome 6. The system comprises six genetic loci - HLA-A, -B, -C, -D, -DR and -DQ. Each locus may be one of many polymorphic forms or alleles, which number over 40 in the case of HLA-B. The combination or segregation of the A, B, C, D, DR and DQ alleles in any one individual is called the haplotype. A list of the main HLA antigens is presented in Table 4.8. The HLA molecules are distributed throughout the body tissues and it is through differences in HLA that cells are classified as self or non-self. The possibility of two different individuals having the same combination of HLA molecules is very remote. Although it is this that enables the immune system to recognize foreign cells and molecules, it is also the aspect of the immune system that presents problems for organ transplantation. Unless the HLA types of the donor and the recipient are virtually identical, the organ graft will be recognized as non-self and rejected by the immune system of the host. Thus donors and recipients have to be tissue typed to find the best-matched organ or bone marrow. Some diseases show a close association with HLA type.

Genetic linkage

The genes at a given locus are inherited as co-dominants, so that each individual expresses both alleles, one from the mother and the other from the father. Because of the close linkage between the loci, all the genes in the MHC tend to be inherited together. 'Crossing over' can occur within the HLA region. However, certain alleles occur more frequently in the same haplotype than expected by chance and this is known as 'linkage disequilibrium'; for example, the haplotype Al B8 occurs more frequently than would be expected from the individual gene frequencies of Al or B8. There is a wide inter-racial variation in HLA antigens.

Products of the HLA genes

The HLA genes code for cell-surface glycoproteins that extend from the plasma membrane to the cytoplasm and are known as class I and class II molecules. These

DR7	Minimal change disease (nephrotic)
MHC class III	C4A associated with SLE

GBM, glomerular basement membrane

glycoproteins consist of two chains of unequal size (a and P chains). The chains form a groove in which an antigenie peptide sits ready for presentation to T cells.

Class I molecules

Class I (HLA-A, -B and -C) antigens are expressed on all cell types except erythrocytes and trophoblasts. Striated muscle cells and liver parenchymal cells are normally negative but become strongly positive in inflammatory reactions. Class I molecules interact with CD8 T cells during antigen presentation and therefore are involved in driving mainly cytotoxic reactions.

Class II molecules

Class II antigens (HLA-D and -DR, D-related) are constitutively expressed only on professional antigen-presenting cells (B cells, monocytes/macrophages, Langerhans' cells, dendritic cells) and activated T cells. Other cells do not normally express this antigen but may be induced to do so in the presence of gamma-interferon at sites of inflammation and can then become antigen-presenting cells. Class II antigens link with CD4 molecules during antigen presentation and the reaction induced by cells bearing this molecule is therefore of the helper type.

Regulation of antigen-specific responses

Activation of antigen-specific cells is closely regulated. This is essential as the receptors on T cells are very sensitive and a cell can be activated by interaction with a very few molecules of the relevant antigen, leading to the potential for inappropriate and excessive responses. The antigen-presentation system ensures that only antigens that have invaded far enough to be within cells, or those which are recognized and engulfed by antigen-presenting cells, are presented to T lymphocytes.

Antigen presentation to T cells (Fig. 4.9)

For T-cell activation to occur, several interactions between the antigen and the T-cell receptor have to take place. Firstly, the antigen must be presented to the T cell as a peptide fragment within the groove of the MHC molecules on the antigen-presenting cell. This is necessary as the TCR only recognizes the combined shape of the foreign antigen together with self-MHC. Free antigen will have no effect. The combination of T-cell receptor, MHC molecule and antigen fragment is known as the *trimolecular complex.* The antigen gains access to the MHC molecule during intracellular processing in which the peptide enters the MHC cleft during the assembly of this molecule. The whole molecule is then expressed on the surface of the cell. $CD8^+$ cells recognize antigen with class I MHC. As this molecule is present on nearly all nucleated cells, most cells can present to cytotoxic cells. Antigen expressed with class I is endogenous, i.e. the molecules are produced from within the cell, such as viral proteins and tumour antigens. CD4 cells are more limited as they can only be stimulated by cells that bear MHC class II. Such cells are mainly cells of the immune system that have the specific function of antigen presentation, sometimes termed *accessory cells.* These cells take up exogenous antigen by endocytosis and degrade it intracellularly. The processed antigen is then re-expressed on the cell surface with class II.

As there are differences in the three-dimensional shape of the MHC molecules owing to genetic variation, some antigens may be more effective than others in inducing immune responses, because they present an optimum shape or conformation to the T cells. Immune responses that only occur with certain antigen-MHC combinations are called MHC restricted. The host MHC reacts with either CD4 (MHC class II) (Fig. 4.10) or CD8 accessory molecules (MHC class I) on the T cell. These interactions stabilize the TCR/ MHC/ antigen reaction and act as costimulatory molecules to further activate the T cell through intracellular signalling cascades.

The interaction of another molecule, B7 on antigen-presenting cells with its ligand CD28 on T cells is also a

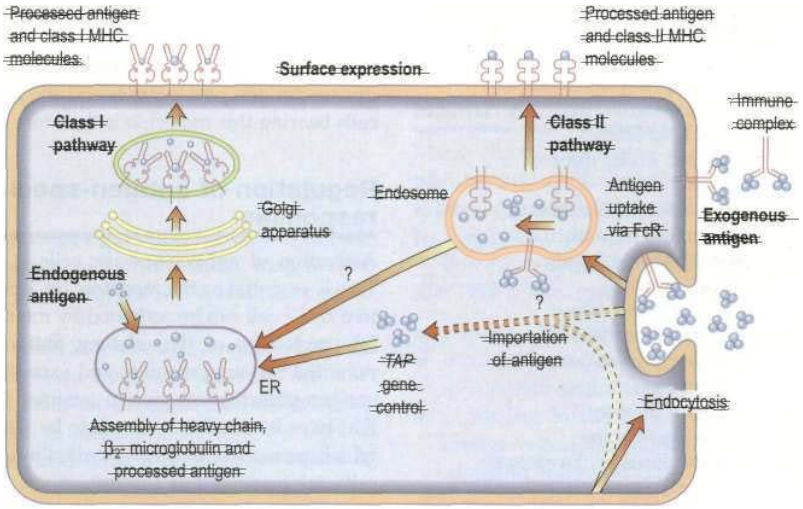

Fig. 4.9 **Antigen presentation.** Antigen processing is different for endogenous antigens compared to exogenous antigens which have to be taken up by antigen-presenting cells prior to processing. **Endogenous antigen** peptide fragments are transported into the endopiasmic reticulum, where they are picked up in the peptide-binding groove of MHC class I molecules. The antigen-bearing MHC molecules are then expressed on the surface of the cell. All nucleated cells produce class I molecules. **Exogenous antigen** is internalized by specialized antigen-presenting cells. Acidification occurs within the endosome, causing breakdown of the protein to peptide fragments. MHC class II molecules made within the endopiasmic reticulum are transported to the endosome via the Golgi apparatus. The peptides bind to the class II molecules, which are then expressed on the cell surface. The restriction of MHC class II molecule expression to antigen-presenting cells means that only a few cells can perform this process. ER, endopiasmic reticulum. Modified from a figure in *Immunology Today* 14, Raychaudhuri S, Morrow WJW pp. 344-348. © 1993, with permission from Elsevier.

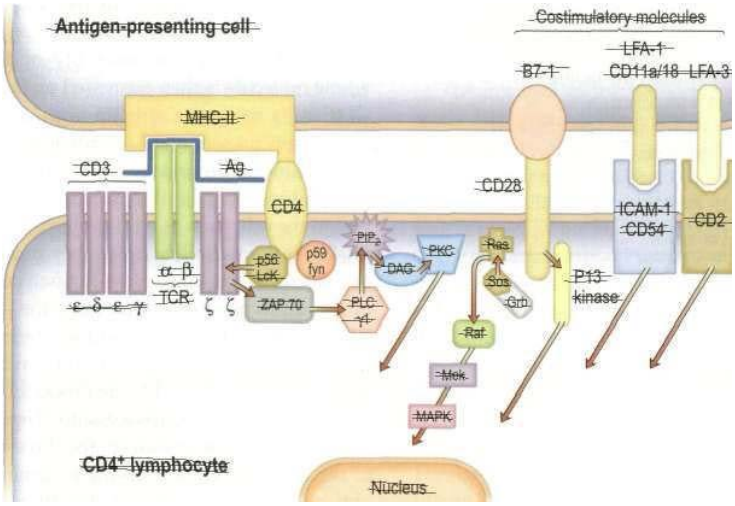

Fig. 4.10 **Activation of T cells.** This figure shows the complex interaction of the antigen-presenting cell with the $CD4^+$ T lymphoctye. Cross-linking of the T-cell receptor (TCR) causes aggregation with the CD3 complex containing e, 5 and γ chains together with the three dimers. This leads to activation of phosphorylation and differentiation. If the costimulatory molecules are not activated at the same time, a different sequence of signals is activated, leading to cell death and apoptosis. major costimulating interaction. Cytokines produced during the reaction by the antigen-presenting cell (interleukins-1 and -12) and the early activation steps of the T cells (interleukin-2) enhance the reaction by decreasing the threshold for T-cell activation.

Antigen-presenting cells

The main antigen-presenting cells are macrophages (which are widely distributed throughout the tissues), Langerhans' cells (found in skin) and dendritic or veiled cells (found in the mucosa, lymph and blood). These cells (p. 200) are of the same lineage. Follicular dendritic cells are of a different lineage and are located in the germinal centres of lymph nodes (follicles). They are surrounded by B lymphocytes to which they present antigen, usually complexed with antibody, on the surface of their dendrites. Their surfaces are rich in Fc and C3b receptors to facilitate antigen trapping. B cells are also class II positive and trap antigen in immune complexes through their Fc receptors. They are able to present to T cells.

Antibody-dependent cytotoxic cells (ADCC)

These are populations of lymphocytes that are not characterized by their surface molecules, but by function. ADCC are NK cells that bear Fc receptors on their surface, and recognize target cells coated with immunoglobulin. They may have a role in eradicating virus-infected and tumour cells.

Lymphokine-activated killer (LAK) cells

Incubation of lymphocytes with interleukin-2 (IL-2) causes them to become highly cytotoxic (hence 'lymphokine activated') particularly to tumour cells. These artificially stimulated cells have been used in the treatment of malignancies, where patients' blood lymphocytes have been harvested, cultured with IL-2 and then re-infused to target tumours.

THE IMMUNE SYSTEM IN CONCERT

The immune system is not fixed, but dynamic. Cells traffic to different sites within the body via blood and lymphatic vessels, using adhesion molecules and chemokines/chemoattractants. Following an antigenic stimulus, the components of the immune system cooperate to meet and eliminate the challenge. The cells return to lymphoid tissue, bringing antigen to these specialized processing and presenting sites. Activated lymphocytes proliferate and leave the lymphoid tissue as armed effector cells to return to the site of infection. The immune system communicates intimately with, and is regulated by the neuroendocrine axis. Corticosteroids inhibit T-cell responses by reducing IL-2 and other pro-inflammatory cytokine production. Reduction in adhesion molecule expression by steroids also affects neutrophil function. Neuropeptides such as prolactin, which antagonizes corticosteroids and activates T cells, B cells and macrophages, are produced by both the pituitary and peripheral blood mononuclear cells. Another cytokine, macrophage inhibitory factor (MIF), which was thought to be exclusively a product of the immune system, has also been found to be produced by the pituitary. Substance P, produced by sensory nerves on stimulation, binds to receptors on endothelial cells and lymphocytes and induces an inflammatory reaction.

Therefore, infection, tumour, autoimmune disease, pain or other stress, may induce immune reaction and a change in hypothalamic-pituitary-adrenal hormone production which prepares the body to repair tissues and regulates the inflammatory response.

IMMUNODEFICIENCY - CONGENITAL AND ACQUIRED

General principles

While many specific congenital immunodeficiencies are relatively rare, HIV infection and the widespread use of corticosteroid and immunosuppressive therapies mean that immunosuppression is a major aspect of clinical practice in many fields. Prompt recognition, appropriate management and referral of patients with suspected immunodeficiency are vital. Furthermore, the occurrence of infections in the context of specific immune defects can illuminate the physiological role of those parts of immune defence in the normal control of infection.

The main categories of immunodeficiency, by host mechanism, are:

- reduced neutrophil (and monocyte/macrophage) numbers and/or function
- deficiencies of individual complement components
- B cell defects, causing antibody deficiency
- T cell defects, impairing cell-mediated immunity
- combined T and B cell defects.

Congenital immunodeficiencies (Table 4.9)

These are usually due to specific genetic defects, leading to abnormalities in defined molecular and cellular mechanisms; most are rare. They usually present in childhood, but some types and the less severe forms may not become apparent until adult life. Abnormalities can be restricted to the immune system, but in others the immune defects are part of a wider range of congenital defects.

Acquired immunodeficiencies (Table 4.9)

These are much more common, but often less-precisely defined in terms of immunological mechanisms. They can result from malnutrition, splenectomy, some infections and autoimmune disorders, tumours of the immune system, immunosuppressive therapy or drug side-effects (Table 4.9). The most common infective cause is HIV infection,

Table 4.9 Congenital and acquired immunodeficiencies

Congenital	Acquired
Phagocytes	
Congenital neutropenia	Neutropenia due to myelosuppression
Cyclical neutropenia	Hypersplenism
Leucocyte adhesion defects	Autoimmune neutropenia
Hyper-IgE syndrome	Corticosteroid therapy
Shwachman's syndrome	Diabetes mellitus

Combined T and B cell immunodeficiencies	
Severe combined immunodeficiency: X-linked severe combined Protein-calorie malnutrition immunodeficiency syndrome Adenosine deaminase deficiency Purine nucleoside phosphorylase deficiency Non-expression of MHC class II Reticular dysgenesis Wiskott-Aldrich syndrome Ataxia telangiectasia EBV-associated immunodeficiency Hyper-IgM syndrome	Immunodeficiency of prematurity AIDS

which leads to the acquired immunodeficiency syndrome (AIDS); this is covered in some detail (see p. 129).

Opportunist infections

Infection is the result of microbial virulence on the one hand and weakness of host defence on the other. Pathogenic organisms have mechanisms of evading normal defence mechanisms. Organisms of low virulence can only cause disease if the host defence mechanisms that normally control them are defective. Organisms taking advantage of the opportunity of impaired host defence mechanisms are called *opportunists*. Different host defence defects cause increased susceptibility to different groups of organisms. Therefore, recognizing a pattern of infections can provide the best clinical clue to the type of underlying defence defect.

Patterns of opportunist infection

Examples of opportunist organisms in the setting of non-immunological innate defence defects include: staphylococci and *Pseudomonas* in burns patients; *Haemophilus influenzae* and pneumococci in smokers; *Pseudomonas* in cystic fibrosis patients; Gram-negative infections where there is urinary obstruction; staphylococcal and candidal infections with indwelling venous catheters and other foreign bodies; *Candida* and pathogenic *Escherichia coli* following elimination of gut flora after antibiotic therapy.

Table 4.10 shows the main infecting organisms for the principal classes of immunodeficiency. In broad terms, the following principles apply:

- *Neutrophil defects*. Extracellular infections mainly consist of bacterial diseases (e.g. staphylococci, Gram-negative organisms) and systemic fungal infections. These organisms are able to survive and replicate in the extracellular environment. The main defence against such infections is through neutrophil phagocytosis and intracellular killing, which is enhanced

Table 4.10 Immune defects and some opportunist organisms

Neutropenia and defective neutrophil function
Staphylococcus aureus *Staphylococcus epidermidis* *Escherichia coli* *Klebsiella pneumoniae* *Proteus mirabilis* *Pseudomonas aeruginosa* *Serratia marcescens* *Bacteroides* spp. *Aspergillus fumigatus* *Candida* spp. (systemic) *Mucor* spp.

Opsonin defects (antibody/complement deficiency, splenectomy)
Pneumococcus
Haemophilus influenzae
Meningococcus
Streptococcus spp. (capsulated)

Antibody deficiency only
Campylobacter spp.
Mycoplasma spp.
Ureaplasma spp.
Echovirus

Lytic complement pathway defects (C5-9)
Meningococcus Gonococcus (disseminated)

Cell-mediated immunodeficiency
Listeria monocytogenes *Legionella pneumophila* *Salmonella* spp. (non-typhi) *Nocardia asteroides* *Mycobacterium tuberculosis* Atypical mycobacteria, especially *M. avium-intracellulare*
Candida spp. (mucocutaneous) *Cryptococcus neoformans* *Histoplasma capsulatum* *Pneumocystis carinii* *Toxoplasma gondii* Herpes simplex Herpes zoster Cytomegalovirus Epstein-Barr virus Measles virus Papovaviruses

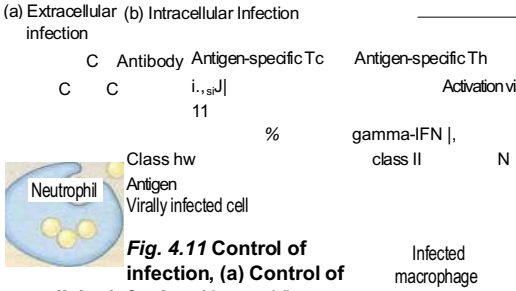

***Fig. 4.11* Control of infection, (a) Control of extracellular infection.** Neutrophils phagocytose and kill antibody- and complement (C')-coated antigens, e.g. bacteria, **(b) Control of intracellular infection by two immune mechanisms.** Intracellular viral proteins are complexed with MHC class I molecules and expressed on the surface of the virally infected cell. Antigen-specific $CD8^+$ cytotoxic T cells (Tc) lyse the infected cells. Infected macrophages activate specific $CD4^+$ helper T cells (Th) that produce gamma-interferon (IFN) which activates macrophages to kill the intracellular infection.

100-fold by coating (opsonization) of organisms by complement and antibody to specific receptors on the neutrophil surface (Fig. 4.11a). Failure of neutrophils to eradicate these extracellular organisms leads to infection.

Opsonic defects due to antibody deficiencies or defects of the main complement pathways, and splenectomy lead to infection with capsulated organisms. These cannot be eliminated by neutrophils alone, as the capsule prevents phagocytosis unless opsonized by either antibody or complement.

Defects of the lytic pathway of complement cause susceptibility to disseminated infections with Gram-negative cocci (mainly *Neisseria,* meningococcal meningitis).

Cell-mediated immune defects. Neutrophils, antibody and complement react with the surface of the organism and therefore cannot detect intracellular infections. These are mainly due to viruses which require the intracellular environment for their replication, as well as fungi and protozoa which often parasitize macrophages. Some bacteria, especially mycobacteria, are facultative intracellular parasites that can also live within macrophages. The immune system has two mechanisms to eradicate such pathogens (Fig. 4.11b). Virally infected cells produce endogenous viral proteins that are complexed with MHC class I molecules and expressed on the cell surface. These are recognized by antigen-specific $CD8^+$ cytotoxic T cells, which lyse the infected cell. Organisms within macrophages are killed through a different mechanism. This involves activation of specific $CD4^+$ helper T cells that produce gamma-interferon locally. This activates the macrophages to kill the intracellular infections. The different mechanisms of control explain why patients with neutrophil, complement or antibody deficiency tend to have bacterial infections, whereas those with T-cell defects have viral, fungal and protozoal disease.

PHAGOCYTE DEFECTS

Neutropenia

Congenital neutropenias are rare and, if severe, are often fatal at an early age. Most, however, are relatively mild and benign and may even be incidental findings. They generally reflect defects of maturation and release of neutrophils from bone marrow. A particular and typically benign variant is *cyclical neutropenia,* with cycles of 3-5 weeks.

Acquired neutropenias are due to myelosuppression by disease, such as the leukaemias, or due to drug therapy. Myelosuppressive drugs used in the treatment of tumours, for prevention or treatment of transplant rejection, and in severe autoimmune disease are common causes. A number of other drugs, such as some antiviral drugs (e.g. zidovudine, ganciclovir) are myelosuppressive and can cause neutropenia; agranulocytosis can also be an idiosyncratic side-effect (e.g. chloramphenicol). Neutropenia due to an increased rate of destruction of neutrophils is seen in hypersplenism and in autoimmune neutropenia.

The risk of infection rises steeply once the neutrophil count falls below 0.5×10^9/L, regardless of cause. The risk is less if the monocyte count is preserved, as these cells can serve as a back-up phagocyte population. (In cyclical neutropenia, monocytes usually have cycles of opposite phase, which is probably why serious infections are uncommon.) Infections are typically disseminated, with septicaemia, fungaemia and deep abscess formation. Colonization of the gut with pathogens can readily lead to septicaemia. Local infections often affect the mouth, perianal area and sites of skin damage, including indwelling vascular catheters, and these can readily lead to systemic infection. Pus, which largely comprises neutrophils, may be scanty and may appear serous.

If myelosuppressive agents are being used, the dose should be reduced, or the drug stopped. The duration of neutropenia can be reduced by the use of G-CSF or GM-CSF, which appear to reduce infective episodes. Antibiotic or antifungal prophylaxis may be valuable. Otherwise, prompt antimicrobial therapy for febrile episodes during neutropenia is essential, using agents with broad cover for the common organisms encountered (see p. 30).

Defects of neutrophil function

Defects of neutrophil function (some of which also affect monocyte/macrophage function) interfere with migration into the tissues through vascular endothelium, locomotion in tissues, phagocytosis or intracellular killing.

Clinical features

Mucocutaneous sepsis in the mouth and perianal areas is common and local infections often lead to chronic abscess formation in the tissues or draining lymph nodes. Granulomas may be seen, because of failure of neutrophils to degrade microbes effectively. Systemic spread is less common than with neutropenia. Congenital causes may

first present with infection or delayed separation of the umbilical stump.

Congenital

Leucocyte adhesion defect

This is an autosomal recessive disorder caused by abnormal synthesis of the P-chain CD18 that is shared by the CDUa, b and c molecules to form leucocyte function antigen (LFA) LFA-1, the C3bi (inactivated C3b) receptor and the C3dg receptor (pl50/95). There is impaired leucocyte tissue localization, locomotion and endocytosis. Bone marrow transplantation has been successful in a few cases.

Hyper-IgE syndrome

The syndrome is characterized by very high levels of IgE (much of it anti-staphylococcal), impaired neutrophil locomotion and severe eczema, with frequent staphylococcal secondary infections and abscesses. Other immune defects may be seen, causing a wider spectrum of pyogenic and fungal infections.

Shwachman's syndrome

This may resemble cystic fibrosis clinically, with exocrine pancreatic insufficiency and pyogenic infections, in which mild neutropenia is associated with a defect of neutrophil migration.

Chronic granulomatous disease (CGD)

This is the prototype congenital defect of neutrophil (and monocyte) killing.

Pathogenesis

In this disorder, the oxidative pathway of microbial killing is severely impaired, either owing to a defective cytochrome b558 (X-linked CGD) or components of the associated NADPH oxidase (autosomal recessive CGD). Production of superoxide is abnormal, this being the first of a cascade of microbicidal oxygen radicals, including hydrogen peroxide, hypohalites, hydroxyl radicals and singlet oxygen. Impaired production of oxygen radicals can also affect the efficiency of non-oxidative killing.

Clinical features

Patients have chronic suppurative granulomas or abscesses affecting skin, lymph nodes and sometimes lung and liver, as well as osteomyelitis. They may present during early or late childhood years, depending on the severity of the defect. Most of the typical infections associated with neutrophil defects can be seen, particularly those that produce catalase, which inactivates any endogenous microbial peroxide that can kill organisms inside the phagocytic vacuole. Because macrophages are also affected, cell-mediated opportunist infections may also be seen, such as atypical mycobacteria, *Nocardia* and salmonellae.

Diagnosis

Diagnosis is made with the nitroblue tetrazolium (NBT) test, which uses a coloured dye reaction to assay the oxidative pathway; it can also be used to screen carriers.

Treatment

Infections respond to appropriate antimicrobial therapy and surgical measures as needed; in some patients prophylaxis may be merited. Regular gamma-interferon can reduce the frequency of infections, probably through enhanced monocyte/macrophage killing.

Chediak-Higashi syndrome

This autosomal recessive disorder is characterized by giant granules in myeloid cells and large granular lymphocytes. Abnormal microbial killing, and hence recurrent infections, are due to defective phagolysosome fusion; NK cell activity is similarly impaired. Similar fusion abnormalities in melanocytes cause partial oculocutaneous albinism.

A wide variety of other rare disorders can impair microbial killing, including other inborn errors in microbicidal mechanisms, such as leucocyte G6PD deficiency (much less common than that affecting red cells) and myeloperoxidase deficiency. Storage diseases, such as Gaucher's and glycogen storage diseases, can impair phagocyte function.

Acquired

The commonest of these is corticosteroid therapy, which also affects T cell-macrophage cooperation, causing cell-mediated immunodeficiency. The main effect of corticosteroids on neutrophils is to impair leucocyte-endothelial adhesion. This reduces the marginated pool of leucocytes and impairs their attachment to endothelium at the site of tissue injury or infection. Corticosteroids thus prevent neutrophils reaching the tissues. The corollary of reduced margination is a rise in the neutrophil count; this can be deceptive if its significance is not appreciated.

The effect of corticosteroid therapy on neutrophil function is reflected by increased focal and systemic infections with staphylococci and Gram-negative bacteria. The effect is usually apparent above doses of 15 or 20 mg prednisolone daily or equivalent, and can be substantially reduced (as can other side-effects) by alternate-day therapy.

An infective cause of acquired neutrophil dysfunction is influenza, which causes a specific transient impairment of phagosome-lysosome fusion. This is the main reason for the high risk of staphylococcal pneumonia in influenza epidemics.

Myeloid leukaemias can cause defective neutrophil function, as well as causing neutropenia. Neutrophil and macrophage function can also be impaired in abnormal metabolic states, such as uncontrolled diabetes mellitus and hypophosphataemia. The latter may be seen during intravenous feeding of critically ill patients. Inhibitors of endogenous chemotactic factors for neutrophils may be seen in Hodgkin's disease and alcoholic cirrhosis, and may be responsible for their increased pyogenic infections.

COMPLEMENT DEFICIENCIES

There are two major patterns of infection **associated with** complement deficiencies:

- *Deficiencies ofC3, Clq or of factors Horl* cause increased susceptibility to capsulated bacteria. These patients may also develop immune complex disorders and SLE-like disorders, as do patients with deficiencies of other classical pathway components of complement.
- *Deficiencies of the lytic complement pathway, C5-9,* cause susceptibility to disseminated neisserial infections, meningococcaemia and gonococcaemia; the latter has also been seen in association with disorders of comp lement function.

These complement deficiencies are rare, but functional defects of complement deposition on microbial surfaces are common. These are responsible for increased infections with *Haemophilus* and pneumococcal infections, especially in the early childhood years before a sufficiently wide specific antibody repertoire is acquired.

A common and well-defined opsonization defect is caused by *mannan-binding lectin (MBL)* deficiency. MBL is a member of the *collectin* family, which is in the serum in the form of multimers of the basic 32 kDa peptide. It activates the classical complement Cl complex in the absence of other activating factors. Mutations in codons 52, 54 or 57 prevent the formation of the multimers, leading to intracellular degradation or defective function. The defect is present in up to 5% of Caucasian populations, but appears to be associated with recurrent viral and pyogenic infections in children.

The C3 depletion caused by C3nef, an autoantibody that stabilizes the alternative pathway convertase and is seen in association with partial lipodystrophy, may also increase the risk of pyogenic infection.

Cl esterase inhibitor deficiency (see p. 1335) is not associated with infection but with hereditary angio-oedema, with episodes of localized oedema in skin of limbs or face, and the mucosa of the larynx or gut; the latter can cause life-threatening respiratory obstruction or severe episodes of abdominal pain.

ANTIBODY DEFICIENCIES

Congenital

X-linked hypogammaglobulinaemia

There is a profound reduction in all immunoglobulin classes; B cells and plasma cells are reduced. The defect is in the differentiation of pre-B cells into B cells; T cells are normal. The specific gene defect has now been shown to be in the *btk* gene for a tyrosine kinase signal transducing molecule involved in the maturation of B cells; the gene is at a position Xq 21.2-22 on the long arm of the X chromosome. It typically presents with infections, e.g. meningitis, mycoplasmal infections, after the first 3-6 months of life, when the protection from passively transferred maternal antibody has largely been lost. Immunoglobulin replacement therapy is very successful and is now generally given intravenously. Many patients treat themselves at home.

Common variable immunodeficiency (CVI)

This is a late-onset antibody deficiency, which may present in childhood or adult life. IgG levels are especially low. B-cell numbers are usually normal; the defect appears to result from failure of their further differentiation. Some tests of T-cell function may be abnormal but few clinical manifestations of T-cell immunodeficiency are documented. CVI is probably a heterogeneous group of disorders in its cellular and molecular origins, reflecting defective interactions between T and B cells, with arrested maturation of B cells.

The patients have similar infections to those with the X-linked variety. However, a particular feature is follicular hyperplasia of lymph nodes, which in the gut takes the form of nodular lymphoid hyperplasia, and there may be splenomegaly. CVI patients may develop autoimmune disease and there is also an increased risk of lymphoreticular malignancy. The finding of reduced immunoglobulin levels and normal B-cell numbers indicates the diagnosis. Most of the manifestations are satisfactorily prevented by regular immunoglobulin replacement therapy.

IgA deficiency

This is an extremely common disorder (affecting 1 in 600 of the UK population) but is often symptomless. Only a small proportion have an increased risk of pyogenic infection and many of these have another defect, such as IgG_2 subclass deficiency. Some have allergic disorders or gluten hypersensitivity, and autoimmune disorders may also occur.

Other rare deficiencies

Isolated lgG$_2$ subclass deficiency. This is a rare cause of increased infection with capsulated organisms, for which it is the main immunoglobulin subclass; intravenous immunoglobulin replacement provides effective restoration.

Hypogammaglobulinaemia with raised IgM. **There is** a defect in isotype switching; the genetic basis has been shown to be due to the mutations in the gene for CD40 ligand, which is at Xq26 on the long arm of the X chromosome. **Patients** have recurrent bacterial infections and are susceptible to *Pneumocystis carinii* pneumonia.

Functional dysgammaglobullnaemia. Patients have increased bacterial infections with apparently normal levels of immunoglobulin but fail to produce specific antibodies to certain organisms.

Acquired

Hypogammdglobulinaemia is **seen in the** immune paresis of patients with myeloma and chronic lymphocytic leukaemia or lymphoma. Infection with capsulated bacteria may be seen, especially with myeloma. Splenectomy

causes impairment of defence against capsulated bacteria, especially pneumococcus, partly because T-independent antibody responses are largely made in the spleen and partly because of its role as part of the fixed reticuloendothelial system. Hyposplenism associated with severe sickle cell disease is responsible for the increased risk of infection in such patients. Pneumococcal, meningococcal and Hib vaccination (see p. 42) before elective splenectomy and the use of penicillin prophylaxis can largely eliminate risk of serious infection. Hypogammaglobulinaemia can occur in congenital rubella.

T-CELL IMMUNODEFICIENCIES

Congenital

DiGeorge anomaly (22q11 deletion syndrome)

This defect occurs in 1 in 4000 live births. It is a defect of branchial arch development leading to abnormal thymic growth. It is of varying clinical severity and is associated with other branchial arch defects: dysmorphic facies, hypoparathyroidism and cardiac defects. Patients present with infections including mucocutaneous candidiasis and *Pneumocystis carinii* pneumonia, together with chronic diarrhoea due to a variety of pathogens. The absent thymus can be documented radiologically. CD3 T cells are variably reduced in number, but the CD4 subset is usually reduced and T-cell proliferative responses are impaired. Immunoglobulin production is typically normal. Thymic transplants and thymic hormone have been reported to have reconstituted some patients with severe disease, and bone marrow transplants have also had some success. The defect for this condition has been found on chromosome 22.

Other causes of cellular immunodeficiency

Various other rare congenital defects have been reported that predominantly affect T-cell responses, including:

- isolated CD4 lymphopenia
- IL-2/IL-2-receptor deficiency
- defects in signal transduction via the T-cell receptor (e.g. *Zap-70* deficiency, p. 506).
- IFN-y or IFN-y-receptor deficiency

Acquired

Acquired immunodeficiency syndrome (AIDS)

By far the most common immunodeficiency worldwide is that due to infection with the human immunodeficiency virus (HIV), the cause of AIDS. Although the most profound deficiency is in CD4 T-cells, B cells are also affected to give a mixed pattern.

Pathogenesis

The primary cellular receptor for HIV is the CD4 molecule, which defines the cells that are susceptible and includes the following cells within the immune system:

1 $CD4^+$ T lymphocytes (which are most affected)
2 monocytes
3 macrophages and other antigen-presenting cells:
   - dendritic cells in the blood
   - Langerhans' cells of the skin
   - follicular dendritic cells of the lymph nodes (the site where much of the early replication of HIV takes place).

Table 4.11 Mechanisms of CD4 loss/dysfunction in HIV infection

Direct cytopathic effects of HIV
Lysis of infected cells by HIV-specific cytotoxic T cells
Tc-mediated lysis of uninfected $CD4^+$ T cells that have bound gp120 to the CD4 molecule Immunosuppressive effects of soluble HIV proteins on uninfected cells, e.g. gp120 envelope protein leading to decreased proliferation Molecular mimicry between gp1207160 and MHC class I inducing autoimmune destruction Signal transduction defects and induction of programmed cell death (apoptosis) by unknown mechanisms

Binding of the HIV envelope glycoprotein gpl20 to CD4 causes the virus to adhere to the cell. A second receptor is required for fusion with the cell membrane and release of the virus into the cell. The second receptor is CXCR4 in lymphocytes and CCR5 in cells of the monocyte/macrophage lineage; these normally function as chemokine receptors.

A number of pathogenic mechanisms have been described to account for the profound cellular immunodeficiency of HIV infection (Table 4.11) leading to progressive clinical changes (see Fig. 2.46).

Immunological abnormalities

The central and most characteristic is the progressive and severe depletion of $CD4^+$ 'helper' lymphocytes. As described earlier, these cells orchestrate the immune response, responding to antigen presented to them via antigen-presenting cells in the context of class II MHC. They proliferate and release cytokines, particularly IL-2. This leads to proliferation of other reactive T-cell clones, including cytotoxic T cells, (which eradicate viral infections), gamma-interferon (which activates NK cells to cytotoxicity) and macrophages (microbicidal activity against intracellular pathogens). Loss of this single cell type can therefore explain nearly all the immunological abnormalities of AIDS, as other cells' functions are so dependent on it. In addition other cells are also affected, if not infected, by HIV. Antigen-presenting cells are directly and productively infected; B cells are polyclonally activated by the soluble envelope proteins of HIV released into plasma.

The effects of highly effective antiretroviral therapy (HAART) on immune function in HIV infection

Antiretroviral therapy, using combinations of drugs against the reverse transcriptase and protease enzymes, has proved effective in controlling HIV replication. On

these regimens, many patients show a marked improvement in CD4 cell numbers within a matter of 4-8 weeks, mainly due to redistribution of lymphocytes from the tissues and proliferation of pre-existing memory T-cells. Functional improvement with regeneration of T cells showing the naive phenotype, and antigen-specific responses (immune reconstitution) takes about 6 months to be established and continues to improve slowly thereafter. Immune reconstitution disorders due to intensive lymphocyte reactions may occur. For the presentation and management of HIV infection and AIDS, see p. 132.

Measles

Measles can cause a transient T-cell immunodeficiency, but it is rarely long-lasting enough for severe clinical problems to ensue.

Immunosuppressive therapy

Immunosuppressive therapy with cytotoxic agents such as cyclophosphamide and azathioprine tends to cause predominant T-cell immunosuppression. Ciclosporin and tacrolimus are potent immunosuppressive agents, which interfere with T-cell activation mechanisms at an intracellular level. Surprisingly, they are associated with only modest increases in infection, unless combined with corticosteroids or other agents. In such combinations, increased risk of Epstein-Barr virus (EBV)-associated lymphoma has been reported. Antilymphocyte immunoglobulin or monoclonal anti-CD3 antibody therapy also suppresses T-cell responses transiently. TNF-oc inhibitors have good activity in controlling inflammatory conditions such as rheumatoid arthritis, inflammatory bowel disease and vasculitides. However, their use is associated with increased mycobacterial and other infections.

Corticosteroid therapy

This interferes with cell-mediated immunity, in particular T cell-macrophage cooperation. This is due to effects on T-cell traffic and impairment of macrophage responses to cytokines, together with impaired antigen presentation. Mucocutaneous candidiasis, *Pneumocystis carinii* pneumonia, cytomegalovirus infection, mycobacterial infection, *Nocardia,* non-typhi *Salmonella* septicaemia and cryptococcosis are some of the very many infections seen with prolonged high-dose steroid therapy.

COMBINED T AND B IMMUNODEFICIENCIES

The most severe immunodeficiencies are those that affect both B- and T-cell responses. These can stem from a variety of defective mechanisms in lymphocyte function, but tend to have rather similar clinical features, combining the opportunist infections of cell-mediated immunodeficiency with those of antibody deficiency.

Congenital

Severe combined immunodeficiency (SCID)

This typically presents in the first weeks of life. Failure to thrive, absent lymphoid tissue, lymphopenia and hypogammaglobulinaemia with multiple severe infections are characteristic.

There are primary X-linked and autosomal recessive variants of SCID. The X-linked defect has been mapped to Xql3 which leads to mutations in the gamma chain common to the IL-2, IL-4, IL-7, IL-11 and IL-15 receptors, leading to failure to respond to these growth factors in T and B cells. There is complete absence of CD3 and NK cells. Other causes include adenosine deaminase (ADA) deficiency, in which a defective purine salvage enzyme that is expressed in all cells, has a particular effect on lymphocytes because of the accumulation of substrates and metabolites that interfere with lymphocyte function. An analogous disorder is seen in purine nucleoside phosphorylase deficiency. Non-expression of MHC class II, owing to a variety of defects in class II transactivating proteins, and reticular dysgenesis cause similar syndromes. Milder expressions of these defects exist, some presenting in later life, and are sometimes termed *benign combined immunodeficiency* or *Nezelof's syndrome.*

Even with supportive and antimicrobial therapy, most of these conditions have a very poor prognosis without reconstitutive therapy. Immunoglobulin therapy is effective for the antibody deficiency, but the cell-mediated opportunists are the main determinant of outcome. Bone marrow transplantation is the definitive approach and has had significant success, especially if undertaken before extensive infection has set in. Recent approaches have included attempts to restore the defective enzymes in ADA deficiency, and gene therapy has had some success.

Hyper-IgM syndrome

This is usually an X-linked, but occasionally autosomal recessive, condition associated with mutation in the CD40L (ligand) gene. There is failure to switch from IgM to the other classes of antibody, leading to normal or high levels of IgM, and very low IgG and IgA. There is also a marked defect in T-cell function. Opportunistic infection (mainly due to this defect) occur with *Pneumocystis carinii, Cryptosporidium* (including sclerosing cholangitis), herpes virus infection and candidiasis or cryptococcosis.

Wiskott-Aldrich syndrome

This is an X-linked defect (at Xpll-23) with associated eczema and thrombocytopenia; a mainly cell-mediated defect with falling immunoglobulins is seen, and autoimmune manifestations and lymphoreticular malignancy may develop.

Ataxia telangiectasia

These patients have defective DNA repair mechanisms and have cell-mediated defects with low IgA and IgG_2; lymphoid malignancy is again common.

EBV-associated immunodeficiency (Duncan's syndrome)

Apparently normal, but genetically predisposed (usually X-linked) individuals develop overwhelming EBV infection, polyclonal EBV-driven lymphoproliferation, com-

bined immunodeficiency, aplastic anaemia and lymphoid malignancy. EBV appears to act as a trigger for the expression of a hitherto silent immunodeficiency.

Acquired

Protein-calorie malnutrition

This is a very common cause of acquired combined immunodeficiency, with predominantly cell-mediated defects. Mechanisms are not fully established. Measles is a major cause of morbidity and mortality among children. *Pneumocystis carinii* is also a major pathogen, causing pneumonia, and this was first recognized in the Warsaw ghetto.

The immunodeficiency of prematurity

An immune response is not essential for normal fetal development and growth, but is necessary for survival after birth. Premature infants of 26 weeks' gestation and under are now surviving and have several immunological deficiencies and problems:

- *Antibody deficiency.* IgM synthesis does not occur before 30 weeks' gestation and IgG production occurs several weeks after birth. Active placental transfer of maternal antibody does not occur until the third trimester and therefore babies born before 28 weeks have hypogammaglobulinaemia, with antibody levels continuing to drop further after birth owing to loss of maternal IgG.
- *Neutropenia and impaired chemotaxis.*
- *Disruption of host defence barriers:*
  - insertion of foreign bodies, such as indwelling catheters and ventilator tubes
  - antibiotic therapy, which reduces resistance.

HYPERSENSITMITY DISEASES

Allergy or hypersensitivity was initially defined by Von Pirquet in 1906 as: 'Specifically changed reactivity of an host to an agent on a second or subsequent occasion'. This definition would apply to all specific immune responses, and allergy is now taken to mean a damaging reaction. Hypersensitivity reactions underlie a number of autoimmune and allergic conditions. The immunological classification of these reactions is shown in Table 4.12. This scheme devised by Gell and Coombs is useful to group conditions with a similar underlying pathogenesis.

"ALLERGIC DISEASE (TYPE I REACTION OR IMMEDIATE HYPERSENSITIVITY REACTIONS)

The type I reaction is an allergic response produced within 5-10 minutes of exposure to a specific allergen. Type I reactivity is mediated by IgE, although later in the reaction other mechanisms of inflammation including infiltration with eosinophils and lymphocytes may contribute. Allergens (antigens that evoke allergic responses), e.g. house-dust mite, pollens, animal danders or moulds, only elicit significant IgE reactions in genetically predisposed individuals, who are said to be *atopic.* Atopic diseases include, extrinsic asthma, some forms of eczema, allergic rhinitis/ conjunctivitis, food allergies, anaphylaxis and angio-oedema. The diagnosis is made by a typical clinical history and examination in conjunction with either skin-prick testing (when a type I wheal and flare reaction is elicited by pricking the skin through a solution of the test antigens) or by measuring specific IgE in the serum.

Susceptibility to atopic disease

In all cases of true allergic disease the individual must have been previously sensitized to the allergen. There is an inherited component, because if one parent is atopic the child has a 25^10% chance of also being atopic; if both parents are affected the risk rises to 50-75%. This is compared to a background incidence in the developed world of approximately 30% (this figure is continually rising). There is also an association with HLA-A1, B8, Dw3 and HLA-A3, Dw2, although no specific 'allergy gene' has been identified. However, not all individuals who make IgE antibody to environmental allergens suffer with atopic disease; other factors play a part:

Age. Exposure in the first few years of life is more likely to induce atopic disease. In addition, childhood atopic disease tends to improve with age.

Intercurrent infections. Viral infections may induce atopic disease, potentially by damaging the respiratory mucosa and allowing greater allergen penetration and sensitization.

Non-specific irritants. Pollutants such as diesel emission particles (DEPs) and cigarette smoke increase bronchial reactivity and may also damage the mucosa.

Immunodeficiency. Patients with underlying immunodeficiency are more susceptible to atopic disease. This may be due to greater allergen exposure after damage to the respiratory or gut mucosa by infection or due to decreased T cell regulation of IgE production.

Mechanisms of allergic disease

High-affinity FceRI on mast cells tightly bind locally produced allergen-specific IgE. On subsequent allergen exposure, cross-linkage of the surface IgE molecules causes *degmnulation* of the mast cell and release of preformed (granule-derived) and newly formed (membrane-derived) mediators. These initiate the allergic response through increasing vascular permeability (causing swelling of the tissue), inducing chemotaxis of neutrophils and eosinophils and later lymphocytes (inflammation) and increasing airways hyperactivity (bronchoconstriction) (Box 4.1).

Arachidonic acid metabolites

Arachidonic acid is generated in sensitized cells from membrane lipids following the binding of specific allergen.

Table 4.12 **Hypersensitivity reactions**

	I (immediate)	II (cytotoxic)	III (immune complex)	IV (delayed)	V (stimulating/ blocking)*
Antigens	Pollens, moulds, mites, drugs, food and parasites	Cell surface or tissue bound	Exogenous (viruses, bacteria, fungi, parasites) Autoantigens	Cell/tissue bound	Cell surface receptors
Mediators	IgE and mast cells	IgG, IgM and complement and lymphokines	IgG, IgM, IgA and complement	Td, Tc, activated macrophages	IgG
Diagnostic tests	Skin-prick tests: wheal and flare Specific IgE in serum	Coombs' test Indirect immunofluorescence (antibodies) Red cell agglutination Precipitating antibodies ELISA	Immune complexes	Skin test: erythema induration (e.g. tuberculin test)	Indirect immuno-fluorescence
Time taken for reaction to develop	5-10 min	6-36 hours	4-12 hours	48-72 hours	Variable
Immuno-pathology	Oedema, vasodilatation, mast cell degranulation, eosinophils	Antibody-mediated damage to target cells	Acute inflammatory reaction, neutrophils, vasculitis	Perivascular inflammation, mononuclear cells, fibrin Granulomas Caseation and necrosis in TB	Hypertrophy or normal
Diseases and conditions produced	Asthma (extrinsic) Urticaria/oedema Allergic rhinitis Anaphylaxis Food allergies	Autoimmune haemolytic anaemia Transfusion reactions Haemolytic disease of newborn Goodpasture's syndrome Addisonian pernicious anaemia Myasthenia gravis	Autoimmune (e.g. SLE, glomerulonephritis, rheumatoid arthritis) Low-grade persistent infections (e.g. viral hepatitis) Disease caused by environmental antigens (e.g. farmer's lung)	Pulmonary TB Contact dermatitis Graft-versus-host disease Insect bites Leprosy	Neonatal hyperthyroidism Graves' disease Myasthenia gravis
Treatment	Antigen avoidance Antihistamines Corticosteroids (usually topical) Leukotriene receptor antagonists Sodium cromoglicate Epinephrine (adrenaline) for life-threatening anaphylaxis	Exchange transfusion Plasmapheresis Immunosuppressives/ cytotoxics	Corticosteroids Immunosuppressives/ cytotoxics Plasmapheresis Anti TNF antibody Anti B cell antibody Anti CTLA-4 antibody	Immunosuppressives Corticosteroids Removal of antigen	Treatment of individual disease

"Type V hypersensitivity may also be classified with type II reactions

RAST, radioallergosorbent test; SLE, systemic lupus erythematosus; TB, tuberculosis; Tc, T cytotoxic; Td, T delayed hypersensitivity

Box 4.1 **Mediators involved in the allergic response**

Preformed mediators

Histamine and serotonin:
- Bronchoconstriction
- Increased vascular permeability

Neutrophil and eosinophil chemotactic factors (NCF and ECF):
- Induce inflammatory cell infiltration.

Newly formed mediators (membrane-derived)

Leukotriene (LT) B4:
- Chemoattractant

LTC4, -D4, -E4 (slow-reacting substance of anaphylaxis, SRS-A):
- Sustained bronchoconstriction and oedema

Prostaglandins and thromboxanes:
- Platelet-activating factor (PAF)
- Prolonged airway hyperactivity

It is subsequently metabolized to produce prostaglandins (cyclo-oxygenase pathway), leukotrienes (lipoxygenase pathway) or platelet-activating factor (PAF acetylation), depending on which cell type is being activated. Leukotrienes and prostaglandins are together termed eicosanoids. The arachidonic acid metabolites involved in type 1 hypersensitivity reactions are PAF, leukotrienes (LT) B_4, C_4, D_4 and E_4 and prostaglandins (PG) D_2, E_2 and F_2. They have four main actions:

- *Inflammatory cell mucosal infiltration.* This is mediated by LTB_4 and PAF, which attract and activate neutrophils, eosinophils and monocytes/macrophages. LTB_4 is released by activated mast cells and macrophages, and PAF is released by mast cells, neutrophils and eosinophils.
- *Bronchoconstriction.* This is mediated by several metabolites including PAF, LTQ, LTD_4, LTE_4, PGD_2 and PGF_2. LTQ and PGD_2 are the major arachidonic acid metabolites released by mast cells. The remaining eicosanoids are generated by human lung tissue and/or alveolar macrophages.
- *Bronchial mucosal oedema* is mediated by LTQ, LTD_4 and PGE_2. PGE_2 is released from alveolar macrophages and human lung tissue.
- *Mucus hypersecretion* is mediated by LTQ and LTD_4.

This reaction is termed the *early-phase response.* The *late-phase reaction* comes 4-6 hours later and is characterized by inflammatory cell infiltrates with neutrophils, eosinophils and lymphocytes. It is likely that this reaction is involved in asthma pathogenesis.

Regulation of IgE production

The regulation of IgE production appears to be controlled by functional subsets of helper T lymphocytes termed *Thl* and *Thl,* which develop after antigen stimulation from an undifferentiated population termed *ThO* (p. 208).

Thl cells produce the cytokines gamma-interferon and interleukin-2 and suppress IgE production by B cells. Th2 cells produce mainly IL-4 and IL-5. IL-4 is the switch factor for B cells to produce IgE. IL-5 drives eosinophil production. Thus Th2 cells drive an atopic response and Thl cells suppress it. There appears to be a dysregulation towards a Th2 response in atopic individuals.

Therapeutic interventions

Various therapeutic agents act at different stages of the pathways described above to control allergic disease. Sodium cromoglicate stabilizes mast cell membranes to reduce degranulation, antihistamine-receptor (Hj) blockers reduce the effect of histamine release, corticosteroids reduce production of mediators and the inflammatory response. Leukotriene receptor blockers are used in asthma. All these agents, in conjunction with p"-adrenergic drugs, help to control allergic disease but do not alter the underlying sensitivity. *Hyposensitization* is a technique used to reduce IgE responses. This involves the injection of gradually increasing doses of the allergen, starting at very tiny amounts. This leads to a switch from an IgE to an IgG response. However, there is the risk of anaphylaxis and its use is largely confined to the treatment of life-threatening allergy (e.g. that to bee or wasp venom) and only at specialist centres with on-site resuscitation facilities. Experimental approaches using anti-IL-4 agents and anti-IgE antibodies are under investigation.

AUTOIMMUNITY (TYPE II HYPERSENSITIVITY)

An autoimmune disease occurs when the immune system fails to recognize the body's own tissues and attacks itself. Autoimmune disorders (Table 4.13) comprise some common diseases, such as rheumatoid arthritis, multiple sclerosis, insulin-dependent diabetes and thyroiditis. Illnesses are often divided into those that are organ specific and organ non-specific or multisystemic. The diseases are characterized by the presence of autoantibodies or autoreactive T cells. These autoreactive antibodies or cells may be directly pathogenic (for example the autoantibodies in autoimmune cytopenias and antiglomerular antibody in Goodpasture's disease). In other circumstances autoantibodies may not directly cause damage (such as antinuclear antibodies in various connective tissue diseases) but are a marker of an autoimmune state.

Mechanism of development of autoimmune disease

In the healthy individual the immune system is made tolerant to self-antigens at an early stage of immune development (tolerance is a state in which the immune system fails to respond to a given antigen). On occasions when tolerance fails or is incomplete, autoimmunity can result.

Several factors influence the balance between the development of either tolerance or immunity. Continuous antigenic stimulation over several days, e.g. by self-antigens, usually transmits tolerogenic stimuli. A sudden increase in antigens, e.g. infection, usually transmits an

^H *Table 4.13* **Autoimmune diseases and their ^U antigens**

Disease	Antigens
Graves' disease	Thyroid-stimulating hormone receptor
Hashimoto's thyroiditis	Thyroid peroxidase, thyroglobulin
Pernicious anaemia	H^+/K^+-ATPase, intrinsic factor
Addison's disease	21-Hydroxylase
Diabetes mellitus type 1	GAD
Goodpasture's syndrome	Type IV collagen
Myasthenia gravis	Acetylcholine receptor
Pemphigus vulgaris	Desmoglein-3
Multiple sclerosis	Myelin basic protein Myelin oligodendritic glycoprotein
Primary biliary cirrhosis	PDC.E2
Coeliac disease	Tissue transglutaminase
Wegener's granulomatosis	ANCA+
Sjogren's syndrome	Ro/La ribonuclear particle
Rheumatoid arthritis	Citrullinated cyclic peptide IgM
Polymyositis/ dermatomyositis	tRNA synthases
Scleroderma	Topoisomerase
Systemic lupus erythematosus	Sm/RNP, Ro/La (SS-A/SS-B) histone and native DNA

ANCA, antinuclear cytoplasmic antibodies; GAD, glutamic acid decarboxylase; PDC.E2, pyruvate dehydrogenase complex, E2 component

immunologenic signal. Binding of antigens during immature lymphocyte formation in the bone marrow/ thymus produces tolerance, whereas binding of mature lymphocytes produces immunity.

Tolerance

Positive and negative selection (central tolerance) (see Fig. 4.5)

There are several mechanisms of T-cell tolerance. One occurs in the thymus by means of a complicated, multi-step selection mechanism. In the first stage of this process, immature T cells which do not bear either of the CD4 and CD8 molecules (double-negative cells) enter the sub-capsular region of the thymus, divide and proliferate. T-cell receptors, CD4 and CD8 molecules, are then co-expressed simultaneously; these cells are termed 'double-positive'. Maturing cells migrate towards the cortex of the thymus where the selection process occurs. T cells that can engage with MHC class I or II molecules on the epithelium of the thymic cortex are said to be 'positively selected' and they undergo further processing. They will lose either the CD4 or CD8 co-receptor, depending on which particular MHC molecule they engage. Cells that do not interact with the MHC undergo programmed cell death (apoptosis). Thus after positive selection, only cells that can recognize MHC molecules (and thus antigenic peptides presented in association with these structures) remain.

However, another step is necessary to remove cells that can react with self-peptides, and this occurs through negative selection. This part of the selection process occurs in the corticomedullary junction, which is rich in dendritic cells and macrophages. If either CD4 or CD8 cells engage with cells bearing MHC class I or II molecules containing self-peptide (i.e. autoreactive T cells) they undergo apoptosis and are clonally deleted. The remaining cells pass through the thymus and become part of the mature T-cell pool. Negative selection is probably the most significant aspect of tolerance induction. The loss of thymocytes through the positive and negative selection process is high, with over 90% of cells undergoing apoptosis.

Peripheral tolerance

Self-reactive cells occasionally escape the elimination process in the thymus and become part of the circulating pool of T cells. While these lymphocytes may become auto-aggressive there are other forms of tolerance that occur outside the thymus. Although poorly understood, processes exist to eliminate (by specialized cytotoxic T cells) or inactivate (anergize) both self-reactive T and B lymphocytes. In the case of B cells, anti-idiotypic antibodies (which bind to the idiotype marker on the autoreactive B cell) may also play a part.

There are several mechanisms proposed to account for a change from tolerance to immunity.

Immune dysregulation

T cells regulate any autoreactive T and B cells that have survived clonal deletion. It is hypothesized that dysregulation of T-cell function could therefore lead to loss of control and the development of autoimmune disease. This is backed up by the observation that immunodeficiency diseases such as hypogammaglobulinaemia and HIV infection are commonly associated with autoimmune phenomena. However, most patients with autoimmune disease do not have obvious immune deficiency.

Tissue damage

There are some autoantigens to which the developing immune system is not usually exposed because these antigens are 'hidden' within the cells or tissues. Therefore clonal deletion of self-reactive cells does not occur. Normally these self-antigens remain hidden, so no autoimmune disease develops. If, however, the tissue is damaged by trauma, infection or tumour, the antigens may be released and evoke an autoimmune response. Examples of this in clinical practice are Dressier's syndrome in which patients with myocardial infarction develop acute pericarditis secondary to the production of antimyocardial antibodies, or the association of Coxsackie virus infection with the development of insulin-dependent diabetes. The presence of inflammatory cytokines at the site of injury may enhance the expression of costimulatory molecules on local antigen-presenting cells and increase the likelihood of an autoreactive T-cell response still

further. This hypothesis may be supported by the observation that patients given alpha-interferon (which upregulates class I expression) develop thyroid autoantibodies on therapy.

T-cell bypass

This is a mechanism by which T cells are tricked into providing help to autoreactive B cells rather than suppressing them. For this to occur the self-antigen needs to be attached to a foreign antigen that is recognized by the T cell. T-cell activation will occur with the production of cytokines such as IL-4. If an autoreactive B cell has also bound the self-antigen it will then receive the signals to proliferate and produce autoantibody. There are several examples of this in drug-induced autoimmune responses. Quinine binds to platelets, creating a foreign epitope for T cells and inducing autoreactive B cells to make antiplatelet antibodies with sometimes fatal thrombocytopenia developing. Methyldopa or infection with mycoplasma causes changes in red cell epitopes to induce a similar autoantibody response to red cells with haemagglutination or lysis.

Molecular mimicry

This occurs when an organism has a similar antigenic structure to self-molecules. The infection generates antigen-specific T cells and antibodies that cross-react with host tissues and cause autoimmune disease. Examples where there is known cross-reaction between an infective agent and host antigen include the production of anticardiac antibodies (antimyosin) after streptococcal infection leading to rheumatic fever, Klebsiella and HLA-B27 in ankylosing spondylitis, and Coxsackie and glutamic acid decarboxylase in insulin-dependent diabetes.

The development of autoimmune disease can be viewed as either a loss of tolerogenic signals to lymphocytes, or an increase in immunogenic signals. The underlying mechanism appears to be the activation of lymphocytes by different pathways.

HLA and autoimmunity

There is a strong association between certain HLA types and the development of (or sometimes protection from) autoimmune diseases (Table 4.8). These may represent linkage-disequilibrium with a true disease-susceptibility gene that has not yet been identified (this seems particularly likely in those conditions such as narcolepsy that are not immunologically mediated but where there is a strong HLA association). The other possibilities are that HLA types determine the degree of immune response to antigens (the polymorphisms of HLA will determine how well a particular antigen fits within the cleft for presentation) and therefore the ease of autoimmune reactions ('high-reactor' status).

Immunopathology of autoimmune disease

(Fig. 4.12)

Formation of autoantibodies may be a normal physiological process and help to remove tissue debris. Many autoantibodies are detectable at low levels in normal individuals or may rise temporarily in inflammatory conditions without any evidence of pathogenicity. However, excessive and persistent production of such antibodies can be harmful. Antibodies may directly react with a specific tissue, resulting in inflammation and tissue damage by complement activation, neutrophil, mast cell, or antibody-dependent cellular cytotoxic attack (Fig. 4.12a). Autoantibodies in some situations do not damage the tissue but block or stimulate function, type V hypersensitivity which in turn leads to disease (Fig. 4.12b). The activation of autoantigen-specific T cells causes infiltration of the tissues with lymphocytes and damage.

A third type of hypersensitivity reaction is caused by immune complex formation. The immune complexes may either be formed from antibody binding pathogen or autoantigen.

IMMUNE COMPLEX DISEASE (TYPE III HYPERSENSITIVITY)

Immune complexes are often found in healthy individuals; for example after eating, circulating complexes with food antigens are normal. However, if the complexes are persistent, disease may develop. Immune complexes are normally removed from the circulation attached to receptors on red blood cells and removed by the liver or spleen. Complexes with antibody or antigen excess are either easily removed or remain soluble but those at around equivalence are more difficult to remove, yet precipitate easily.

Immune complexes can be formed in tissues causing a local (Arthus) reaction, or in the circulation, causing systemic disease. Examples of the former are extrinsic allergic alveolitis (e.g. farmer's lung) where repeated inhaled exposure to an antigen such as mouldy hay leads to the production of high levels of specific antibody in the lung. Further exposure causes local immune complex production and inflammatory responses leading to chronic progressive lung fibrosis. Examples of diseases where systemic immune complexes play a major role are listed in Table 4.13, and include the major vasculitides such as systemic lupus erythematosus and other connective tissue diseases, as well as accounting for the vasculitic component of rheumatoid arthritis and other conditions. Serum sickness used to be common in patients receiving horse antisera for the treatment of tetanus and diphtheria (before effective vaccination programmes) as they made anti-horse immunoglobulin antibodies which formed immune complexes with the antiserum. A similar reaction is once again being observed as an adverse effect of the newly developed mouse-derived monoclonal antibodies under investigation as immunosuppressants (owing to anti-mouse immunoglobulin antibodies) and in patients receiving streptokinase post-myocardial infarction (who may have unsuspected high circulating antistreptococcal antibody levels because of intercurrent streptococcal infections).

Others such as monoclonal antibodies can be produced to inhibit or enhance immune responses. Some have proven to be very effective, such as the success of anti-TNF in rheumatoid arthritis, inflammatory bowel disease and psoriasis. However, there are also complications of modulating the immune response; for example, the increased rate of infection with anti-TNF therapy and the development of autoimmune conditions with interferon. Gene therapy has been used in the management of severe immunodeficiences (SCID) to replace the defective gene in lymphocytes in a few patients. Although significant immune reconstitution has been observed, there has also been development of T-cell leukaemia in relation to retroviral gene insertion.

Some are still in trials (Table 4.14).

Table 4.14 **Immunological interventions**

Intravenous immunoglobulin
Replacement (e.g. in hypogammaglobulinaemic states)
Fc-receptor blockade (e.g. in autoimmune cytopenias; idiopathic thrombocytopenic purpura)
Immunomodulation in autoimmune disease
Guillain-Barre syndrome
Chronic inflammatory demyelinating polyneuropathies
Lambert-Eaton myasthenic syndrome
Adult dermatomyositis

Cytokines
Interferons
Antiproliferative agents (e.g. in hairy cell leukaemia; Kaposi's sarcoma)
Antiviral and immunomodulatory agents (e.g. in chronic hepatitis B and C infection; multiple sclerosis)
Immunomodulation (e.g. gamma-interferon in chronic granulomatous disease)

Interleukins
Interleukin-2 to enhance CD4 reconstitution in HIV treatment

Colony-stimulating factors
e.g. Granulocyte and granulocyte-monocyte colony-stimulating factors (G-CSF and GM-CSF) in neutropenia

Monoclonal antibodies
Immunosuppressives (e.g. anti-T-cell antibody to prevent graft-versus-host disease
Anti-inflammatory agents (e.g. anti-TNF, anti-IL-1, anti-CD20 B cell in rheumatoid arthritis, inflammatory bowel disease, psoriasis and Behget's disease

Gene therapy
Treatment of ADA deficiency by insertion of gene into bone marrow stem cell X-linked SCID

Adoptive immunotherapy
Growth ex vivo of specific lymphocyte clones for subsequent reinjection to treat disease, e.g. management of CMV infection after bone marrow transplant

Immune modulation
Anti-IgE antibodies in suppressing IgE response in peanut-allergic individuals

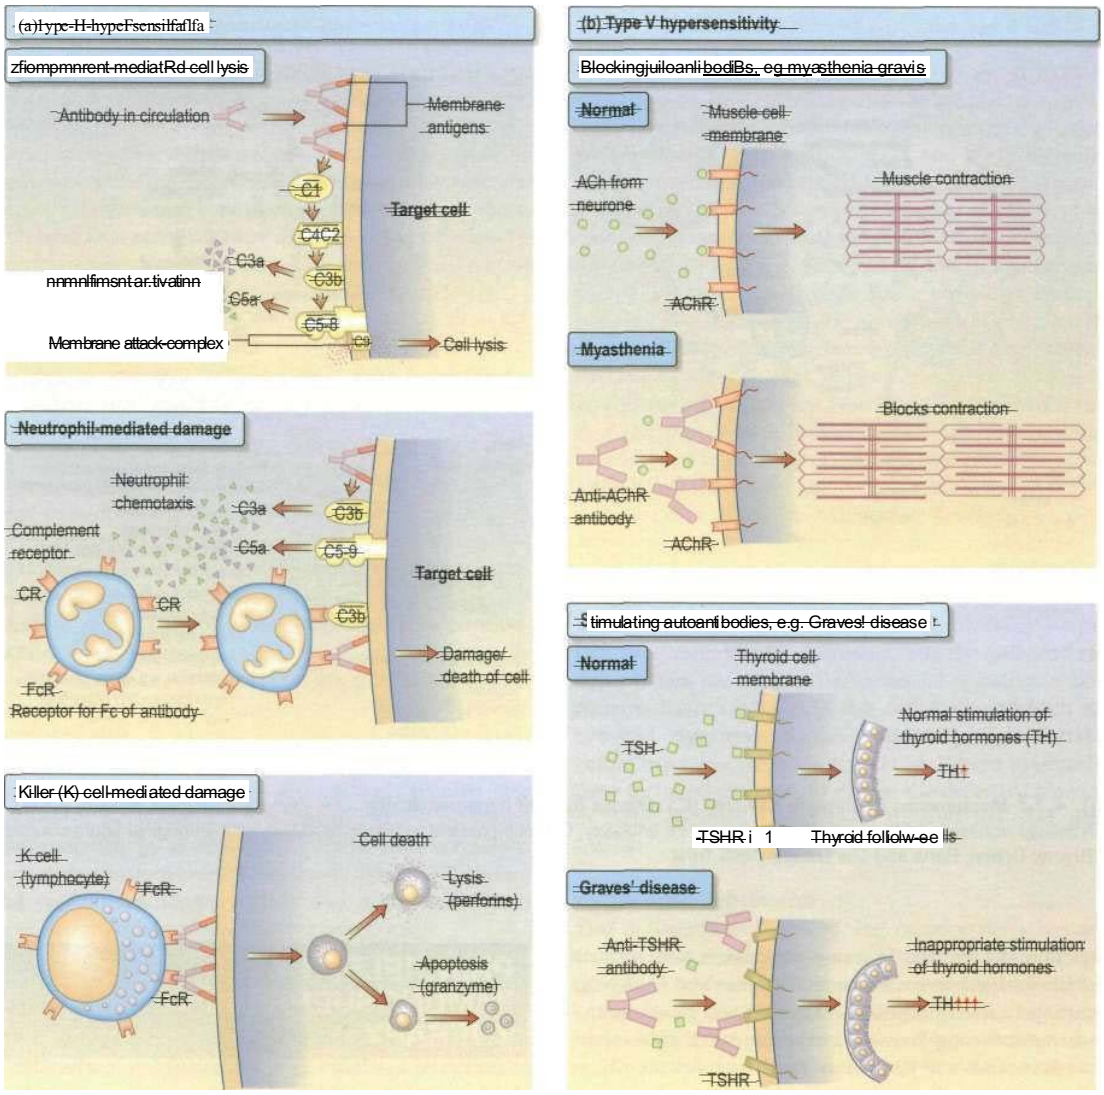

Fig. 4.12 **Mechanisms of autoimmunity (type II and V hypersensitivity).**
(a) Type II hypersensitivity occurs when a cell-bound autoantigen is recognized by the immune system. Damage occurs in several different ways. Antibody binding to the autoantigen leads to local complement activation and lysis of the cells. Complement activation products recruit neutrophils, which bind to the IgG and release their granules directly onto the surface of the cell. Lymphocytes binding antigen-specific Ig (killer cells) can bind to the autoantigens on cells and induce their killing by apoptosis.
(b) Type V hypersensitivity. Some autoantibodies do not cause tissue destruction, but affect cellular regulation. In myasthenia gravis an anti-acetylcholine-receptor antibody binds to the receptors at the neuromuscular junction and blocks any further activation. In Graves' disease the autoantibody, thyroid-stimulating immunoglobulin (TSI), binds to TSH receptors on thyrocytes and causes prolonged excess thyroid hormone secretion. Modified from an original figure courtesy of Bryony Cohen, Barts and The London NHS Trust.

Immunopathogenesis of immune complex disease (Fig. 4.13)

Immune complexes activate the classical pathway of complement, releasing C3a and C5a, which cause increased adhesion molecule expression on the vascular endothelial cells and on circulating neutrophils. This causes the circulating neutrophils to adhere to the vascular endothelial cells. The neutrophils bind the immune complexes via their Fc and C receptors and are activated, leading to the release of toxic oxygen metabolites through the respiratory burst, which results in tissue damage. The inflammatory mediators cause separation of the vascular endothelial cells and immune complexes and neutrophils

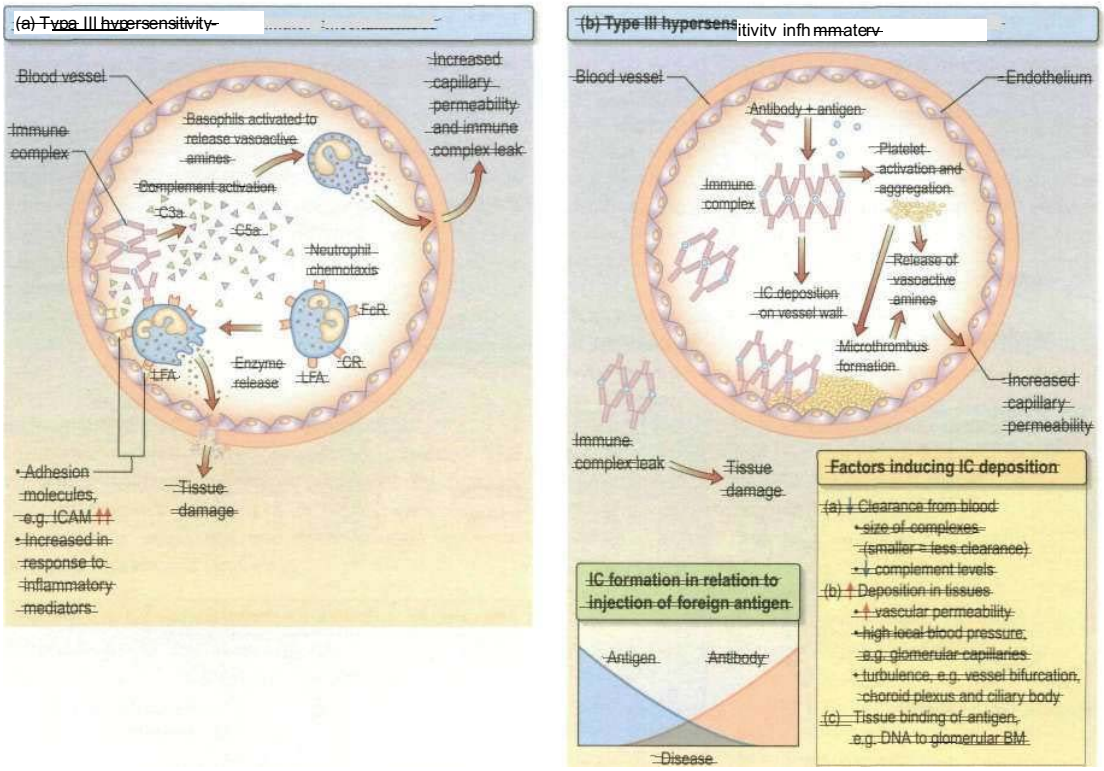

Fig. 4.13 **Mechanisms of immune complex (IC) disease (type III hypersensitivity).** LFA, leucocyte function antigen; I CAM, intercellular adhesion molecule; FcR, receptor for Fc antibody; CR, complement receptor. pass into the tissues. Immune complexes also activate *platelets* with release of vasoactive amines and clumping, resulting in microthrombus formation and tissue infarction. Immune complexes tend to be deposited in the walls of vessels at sites of turbulence (such as bifurcations), at hydrostatic pressure gradients (such as in the glomerulus and synovium), or where the complex contains an antigen that binds to tissue (such as in the presence of DNA in immune complexes in SLE, which is attracted by charge differences to the glomerular basement membrane). Inflammation in larger vessels causes weakening of the blood vessel wall and microaneurysm formation (e.g. in polyarteritis nodosa, PAN). In smaller vessels the inflammation and thrombus formation leads to infarction and necrosis of tissue.

DELAYED TYPE (TYPE IV HYPERSENSITIVITY)

This is mediated by macrophages and T-cell responses to antigens, often after chronic stimulation. It is the cause of granulomatous reactions to foreign particles (e.g. silicosis in lungs) as well as some forms of allergic drug reaction and eczema. It is also the basis of the 'patch' test for contact sensitivity skin testing.

PRINCIPLES OF IMMUNOSUPPRESSIVE THERAPY

Treatment to suppress the inflammation caused by autoimmune reactions includes systemic steroids to suppress neutrophil-driven inflammation, and cytotoxics, such as methotrexate, azathioprine and cyclophosphamide, to suppress lymphocyte numbers and function, including antibody production. More intense lymphocyte suppression is provided by ciclosporin A, tacrolimus, mycophenolate and monoclonal antilymphocyte immunoglobulin and anti-TNR Opportunist infection and tumours are major side-effects of these therapies. Where the antibody is known to be directly damaging (e.g. Goodpasture's syndrome), plasmapheresis can be used to reduce the levels rapidly.

Immunological interventions

A number of products of the immune response can now be produced for therapeutic use by purification from blood (immunoglobulins and Cl esterase inhibitor), cell culture (e.g. fibroblast interferons) and molecular techniques (recombinant interferons, interleukin-2, colony-stimulating factors).

Nutrition

5

GENERAL ASPECTS

In developing countries, lack of food and poor usage of the available food can result in protein-energy malnutrition (PEM); 50 million pre-school African children have PEM. In developed countries, excess food is available and the most common nutritional problem is obesity.

Diet and disease are interrelated in many ways. Excess energy intake, particularly when high in animal (saturated) fat content, is thought to contribute to a number of diseases, including ischaemic heart disease and diabetes. A relationship between food intake and cancer has been found in many epidemiological studies; an excess of energy-rich foods (i.e. fat and sugar containing), often with physical inactivity, plays a role in the development of certain cancers, while diets high in vegetables and fruits reduce the risk of most epithelial cancers. Numerous carcinogens, either intentionally added to food (e.g. nitrates for preserving foods) or accidental contaminants (e.g. moulds producing aflatoxin and fungi), may also be involved in the development of cancer.

The proportion of processed foods eaten may affect the development of disease. A number of processed convenience foods have a high sugar and fat content and therefore predispose to dental caries and obesity respectively. They also have a low fibre content, and dietary fibre is possibly necessary in the prevention of a number of diseases (see p. 234). Some epidemiological data suggest that there are long-term effects of undernutrition; low growth rates in utero being associated with high death rates from cardiovascular disease in adult life.

In 1991 the Department of Health published the dietary reference values for food and energy and nutrients for the United Kingdom. Values were based on all of the available information including data from the 1985 Food and Agriculture Organization (FAO-WHO), United Nations University (UNU) expert committee, so that there is broad agreement on the reference values given. In the UK recommended daily amounts (RDAs) are no longer used, but have been replaced by the *reference nutrient intake* (RNI) to provide more help in interpreting dietary surveys.

The RNI is roughly equivalent to the previous RDA, and is sufficient or more than sufficient to meet the nutritional needs of 97.5% of healthy people in a population. Most people's daily requirements are less than this, and so an *estimated average requirement* (EAR) is also given, which will certainly be adequate for most. A lower reference nutrient intake (LRNI) which fails to meet the requirement of 97.5% of the population is also given. The RNI figures quoted in this chapter are for the age group 19-50 years. These represent values for healthy subjects and are not always appropriate for patients with disease.

WATER AND ELECTROLYTE BALANCE

Water and electrolyte balance is dealt with fully in Chapter 12. About 1 L of water is required in the daily diet to balance insensible losses, but much more is usually drunk, the kidneys being able to excrete large quantities. The daily RNI for sodium is 70 mmol (1.6 g) but daily sodium intake varies in the range 90-^40 mmol (2-10 g). These are needlessly high intakes of sodium which are

thought by some to play a role in causing hypertension (see p. 858).

DIETARY REQUIREMENTS

Energy

Food is necessary to provide the body with energy (Fig. 5.1). The SI unit of energy is the joule (J), and 1 kj = 0.239 kcal. The conversion factor of 4.2 kj, equivalent to 1 kcal, is used in clinical nutrition.

Energy balance

Energy balance is the difference between energy intake and energy expenditure. Weight gain or loss is a simple, but accurate, way of indicating differences in energy balance.

Energy requirements

There are two approaches to assessing energy requirements for subjects who are weight stable and close to energy balance:

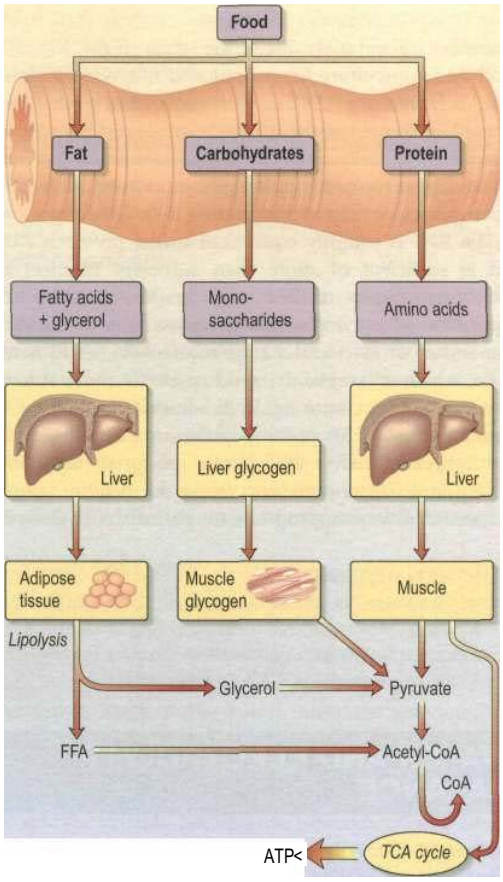

Fig. 5.1 **The production of energy from the main constituents of food.** Alcohol produces up to 5% of total calories, but the variation between individuals is wide. 1 mol of glucose produces 36 mol of ATP. FFA, free fatty acids; ATP, adenosine triphosphate.

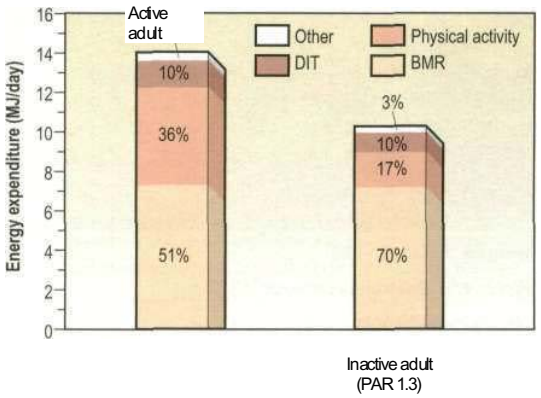

Fig. 5.2 **Daily energy expenditure in an active and a sedentary 70 kg adult.** BMR, basal metabolic rate; DIT, dietary induced thermogenesis; PAR, physical activity ratio.

- assessment of energy intake
- assessment of total energy expenditure.

Energy intake

This can be estimated from dietary surveys and in the past has been used to decide daily energy requirements. However, measurement of energy expenditure gives a more accurate assessment of requirements.

Energy expenditure

Daily energy expenditure (Fig. 5.2) is the sum of:

- the basal metabolic rate (BMR)
- the thermic effect of food eaten
- occupational activities
- non-occupational activities.

Total energy expenditure can be measured using a double-labelled water technique. Water containing the stable isotopes ^{2}H and ^{18}O is given orally. As energy is expended carbon dioxide and water are produced. The difference between the rates of loss of the two isotopes is used to calculate the carbon dioxide production, which is then used to calculate energy expenditure. This can be done on urine samples over a 2- to 3-week period with the subject ambulatory. The technique is accurate, but it is expensive and requires the availability of a mass spectrometer. An alternative tracer technique for measuring total energy expenditure is to estimate CO_2 production by isotopic dilution. A subcutaneous infusion of labelled bicarbonate is administered continuously by minipump, and urine is collected to measure isotopic dilution by urea, which is formed from CO_2. Other methods for estimating energy expenditure, such as heart rate monitors or activity monitors, are also available but are less accurate.

Basal metabolic rate. The BMR can be calculated by measuring oxygen consumption and CO_2 production, but it is more usually taken from standardized tables (Table 5.1) that require knowledge of the subject's age, weight and sex.

Table 5.1 Equations for the prediction of basal metabolic rate (in MJ per day)

Age range (years)	Prediction equation (BMR=)		95% confidence limits

'Bodyweight (wt) in kilograms

Data reproduced with permission of Department of Health, 1991

Table 5.2 Physical activity ratio (PAR) for various activities (expressed as multiples of BMR)

	PAR
Occupational activity	
Professional/Housewife	1.7
Domestic helper/Sales person	2.7
Labourer	3.0
Non-occupational activity	
Reading/Eating	1.2
Household/Cooking	2.1
Gardening/Golf	3.7
Jogging/Swimming/Football	6.9

Physical activity. The physical activity ratio (PAR) is expressed as multiples of the BMR for both occupational and non-occupational activities of varying intensities (Table 5.2).

Total daily energy expenditure = BMR X [Time in bed + (Time at work X PAR) + (Non-occupational time X PAR)].

Thus, for example, to determine the daily energy expenditure of a 63-year-old, 50 kg female doctor, with a BMR of 4805 kj per day spending one-third of a day sleeping, working or engaged in non-occupational activities, the latter at a PAR of 2.1, the following calculation ensues:

(4805 kj/day) x [0.3 + (0.3 x 1.7) + (0.3 x 2.10)] = 6919 kj or 1655 kcal/ day.

In the UK the estimated 'average' daily requirement is:

- for a 55-year-old female - 8100 kj (1940 kcal)
- for a 55-year-old male -10 600 kj (2550 kcal).

This is at present made up of 50% carbohydrate, 35% fat, 15% protein plus or minus 5% alcohol. In developing countries, however, carbohydrate may be more than 75% of the total energy input, and fat less than 15% of the total energy input.

Energy requirements increase during the growing period, with pregnancy and lactation, and sometimes following infection or trauma. In general, the increased BMR associated with inflammatory or traumatic conditions is counteracted or more than counteracted by a decrease in physical activity, so that total energy requirements are not increased.

In the basal state, energy demands for resting muscle are 20% of the total energy required, abdominal viscera 35^0%, brain 20% and heart 10%. There can be more than a 50-fold increase in muscle energy demands during exercise.

Energy stores

Although virtually all body fat and glycogen are available for oxidation, less than half the protein is available for oxidation. Figure 5.3 shows that fat accounts for the largest reserves of energy in both lean and obese subjects. The size of the stores determines survival during starvation.

Bodyweight

Bodyweight depends on energy balance. Intake depends not only on food availability but also on a number of complex interrelationships that include the stimulus of good food, the role of hunger, metabolic changes (e.g. hypoglycaemia), and the pleasure and habit of eating. Some people are able to keep their bodyweight constant

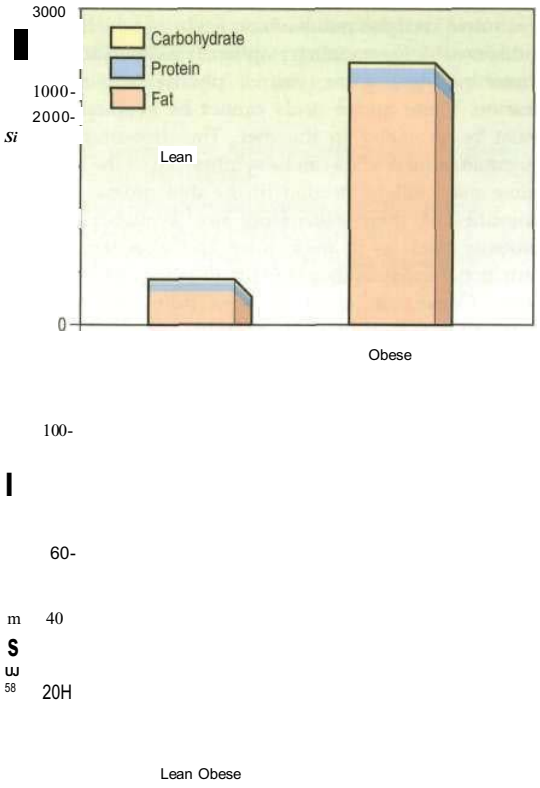

***Fig. 5.3* Available energy reserves from different fuels expressed in MJ (upper) and as a percentage of total (lower) in a lean hypothetical 70 kg adult and an obese 140 kg adult.**

within a few kilograms for many years, but most gradually increase their weight owing to a small but continuous increase of intake over expenditure. A gain or loss of energy of 25-29 MJ (6000-7000 kcal) would respectively increase or decrease bodyweight by approximately 1 kg.

Protein

In the UK the adult daily RNI for protein is 0.75 g/kg, with protein representing at least 10% of the total energy intake. Most affluent people eat more than this, consuming 80-100 g of protein per day. The total amount of nitrogen excreted in the urine represents the balance between protein breakdown and synthesis. In order to maintain nitrogen balance, at least 40-50 g of protein are needed. The amount of protein oxidized can be calculated from the amount of nitrogen excreted in the urine over 24 hours using the following equation:

Grams of protein required = Urinary nitrogen x 6.25
(most proteins contain about 16% of nitrogen).

In practice, urinary urea is more easily measured and forms 80-90% of the total urinary nitrogen (N). In healthy individuals urinary nitrogen excretion reflects protein intake. However, urine N excretion does not match intake either in catabolic conditions (negative N balance) or during growth or repletion following an illness (positive N balance).

Protein contains many amino acids, of which nine are indispensable (essential): trytophan, histidine, methionine, threonine, isoleucine, valine, phenylalanine, lysine, leucine. These amino acids cannot be synthesized and must be provided in the diet. The dispensable (non-essential) amino acids can be synthesized in the body, but some may still be needed in the diet unless adequate amounts of their precursors are available. Animal proteins, such as in milk, meat and eggs, are of high nutritional value as they contain all indispensable amino acids. Conversely, many proteins from vegetables are deficient in at least one indispensable amino acid.

In developing countries, adequate protein intake is achieved mainly from vegetable proteins. By combining foodstuffs with different low concentrations of indispensable amino acids (e.g. maize with legumes), protein intake can be adequate provided enough vegetables are available.

Loss of protein from the body (negative N balance) occurs not only because of inadequate protein intake, but also owing to inadequate energy intake. When there is loss of energy from the body, more protein is directed towards oxidative pathways and eventually gluconeogenesis for energy. Of all the amino acids, glutamine is quantitatively the most significant in the circulation and in inter-organ exchange. Alanine is released from muscle; it is deaminated and converted into pyruvic acid before entering the citric acid cycle. Homocysteine is a sulphur-containing amino acid which is derived from methionine in the diet. A raised plasma concentration is an independent risk factor for vascular disease (see p. 802).

Amino acids may be utilized to synthesize products other than protein or urea. For example:

- haem requires glycine
- melanin and thyroid hormones require tyrosine
- nucleic acid bases require glutamine, aspartate and glycine
- glutathione, which is part of the defence system against free radicals, requires glutamate, cysteine and glycine.

Fat

Dietary fat is chiefly in the form of triglycerides, which are esters of glycerol and free fatty acids. Fatty acids vary in chain length and in saturation (Table 5.3). Unsaturated fatty acids are monounsaturated or polyunsaturated. The hydrogen molecules related to these double bonds can be in the as or the *trans* position, most natural fatty acids in food being in the *cis* position (Box 5.1).

The essential fatty acids (EFAs) are linoleic and a-linolenic acid, both of which are precursors of prostaglandins (see Fig. 14.32). Eicosapentaenoic and docosahexaenoic are also necessary, but can be made to a limited extent in the tissues from linoleic and linolenic, and thus a dietary supply is not essential.

Table 5.3 **The main fatty acids in foods**

Saturated
Laurie C12:0
MyristicC14:0
Palmitic C16:0
Stearic C18:0

Monosatu rated
OleicC18:1 (n-9) Elaidic
C18:1 (n-9 *trans**)

Polyunsaturated
Linoleic C18:2 (n-6) a-Linolenic
C18:3 (n-3) Arachidonic C20:4
(n-6) Eicosapentaenoic C20:5 (n-
3) Docosahexaenoic C22:6 (n-3)

The number of carbon atoms is indicated before the colon; the number of double bonds after the colon. In parentheses the positions of the double bonds (designated either n as here or (o) are shown counted from the methyl end of the molecule. All double bonds are in the *cis* position except that marked with an asterisk (*)

Box *5.1* Dietary sources of fatty acids

Type of acid	Sources
Saturated fatty acids	Mainly animal fat
n-6 fatty acids	Vegetable oils and other plant foods Vegetable foods, rapeseed oil, fish oils Hydrogenated fat or oils, often in margarine
n-3 fatty acids *trans* fatty acids	

Synthesis of triglycerides, sterols and phospholipids is very efficient, and even with low-fat diets subcutaneous fat stores can be normal.

Dietary fat provides 37 kj (9 kcal) of energy per gram. A high fat intake has been implicated in the causation of:

- cardiovascular disease
- cancer (e.g. breast, colon and prostate)
- obesity
- type 2 diabetes.

The data on causation are largely epidemiological and disputed by many. Nevertheless, it is often suggested that the consumption of saturated fatty acids should be reduced, accompanied by an increase in monounsaturated fatty acids (the 'Mediterranean diet') or polyunsaturated fatty acids. Any increase in polyunsaturated fats should not, however, exceed 10% of the total food energy, particularly as this requires a big dietary change.

Increased consumption of hydrogenated vegetable and fish oils in margarines has led to an increased *trans* fatty acid consumption and their intake should not, on present evidence, increase more than the current estimated average of 5 g per day or 2% of the dietary energy. This is because *trans fatty acids* (also called *trans* fats) behave as if they were saturated fatty acids, increasing circulating low-density lipoprotein (LDL) cholesterol concentration, which in turn increases the risk of cardiovascular disease. For this reason, the US Food and Drug Administration recommended in 2003 that in nutritional labelling, *trans* fatty acids should be listed separately under saturated fatty acids.

The *n-6 polyunsaturated fatty acids* (PUFA) are components of membrane phospholipids, influencing membrane fluidity and ion transport. They also have anti-arrhythmic, anti-thrombotic and anti-inflammatory properties, all of which are potentially helpful in preventing cardiovascular disease. In addition, n-3 PUFA increase circulating high-density lipoprotein (HDL) cholesterol and lower triglycerides, both of which might reduce cardiovascular risk. Some of the actions of n-3 PUFA are mediated by a range of leukotrienes and eicosanoids, which differ in pattern and functions from those produced from n-6 PUFA. A number of epidemiological studies and clinical intervention studies suggest that n-3 PUFA may have effects in the *secondary* prevention of cardiovascular disease and 'all-cause mortality' (e.g. 20-30% reduction in mortality from cardiovascular disease according to some studies). The benefits, which have been noted as early as 4 months after intervention, have been largely attributed to the anti-arrhythmic effects of n-3 PUFA, but recent work suggests that n-3 PUFA administered as capsules, can be rapidly incorporated into atheromatous plaques, stabilizing them and preventing rupture. Whether these effects are due directly to n-3 PUFA or other changes in the diet is still debated. To answer this, the GISSI Prevention Trial, which followed over 11000 patients for 3.5 years after a myocardial infarction, administered the fish oils (eicosopentanoic acid (EPA) and decohexanoic acid (DHA)) in the form of capsules and demonstrated a striking benefit. The effects of vitamin E (300 mg a-tocopherol/day) were also studied, but no benefit was found.

The British Nutrition Foundation and the American Heart Association presently recommend a two-fold increase of the current intake of total n-3 PUFA (several fold increase in the intake of fish oils, and a 50% increase in the intake of a-linolenic acid). Implementing this recommendation will mean either a major change in the dietary habits of populations that eat little fish, or ingestion of capsules containing fish oils. Some government agencies have warned of the hazards of eating certain types of fish, which increase the risk of mercury poisoning and possibly other toxicities.

The current recommendations for fat intake for the UK are as follows:

- saturated fatty acids should provide approximately 10% of the dietary energy
- cis-monounsaturated acids (mainly oleic acid) should continue to provide approximately 12% of the dietary energy
- cfs-polyunsaturated acids should provide 6% of dietary energy, and are derived from n-6 and n-3 poly unsaturated fatty acids, which should provide ~ 0.5% of total energy intake
- total fat intake should be no more than 35% of the total dietary energy, and restriction to 30% is desirable.

Cholesterol is found in all animal products. Eggs are particularly rich in cholesterol, which is virtually absent from plants. The average daily intake in the UK is 300-500 mg. Cholesterol is also synthesized (see p. 350) and only very high or low dietary intakes will significantly affect blood levels.

Essential fatty acid deficiency

Essential fatty acid deficiency may accompany protein-energy malnutrition (PEM), but it has been clearly defined as a clinical entity only in patients on long-term parenteral nutrition given glucose, protein and no fat. Alopecia, thrombocytopenia, anaemia and a dermatitis occur within weeks with an increased ratio of triene (n-9) to tetraene (n-6) in plasma fatty acids.

Carbohydrate

Carbohydrates are readily available in the diet, providing 17 kj (4 kcal) per gram of energy (15.7 kj (3.75 kcal) per gram monosaccharide equivalent).

Carbohydrate intake comprises the polysaccharide starch, the disaccharides (mainly sucrose) and monosaccharides (glucose and fructose). Carbohydrate is cheap compared with other foodstuffs; a great deal is therefore eaten, usually more than required.

Dietary fibre, which is largely *non-starch polysaccharide* (NSP) (entirely NSP according to some authorities), is often removed in the processing of food. This leaves highly refined carbohydrates such as sucrose which contribute to the development of dental caries and obesity. Lignin is included in dietary fibre in some

classification systems, but it is not a polysaccharide. It is only a minor component of the human diet. The principal classes of NSP are:

- cellulose
- hemicelluloses
- pectins
- gums.

None of these is digested by gut enzymes. However, NSP is partly broken down in the gastrointestinal tract, mainly by colonic bacteria, producing gas and volatile fatty acids, e.g. butyrate.

All plant food, when unprocessed, contains NSP, so that all unprocessed food eaten will increase the NSP content of the diet. *Bran,* the fibre from wheat, provides an easy way of adding additional fibre to the diet: it increases faecal bulk and is helpful in the treatment of constipation.

The average daily intake of NSP in the diet is approximately 16 g. *NSP deficiency* is accepted as an entity by many authorities in the UK. It is suggested that the total NSP be increased to up to 30 g daily. This could be achieved by increased consumption of bread, potatoes, fruit and vegetables, with a reduction in sugar intake in order not to increase total calories. Each extra gram of fibre daily adds approximately 5g to the daily stool weight.

Pectins and gums have been added to food to slow down monosaccharide absorption, particularly in type 2 diabetes. A high intake of dietary fibre reduces blood lipids (p. 1139). A high intake of fruits and vegetables probably reduces the risk of cancer, although this is controversial. Recently, however, a large scale multi-ethnic study in the USA (Prostate, Lung, Colorectal, and Ovarian screening study; PCLO) and the European Prospective Investigation into Cancer and Nutrition (EPIC), which operated across 10 European countries, showed an association between a high-fibre diet and protection against colonic adenomas or colonic cancer, and partly because of this, eating a diet rich in plant foods (fruits, vegetables, cereals and whole grain) is still generally recommended for general health promotion, including protection against colorectal cancer.

Health promotion

Many chronic diseases - particularly obesity, diabetes mellitus and cardiovascular disease - cause premature mortality and morbidity and are potentially preventable by dietary change.

Box 5.2 suggests the composition of the 'ideal healthy diet'. The values given are based on the principle of:

- reducing total fat in the diet, particularly saturated fat
- increasing consumption of fish which contain n-3 (or co-3) polyunsaturated fatty acids
- increasing intake of whole-grain cereals, green and orange vegetables and fruits, leading to an increase in fibre and antioxidants.

Reductions in dietary sodium and cholesterol have also been suggested. There would be no disadvantage in this, and most studies have suggested some benefit.

Fortification of foods with specific nutrients is common. In the UK *margarine* and *milk* are fortified with vitamins A and D, *flour* with calcium, iron, thiamin and niacin, and *breakfast cereals* with several vitamins and iron. Not all substances used in fortification have nutritive value. For example, *Olestra* is a polymer of sucrose and six or more triglycerides which has been introduced to combat obesity. It is not absorbed and is therefore used particularly in savoury snack foods (where it has FDA approval) as a 'fake fat'. Therefore, it results in a reduction in total calories. It has side-effects (mainly in the gut) and its use is being carefully monitored.

The interests of the individual are often different from those associated with government policy. A distinction needs to be made about nutrient goals and dietary guidelines. Nutrient goals refer to the national intakes of nutrients that are considered appropriate for optimal health in the population, whereas dietary guidelines refer to the dietary methods used to achieve these goals. Since dietary habits in different countries vary, dietary

Box 5.2 **Recommended healthy dietary intake**

Dietary component	Approximate amounts (% of total energy unless otherwise stated)*	General hints
Total carbohydrate	55 (55-75)	Increase fruit vegetables, beans, pasta, bread
Free sugar	10 (< 10)	Decrease sugary drinks Decrease red meat (see fat
Protein	15(10-15)	below) Increase vegetable (including olive oil) and fish
Total fat Saturated	30(15-30)	oil and decrease animal fat
fat Unsaturated	10 (< 10)	
fat	20	Decrease meat and eggs
Cholesterol	< 300 (< 300) mg/day	Decrease prepared meats and do not add extra salt to food
Salt	< 6 (< 5) g/day	Increase fruit and vegetables and wholegrain foods
Total dietary fibre	30 (> 25) g/day	

* Values in parentheses are goals for the intake of populations, as given by the WHO (including populations who are already on low-fat diets). Some of the extreme ranges are not realistic short-term goals for developed countries, e.g. 75% of total energy from carbohydrate and 15% fat.

guidelines may also differ, even when the nutrient goals are the same. Nutrient goals are based on scientific information that links nutrient intake to disease. Although the information is incomplete, it includes evidence from a wide range of sources, including experimental animal studies, clinical studies and both short-term and long-term epidemiological studies.

PROTEIN-ENERGY MALNUTRITION (PEM)

IN DEVELOPED COUNTRIES

Starvation uncomplicated by disease is relatively uncommon in developed countries, although some degree of undernourishment is seen in very poor areas. Most nutritional problems occuring in the population at large are due to eating wrong combinations of foodstuffs, such as an excess of refined carbohydrate or a diet low in fresh vegetables. Undernourishment associated with disease is common in hospitals and nursing homes, and Table 5.4 gives a list of conditions in which malnutrition is often seen. Surgical complications, with sepsis, are a common cause. Many patients are admitted to hospital undernourished, and a variety of chronic conditions predispose to this state (Table 5.5).

The majority of the weight loss, leading to malnutrition, *is due to poor intake secondary to the anorexia associated with the underlying condition.* Disease may also contribute by causing malabsorption and increased catabolism, which is mediated by complex changes in cytokines, hormones, side-effects of drugs, and immobility. The elderly are particularly at risk of malnutrition because they often suffer from diseases and psychosocial problems such as social isolation or bereavement (Table 5.5).

Pathophysiology of starvation (Fig. 5.4) In the first 24 hours following low dietary intake, the body relies for energy on the breakdown of hepatic glycogen to glucose. Hepatic glycogen stores are small and therefore gluconeogenesis is soon necessary to

Table 5.4 **Common conditions associated with protein-energy malnutrition**

Sepsis	Trauma
Surgery, particularly of GI tract with complications	GI disease, particularly involving the small bowel
Dementia	
Malignancy	
Any very ill patient	
Severe chronic inflammatory diseases	Psychosocial: poverty, social isolation, anorexia nervosa, depression

Table 5.5 **Nutritional consequences of disease and the underlying risk factors (physical/psychosocial problems)**

Risk factors	Consequence
Underlying disease	
Almost any moderate/severe chronic disease Recovery from severe acute/subacute disease	Anorexia, increased requirements for some nutrients, and *other effects indicated below (depending on condition)*
Physical problems	
Muscle weakness (respiratory and peripheral muscles) and/or incoordination	Problems with shopping, cooking and eating
Severe arthritis in hands and arms	Problems with shopping, cooking and eating
Swallowing problem (neurological causes), painful or obstructive conditions of mouth and gastrointestinal tract (GIT)	Inadequate food intake, and/or risk of aspiration pneumonia
GIT symptoms (e.g. nausea, vomiting, diarrhoea, jaundice)	Food aversion, malabsorption (small bowel disease), anorexia
Sensory deficit (e.g. impaired sight, hearing and other deficits)	Difficulties in shopping, cooking and/or decreased intake of food
Psychosocial problems	
Loneliness, depression, bereavement, confusion, living alone, poverty, alcoholism, drug addiction	Self-neglect, inadequate intake of food or quality of food
Multiple drug use (polypharmacy)	Indicates severe disease or multiple physical and psychosocial problems; drugs may lead to confusion, sedation, depression and GIT side-effects (including malabsorption of nutrients)

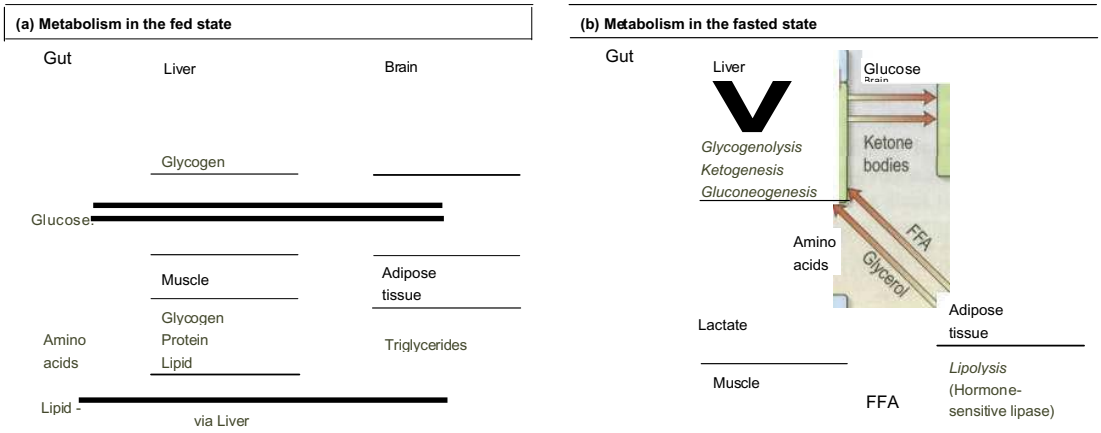

Fig. 5.4 Metabolism in (a) the fed and (b) the fasted state. FFA, free fatty acids.

maintain glucose levels. Gluconeogenesis takes place mainly from pyruvate, lactate, glycerol and amino acids, especially alanine and glutamine. The majority of protein breakdown takes place in muscle, with eventual loss of muscle bulk.

Lipolysis, the breakdown of the body's fat stores, also occurs. It is inhibited by insulin, but the level of this hormone falls off as starvation continues. The stored triglyceride is hydrolysed by lipase to glycerol, which is used for gluconeogenesis, and also to non-esterified fatty acids that can be used directly as a fuel or oxidized in the liver to ketone bodies.

As starvation continues, *adaptive processes* take place lest the body's available protein be completely utilized. There is a decrease in metabolic rate and total body energy expenditure. Central nervous metabolism changes from glucose as a substrate to ketone bodies, which now become the main source of energy for the brain. Gluconeogenesis in the liver decreases as does protein breakdown in muscle, both of these processes being inhibited directly by ketone bodies, which are derived from fat. Most of the energy at this stage comes from adipose tissue, with some gluconeogenesis from amino acids, particularly from alanine in the liver, and glutamine in the kidney.

The metabolic response to prolonged starvation differs between lean and obese individuals. One of the major differences concerns the proportion of energy derived from protein oxidation, which determines the proportion of weight loss from lean tissues. This proportion may be up to three times smaller in obese subjects than lean subjects. It can be regarded as an adaptation which depends on the compensation of the initial reserves (Fig. 5.3). This means that deterioration in body function is more rapid in lean subjects. Furthermore, survival time is much less in lean subjects (~ 2 months), compared to the obese (can be at least several months).

Following trauma or shock, some of the adaptive changes do not take place. Glucocorticoids and cytokines (see below) stimulate the ubiquitin-proteasome pathway in muscle, which is responsible for accelerated proteolysis in muscle in many catabolic illnesses. In starvation there is a decrease in BMR, whilst in inflammatory and traumatic disease, the BMR is often increased. These changes all result in continuing gluconeogenesis with massive muscle breakdown, and further reduction in survival time.

Regulation of metabolism

Tissue metabolism is regulated by multiple coordinated processes. Some are rapid, involving nerves, whilst others are slower involving circulating substrates and hormones. The availability of substrates (e.g. glucose, non-esterified fatty acids (NEFA), and ketone bodies) in the circulation can have major effects on tissue metabolism, as a result of mass action effects that are *independent of hormones.* For example, the markedly elevated circulating ketone body concentration during starvation (up to 5 or more mmol/L), leads to increased uptake and metabolism of tissues such as the brain. The liver that produces these ketone bodies can be regarded as controlling the metabolism of the brain. Adipose tissue, which releases NEFA, controls hepatic metabolism, which in turn depends on this substrate for ketogenesis. Substrates may also compete with each other, again independently of hormones. Tissue triglyceride and glycogen (which produce NEFA and glucosyl units on hydrolysis) also compete for uptake and metabolism in muscle and heart.

Blood flow to a tissue can also influence metabolism by affecting the delivery of substrates to the tissue or their release into the circulation. NEFA are bound to two or three high affinity sites on albumin, and when these high affinity sites become nearly saturated, the efflux of NEFA would be limited. During starvation or prolonged exercise, when there is increased demand for NEFA, there is a major increase in the blood flow to adipose tissue, which supplies more albumin with unsaturated binding sites.

In many tissues there is coupling between metabolic activity and blood flow with the arterioles regulating blood flow to the tissue according to demand.

Hormonal signals also regulate intracellular metabolism.

The activation of lipoprotein lipase, which hydrolyses circulating triglycerides so that NEFA can enter adipose tissue for storage is delayed several hours after a meal to

coincide with the rise in circulating triglycerides, which occurs later than the changes of other metabolites such as glucose, NEFA and amino acids.

In the fed state, insulin/glucagon ratios are high. Insulin promotes synthesis of glycogen, protein and fat, and inhibits lipolysis and gluconeogenesis.

In the fasted state, the insulin/ glucagon ratios are low. Glucagon acts mainly on the liver and has no action on muscle. It increases glycogenolysis and gluconeogenesis, as well as increasing ketone body production from fatty acids. It also stimulates lipolysis in adipose tissue. Catecholamines have a similar action to glucagon but also affect muscle metabolism. Both these agents act via cyclic adenosine monophosphate (cAMP) to stimulate lipolysis, producing free fatty acids that can then act as a major source of energy.

Cytokines, such as interleukin-1, interleukin-6 and tumour necrosis factor (TNF), have also been shown to play a role in regulating metabolism. In acute diseases they contribute to the catabolic process, glycogenolysis, and acute-phase protein synthesis. TNF, which inhibits lipoprotein lipase, is the 'cachexia factor' in patients with cancer.

It is now recognized that the metabolic response to trauma, injury and inflammation depends on the balance between pro-inflammatory and anti-inflammatory cytokines (e.g. IL-10) and that the production of many of these cytokines is influenced by genetic polymorphisms. Since many chronic diseases, including atherosclerosis, have an inflammatory component, these considerations have wide-reaching metabolic implications.

It is unclear how these cytokines interact with central feeding pathways to cause anorexia. However, in animal models of both cancer and inflammatory bowel disease, many peripheral and central mediators of appetite are involved. For example, neuropeptide Y levels in the hypothalamus are often inappropriately low, so there is a reduced drive to feeding.

Clinical features

Patients are sometimes seen with loss of weight or malnutrition as the primary symptom (failure to thrive in children). Mostly, however, malnourishment is only seen as an accompaniment of some other disease process, such as malignancy. Severe malnutrition is seen mainly with advanced organic disease or after surgical procedures followed by complications. Three key features which help in the detection of chronic protein-energy malnutrition (PEM) in adults are:

1. *The body mass index (BMI):*

   m Probable chronic PEM: < 18.5 kg/m^2
   ■ Possible chronic PEM: 18.5-20 kg/m^2
   ■ Little or no risk of chronic PEM: > 20 kg/m^2.

   In patients with oedema or dehydration the BMI may be somewhat misleading.

2. *Weight loss in previous 3-6 months:* > 10%, high risk; 5-10%, possible risk; < 5% low/no risk of developing PEM.

3. *Acute disease effect:* Diseases that have resulted or are likely to result in no dietary intake for more than 5 days are associated with a high risk of malnutrition (e.g. prolonged unconsciousness, persistent swallowing problems after a stroke, or prolonged ileus after abdominal surgery).

Other factors:

* History of decreased food intake/loss of appetite
■ Clothes becoming loosely fitting (weight loss) and a general appearance indicating obvious wasting
■ Physical and psychosocial disturbances likely to have contributed to the weight loss.

These factors act as a link between detection and management (Fig. 5.5). If the underlying physical or psychosocial problems are not adequately addressed, treatment may not be successful.

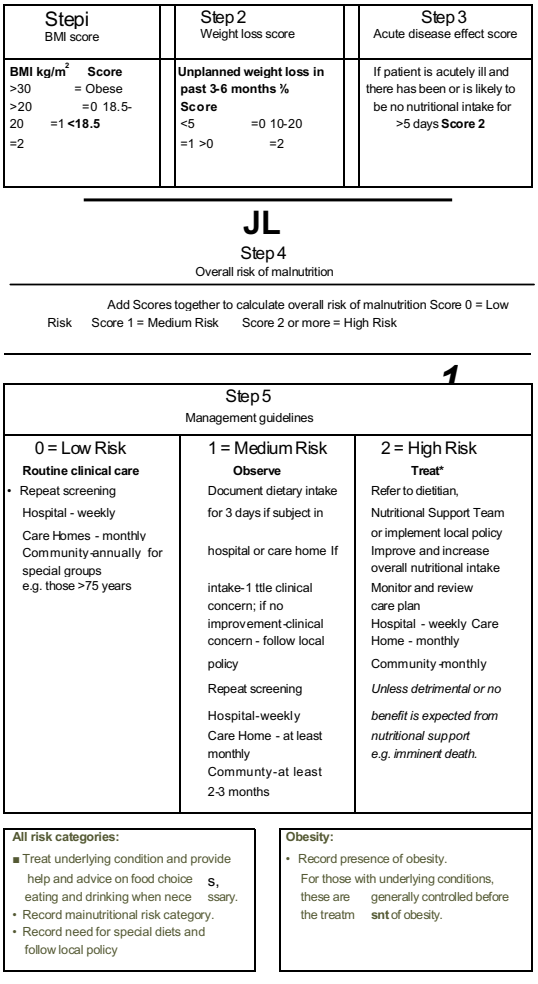

Fig. 5.5 **Malnutrition Universal Screening Tool (MUST).** Reproduced with permission from the Malnutrition Advisory Group - A Standing Committee of British Association of Parenteral and Enteral Nutrition (BAPEN): http://www.bapen.org.uk. .

PEM leads to a depression of the immunological defence mechanism, resulting in a decreased resistance to infection. It also detrimentally affects muscle strength and fatigue, reproductive function (e.g. in anorexia nervosa, which is common in adolescent girls; p. 1310), wound healing, and psychological function (depression, anxiety, hypochondriasis, loss of libido).

Treatment (see also pp. 257 and 260) When malnutrition is obvious and the underlying disease cannot be corrected at once, some form of nutritional support is necessary. Nutrition should be given enterally if the gastrointestinal tract is functioning adequately. This can most easily be done by encouraging the patient to eat more often and by giving a high-calorie supplement. If this is not possible, a liquefied diet may be given intragastrically via a fine-bore tube or by a percutaneous endoscopic gastrostomy (PEG). If both of these measures fail, parenteral nutrition is given.

IN DEVELOPING COUNTRIES

In many areas of the world, people are on the verge of malnutrition. In addition, if events such as drought, war or changes in political climate occur, millions suffer from starvation. Although the basic condition of PEM is the same in all parts of the world from whatever cause, malnutrition resulting from long periods of near-total starvation produces unique clinical appearances in children virtually never seen in high-income countries. The term 'protein-energy malnutrition' covers the spectrum of clinical conditions seen in adults and children. Children under 5 years may present with:

- *Marasmus* is the childhood form of starvation, which is associated with obvious wasting. The child looks emaciated, there is obvious muscle wasting and loss of body fat. There is no oedema. The hair is thin and dry (Fig. 5.6a). The child is not so apathetic or anorexic as with kwashiorkor. Diarrhoea is frequently present and signs of infection must be looked for carefully.
- *Kwashiorkor* occurs typically in a young child displaced from breast-feeding by a new baby. It is often precipitated by infections such as measles, malaria and diarrhoeal illnesses. The child is apathetic and lethargic with severe anorexia. There is generalized oedema with skin pigmentation and thickening (Fig. 5.6b). The hair is dry, sparse and may become reddish or yellow in colour. The abdomen is distended owing to hepatomegaly and/ or ascites. The serum albumin is always low. The exact cause is unknown, but theories related to diet (low in protein, and high in carbohydrate) and free radical damage in the presence of inadequate antioxidant defences have been proposed.

A recent classification of severe malnutrition by the World Health Organization (Table 5.6) makes no distinction between kwashiorkor and marasmus, because their approach to treatment is similar.

The World Health Organization (WHO) classification of chronic undernutrition in children is based on standard deviation (SD) scores. Thus, children with an SD score between -2 and -3 (between 3 and 2 standard deviation scores below the median - corresponding to a value between 0.13 and 2.3 centile) can be regarded as being at moderate risk of undernutrition, and below an SD score of -3, of severe malnutrition. A low weight-for-height is a measure of thinness (wasting when pathological), and a low height-for-age is a measure of shortness (stunting when pathological). Those with oedema and clinical signs of severe malnutrition are classified as having oedematous malnutrition.

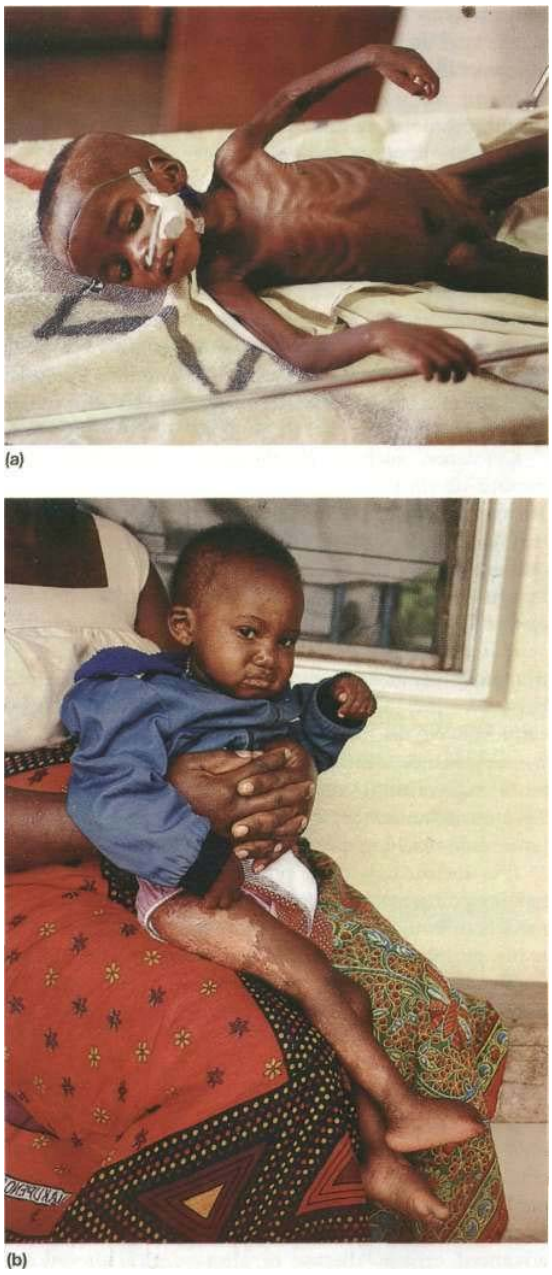

Fig. 5.6 Malnourished children: (a) marasmus and (b) kwashiorkor. Courtesy of Dr Paul Kelly.

Table 5.6 **Classification of childhood malnutrition**

	Moderate malnutrition	Severe malnutrition*
Symmetrical oedema	No	Yes (oedematous malnutrition)*
Weight-for-height	SD score -3 to -2 (70-79%)*	SD score below -3 (< 70%)* (severe wasting)§
Height-for-age	SD score -3 to -2 (85-89%)*	SD score below -3 (< 85%)* (severe stunting)

The diagnoses are not mutually exclusive
^his includes kwashiorkor and marasmic-kwashiorkor in the older classifications. To avoid confusion with the clinical syndrome of kwashiorkor, which includes other features (see text), the term oedematous malnutrition is preferred
♦Percentage of the median National Centre for Health Statistics/WHO reference
§This corresponds to marasmus (without oedema) in the Weilcome classification and to grade II in the Gomez classification. To avoid confusion the term 'severe' wasting is preferred

Starvation in adults may lead to extreme loss of weight depending upon the severity and duration. They may crave for food, are apathetic and complain of cold and weakness with a loss of subcutaneous fat and muscle wasting. Infections such as gastrointestinal or bronchopneumonia are common. The WHO classification is based on body mass index, with a value less than 18.5 kg/m^2 indicating malnutrition (severe malnutrition if less than 16.0 kg/m^2.

Severely malnourished adults and children are very susceptible to respiratory and gastrointestinal infections, leading to an increased mortality in these groups.

Investigation

It must be realized that this is not always practicable.

- **Blood tests**
  - **(a)** Anaemia due to folate, iron and copper deficiency is often present, but the haematocrit may be high owing to dehydration.
  - (b) Eosinophilia suggests parasitic infestation.
  - (c) Electrolyte disturbances are common.
  - (d) Malarial parasites should be looked for.
  - (e) HIV tests.
- **Stools** should be examined for parasitic infestations.
- **Chest X-ray** - tuberculosis is common and is easily missed if a chest X-ray is not performed.

Treatment

Treatment must involve the provision of protein and energy supplements and the control of infection.

Resuscitation and stabilization

The severely ill child will require correction of fluid and electrolyte abnormalities, but intravenous therapy should be avoided if possible because of the danger of fluid overload. Treatment of shock may require oxygen. Treatment should also focus on hypoglycaemia (blood glucose < 3 mmol/L), hypothermia (reduce heat loss, and provide additional heat if necessary) and infection (antibiotics), which often coexist. The standard WHO oral hydration solution has a high sodium and low potassium content and is not suitable for severely malnourished children. Instead, the rehydration solution for malnutrition (ReSoMal) is recommended. It is commercially available but can be produced by modification of the standard WHO oral hydration solution.

Diarrhoea is often due to bacterial or protozoal overgrowth; metronidazole is very effective and is often given routinely. Parasites are also common and, as facilities for stool examination are usually not available, mebendazole 100 mg twice daily should be given for 3 days. In high-risk areas, antimalarial therapy is given. Large doses of vitamin A are also given because deficiency of this vitamin is common. After the initial resuscitation, further stabilization over the next few days is undertaken, as indicated in Table 5.7.

Refeeding

This needs to be planned carefully. During the initial treatment of the acute situation, a balanced diet with

Table 5.7 **Time frame for the management of the child with severe malnutrition (the 10-step approach recommended by the WHO)**

	Stabilization Days 1-2 Days 3-7	Rehabilitation Weeks 2-6	Follow-up Weeks 7-26
1. Treat or prevent hypoglycaemia			
2. Treat or prevent hypothermia			
3. Treat or prevent dehydration

sufficient protein and energy is given to maintain a steady state. Large increases in energy lead to heart failure, circulatory collapse and death (refeeding syndrome). Initial feeding involves administration of feeds of low osmolarity and low in lactose (WHO recommendations: 100 kcal/kg/day, 1.0-1.5 g protein/kg/day and 130 mL liquid/kg/day (100 mL/kg/day if the child has marked oedema). Attempts should be made to give the feeds slowly and frequently (e.g. 2-hourly during days 1-2; 3-hourly during days 3-5; and 4-hourly thereafter), although anorexia is often a problem and can be exacerbated by excessive feeding. If necessary, fluids and food should be given by nasogastric tube. The child is then gradually weaned to liquids and then solids by mouth. All severely malnourished children have vitamin and mineral deficiencies. Although anaemia is common, the WHO recommends to give iron only after the child develops a good appetite and starts gaining weight, because of concern about making the infection worse (iron is a pro-oxidant). The child should be given daily micronutrient supplements for at least 2 weeks. These should include a multivitamin supplement with folic acid, zinc and copper.

Rehabilitation

Gradually, as the child improves, more energy can be given, and during rehabilitation weight gain is achieved by providing extra energy and protein ('catch-up weight gain'). Children who have been severely ill need constant attention right through the convalescent period, as often home conditions are poor and feeds are refused. Sensory stimulation and emotional support is a major component of management during both the stabilization and rehabilitation phases.

Adults do not usually suffer such severe malnutrition, but the same general principles of treatment should be followed.

Prognosis

Children with extreme malnutrition have a mortality of over 50%. By careful management this can be reduced significantly to 1-2%, depending on the availability of facilities. Brain development takes place in the first years of life, a time when severe PEM frequently occurs. There is evidence that intellectual impairment and behavioural abnormalities occur in severely affected children. Physical growth is also impaired. Probably both of these effects can be alleviated if it is possible to maintain a high standard of living with a good diet and freedom from infection over a long period.

Prevention

Prevention of PEM depends not only on adequate nutrients being available but also on education of both governments and individuals in the importance of good nutrition and immunization (Box 5.3). Short-term programmes are useful for acute shortages of food, but long-term programmes involving improved agriculture are equally necessary. Bad feeding practices and infections are more prevalent than actual shortage of food in many areas of the world. However, good surveillance is necessary to avoid periods of famine.

Box 5.3 **Prevention of protein-energy malnutrition - GOBIF (a WHO priority programme)**

Growth monitoring: The WHO has a simple growth chart that the mother keeps
Oral rehydration, particularly for diarrhoea
Breast-feeding supplemented by food after 6 months
Immunization: against measles, tetanus, pertussis, diphtheria, polio and tuberculosis
Family planning

Food supplements (and additional vitamins) should be given to 'at-risk' groups by adding high-energy food (e.g. milk powder, meat concentrates) to the diet. Pregnancy and lactation are times of high energy requirement and supplements have been shown to be beneficial.

VITAMINS

Deficiencies due to inadequate intake associated with PEM (Table 5.8) are commonly seen in the developing countries. This is not, however, invariable. For example, vitamin A deficiency is never seen in Jamaica, but is common in PEM in Hyderabad, India. In the West, deficiency of vitamins is rare except in the specific groups shown in Table 5.9. The widespread use of vitamins as 'tonics' is unnecessary and should be discouraged. Toxicity from excess fat-soluble vitamins is occasionally seen.

FAT-SOLUBLE VITAMINS

Vitamin A

Vitamin A (retinol) is part of the family of retinoids which is present in food and the body as esters combined with

Table 5.8 **Fat-soluble and water-soluble vitamins: reference nutrient intake (RNI) and lower reference nutrient intake (LRNI)**

Vitamin	RNI/day (sufficient)	LRNI/day (insufficient)	Major clinical features of deficiency
Fat-soluble			
A (retinol)	700 ug	300 Mg	Xerophthalmia, night blindness, keratomalacia, follicular hyperkeratosis
D (cholecalciferol)	No dietary intake required	10 Mg (living indoors)	Rickets, osteomalacia
K	1 ug/kg bodyweight		Coagulation defects
E (a-tocopherol)	10*		Neurological disorders, e.g. ataxia
Water-soluble			
B, (thiamin)	0.4 mg per 1000 kcal[f]	0.23 mg per 1000 kcal[f]	Beriberi, Wernicke-Korsakoff syndrome
B_2 (riboflavin)	1.3 mg	0.8 mg	Angular stomatitis
Niacin	6.6 mg per 1000 kcal	4.4 mg per 1000 kcal	Pellagra
B_6 (pyridoxine)	15 ug per g of dietary protein	11 Mg per g of dietary protein	Polyneuropathy
B_{12} (cobalamin)	1.5 Mg	1.0 Mg	Megaloblastic anaemia, neurological disorders
Folate	200 pg	100 Mg	Megaloblastic anaemia
C (ascorbic acid)	40 mg	10 mg	Scurvy

*No official RNI because amount varies depending upon polyunsaturated fatty acid content of diet
[t]Thiamin requirements are related to energy metabolism

Table 5.9 **Some causes of vitamin deficiency in developed countries**

Decreased intake
Alcohol dependency: chiefly B vitamins (e.g. thiamin)
Small bowel disease: chiefly folate, occasionally fat-soluble vitamins
Vegans: vitamin D (if no exposure to sunlight), vitamin B_{12}
Elderly with poor diet: chiefly vitamin D (if no exposure to sunlight), folate
Anorexia from any cause: chiefly folate

Decreased absorption
Heal disease/resection: only vitamin B_{12}
Liver and biliary tract disease: fat-soluble vitamins
Intestinal bacterial overgrowth: vitamin B_{12}
Oral antibiotics: vitamin K

Miscellaneous
Long-term enteral or parenteral nutrition: usually vitamin supplements are given
Renal disease: vitamin D
Drug antagonists (e.g. methotrexate interfering with folate metabolism

long-chain fatty acids. The richest food source is liver, but it is also found in milk, butter, cheese, egg yolks and fish oils. Retinol or carotene is added to margarine in the UK and other countries.

Beta-carotene is the main carotenoid found in green vegetables, carrots and other yellow and red fruits. Other carotenoids, lycopene and lutein, are probably of little quantitative importance as dietary precursors of vitamin A.

Beta-carotene is cleaved in the intestinal mucosa by carotene dioxygenase, yielding retinaldehyde which can be reduced to retinol. Between a quarter and a third of dietary vitamin A in the UK is derived from retinoids. Nutritionally, 6 u,g of (5-carotene is equivalent to 1 u,g of preformed retinol; vitamin A activity in the diet is given as retinol equivalents.

Function

Retinol is stored in the liver and is transported in plasma bound to an a-globulin, retinol-binding protein (RBP). Vitamin A has several metabolic roles:

- Retinaldehyde in its *cis* form is found in the opsin proteins in the rods (rhodopsin) and cones (iodopsin) of the retina. Light causes retinaldehyde to change to its *trans* isomer, and this leads to changes in membrane potentials that are transmitted to the brain.
- Retinol and retinoic acid are involved in the control of cell proliferation and differentiation.
- Retinyl phosphate is a cofactor in the synthesis of most glycoproteins containing mannose.

Deficiency

Vitamin A deficiency and xerophthalmia (see below) is the major cause of blindness in young children despite intensive preventative programmes. The WHO estimates that between six and seven million new cases of xerophthalmia occur each year, with 20% of survivors being totally blind and 50-56% partially blind. South and East Asia, parts of Africa and Latin America as well as the Middle East are the most severely affected.

Xerophthalmia has been classified by the WHO (Table 5.10). Impaired adaptation followed by night blindness is the first effect. There is dryness and thickening of the conjunctiva and the cornea (xerophthalmia occurs as a result of keratinization). Bitot's spots - white plaques of keratinized epithelial cells - are found on the conjunctiva of young children with vitamin A deficiency. These spots can, however, be seen without vitamin A deficiency, possibly caused by exposure. Corneal softening, ulceration and dissolution (keratomalacia) eventually occur; superimposed infection is a frequent accompaniment and both lead to blindness.

Table 5.10 Classification of xerophthalmia by ocular signs

Night blindness (XN)
Conjunctival xerosis (XIA)
Bitot's spot (X2)
Corneal xerosis (X2)
Corneal ulceration/keratomalacia < V_3 corneal surface
(X3A) Corneal ulceration/keratomalacia = V_3 corneal surface
(X3B)
Corneal scar (XS)
Xerophthalmic fundus (XF)

X, xerophthalmia

In PEM, retinol-binding protein along with other proteins is reduced. This suggests vitamin A deficiency, although body stores are not necessarily reduced.

Vitamin A in malnourished children

Vitamin A supplementation appears to improve morbidity and mortality from measles. It has also been suggested that supplementation reduces morbidity and/ or mortality from diarrhoeal diseases and respiratory infections and improves growth. However, despite the large number of studies in both developed and developing countries over the last two decades, the results remain controversial. Furthermore, although low circulating concentrations of vitamin A in HlV-infected individuals are associated with increased risk of vertical transmission of HIV, vitamin A supplementation during pregnancy and the interpartum period is unlikely to reduce vertical transmission to the child.

Diagnosis

In parts of the world where the deficiency is common, diagnosis is made on the basis of the clinical features, and deficiency should always be suspected if any degree of malnutrition is present. Blood levels of vitamin A will usually be low, but the best guide to the diagnosis is a response to replacement therapy.

Treatment

Urgent treatment with retinol palmitate 30 mg orally should be given on 2 successive days. In the presence of vomiting and diarrhoea, 30 mg of vitamin A is given intramuscularly. Associated malnutrition must be treated, and superadded bacterial infection should be treated with antibiotics. Referral for specialist ophthalmic treatment is necessary in severe cases.

Prevention

Most western diets contain enough dairy products and green vegetables, but vitamin A is added to foodstuffs (e.g. margarine) in some countries. Vitamin A is not destroyed by cooking.

In some developing countries vitamin A supplements are given at the time the child attends for measles vaccination. Food fortification programmes are another approach. Education of the population is necessary and people should be encouraged to grow their own vegetables. In particular, pregnant women and children should be encouraged to eat green vegetables.

Other effects of vitamin A

The effect of (3-carotene in cardiovascular and other diseases is discussed below in the section entitled 'Dietary antioxidants'. Retinoic acid and some synthetic retinoids are used in dermatology (p. 1338).

Possible adverse effects

- *High intakes of vitamin A.* Chronic ingestion of retinol can cause liver and bone damage, hair loss, double vision, vomiting, headaches and other abnormalities. Single doses of 300 mg in adults or 100 mg in children can be harmful.
- *Retinol is teratogenic.* The incidence of birth defects in infants is high with vitamin A intakes of more than 3 mg a day during pregnancy. In pregnancy, extra vitamin A or consumption of liver is not recommended in the UK. However, fi-carotene is not toxic.

Vitamin D

See page 592.

Vitamin K

Vitamin K is found as phylloquinone (vitamin Kj) in green leafy vegetables, dairy products, rape seed and soya bean oils. Intestinal bacteria can synthesize the other major form of vitamin K, menaquinone (vitamin K_2), in the terminal ileum and colon. Vitamin K is absorbed in a similar manner to other fat-soluble substances in the upper small gut. Some menaquinones must also be absorbed as this is the major form found in the human liver.

Function

Vitamin K is a cofactor necessary for the production not only of blood clotting factors (p. 475), but also for proteins necessary in the formation of bone.

Vitamin K is a cofactor for the post-translational carboxylation of specific protein-bound glutamate residues in y-carboxyglutamate (Gla). Gla residues bind calcium ions to phospholipid templates, and this action on factors II, VII, IX and X, and on proteins C and S, is necessary for coagulation to take place.

Bone osteoblasts contain three vitamin K-dependent proteins, osteocalcin, matrix Gla protein and protein S, which have a role in bone matrix formation. Osteocalcin contains three Gla residues which bind tightly to the hydroxyapatite matrix depending on the degree of carboxylation; this leads to bone mineralization. There is, however, no convincing evidence that vitamin K deficiency or antagonism affects bone other than rapidly growing bone.

Vitamin K deficiency

Vitamin K deficiency results in inadequate synthesis of clotting factors (p. 475), which leads to an increase in the

prothrombin time and haemorrhage. Deficiency occurs in the following circumstances:

The newborn
Deficiency occurs in the newborn owing to:

- poor placental transfer of vitamin K
- little vitamin K in breast milk
- no hepatic stores of menaquinone (no intestinal bacteria in the neonate).

Deficiency leads to a haemorrhagic disease of the newborn, which can be prevented by prophylactic vitamin K. The Chief Medical and Nursing Officers (England) recommend administration of vitamin K to all neonates after risks have been discussed with parents and consent obtained.

Cholestatic jaundice
When bile flow into the intestine is interrupted, malabsorption of vitamin K occurs as no bile salts are available to facilitate absorption and the prothrombin time increases. This can be corrected by giving 10 mg of phytomenadione intramuscularly. (Note that an increased prothrombin time because of liver disease does not respond to vitamin K injection, there being no shortage of vitamin K, just bad liver function.) In patients with chronic cholestasis (e.g. primary biliary cirrhosis) oral therapy using a water-soluble preparation, menadiol sodium phosphate 10 mg daily, is used.

Concomitant vitamin K antagonists
Oral anticoagulants antagonize vitamin K (p. 480). Antibacterial drugs also interfere with the bacterial synthesis of vitamin K.

Vitamin E

Vitamin E includes eight naturally occurring compounds divided into tocopherols and tocotrienoles. The most active compound and the most widely available in food is the natural isomer d- (or RRR) oc-tocopherol, which accounts for 90% of vitamin E in the human body. Vegetables and seed oils, including soya bean, saffron, sunflower, cereals and nuts, are the main sources. Animal products are poor sources of the vitamin.

Vitamin E is absorbed with fat, transported in the blood largely in low-density lipoproteins (LDL).

An individual's vitamin E requirement depends on the intake of polyunsaturated fatty acids (PUFAs). Since this varies widely, no daily requirement is given in the UK. The requirement stated in the USA is approximately 7-10 mg per day, but average diets contain much more than this. If PUFAs are taken in large amounts, more vitamin E is required.

Function
The biological activity of vitamin E results principally from its antioxidant properties. In biological membranes it contributes to membrane stability. It protects cellular structures against damage from a number of highly reactive oxygen species, including hydrogen peroxide, superoxide and other oxygen radicals. Vitamin E may also affect cell proliferation and growth.

Vitamin E deficiency
The first deficiency to be demonstrated was a haemolytic anaemia described in premature infants. Infant formulations now contain vitamin E.

Deficiency is seen only in children with abetalipoproteinaemia (p. 308) and in patients on long-term parenteral nutrition. The severe neurological deficit (gross ataxia) can be prevented by vitamin E injection.

Plasma or serum levels of a-tocopherol can be measured and should be corrected for the level of plasma lipids by expressing the value as per milligram of plasma lipid or cholesterol.

WATER-SOLUBLE VITAMINS

Water-soluble vitamins are non-toxic and relatively cheap and can therefore be given in large amounts if a deficiency is possible. The daily requirements of water-soluble vitamins are given in Table 5.8.

Thiamin (vitamin BJ

Thiamin consists of pyrimidine and thiazole rings. The alcohol side-chain is esterified with one, two or three phosphates (Fig. 5.7a).

Function
Thiamin diphosphate, often called thiamin pyrophosphate (TPP), is an essential cofactor, particularly in carbohydrate metabolism.

TPP is involved in the oxidative decarboxylation of acetyl CoA in mitochondria. In the Krebs cycle, TPP is the key enzyme for the decarboxylation of oc-ketoglutarate to succinyl CoA. TPP is also the cofactor for transketolase, a key enzyme in the hexose monophosphate shunt.

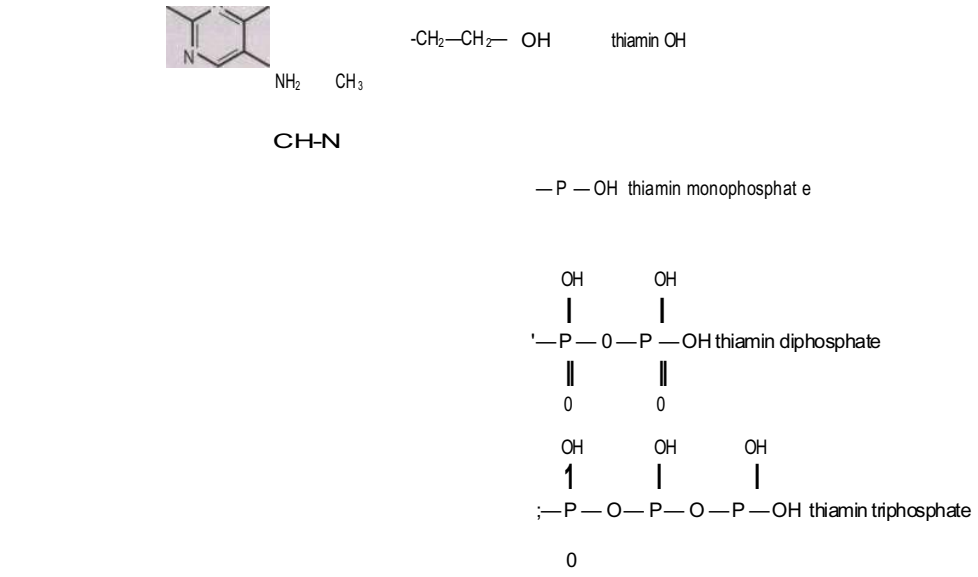
Thiamin is found in many foodstuffs, including cereals, grains, beans, nuts, as well as pork and duck. It is often added to food (e.g. in cereals) in developed countries. The dietary requirement (see Table 5.8) depends on energy intake, more being required if the diet is high in carbohydrates.

Following absorption, thiamin is found in all body tissues, the majority being in the liver. Body stores are small and signs of deficiency quickly develop with inadequate intake.

There is no evidence that a high oral intake is dangerous, but ataxia has been reported after high parenteral therapy.

Thiamin deficiency
Thiamin deficiency is seen:

- as beriberi, where the only food consumed is polished rice
- in chronic alcohol-dependent patients who are consuming virtually no food at all



(a)

(b)

Fig. 5.7 **(a) Thiamin. (b) Pellagra.** A child with pellagra showing chronic thickening and pigmentation of the skin, particularly on the backs of hands. Courtesy of Professor David Warrell.

- rarely in starved patients (e.g. with carcinoma of the stomach), and in severe prolonged hyperemesis gravidarum, especially when treated by intravenous fluids alone.

Beriberi

This is now confined to the poorest areas of South East Asia. It can be prevented by eating undermilled or par-boiled rice, or by fortification of rice with thiamine. Probably the most important factor in the reduction of beriberi is the general increase in overall food consumption so that the staple diet is varied and contains legumes and pulses, which contain a large amount of thiamin. There are two main clinical types of beriberi, which, surprisingly, only rarely occur together.

Dry beriberi usually presents insidiously with a symmetrical polyneuropathy. The initial symptoms are heaviness and stiffness of the legs, followed by weakness, numbness, and pins and needles. The ankle jerk reflexes are lost and eventually all the signs of polyneuropathy that may involve the trunk and arms are found (p. 1262). Cerebral involvement occurs, producing the picture of the Wernicke-Korsakoff syndrome (p. 1263). In endemic areas, mild symptoms and signs may be present for years without unduly affecting the patient.

Wet beriberi causes oedema. Initially this is of the legs, but it can extend to involve the whole body, with ascites and pleural effusions. The peripheral oedema may mask the accompanying features of dry beriberi.

Thiamin deficiency impairs pyruvate dehydrogenase with accumulation of lactate and pyruvate, producing peripheral vasodilatation and eventually oedema. The heart muscle is also affected and heart failure occurs, causing a further increase in the oedema. Initially there are warm extremities, a full, fast, bounding pulse and a raised venous pressure ('high-output state'), but eventually heart failure advances and a poor cardiac output ensues. The electrocardiogram may show conduction defects.

Infantile beriberi occurs, usually acutely, in breast-fed babies at approximately 3 months of age. The mothers show no signs of thiamin deficiency but presumably their body stores must be virtually nil. The infant becomes anorexic, develops oedema and has some degree of aphonia. Tachycardia and tachypnoea develop and, unless treatment is instituted, death occurs quickly.

Diagnosis

In endemic areas the diagnosis of beriberi should always be suspected and if in doubt treatment with thiamine should be instituted. A rapid disappearance of oedema after thiamine (50 mg i.m.) is diagnostic. Other causes of oedema must be considered (e.g. renal or liver disease), and the polyneuropathy is indistinguishable from that due to other causes. The diagnosis is confirmed by measurement of the circulating thiamin concentration or transketolase activity in red cells using fresh heparinized blood. This enzyme is dependent on TPP. The assay is performed with and without added TPP; an increase in activity of 25% with TPP indicates deficiency.

Treatment

Thiamine 50 mg i.m. is given for 3 days, followed by 25 mg of thiamine daily by mouth. The response in wet beriberi occurs in hours, giving dramatic improvement, but in dry beriberi improvement is often slow to occur. In most cases all the B vitamins are given because of multiple deficiency. Infantile beriberi is treated by giving thiamine to the mother, which is then passed on to the infant via the breast milk.

Thiamin deficiency in patients with alcohol dependence or acute illness

In the western world alcohol-dependent patients and those with severe acute illness receiving high carbohydrate infusions without vitamins are the only major groups to suffer from thiamin deficiency. Rarely they develop wet beriberi, which must be distinguished from alcoholic cardiomyopathy. More usually, however, thiamin deficiency presents with polyneuropathy or with the Wernicke-Korsakoff syndrome.

This syndrome, which consists of dementia, ataxia, varying ophthalmoplegia and nystagmus (see p. 1263), presents acutely and should be suspected in all heavy drinkers. If treated promptly it is reversible; if left it becomes irreversible. It is a major cause of dementia in the USA.

Urgent treatment with thiamine 250 mg i.m. or i.v. twice daily is given for 3 days, often combined with other B-complex vitamins. Anaphylaxis can occur. Thiamine must always be given before any intravenous glucose infusion.

Riboflavin

Riboflavin is widely distributed throughout all plant and animal cells. Good sources are dairy products, offal and leafy vegetables. Riboflavin is not destroyed appreciably by cooking, but is destroyed by sunlight. Riboflavin is a flavoprotein that is a cofactor for many oxidative reactions in the cell.

There is no definite deficiency, although many communities have low dietary intakes. Studies in volunteers taking a low riboflavin diet have produced:

- angular stomatitis or cheilosis (fissuring at the corners of the mouth)
- a red, inflamed tongue
- seborrhoeic dermatitis, particularly involving the face (around the nose) and the scrotum or vulva.

Conjunctivitis with vascularization of the cornea and opacity of the lens has also been described. It is probable, however, that many of the above features are due to multiple deficiencies rather than the riboflavin itself.

Riboflavin 5 mg daily can be tried for the above conditions, usually given as the vitamin B complex.

Niacin

This is the generic name for the two chemical forms, nicotinic acid and nicotinamide, the latter being found in the two pyridine nucleotides, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Both act as hydrogen acceptors in many oxidative reactions, and in their reduced forms (NADH and NADPH) act as hydrogen donors in reductive reactions. Many oxidative steps in the production of energy require NAD, and NADP is equally necessary in the hexose monophosphate shunt (p. 446) for the generation of NADPH, which is necessary for fatty-acid synthesis.

Niacin is found in many foodstuffs, including plants, meat (particularly offal) and fish. Niacin is lost by removing bran from cereals but is added to processed cereals and white bread in many countries.

Niacin can be synthesized in humans from tryptophan, 60 mg of tryptophan being converted to 1 mg of niacin. The amount of niacin in food is given as the 'niacin equivalent', which is equal to the amount of niacin plus one-sixtieth of the tryptophan content. Eggs and cheese contain tryptophan.

Kynureninase and kynurenine hydroxylase are both B_6 and riboflavin dependent, and deficiency of these B vitamins can also produce pellagra.

Pellagra

This is rare and is found in people who eat virtually only maize, for example in parts of Africa. Maize contains niacin in the form of niacytin, which is biologically unavailable, and has a low content of tryptophan. In central America, pellagra has always been rare because maize (for the cooking of tortillas) is soaked overnight in calcium hydroxide, which releases niacin. Many of the features of pellagra can be explained purely by niacin deficiency; but some are probably due to multiple deficiencies, including deficiencies of proteins and of other vitamins.

Clinical features

The classical features are of dermatitis (5.7b), diarrhoea and dementia. Although this is an easily remembered triad, not all are always present and the mental changes are not a true dementia.

- *Dermatitis*. In the areas of skin exposed to sunlight, initially there is redness followed by cracks with occasional ulceration. Chronic thickening, dryness and pigmentation develop. The lesions are always sym-

metrical and often affect the dorsal surfaces of the hands. The perianal skin and vulva are frequently involved. Casal's necklace or collar is the term given to the skin lesion around the neck, which is confined to this area by the clothes worn.

- *Diarrhoea.* This is often a feature but constipation is occasionally seen. Other gastrointestinal manifestations include a painful, red, raw tongue, glossitis and angular stomatitis. Recurring mouth infections occur.
- *Dementia.* This occurs in chronic disease. In milder cases there are symptoms of depression, apathy and sometimes thought disorders. Tremor and an encephalopathy frequently occur. Hallucinations and acute psychosis are seen with more severe cases.

Pellagra may also occur in the following circumstances:

- Isoniazid therapy can lead to a deficiency of vitamin B_6, which is needed for the synthesis of nicotinamide from tryptophan. Vitamin B_6 is now given concomitantly with isoniazid.
- In Hartnup's disease, a rare inborn error, in which basic amino acids including tryptophan are not absorbed by the gut. There is also loss of this amino acid in the urine.
- In generalized malabsorption (rare).
- In alcohol-dependent patients who do not eat.
- Very low protein diets given for renal disease or taken as a food fad.
- In the carcinoid syndrome and phaeochromocytomas, tryptophan metabolism is diverted away from the formation of nicotinamide to form amines.

Diagnosis and treatment

In endemic areas this is based on the clinical features, remembering that other vitamin deficiencies can produce similar changes (e.g. angular stomatitis). Nicotinamide (approximately 300 mg daily by mouth) with a maintenance dose of 50 mg daily is given with dramatic improvement in the skin and diarrhoea. Mostly, however, vitamin B complex is given, as other deficiencies are often present.

An increase in the protein content of the diet and treatment of malnutrition and other vitamin deficiencies is essential.

Vitamin B_B

Vitamin B_6 exists as pyridoxine, pyridoxal and pyridoxamine, and is found widely in plant and animal foodstuffs. Pyridoxal phosphate is a cofactor in the metabolism of many amino acids. Dietary deficiency is extremely rare. Some drugs (e.g. isoniazid, hydralazine and penicillamine) interact with pyridoxal phosphate, producing B_6 deficiency. The polyneuropathy occurring after isoniazid usually responds to vitamin B_6.

Sideroblastic anaemia occasionally responds to vitamin B_6 (see p. 429). A polyneuropathy has occurred after high doses (> 200 mg) given over many months. Vitamin Bf, is used for premenstrual tension: a daily dose of 10 mg should not be exceeded.

Biotin and pantothenic acid

Biotin is involved in a number of carboxylase reactions. It occurs in many foodstuffs and the dietary requirement is small. Deficiency is extremely rare and is confined to a few people who consume raw eggs, which contain an antagonist (avidin) to biotin. It has also been reported in patients receiving long-term parenteral nutrition without adequate amounts of biotin. It causes a dermatitis that responds to biotin replacements.

Pantothenic acid is widely distributed in all foods and deficiency in humans has not been described.

Vitamin C

Ascorbic acid is a simple sugar and a powerful reducing agent, its main role being to control the redox potential within cells. It is involved in the hydroxylation of proline to hydroxyproline, which is necessary for the formation of collagen. The failure of this biochemical pathway in vitamin C deficiency accounts for virtually all of the clinical effects seen.

Humans, along with a few other animals (e.g. primates and the guinea-pig), are unusual in not being able to synthesize ascorbic acid from glucose.

Vitamin C is present in all fresh fruit and vegetables. Unfortunately, ascorbic acid is easily leached out of vegetables when they are placed in water and it is also oxidized to dehydro-ascorbic acid during cooking or exposure to copper or alkalis. Potatoes are a good source as many people eat a lot of them, but vitamin C is lost during storage.

It has been suggested that ascorbic acid in high dosage (1-2 g daily) will prevent the common cold. While there is some scientific support for this, clinical trials have shown no significant effect. Vitamin C supplements have also been advocated to prevent atherosclerosis and cancer, but again a clear benefit has not been demonstrated.

Vitamin C deficiency is seen mainly in infants fed boiled milk and in the elderly and single people who do not eat vegetables. In the UK it is also seen in Asians eating only rice and chapattis, and in food faddists.

Scurvy

In adults the early symptoms may be non-specific, with weakness and muscle pain. Other features are shown in Table 5.11. In infantile scurvy there is irritability, painful legs, anaemia and characteristic subperiosteal haemorrhages, particularly into the ends of long bones.

Table 5.11 **Clinical features of vitamin C deficiency**

Keratosis of hair follicles with 'corkscrew' hair
Perifollicular haemorrhages
Swollen, spongy gums with bleeding and superadded infection, loosening of teeth
Spontaneous bruising
Spontaneous haemorrhage
Anaemia Failure of wound healing

Diagnosis

The anaemia is usually hypochromic but occasionally a normochromic or megaloblastic anaemia is seen. The type of anaemia depends on whether iron deficiency (owing to decreased absorption or loss due to haemorrhage) or folate deficiency (folate being largely found in green vegetables) is present.

Plasma ascorbic acid is very low in obvious deficiency and a vitamin C level of less than 11 (xmol/L (0.2 mg per 100 mL) indicates vitamin C deficiency. The leucocyte-platelet layer (buffy coat) of centrifuged blood corresponds to vitamin C concentrations in other tissues. The normal level of leucocyte ascorbate is 1.1-2.8 pmol per 10^6 cells.

Treatment

Initially the patient is given 250 mg of ascorbic acid daily and encouraged to eat fresh fruit and vegetables. Subsequently, 40 mg daily will maintain a normal exchangeable body pool of about 900 mg (5.1 mmol).

Prevention

Orange juice should be given to bottle-fed infants. The intake of breast-fed infants depends on the mother's diet. In the elderly, eating adequate fruit and vegetables is the best way to avoid scurvy. Careful surveillance of the elderly, particularly those who live alone, is necessary. Ascorbic acid supplements should only be necessary occasionally.

Vitamin B_{12} and folate

These are dealt with on page 430 and daily requirements are shown in Table 5.8. In many developed countries, up to 15% of the population have a partial deficiency of 5,10-methylene tetrahydrofolate reductase, a key folate-metabolizing enzyme. This is due to a point mutation and is associated with an increase in neural tube defects and hyperhomocysteinaemia, which may lead to cardiovascular damage. Autoantibodies against folate receptors have been found in women who have had a pregnancy complicated by neural tube defects.

In the USA and some other countries, enriched cereals are fortified with 1.4 mg/kg grain of folic acid to increase daily requirements.

Dietary antioxidants

Free radicals are generated during inflammatory processes, radiotherapy, and smoking, and during the course of a wide range of diseases. They may cause uncontrolled damage of multiple cellular components, the most sensitive of which are unsaturated lipids, proteins and DNA and they also disrupt the normal replication process. They have been implicated as a cause of a wide range of diseases, including malignant, acute inflammatory and traumatic diseases, cardiovascular disease, neurodegenerative conditions such as Alzheimer's disease, senile macular degeneration, and cataract. The defence against uncontrolled damage by free radicals is provided by antioxidant enzymes (e.g. catalase, superoxide dismutase) and antioxidants, which may be endogenous (e.g. glutathione) or exogenous (e.g. vitamins C and E, carotenoids). A possible causal link between antioxidant and cardiovascular disease has emerged from epidemiological studies although several RCTs have not confirmed this.

Epidemiological studies

Dietary intake

- A high intake of fruits and vegetables has been linked to reduced risk of heart disease, cerebrovascular disease and total cardiovascular morbidity and mortality.
- A high intake of nuts (rich in vitamin E) and dietary components, e.g. red wine, onions, apples (rich in flavonoids), which are strong scavengers of free radicals, have also been linked to reduced risk of cardiovascular disease.
- The seasonal variation in cardiovascular disease, which is higher in winter, has been related to decreased intake of fresh fruit and vegetables.
- The decline in cardiovascular disease in the USA since the 1950s has been associated with a simultaneous increase in the intake of fresh fruit and vegetables.

Status of antioxidant nutrients.

The level of antioxidant nutrients in the circulation, has been reported to be inversely related to cardiovascular morbidity and mortality, extent of atherosclerosis assessed by ultrasound, and clinical signs of ischaemic heart disease. The tissue content of lycopene, a marker of vegetable intake, has been reported to be low in patients with myocardial infarction.

Antioxidants, especially vitamin E, have been shown to prevent the initiation and progression of atherosclerotic disease in animals. They also reduce the oxidation of low-density lipoprotein (LDL) in the arterial wall in vitro. Oxidation of LDL is an initial event in the atherosclerotic process (p. 798).

Randomized controlled trials (RCT) (see also p. 998) For primary or secondary prevention of cardiovascular disease, intervention with P-carotene, ce-tocopherol (vitamin E) and ascorbic acid (vitamin C) has demonstrated no significant benefit. Similarly, intervention with vitamin E or P-carotene in particular conditions, such as stroke and fatal and non-fatal myocardial infarction, has also not yielded benefits. Therefore the initial optimism, based on epidemiological studies, is not borne out by RCT evidence. Indeed, healthy individuals given carotene and tocopherol showed an increased risk of intracerebral and subarachnoid haemorrhage, and a meta-analysis has shown a small increased risk of cardiovascular death and all-cause mortality. An increase in the risk of developing lung cancer has also been established from a systematic analysis of administering large doses of P-carotene to smokers. However, there are limitations to published RCTs. For example, some RCTs have used single rather than multiple antioxidants, the ratios of vitamin E and C combinations may have been different from normal dietary intakes, the doses given may have been insufficient

or too large, the duration may not have been long enough, and the correct metabolic effects may not have been measured. In addition, some of the trials were not set up to primarily assess the cardiovascular risk, some trials have only been in smokers and, lastly, the conditions may have been unsuitable for antioxidants to manifest their properties.

It is also possible that epidemiological studies are confounded by other associated variables, e.g. eating a low-fat diet or undertaking more exercise. The latter may be more valuable in the causal pathway than the intake of antioxidants. Diets rich in fresh fruit and vegetables also contain a range of antioxidants that were not tested in the clinical trials. Therefore, the results of large-scale randomized controlled trials using various combinations and doses of antioxidant nutrients are currently awaited. In the meantime, the policy of encouraging 'healthy' behaviour, which includes increased physical activity, and a varied diet rich in fresh fruit and vegetables, and nuts, is still generally recommended both for the population as a whole and for those at risk of cardiovascular disease.

Homocysteine, cardiovascular disease and B vitamins

The circulating concentration of the amino acid homocysteine is an independent risk factor for cardiovascular disease. A high concentration is related to ischaemic heart disease, stroke, thrombosis, pulmonary embolism, coronary artery restenosis, and heart failure. The strength of the association is similar to that with smoking or hyperlipidaemia. An elevation in homocysteine concentration by 5 (imol/L has been estimated to double the risk of death in patients with coronary heart disease. The risk of cardiovascular disease is *low* when serum homocysteine is < 10 umol/L, *mildly increased* at 10-15 |imol/L, and *high* above 15 umol/L (p. 802).

It is estimated that 5-20% of the population have a homocysteine concentration > 15 umol/L. Factors that increase the plasma homocysteine concentration include physiological factors (male gender, menopause, and increasing age), lifestyle (smoking, high coffee and alcohol intake, and inactivity), vitamin deficiencies (or a low intake of folate, B_{12}, B_6, B_2) and organ dysfunction (liver and kidney dysfunction). It may also result from prescription of some drugs and from genetic causes (see below).

Proposed mechanisms, based on experimental evidence, by which homocysteine detrimentally affects vascular function, include (a) the direct damaging effects of homocysteine on epithelial cells of blood vessels, (b) an increase in blood vessel stiffness, and (c) an increase in blood coagulation. Homocysteine is not found in food and its formation within the body is dependent on enzymatic reactions that involve folic acid, vitamin B_{12} and vitamin B_6 (Fig. 5.8).

A large meta-analysis of the genotypes of the enzyme methylene terrahydrofolate reductase showed that the presence of cytosine instead of thymidine in the gene coding for this enzyme, increases the plasma homocysteine concentration, and at the same time the risk of

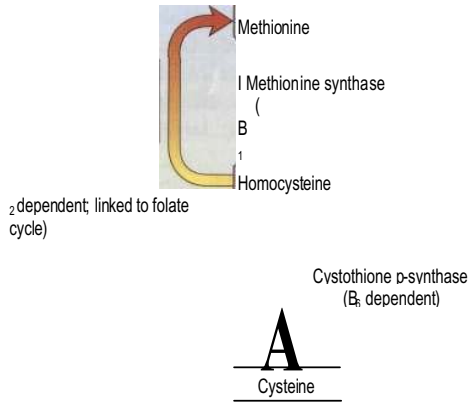


Fig. 5.8 Homocysteine metabolism.

cardiovascular disease. Since there is no relationship between this mutation and other cardiovascular risk factors, it appears that a direct causal link between homocysteine concentrations and the cardiovascular risk is more likely. In the rare autosomal recessive genetic disorder, homocysteinuria, high homocysteine concentrations are associated with premature cardiovascular problems and a thrombotic tendency.

It has been estimated that a reduction in concentration by as little as 3 umol/L, reduces the risk of ischaemic heart disease by 16%, of deep vein thrombosis by 25% and of stroke by 24%. A reduction in homocysteine concentration following administration of three B vitamins (folic acid, vitamin B_{12} and vitamin B_6) reduced the rate and severity of coronary artery restenosis 6-12 months after angioplasty compared to control patients receiving a placebo. However, a recent trial using the same therapy after coronary stenting showed an increased risk of restenosis and further studies are awaited.

Prevalence

Deficiencies of these vitamins are common, especially in the elderly. The National Diet and Nutrition Survey for people aged 65 years and over in the UK revealed that in free-living individuals folate deficiency was present in 29% of subjects (severe deficiency in 8%), and vitamin B_{12} deficiency in 8%. The values for pyridoxine deficiency are not clearly established in the elderly; about half the values were outside the normal range for younger adult populations.

Prevention

Administration of these vitamins, especially folic acid, reduces the circulating concentration of homocysteine, depending on the genotype of the enzyme methylene tetrahydrofolate reductase. Finally, the administration of these vitamins is relatively simple and inexpensive. Folic acid fortification of food is already practised in some countries, including the USA, but not in the UK. There are now a large number of intervention trials assessing the effects of folate, B_{12} and pyridoxine on cardiovascular risk.

MINERALS

A number of minerals have been shown to be essential in animals, and an increasing number of deficiency syndromes are becoming recognized in humans. Long-term total parenteral nutrition allowed trace element deficiency to be studied in controlled conditions; now trace elements are always added to long-term parenteral nutrition regimens. It is highly probable (but difficult to study because of multiple deficiencies) that trace-element deficiency is also a frequent accompaniment of all PEM states. Sodium (RNI 70 mmol/day), potassium (RNI 90 mmol/day), magnesium (RNI 12.3 mmol/day for men and 10.9 for women) and chloride are discussed in Chapter 12.

Iron (see also p. 426)

The daily **RNI** for **men** is 160 |**imol** (8.7 mg) and for women 260 umol (14.8 mg). Iron deficiency is common world-wide, affecting both developing and developed countries. It is particularly prevalent in women of a reproductive age. Dietary iron overload is seen in South African men who cook and brew in iron pots.

Copper

The daily RNI of copper is 1.2 mg (19 umol). Shellfish, legumes, cereals and nuts are good dietary sources.

Deficiency

Menkes' kinky hair syndrome is a rare condition caused by malabsorption of copper. The Menkes' disease gene *(ATP7A)* encodes a copper-transporting ATPase and has a homology to the gene in Wilson's disease. Infants with this sex-linked recessive abnormality develop growth failure, mental retardation, bone lesions and brittle hair. Anaemia and neutropenia also occur. This condition, which serves as a model for copper deficiency, supports the idea that some of the clinical features seen in PEM are due to copper deficiency. Breast and cow's milk are low in copper, and supplementation is occasionally necessary when first treating PEM.

Copper toxicity

This occurs in Wilson's disease; see page 387.

Zinc

The daily RNI of zinc is 9.5 mg (145 urnol) for men, 7 mg (110 (imol) for women and it is widely available in food. Zinc is involved in many metabolic pathways, often acting as a coenzyme; it is essential for the synthesis of RNA and DNA.

Deficiency

Acrodermatitis enteropathica is an inherited disorder caused by malabsorption of zinc. Infants develop growth retardation, severe diarrhoea, hair loss and associated *Candida* and bacterial infections. This condition provides a model for zinc deficiency. Zinc supplementation results in a complete cure. Deficiency probably also plays a role in PEM.

Zinc levels have been shown to be low in some patients with malabsorption or skin disease, and in patients with AIDS, but the exact role of zinc in these situations is disputed. Zinc has low toxicity, but high zinc levels from water stored in galvanized containers interfere with iron and copper metabolism. Wound healing is impaired with moderate zinc deficiency and is improved by zinc supplements. Impaired taste and smell, hair loss and night blindness are also features of severe zinc deficiency.

Iodine

The daily **RNI** of iodine is 140 ng (1.1 wmol) for men and women, and it is found in milk, meat and seafoods.

It exists in foodstuffs as inorganic iodides which are efficiently absorbed. Iodine is a constituent of the thyroid hormones (p. 1069).

Deficiency

Many mountainous areas throughout the world lack iodine in the soil, and so iodine deficiency, which impairs brain development, is a WHO priority. Endemic goitre occurs in remote areas where the daily intake is below 70 jig, and in those parts 1-5% of babies are born with cretinism. In these areas, iodized oil should be given intramuscularly to all reproductive women every 3-5 years. In developed countries, salt is iodized and endemic goitre has disappeared.

Fluoride

In areas where the level of fluoride in drinking water is less than 1 p.p.m. (0.7-1.2 mg/L), dental caries is relatively more prevalent. Fluoridation of the water provides 1-2 mg daily, resulting in a reduction of about 50% of

tooth decay in children. There is little fluoride in food except for seafish and tea, the latter providing 70% of the daily intake. Fluoride-containing toothpaste may add up to 2 mg a day.

Excessive fluoride intake in areas where the water fluoride level is above 3 mg/L can result in fluorosis, in which there is infiltration into the enamel of the teeth, producing pitting and discoloration.

Selenium

Clinical deficiency of selenium is rare except in areas of China where Keshan disease, a selenium-responsive cardiomyopathy, occurs. Selenium deficiency may also cause a myopathy. Toxicity has been described with very high intakes.

Calcium (see also p. 591)

In the UK, the daily RNI of calcium is 700 mg (17.5 mmol), but substantially higher values are now recommended in the USA. It is found in many foodstuffs, with two-thirds of the intake coming from milk and milk products, only 5% from vegetables. In the UK most flour is fortified. Calcium absorption from the gastrointestinal tract is vitamin D-dependent. Ninety-nine per cent of body calcium is in the skeleton.

Increased calcium is required in pregnancy and lactation, when dietary intake must be increased. Calcium deficiency is usually due to vitamin D deficiency.

The daily RNI of phosphate is the same as that of calcium, i.e. 17.5 mmol. Phosphates are present in all natural foods, and dietary deficiency has not been described. Patients taking large amounts of aluminium hydroxide can, however, develop phosphate deficiency owing to binding in the gut lumen. It can also be seen in total parenteral nutrition. Symptoms include anorexia, weakness and osteoporosis.

Other trace elements

The possible significance of cadmium, chromium, cobalt, manganese, molybdenum, nickel and vanadium is shown in Table 5.12.

Table 5.12 **Other trace elements (see text)**

Element	Deficiency
Cadmium	?
Chromium	Glucose intolerance
Cobalt	Anaemia (vitamin B_{12})
Manganese	Skin rash, ? osteoporosis, ? mood
Molybdenum	? (case study involving parenteral nutrition)
Nickel	? Animals only
Vanadium	?

NUTRITION AND AGEING

Many animal studies have shown that life expectancy can be extended by restricting food intake. It is, however, not known whether the ageing process in humans can be altered by nutrition.

The ageing process

The process of ageing is not well understood. While wear and tear may play a role, it is an insufficient explanation for the causation of ageing. The *'programmed' theories* depend on inbuilt biological clocks that regulate lifespan, and involve genes that are responsible for controlling signals that influence various body systems. The *'error' theories* involve environmental stressors that induce damage (e.g. mitochondrial DNA damage or cross-linking).

The search for a single cause of ageing, e.g. a single gene defect, has been replaced by the view that ageing is a complex multifactorial process that involves an interaction between genetic, environmental, and stochastic (random damage to essential molecules) causes. The following theories have been suggested:

Molecular theories

- *Gene regulation* - ageing, for example, results from changes in expression of genes that regulate both development and ageing. An insulin-like signalling pathway has been linked to the lifespan of worms, flies and mice (activation of a transcription factor in response to reduced insulin-like signalling prolongs lifespan).
- *Codon restriction* - inadequate mRNA translation resulting from inadequate decoding of codons in mRNA.
- *Error catastrophe* - errors in gene expression result in abnormal proteins.
- *Somatic mutation* - cumulative molecular damage mainly to genetic material.
- *Dysdifferentiation* - cumulative random molecular damage detrimentally affects gene expression.

Cellular theories

- *Cellular senescence-telomere* - an increase in senescent cells occurs from:
  (a) Loss of telomeres, which is known to occur with ageing (with each cell division a small amount of DNA is necessarily lost at each end of the chromosome). Activation of the telomerase enzyme regenerates telomeres, prevents senescence (replicative senescence) and immortalizes cell cultures. Cancer cells are known to activate telomerase.

(b) Damage due to a variety of other factors, including DNA damage (stress-induced senescence).

- *Free radical* - production of free radicals during oxidative metabolism which damages fat, protein and DNA.
- *'Wear and tear* - cumulative damage from normal injury/ stress which is unable to repair itself.
- *Apoptosis theory* - programmed cell death due to genetic events

System theories

These theories involve loss in the function of neuro-endocrine or immune systems with consequent age-related physiological changes and an increase in autoimmunity.

Whole body metabolism and energy expenditure theory proposes that there is a fixed limit to the cumulative energy expenditure and metabolism during a lifetime, so that if this limit is reached quickly the lifespan is short. Energy restriction in rodents reduces energy expenditure and prolongs lifespan, but there is a lack of studies in primates or humans.

Evolutionary theories

- *Cumulative mutation* - mutations that accumulate during the lifetime act in older age rather than during the active reproductive period (for which there is evolutionary selection), producing pathology and senescence. The theory was initially based on the observation that Huntington's disease, a dominant lethal mutation which typically manifests itself between 35 and 55 years, allows affected individuals to reproduce.
- *Disposable soma* - the somatic body is maintained to ensure reproductive success, after which it is dispos able. Factors that may enhance reproductive success may have detrimental effects on ageing - a possible example being androgen secretion, which may be beneficial to reproduction but potentially detrimental with development of prostatic cancer and cardio vascular disease in later life.

Several of these theories have strong nutritional components. *Disability and dependency* in older humans are at least partly due to poor nutrition, and correction of deficiencies or nutrient imbalances can prevent the decline in function from falling below the disability threshold (Fig. 5.9). In this way some loss of function may be prevented or reversed, especially if other measures, such as physical activity, which increases muscle mass and strength are undertaken.

Early origins of health and disease in older adults

A low birth weight (and or length) is associated with reduced height, as well as reduced mass and fat-free mass in adult life. These relationships can occur independently of genetic factors, since the smaller of identical twins becomes a shorter and lighter adult. Relationships have also been reported between growth of the fetus and a variety of diseases and risk factors for disease in adults and older people. These include cardiovascular disease, especially ischaemic heart disease, hypertension, and diabetes, and even obesity and fat distribution. However, the strength of association for some of these conditions is in some cases weak. Animal studies involving dietary modifications during pregnancy or early postnatal life (e.g. protein, zinc), even within the normal range of intakes, have clearly demonstrated effects, such as hypertension, which persist through the lifetime of the offspring, and even their offspring. The extent to which these apply to humans is uncertain, and the mechanisms are poorly understood. Since relationships with cardio-vascular disease in old age have also been related to growth in the first few years of life as well as starvation during puberty, it is likely that cumulative environmental stresses, including nutritional, from the time of implantation of the fertilized egg, to fetal and postnatal growth and development, and adult life, summate to produce an overall disease risk (Fig. 5.9).

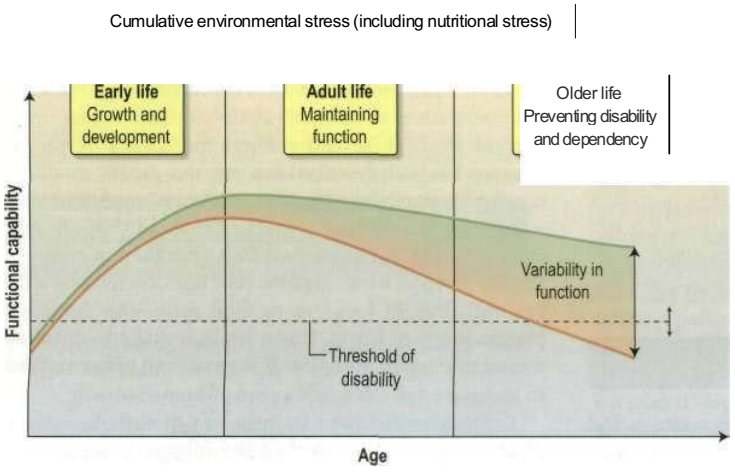

Fig. 5.9 **Nutrition and ageing.** Nutrition is a contributory cause of the variability in function during the lifespan. Appropriate nutrition may improve function, or delay deterioration below the threshold of disability and dependence.

Nutritional requirements in the elderly

These are qualitatively similar to the requirements of younger adults, but as energy expenditure is less, there is a lower energy requirement. However, maintaining physical activity is required for the overall health of the elderly.

The daily energy requirement of 'elderly people' (aged 60 and above, irrespective of age) has been set to be approximately 1.5 x BMR. The BMR is reduced, owing to a fall in the fat-free mass, from an average of 60 kg to 50 kg in men and from 40 kg to 35 kg in women. In disease, physical activity is usually decreased. The diet should contain approximately the same *proportions* of nutrients, and essential nutrients are still required. Although disabilities and diseases are common in older people, the RNIs are intended for healthy people without disease. The nutrient requirements for those with disease are less well defined.

Nutritional deficits in the elderly are common and may be due to many factors, such as dental problems, lack of cooking skills (particularly in widowers), depression and lack of motivation. Significant malnourishment in developed countries is usually secondary to social problems or disease. In the elderly who are institutionalized, multiple nutrient deficiencies are common. Vitamin D supplements may be required because often these people do not go into the sunlight. Owing to the high prevalence of osteoporosis in elderly people, daily calcium intake of 1-1.5 g/day is often recommended.

OBESITY

Obesity is almost invariable in developing countries and almost all people accumulate some fat as they get older.

Table 5.13 **Conditions in which obesity is an associated feature**

Genetic syndromes associated with hypogonadism (e.g. Prader-Willi syndrome, Laurence-Moon-Biedl syndrome) Hypothyroidism Cushing's syndrome Stein-Leventhal syndrome Drug-induced (e.g. corticosteroids) Hypothalamic damage (e.g. due to trauma, tumour)

The World Health Organization also acknowledges that obesity (body mass index > 30 kg/m^2) is a world-wide problem which also affects many developing countries. Obesity implies an excess storage of fat, and this can most easily be detected by looking at the undressed patient.

Most patients suffer from *simple obesity,* but in certain conditions obesity is an associated feature (Table 5.13). Even in the latter situation, the intake of calories must have exceeded energy expenditure over a prolonged period of time. Hormonal imbalance is often incriminated in women (e.g. postmenopause or when taking contraceptive pills), but most weight gain in such cases is usually small and due to water retention.

Not all obese people eat more than the average person, but all obviously eat more than they need. . .

Suggested mechanisms

Genetic and environmental factors

These have always been difficult to separate when studying obesity. However, refeeding experiments in both monozygotic and dizygotic twins, reared together or apart, suggest that genetic influences account for 70% of the difference in body mass index (BMI) later in life, and that the childhood environment has little or no influence.

These refeeding experiments also showed that weight gain did not occur in all pairs of twins, suggesting that in some a facultative increase in thermogenesis occurred so that part of their extra dietary energy was expended inefficiently. Genetic factors have led to the discovery of a putative gene, firstly in the obese *(ob ob)* mouse and now in humans. The *ob* gene was shown to be expressed solely in both white and brown adipose tissue. The *ob* gene is found on chromosome 7 and produces a 16 kDa protein called leptin. In the *ob ob* mouse a mutation in the *ob* gene leads to production of a non-functioning protein. Administration of normal leptin to these obese mice reduces food intake and corrects the obesity. A similar situation has been described in a very rare genetic condition causing obesity in humans, in which leptin is not expressed.

In massively obese subjects, leptin mRNA in subcutaneous adipose tissue is 80% higher than in controls. Plasma levels of leptin are also very high, correlating with the BMI. Weight loss due to food restriction decreases plasma levels of leptin. However, in contrast to the *ob ob* mouse, the leptin structure is normal, and abnormalities in leptin are not the prime cause of human obesity.

Leptin secreted from fat cells was thought to act as a feedback mechanism between the adipose tissue and the

brain, acting as a 'lipostat' (adipostat), controlling fat stores by regulating hunger and satiety (see below). However, many other signals are involved. It is interesting that obesity is largely restricted to humans, and animals that are domesticated or in zoos.

Food intake

Many factors related to the home environment, such as finance and the availability of sweets and snacks, will affect food intake. Some individuals eat more during periods of heavy exercise or during pregnancy and are unable to get back to their former eating habits. The increase in obesity in social class 5 can usually be related to the type of food consumed (i.e. food containing sugar and fat). Psychological factors and how food is presented may override complex biochemical interactions.

It has been shown that obese patients eat more than they admit to eating, and over the years a very small daily excess can lead to a large accumulation of fat. For example, a 44 kj (10.5 kcal) daily excess would lead to a 10 kg weight gain over 20 years.

Control of appetite

Appetite is the desire to eat and this usually initiates food intake. Following a meal, satiation occurs. This depends on gastric and duodenal distension and the release of many substances peripherally and centrally.

Following a meal, cholecystokinin (CCK), bombesin, glucagon-like peptide 1 (GLP1), enterostatin, and somatostatin are released from the small intestine, and glucagon and insulin from the pancreas. All of these hormones have been implicated in the control of satiety. Centrally, the hypothalamus - particularly the lateral hypothalamic area, and paraventricular and arcuate nuclei - plays a key role in integrating signals involved in appetite and bodyweight regulation (Fig. 5.10). There are two main pathways in the arcuate nucleus (see Fig. 5.10):

- *The central appetite-stimulating (orexogenic) pathway* in the ventromedial part of the arcuate nucleus, which expresses NPY (neuropeptide Y) and AgRP (agouti-related protein). Animal studies suggest that this pathway also decreases energy expenditure.
- *The central appetite-suppressing (anorexogenic pathway, or leptin-melanocortin pathway)* in the dorsolateral part of the arcuate nucleus, which expresses POMC/CART (pro-opiomelanocortin/cocaine-and-amfetamine-regulated transcript). In this pathway, a-MSH (a-melanocyte-stimulating hormone), formed by cleavage of POMC by PCI (prohormone convertase), exerts its appetite-suppressing effect via the Mc4R (melanocortin-4 receptors) in areas of the brain that regulate food intake and autonomic activity. Animal studies suggest that this pathway also increases energy expenditure.

These pathways interact with each other and feed into the lateral hypothalamus, which communicates with other parts of the brain, and influence the autonomic nervous system and ingestive behaviour. These central pathways are in turn influenced by a variety of peripheral signals

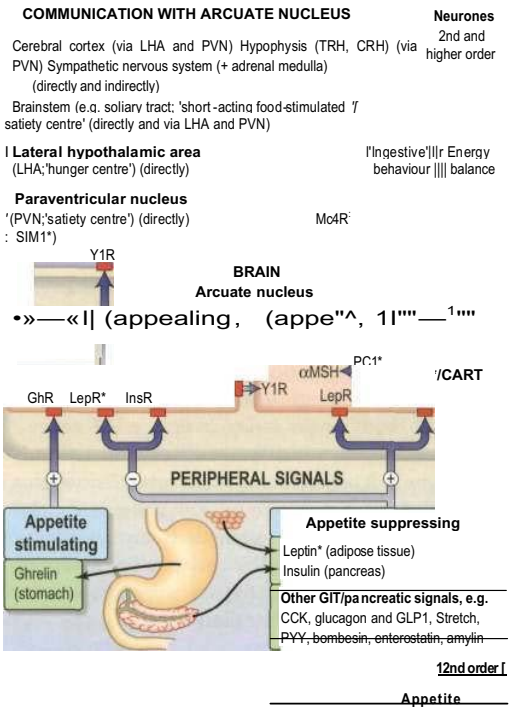

Fig. 5.10 **Peripheral signals and central pathways (central nervous system) involved in the control of food intake.**
(i) the stimulatory and suppressive peripheral signals and central pathways are identified (NPY/AgRP (neuropeptide Y/agouti-related protein) involved in the stimulatory pathway) and POMC/CART (pro-opiomelanocortin/cocaine-and-amfetamine-regulated transcript) involved in the suppressive pathway). POMC is converted to melanocortins including a-MSH (a-melanocyte-stimulating hormone) through the action of prohormone convertase (PC1).
(ii) The solid red areas represent receptors for a variety of signals (GhR, ghrelin receptor; LepR, leptin receptor; InsR, insulin receptor; Mc3R, melanocortin 3 receptor; Mc4R, melanocortin 4 receptor; Y1R, Y1 subtype of neuropeptide Y (NPY) receptor).
(iii) Asterisks (*) indicate mutations that have resulted in human obesity.
CCK, cholecystokinin; CRH, corticotrophin-releasing hormone; GLP1, glucagon-like peptide; PVN, paraventricular nucleus; PYY, peptide YY; TRH, thyrotrophin-releasing hormone.

which can also be classified as appetite stimulating or appetite suppressing.

- *Peripheral appetite-suppressing: Leptin* and *insulin* act centrally to activate the appetite-suppressing pathway (whilst also inhibiting the appetite-stimulating pathway). Since these hormones circulate in proportion to adipose tissue mass, they can be regarded as long-term signals, although they probably also modulate short-term signals (insulin also responds acutely to meal ingestion). Peptide YY (PYY) is produced by the L cells of the large bowel and distal small bowel in proportion to the energy ingested. The

release of this rapidly responsive (short-acting) signal begins shortly after food intake, suggesting that the initial response involves neural pathways, before ingested nutrients reach the site of PYY production. PYY is thought to reduce appetite, at least partly through inhibition of the appetite-stimulating pathway (NPY/AgRP-expressing neurones). ■ *Peripheral appetite-stimulating: Ghrelin is a 28-amino-acetylated peptide* produced by the oxyntic cells of the fundus of the stomach. It is the first known gastrointestinal tract peptide that stimulates appetite by activating the central appetite-stimulating pathway. The circulatory concentration is high before a meal and is reduced rapidly by ingestion of a meal or glucose (cf. peptide YY, which increases after a meal). It may also act as a long-term signal, as its circulating concentration in weight-stable individuals is inversely related to body mass index over a wide range (cf. insulin and leptin which are positively related to BMI (see below)). It is also increased in several situations in which there is a negative energy balance, e.g. long-term exercise, very low-calorie diets, anorexia nervosa and both cancer and cardiac cachexia (an exception is vertical banded gastric bypass surgery, where its concentration is low rather than high).

The single gene mutations affecting this pathway in humans, e.g. leptin, leptin receptor, *POMC, Mc4R, PCI,* and *SIM1,* are rare and recessive, with the exception of the *Mc4R,* which is common and dominant with incomplete penetrance. It appears that the *Mc4R mutation* accounts for 2-6% of human obesity. Affected individuals are obese without disturbances in pituitary function or resting energy expenditure, although children tend to be tall. However, these mutations are of little significance as obesity is predominantly polygenetic in origin (the human obesity gene map has already identified several hundreds of candidate genes).

The recent obesity epidemic is mainly due to behaviour and lifestyle changes (although it may be that individuals with certain genes are affected more than others) with a trebling in the prevalence of obesity in the UK over the last 25 years.

The control of appetite is extremely complex. For example, if one considers only one signal, i.e. leptin, there can be leptin resistance where obese individuals have high circulating leptin but with no reduction of appetite. Alternatively in starvation there may be inappropriate correlation between leptin release and loss of adipose tissue. It is known that cytokines, such as TNF and IL-2, which are elevated in a wide range of inflammatory and traumatic conditions, also suppress appetite, although the exact pathways involved are not entirely clear. Finally, there are a range of transmitters in the central nervous system, some of which appear to inhibit appetite (dopamine, serotonin, Y-[am;no]butyric acid) and others which stimulate appetite (e.g. opioids).

Energy expenditure *Basal metabolic rate (BMR).* BMR in obese subjects is higher than in lean subjects, which is not surprising since obesity is associated with an increase in lean body mass.

Physical activity. Obese patients tend to expend more energy during physical activity as they have a larger mass to move. On the other hand, many obese patients decrease their amount of physical activity. The energy expended on walking at 3 miles per hour is only 15.5 kj/min (3.7 kcal/min) and therefore increasing exercise plays only a small part in losing weight. Nevertheless, because increased body fat develops insidiously over many years, any change in energy balance is helpful.

Thermogenesis

About 10% of ingested energy is dissipated as heat and is unconnected with physical activity. This dietary induced thermogenesis has been reported to be lower in obese and post-obese subjects than in lean subjects.

This would tend to favour energy deposition in obesity and those predisposed to obesity. However, other workers have found no difference in dietary induced thermogenesis between lean and obese subjects.

Brown adipose tissue in animals, when stimulated by cold or food, dissipates the energy derived from ingested food into heat. This can be a major component of overall energy balance in small mammals. However, the importance of brown adipose tissue thermogenesis in adult humans is likely to be very small, and of doubtful clinical significance. (β_3-Adrenergic receptors are the principal receptors mediating catecholamine-stimulated lipolysis in brown adipose tissue and to a lesser extent at other sites. Drugs with β_3-adrenergic activities have been developed, but side-effects have limited their use.

Morbidity and mortality

Obese patients are at risk of early death, mainly from diabetes, coronary heart disease and cerebrovascular disease. The greater the obesity the higher the morbidity and mortality rates. For example, men who are 10% overweight have a 13% increased risk of death, while the increase in mortality for those 20% overweight is 25%. The rise is less in women, and in men over 65 obesity is not an independent risk factor. Weight reduction reduces this mortality and therefore should be strongly encouraged. The benefits are probably greater in more obese subjects (Table 5.14).

Clinical features

Most patients recognize their own problems, although often they are unaware of the main foods that cause obesity. Many symptoms are related to psychological problems or social pressures, such as the woman who cannot find fashionable clothes to wear.

The degree of obesity can be assessed by comparison with tables of ideal weight for height, from the BMI (Box 5.4), and by measuring skinfold thickness. The latter should be measured over the middle of the triceps muscle; normal values are 20 mm in a man and 30 mm in a woman. A central distribution of body fat (a waist/hip

Box 5.4 **Ranges of body mass index (BMI) used to classify degrees of overweight and associated risk of co-morbidities**

WHO classification	BMI (kg/m*)	Risk of co-morbidities
Overweight	25-30	Mildly increased
Obese	>30	
Class 1	30-35	Moderate
Class II	35-40	Severe
Class III	>40	Very severe

Table 5.14 **Potential benefits that may result from the loss of 10 kg in patients who are initially 100 kg and suffer from co-morbidities**

Mortality	20-25% fall in total mortality 30-40% fall in diabetes-related deaths 40-50% fall in obesity-related cancer deaths Blood pressure Fall of about 10 mmHg (systolic and diastolic)
Diabetes	Reduces risk of developing diabetes by > 50% Fall of 30-50% in fasting blood glucose Fall of 15% in HbA_{1c}
Serum lipids	Fall of 10% in total cholesterol Fall of 15% in LDL cholesterol Fall of 30% in triglycerides Increase of 8% in HDL cholesterol

circumference ratio of > 1.0 in men and > 0.9 in women) is associated with a higher risk of morbidity and mortality than is a more peripheral distribution of body fat (waist/hip ratio < 0.85 in men and < 0.75 in women). This is because fat located centrally, especially inside the abdomen, is more sensitive to lipolytic stimuli, with the result that the abnormalities in circulating lipids are more severe.

Table 5.15 shows the conditions and complications that are associated with obesity.

The metabolic syndrome (syndrome X) is a cluster of cardiovascular risk factors associated with excess fat. A commonly used definition (NCEP ATP III) defines the syndrome as the coexistence of three or more of the following five abnormalities: high blood pressure (> 130/85 mmHg); elevated serum triglycerides (>1.5 g/L); serum LDL cholesterol > 0.4 g/L (men) or > 0.5 g/L (women); increased abdominal circumference > 102 cm (men) or > 88 cm (women); and impaired fasting glucose (> 1.1 g/L or > 6.1 mmol/L). It is estimated that it affects up to about a quarter of adults in the USA.

Table 5.15 **Conditions and complications associated with obesity**

Psychological	Hypertension
Osteoarthritis of knees and hips	Breathlessness
Varicose veins	Ischaemic heart disease
Hiatus hernia	Stroke
Gallstones	Diabetes mellitus (type 2)
Postoperative problems	Hyperlipidaemia
Back strain	Menstrual abnormalities
Accident proneness	Increased morbidity and mortality
Obstructive sleep apnoea	Increased cancer risk
	Heart failure

The relationship between cardiovascular disease (hypertension or ischaemic heart disease), hyperlipidaemia, smoking, physical exercise and obesity is complex. Difficulties arise in interpreting mortality figures because of the number of factors involved. Many studies do not differentiate between the types of physical exercise taken or take into account the cuff-size artefact in the measurement of blood pressure (an artefact will occur if a large cuff is not used in patients with a large arm). Nevertheless, obesity almost certainly plays a part in all of these diseases and should be treated. An exception is that stopping smoking, even if accompanied by weight gain, is more beneficial than any of the other factors. Physical fitness is also helpful, and there is some evidence to suggest that a fit obese person may have similar or even lower cardiovascular risk than a leaner unfit person.

Treatment

Dietary control

This largely depends on a reduction in calorie intake.

The most common diets allow a daily intake of approximately 4200 kj (1000 kcal), although this may need to be nearer 6300 kj (1500 kcal) for someone engaged in physical work. Very low calorie diets are also advocated by some, usually over shorter periods of time, but unless they are accompanied by changes in lifestyle, weight regain is likely. Patients must realize that prolonged dieting is necessary for large amounts of fat to be lost. Furthermore, a permanent change in eating habits is required to maintain the new low weight. It is relatively easy for most people to lose the first few kilograms, but long-term success in moderate obesity is poor, with an overall success rate of no more than 10%.

Many dietary regimens aim to produce a weight loss of approximately 1 kg per week. Weight loss will be greater initially owing to accompanying protein and glycogen breakdown and consequent water loss. After 3-4 weeks, incremental weight loss may be very small because only adipose tissue is broken down and there is less accompanying water loss.

Patients must understand the principles of energy intake and expenditure, and the best results are obtained in educated, well-motivated patients. Constant supervision by healthcare professionals, by close relatives or through membership of a slimming club helps to encourage compliance. It is essential to establish realistic aims. A10% weight loss, which is regarded by some as a 'success' (see Table 5.14) is a realistic initial aim.

An increase in exercise will increase energy expenditure and should be encouraged — provided there is no contraindication - since weight control is usually not achieved without exercise. The effects of exercise are complex and not entirely understood. However, exercise alone will usually produce little long-term benefit. On the

other hand there is evidence to suggest that in combination with dietary therapy, it can prevent weight being regained. In addition, regular exercise (30 min daily) will improve general health.

The diet should contain adequate amounts of protein, vitamins and trace elements. A diet of 4200 kj (1000 kcal) per day should be made up of more than 50 g protein, approximately 100 g of carbohydrate, and 40 g of fat. The carbohydrate should be in the form of complex carbohydrates such as vegetables and fruit rather than simple sugars. Alcohol contains 29 kj/g (8 kcal/g) and should be discouraged. It can be substituted for other foods in the diet, but it often reduces the willpower. With a varied diet, vitamins and minerals will be adequate and supplements are not necessary.

A balanced diet, attractively presented, is of much greater value and safer than any of the slimming regimens often advertised in magazines.

Most obese people oscillate in weight; they often regain the lost weight, but many manage to lose weight again. This 'cycling' in bodyweight may play a role in the development of coronary artery disease.

A wide range of diets are available, including low-fat or low-carbohydrate diets, and some suit certain individuals better than others. The following general statements can be made about them.

- All low-calorie diets produce loss of bodyweight and fat, irrespective of dietary composition. Short-term weight loss is faster on low-carbohydrate diets, as a result of greater loss of body water, which is regained after the end of dietary therapy.
- Very low-fat diets are low in vitamins E, B_{12}, and zinc. Very low-carbohydrate diets are also nutritionally inadequate, and may lead to deficiencies.
- Low-fat diets decrease LDL triglycerides and increase HDL, whereas low-carbohydrate diets produce a greater decrease in HDL and triglyceride, with no change in LDL.
- There are some potential long-term concerns with low-carbohydrate diets (high in fat and protein), including increased risk of osteoporosis, renal stones and atheroma (due to high saturated fat, high *trans* fat and cholesterol and the lack of fruits, vegetables and whole grains), but long-term studies are lacking.

Behavioural modification

The aim of behavioural modification is to encourage the patient to take personal responsibility for changing lifestyle, which will determine dietary habits and physical activity. Family therapy may also be useful, especially when it involves obese children. It can be time-consuming and expensive. Cognitive behavioural therapy is even more time-consuming and expensive.

Drug therapy

Drugs can be used in the short term (up to 3 months) as an adjunct to the dietary regimen, but they do not substitute for strict dieting.

Centrally acting drugs:

- Drugs acting on the noradrenergic pathways do suppress appetite but all have been withdrawn in the UK because of cardiovascular side-effects.
- Drugs acting on both serotoninergic and noradrenergic pathways, e.g. sibutramine.

Peripherally acting drugs. Orlistat is an inhibitor of pancreatic and gastric lipases. It reduces dietary fat absorption and aids weight loss. Weight regain occurs after the drug is stopped. It has been used continuously in a large-scale trial for up to 2 years. The patients may complain of diarrhoea during treatment and to avoid this take a low-fat diet resulting in weight loss.

A recent systematic review on long-term pharmacotherapy concluded that there was a paucity of long-term studies with antiobesity agents, and that in weight loss trials of 1-year duration, orlistat and sibutramine appear to be only modestly effective in promoting weight loss (2.7 and 4.3 kg greater weight loss respectively than the control group).

Surgical treatment

Surgery is used in some cases of morbid obesity (BMI > 40 kg/m^2) or patients with a BMI > 35 kg/m^2 and obesity-related complications, after conventional medical treatments have failed. A variety of gastrointestinal surgical procedures have been used. They fall into two main groups;

- restrictive procedures, which restrict the ability to eat
- malabsorptive procedures, which reduce the ability to absorb nutrients.

A systematic analysis of bariatric surgical procedures concluded that in comparison to non-surgical treatments, they produced significantly more weight loss (23-37 kg), which was maintained to 8 years and associated with improvement in quality of life and co-morbidities.

- *Roux-en-Y gastric bypass.* This procedure incorporates both restrictive and malabsorptive elements (gastrojejunostomy). This procedure, like other malabsorptive procedures, may result in nutrient deficiencies requiring careful long-term follow-up.
- *Bilio-pancreatic diversion (including the duodenal switch variation).* This is another malabsorptive procedure that requires long-term evaluation.
- *Laparoscopic adjustable gastric banding.* This is a restrictive procedure, in which a band is placed around the upper stomach to produce a small proximal pouch and a large distal remnant. It has a perioperative mortality of < 0.5%, and results in loss of about 60% (43-78%) of the excess weight after 3 years, although longer-term follow-up studies are required. Laparoscopic adjustable gastric banding has been reported to produce greater weight loss, fewer side-effects (e.g. vomiting) and operative revisions than with vertical banded gastroplasty.
- *Liposuction.* The removal of large amounts of fat by suction (liposuction) does not deal with the

underlying problem and weight regain frequently occurs. There is no reduction in cardiovascular risk factors.

- *Jaw wiring.* This procedure, which permits liquid feeds only, requires good dental hygiene. It is only a temporary measure, since weight regain usually occurs after the wires have been removed, and therefore it is rarely practiced.

Prevention

Preventing obesity must always be the goal because most obese people find it difficult to maintain any weight loss they have managed to achieve. All health professionals must be aware of the dangers of obesity and encourage children, young as well as older adults, from gaining too much weight. A small gain each year over a long period produces an obese individual for whom treatment is difficult. Public health policies should consider creation of public places to encourage physical activity and fitness, education about the benefits of losing weight or not gaining it through healthy eating and physical activity, and changes in food composition (alternatives to high-fat high-energy dense foods).

NUTRITIONAL SUPPORT IN THE HOSPITAL PATIENT

Nutritional support is recognized as being necessary in many hospitalized patients. The pathophysiology and hallmarks of malnutrition have been described earlier (p. 237); here the forms of nutritional support that are available are discussed, along with special nutritional requirements in some diseases.

Principles

Some form of nutritional supplementation is required in those patients who cannot eat, should not eat, will not eat or cannot eat enough. It is usually necessary to provide nutritional support for:

- all severely malnourished patients on admission to hospital
- moderately malnourished patients who, because of their physical illness, are not expected to eat for more than 3-5 days
- normally nourished patients expected not to eat for more than 5 days or to eat less than half their intake for more than 8-10 days.

Enteral rather than parenteral nutrition should be used if the gastrointestinal tract is functioning normally.

Nutritional requirements for adults

- *Water.* Typical requirements are ~ 2-3 L/day. Increased requirements occur in patients with large-ouput fistulae, nasogastric aspirates and diarrhoea. Reduced requirements occur in patients with oedema, hepatic failure, renal failure (oliguric and not dialysed) and brain oedema.
- *Energy.* Typical requirements are ~ 7.5—10.0 MJ/day (1800-2400 kcal/day). Disease increases resting energy expenditure but decreases physical activity. Extra energy is given for repletion and reduced energy for obesity.
- *Protein.* Typically 10-15 g N/day (62-95 g protein/day) or 0.15-0.25 g N/kg/day (0.94-1.56 g protein/kg/day). Extra protein may be needed in severely catabolic conditions, such as extensive burns.
- *Major minerals.* Typical requirements for sodium and potassium are 70-100 mmol/day. Increased requirements occur in patients with gastrointestinal effluents. The excretion of these minerals in various effluents can provide an indication of the additional requirements (Table 12.9, p. 702). Low requirements may be necessary in those with fluid overload (or patients with hypernatraemia and hyperkalaemia). The requirements of calcium and magnesium are higher for enteral than for parenteral nutrition because only a proportion of these minerals is absorbed by the gut.
- *Trace elements.* For trace elements such as iodide, fluoride, and selenium that are well absorbed, the requirements for enteral and parenteral nutrition are similar. For other trace elements, such as iron, zinc, manganese and chromium, the requirements for parenteral nutrition are substantially lower than for enteral nutrition (Fig. 5.11).
- *Vitamins.* Many vitamins are given in greater quantities in patients receiving parenteral nutrition than in those receiving enteral nutrition (Fig. 5.12). This is because patients on parenteral nutrition may have increased requirements, partly because of severe disease, partly because they may already have depleted pools of vitamins, and partly because some vitamins

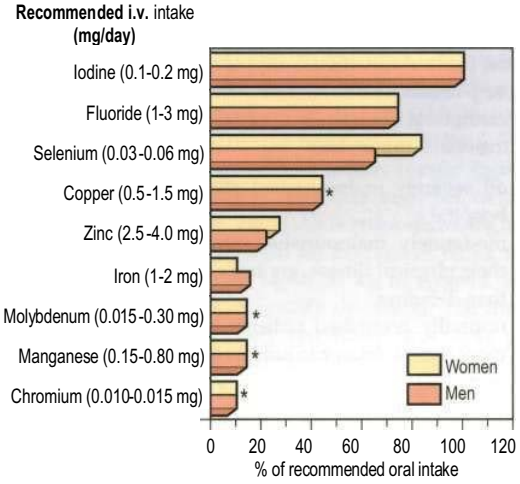

Fig. 5.11 **Recommended intravenous intake of trace elements in absolute values and as a percentage of recommended oral intake.** Trace elements marked with an asterisk are those for which there was too little information to establish recommended value for dietary oral intake: therefore the midpoint of estimated safe and adequate oral intake is used for comparison.

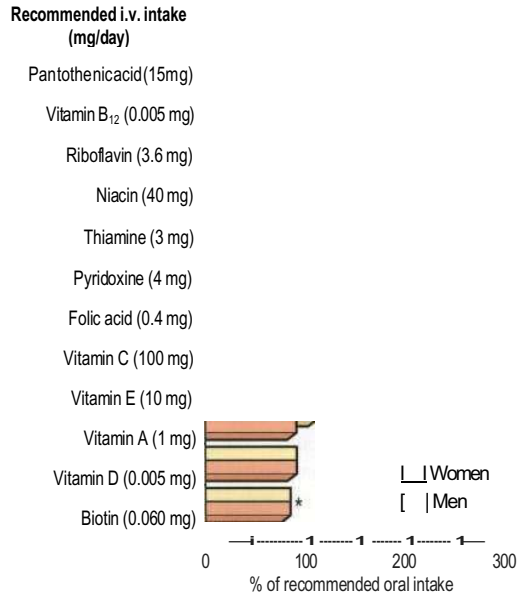

Fig. 5.12 **Recommended intravenous intake of vitamins in absolute values and as a percentage of recommended oral intake.** Vitamins marked with an asterisk are those for which there was too little information to establish recommended dietary oral intake: therefore the midpoint of estimated safe and adequate oral intake is used for comparison.

degrade during storage. Vitamin K is usually absent from parenteral nutrition regimens and therefore it may need to be administered separately.

Enteral nutrition (EN) (Practical box 5.1)

Feeds can be given by various routes:

- By mouth.
- By fine-bore nasogastric tube.
- Percutaneous endoscopic gastrostomy (PEG) is useful for patients who need enteral nutrition for a prolonged period (e.g. more than 30 days), such as those with swallowing problems following a head injury or in elderly people after a stroke. A catheter is placed percutaneously into the stomach under endoscopic control.
- With needle catheter jejunostomy, a fine catheter is inserted into the jejunum at laparotomy and brought out through the abdominal wall.

Diet formulation (see Table 5.16)

A polymeric diet with whole-protein and fat can be used, except in patients with severely impaired gastrointestinal

Practical Box 5.1 **Enteral feeding**

Procedure

* Insert fine-bore tube intranasally with wire stylet. » Confirm position of tube in stomach by aspiration of gastric contents and auscultation of the epigastrium. Check by X-ray if aspiration or auscultation is unsuccessful.

Problems

No satisfactory way of keeping nasogastric tubes in place (up to 60% come out).

Main complications

Regurgitation and aspiration into bronchus. Blockage of the nasogastric tube. Gastrointestinal side-effects, the most common being diarrhoea.

- Metabolic complications including hyperglycaemia and hypokalaemia, as well as low levels of magnesium, calcium and phosphate, occur.

Table 5.16 **Standard enteric diet, providing 8.4 MJ per day (= 2000 kcal)**

Energy

Carbohydrate as glucose polymers (49-53% of total energy) Fat as triglycerides (30-35% of total energy)

Nitrogen

Whole protein (10-14 g of nitrogen/day) Additional electrolytes, vitamins and trace elements

Features

Ratio of energy to nitrogen kJ : g = 620 :1 (kcal: g = 150 : 1)
Osmolality = 285-300 mOsm/kg

function who may require a predigested (i.e. elemental) diet. In these patients, the nitrogen source is purified low-molecular-weight peptides or amino acid mixtures, with sometimes the fat being given partly as medium-chain triglycerides.

Management

Daily amounts of diet vary between 2 and 2.5 L and the full amount can be started immediately.

Hypercatabolic patients require a high supply of nitrogen (15 g daily) and often will not achieve positive nitrogen balance until the primary injury is resolved.

The success of enteral feeding depends on careful supervision of the patient, with monitoring of weight, biochemistry and diet charts.

Total parenteral nutrition (TPN)

Peripheral parenteral nutrition

Specially formulated mixtures for peripheral use are available, with a low osmolality and containing lipid emulsions. Heparin and corticosteroids can be added to the infusion and local application of glyceryl trinitrate patches reduces the occurrence of thrombophlebitis and prolongs catheter life. Peripheral parenteral nutrition is often preferred initially (each catheter will last for about 5 days), allowing time to consider the necessity for having to insert a central venous catheter.

Parenteral nutrition via a central venous catheter (see Practical box 5.2)

A silicone catheter is placed into a central vein, usually using the infraclavicular approach to the subclavian vein. The skin-entry site should be dressed carefully and not disturbed unless there is a suggestion of catheter-related sepsis.

Complications of catheter placement include central vein thrombosis, pneumothorax and embolism, but the major problem is catheter-related sepsis. Organisms, mainly staphylococci, enter along the side of the catheter, leading to septicaemia. Sepsis can be prevented by careful and sterile placement of the catheter, by not removing the dressing over the catheter entry site, and by not giving other substances (e.g. blood products, antibiotics) via the central vein catheter.

Sepsis should be suspected if the patient develops fever and leucocytosis. In two-thirds of cases, organisms can be grown from the catheter tip. Treatment involves removal of the catheter and appropriate systemic antibiotics.

Nutrients

With TPN it is possible to provide sufficient nitrogen for protein synthesis and calories to meet energy requirements. Electrolytes, vitamins and trace elements are also necessary. All of these substances are infused simultaneously.

Nitrogen source

Most patients receive at least 11-15 g N per day, in the form of synthetic L-amino acids.

Practical Box 5.2
Central catheter placement for parenteral nutrition

This should be performed only by experienced clinicians under aseptic conditions in an operating theatre. Give an explanation and obtain consent from the patient.

- The patient is placed supine with 5° of head-down tilt to avoid air embolism.
- The skin below the midpoint of the left clavicle is infiltrated with 1-2% lidocaine (lignocaine) and a 1 cm skin incision is made.
  A 20-gauge needle on a syringe is inserted beneath the clavicle and first rib and angled towards the tip of a finger held in the suprasternal notch.
- When blood is aspirated freely, the needle is used as a guide to insert the cannula through the skin incision and into the subclavian vein.
- The catheter is advanced so that its tip lies in the distal part of the superior vena cava.
- A skin tunnel is created under local anaesthetic using an introducer inserted through a point about 10 cm below and medial to the incision and passed upwards to the incision.
- The proximal end of the catheter (with hub removed) is passed backwards through the introducer to emerge 10 cm below the clavicle, where it is sutured to the chest wall.
  The original infraclavicular entry incision is now sutured.

Energy source

This is provided by glucose, with additional calories provided by a fat emulsion. Fat infusions provide a greater number of calories in a smaller volume than can be provided by carbohydrate. Fat infusions are not hypertonic and they also prevent essential fatty acid deficiency.

Essential fatty acid deficiency has been reported in long-term parenteral nutritional regimens without fat emulsions. It causes a scaly skin, hair loss and a delay in healing.

Electrolytes and trace elements

(see Figs 5.11 and 5.12)

Initially, the electrolyte status should be monitored on a daily basis and electrolyte solutions given as appropriate. Water-soluble vitamins can be given daily but fat-soluble vitamins should be given weekly, as overdose can occur. A trace-metal solution is available for patients on long-term parenteral nutrition, but if the patient requires blood transfusions trace-metal supplements are not needed.

Administration and monitoring

Peripheral parenteral nutrition is administered via 3-L bags over 24 hours, with the constituents being premixed under sterile conditions by the pharmacy. Table 5.17 shows the composition which provides 9 g of nitrogen and 1700 calories in 24 hours.

For a central venous TPN regimen, most hospitals now use premixed 3-L bags. A standard parenteral nutrition

Table 5.17 **Examples of total parenteral nutrition regimens**

CENTRAL: all mixed in 3 L bags and infused over 24 hours		
Nitrogen	L-Amino acids 14 g/L	1L
Energy	Glucose 50%	0.5 L
	Glucose 20%	0.5 L
	plus	
	Lipid 10%	0.5 L
	as either Intralipid or Lipofundin	Fractionated soya oil 100 g/L Soya oil 50 g, medium-chain triglycerides 50 g/L
	+ *Electrolytes, water-soluble vitamins, fat-soluble vitamins, trace elements, heparin and insulin may be added if required. Nitrogen 14 g, non-protein calories 9305 kJ (2250 kcal)*	
PERIPHERAL: all mixed in 3 L bags and infused over 24 hours		
Nitrogen	L-Amino acids 9 g/L	1 L
Energy	Glucose 20%	1 L
	Lipid 20%	0.5 L
	+ 7race *elements, electrolytes, and water-soluble and fat-soluble vitamins, heparin 1000 UL and hydrocortisone 100 mg; insulin is added if required. Nitrogen 9 g, non-protein calories 7206 kJ (1700 kcal)*	

regimen which provides 14 g of nitrogen and 2250 calories over 24 hours is given in Table 5.17.

Essential monitoring includes daily plasma electrolytes and weekly assessments of nutritional status (weight and skinfold thickness if appropriate callipers are available). Nitrogen balance could also be assessed but complete collections of urine are necessary.

Complications

- Catheter-related (see above)
- Metabolic (e.g. hyperglycaemia - insulin therapy is usually necessary)
- Fluid and electrolyte disturbances
- Hypercalcaemia
- Liver dysfunction.

NUTRITIONAL SUPPORT IN THE HOME PATIENT

In both high- and low-income countries there is considerably more undernutrition in the community than in hospital. However, the principles are very similar: detection of malnutrition and the underlying risk factors; treatment of underlying disease processes and disabilities; correction of specific nutrient deficiencies and provision of appropriate nutritional support. This typically begins with dietary advice, and may involve the provision of 'meals on wheels' by social services. A systematic review of the use of nutritional supplements in the community came to the following conclusions:

- Supplements are generally of more value in patients with a BMI < 20 kg/m^2 and children with growth failure (weight for height < 85% of ideal) than in those with better anthropometric indices. They are likely to be of little or no value in patients with little weight loss and a BMI > 20 kg/m^2. The supplemental energy intake in such subjects largely replaces oral food intake.
- Supplements may be of value in weight-losing patients (e.g. > 10% weight loss compared to pre-illness) with a BMI > 20 kg/m^2, and in children with deteriorating growth performance without chronic protein-energy undernutrition.
- The functional benefits varied according to the patient group. In patients with chronic obstructive airways disease the functional benefits were increased respir atory muscle strength, increase in handgrip strength, and an increase in walking distance/duration of exercise. In the elderly the benefits were reduced number of falls, or increase in activities of daily living, and reduced pressure sore surface area. In patients with HIV/AIDS there were changes in immunological function and improved cognition. Patients with liver disease experienced a lower incidence of severe infec tions and had a lower frequency of hospitalization.
- Acceptability and compliance are likely to be better when a choice of supplements (of type, flavour, consistency) and schedule is decided in conjunction with the patient and/or carer. Changes in these may be necessary when there is a change in patterns of daily activities, disease status, and 'taste fatigue' with prolonged use of the same supplement.
- Nutritional counselling and monitoring are recom mended before and after the start of supplements (see also below).

Some patients receive enteral tube feeding and parenteral nutrition at home. At any one point in time in developed countries enteral tube feeding occurs more frequently at home than in hospital. In adults the commonest reason for starting home tube feeding is for swallowing difficulties. This involves patients with neurological disorders, such as motor neurone disease, multiple sclerosis and Parkinson's disease, but the commonest single diagnosis is cerebrovascular disease. In 1998 it was estimated that almost 2% of patients who had a stroke in the UK received home enteral tube feeding (HETF). The outcome of this is indicated in Table 5.18. Fifteen per cent of patients were able to resume full oral nutrition after a year. It is therefore necessary to intermittently assess the swallowing capabilities of patients in order to avoid unnecessary tube feeding. The patients and/or carers should have adequate training, contacts with appropriate health professions, and a reliable delivery service for feeds and ancillary equipment. They should also be clear about how to manage simple problems associated with the feeding tube, which is usually a gastrostomy tube rather than a nasogastric tube.

Home parenteral nutrition is practised much less frequently, usually under the supervision of specialist centres. The potential value of intestinal transplantation in patients with long-term intestinal failure is still being assessed.

Table 5.18 **Outcome of patients at 1 year after starting home enteral tube feeding (HETF)***

	All patients (n = 15 143)	Cerebrovascular disease (n = 5660)	Motor neurone disease *[n* = 874)	Multiple sclerosis (n = 856)
Continuing on HETF	50.2	**53.0**	35.8	**81.0**
Returned to oral feeding	14.2	**12.9**	1.1	**3.7**
Died	33.5	**32.6**	62.1	**13.7**
Other[1]	2.2	1.5	1.0	**1.6**

*Based on the British Artificial Nutrition Survey (1996-2000). Patients who returned to oral feeding or refused/withdrew from HETF may have died subsequently

FOOD ALLERGY AND FOOD INTOLERANCE

Many people ascribe their various symptoms to food, and many such sufferers are seen and started on exclusion diets. The scientific evidence that food does harm in most instances is weak, although adverse reactions to food certainly exist. These can be divided into those that involve immune mechanisms (food allergy) and those that do not (food intolerance).

Food allergy

Food allergy, which is estimated to affect up to about 5% of young children and about 1-2% of adults, may be IgE mediated or non-IgE mediated (T-cell mediated). The IgE-mediated reactions tend to occur early after a food challenge (within minutes to an hour). Adults tend to be allergic to fish, shellfish and peanuts, while children tend to be allergic to cow's milk, egg white, wheat, and soy. Peanuts are very allergenic and peanut allergy persists throughout life. The following conditions can result from food allergy:

- *Acute hypersensitivity.* An example is urticaria, vomiting or diarrhoea after eating nuts, strawberries or shellfish. These IgE-mediated reactions do not usually produce clinical problems as the patients have already learned to avoid the suspected food. Inadvertent ingestion of the incriminating food can sometimes occur, leading to angioneurotic oedema (p. 1334).
- *Eczema and asthma.* These tend to affect young children and are often due to egg and are IgE mediated.
- *Rhinitis and asthma.* These have been produced by foods such as milk and chocolate, mainly in atopic subjects.
- *Chronic urticaria.* This has been treated successfully by an exclusion diet.
- *Food-sensitive enteropathy.* This may manifest itself as coeliac disease (gluten (wheat) sensitive enteropathy), and cow's milk enteropathy (in infants) and is T-cell mediated.

Food intolerance

- *Migraine.* This sometimes follows the intake of foods such as chocolate, cheese and alcohol, which are rich in certain amines, such as tyramine. Patients on mono-amine oxidase inhibitors, which are involved in the metabolism of these amines, are particularly vulnerable.
- *Irritable bowel syndrome.* In some patients this seems to be related to ingestion of certain food items, such as wheat, but the mechanisms are not clearly defined (p. 1283).
- *Chinese restaurant syndrome.* Monosodium glutamate, a flavour enhancer used in cooking Chinese food, may produce dizziness, faintness, nausea, sweating and chest pains.
- *Lactose intolerance.* Patients develop abdominal bloating and diarrhoea following ingestion of lactose, which is present in milk (p. 300). This is probably the commonest form of food intolerance world-wide, and may be genetic in origin.
- *Phenylketonuria.* This can also be classified as a form of food intolerance, and is due to lack of phenylalanine hydroxylase, which is necessary for the metabolism of phenylalanine present in dietary protein.

A number of other inborn errors of metabolism can also be regarded as forms of food intolerance.

Food intolerance may be due to a constituent of food (e.g. the histamine in mackerel or canned food, or the tyramine in cheeses), chemical mediators released by food (e.g. histamine may be released by tomatoes or strawberries), or toxic chemicals found in food (e.g. the food additive tartrazine).

Many other additives and compounds with certain E numbers have been implicated as causing reactions, but here the evidence for this is poor.

There is little or no evidence to suggest that diseases such as arthritis, behaviour and affective disorders and Crohn's disease are due to ingestion of a particular food.

Multiple vague symptoms such as tiredness or malaise are also not due to food allergy. Most of the patients in this group are suffering from a psychiatric disorder (p. 1283).

Management

m A careful history may help to delineate the causative agent, particularly when the effects are immediate.

- Skin-prick testing with allergen and measurement in the serum of antigen or antibodies have not correlated with symptoms and are usually misleading. 'Fringe' techniques such as hair analysis, although widely advertised, are of limited value.
- Diagnostic exclusion diets are sometimes used, but they are time-consuming. They can occasionally be of value in identifying a particular food causing problems.
- Dietary challenge consists of the food and the test being given sublingually or by inhalation in an attempt to reproduce the symptoms. Again this may be helpful in a few cases.
- Most people who have acute reactions to food realize it and stop the food, and do not require medical attention. In the remainder of patients, a small minority seem to be helped by modifying their diet, but there is no good scientific evidence to support these exclusion diets.

Box 5.5 **The main pathways of ethanol oxidization**

Alcohol dehydrogenase:

m

$$CH_3CH_2OH \underset{\text{(ethanol)}}{} \rightarrow CH_3CHO + NADH \quad \text{(acetaldehyde)}$$

- The liver microsomal enzyme oxidizing system (MEOS) including the specific P450 enzyme, CYP2EI, which **is** induced by ethanol:

$$NADPH + H^+ + CH_3CH_2OH \xrightarrow{MEOS} CH_3CHO + NADP + 2H_2O$$

ALCOHOL

Alcohol is a popular 'nutrient' consumed in large quantities all over the world. In many countries, alcohol consumption is becoming a major problem (see p. 1302).

Ethanol (ethyl alcohol) is oxidized, in the steps shown in Box 5.5, to acetaldehyde. Acetaldehyde is then converted to acetate, 90% in the liver mitochondria. Acetate is released into the blood and oxidized by peripheral tissues to carbon dioxide, fatty acids and water.

Alcohol dehydrogenases are found in many tissues and it has been suggested that enzymes present in the gastric mucosa may contribute substantially to ethanol metabolism.

Ethanol itself produces 29.3 kj/g (8 kcal/g), but many alcoholic drinks also contain sugar, which increases their calorific value. For example, one pint of beer provides 1045 kj (250 kcal), so the heavy drinker will be unable to lose weight if he or she continues to drink.

Effects of excess alcohol consumption

Excess consumption of alcohol leads to two major problems, both of which can be present in the same patient:

- alcohol dependence syndrome (p. 1303)
- physical damage to various tissues.

Each unit of alcohol (defined as one half pint of normal beer, one single measure of spirit, or one small glass of wine) contains 8 g of ethanol (Fig. 5.13). All the long-term effects of excess alcohol consumption are due to excess

Fig. 5.13 **Measures of 1 unit of alcohol.**

***Box 5.6* Guide to sensible drinking of alcohol**

Daily maximum
3 units for men 2 units for women

To help achieve this
Use a standard measure.
Do not drink during the daytime.
Have alcohol-free days each week.

Remember
Health can be damaged without being 'drunk'. Regular heavy intake is more harmful than occasional binges.
Do not drink to 'drown your problems'.
In the UK the drink-before-driving limit of alcohol in the blood is 800 mg/L (80 mg%). One unit of alcohol is eliminated per hour, therefore spread drinking time. Food decreases absorption and therefore results in a lower blood alcohol level. 4-5 units are sufficient to put the blood alcohol level over the legal driving limit in a 70 kg man (less in a lighter person).

ethanol, irrespective of the type of alcoholic beverage; i.e. beer and spirits are no different in their long-term effects. Short-term effects, such as hangovers, depend on additional substances, particularly other alcohols such as isoamyl alcohol, which are known as congeners. Brandy and bourbon contain the highest percentage of congeners.

The amount of alcohol that produces damage varies and not everyone who drinks heavily will suffer physical damage. For example, only 20% of people who drink heavily develop cirrhosis of the liver. The effect of alcohol on different organs of the body is not the same; in some patients the liver is affected, in others the brain or muscle. The differences may be genetically determined.

Thiamin deficiency contributes to both neurological (confusion, Wernicke-Korsakoff syndrome; see p. 1263) and some of the non-neurological manifestations (cardiomyopathy). Susceptibility to damage of different organs is variable and the figures in Box 5.6 are given only as a guide. Heavy persistent drinkers for many years are at greater risk than heavy sporadic drinkers.

Liver disease

In general the effects of a given intake of alcohol seem to be worse in women. The following figures are for men and should be reduced by 50% for women:

- 160 g ethanol per day (20 single drinks) carries a high risk
- 80 g ethanol per day (10 single drinks) carries a medium risk
- 40 g ethanol per day (five single drinks) carries little risk.

Alcohol consumption in pregnancy

Women are advised not to drink alcohol at all during pregnancy because even small amounts of alcohol consumed can lead to 'small babies'. The *fetal alcohol syndrome* is characterized by mental retardation, dysmorphic features and growth impairment; it occurs in fetuses of alcohol-dependent women.

Summary

A summary of the physical effects of alcohol is given in Table 5.19. Details of these diseases are discussed in the relevant chapters. The effects of alcohol withdrawal are discussed on page 1304.

***Table 5.19* Physical effects of excess alcohol consumption**

Central nervous system
Epilepsy
Wernicke-Korsakoff syndrome
Polyneuropathy

Muscles
Acute or chronic myopathy

Cardiovascular system
Cardiomyopathy
Beriberi heart disease
Cardiac arrhythmias
Hypertension

Metabolism
Hyperuricaemia (gout)
Hyperlipidaemia
Hypoglycaemia
Obesity

Endocrine system
Pseudo-Cushing's syndrome

Respiratory system
Chest infections

Gastrointestinal system
Acute gastritis
Carcinoma of the oesophagus or large bowel
Pancreatic disease
Liver disease

Haemopoiesis
Macrocytosis (due to direct toxic effect on bone marrow or folate deficiency)
Thrombocytopenia
Leucopenia

Bone
Osteoporosis
Osteomalacia

Gastrointestinal disease

6

In developed countries gastrointestinal problems are a common reason for attendance at the primary care clinic as well as the outpatient clinic of the hospital. Many of these consultations (approximately 75%) are for symptoms related to non-organic disease. The clinician's main task is therefore to separate out the patients who require investigation, remembering that 20% of all cancers occur in the gastrointestinal tract (Fig. 6.1).

In developing countries, poor hygiene and malnutrition allow the spread of infective organisms. The clinician's main role here is to treat infections promptly and to help with prevention by encouraging improved sanitation and education.

In this chapter, the essential anatomy and principles of physiology are divided and discussed under the relevant sections.

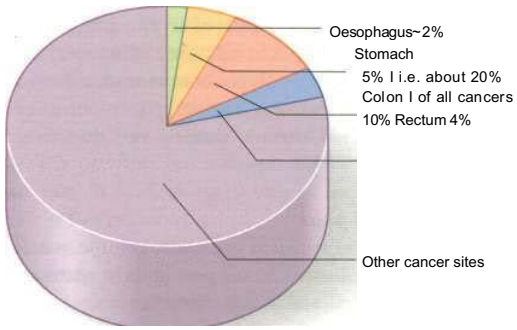

Fig. 6.1 Incidence (approximate) of cancers at various sites of the gastrointestinal tract.

CLINICAL APPROACH TO GASTROINTESTINAL SYMPTOMS AND SIGNS

Dyspepsia and indigestion

Dyspepsia is the term used by healthcare workers to describe upper abdominal symptoms, e.g. nausea, heartburn, acidity, pain or discomfort, wind, fullness or belching. Patients seldom use the term 'dyspepsia'; they are more likely to refer to indigestion to describe any symptom that is food related. Indigestion is common; 80% of the population will have had indigestion at some time. 'Alarm' features suggestive of serious disease are:

- dysphagia
- weight loss
- protracted vomiting
- anorexia
- haematemesis or melaena.

Table 6.1 Causes of vomiting

Any gastrointestinal disease	Drugs, e.g.
Acute infections, e.g.	digoxin toxicity
influenza	levodopa
pertussis	opiates
urinary tract infection	antibiotics
Central nervous disease, e.g.	chemotherapy
raised intracranial pressure	immunotherapy
vestibular disturbances	Reflex, e.g.
migraine	severe pain: myocardial infarction
Metabolic causes, e.g.	Psychogenic
uraemia	Pregnancy
diabetes: ketoacidosis or gastroparesis	Alcohol excess
hypercalcaemia	

Nausea and vomiting

There are three phases:

- nausea - a feeling of wanting to vomit, often associated with autonomic effects including hypersalivation, pallor and sweating
- retching - a strong involuntary effort to vomit
- vomiting - the expulsion of gastric contents through the mouth.

The vomiting centres are located in the lateral reticular formation of the medulla and are stimulated by the chemoreceptor trigger zones (CTZs) in the floor of the fourth ventricle, and also by vagal afferents from the gut. These zones are directly stimulated by drugs, motion sickness and metabolic causes.

Many gastrointestinal conditions are associated with vomiting (Table 6.1), but nausea and vomiting without pain are frequently non-gastrointestinal in origin.

Haematemesis is vomiting blood or 'coffee-grounds' from the stomach.

Large volumes of vomit suggest intestinal obstruction; *faeculent vomit* suggests low intestinal obstruction or the presence of a gastrocolic fistula, while *projectile vomiting* is due to gastric-outflow obstruction.

Chronic nausea + vomiting with no other abdominal symptoms is usually due to a psychological cause (p. 337).

Early-morning vomiting is seen in pregnancy, alcohol dependence and some metabolic disorders (e.g. uraemia).

Flatulence

This is the term used to describe excessive wind. It includes belching, abdominal distension, 'wind' or the passage of flatus per rectum. Swallowing air (aerophagia) is described on page 337. Some of the swallowed air is passed into the intestine where most of it is absorbed. Intestinal bacterial breakdown of food also produces a small amount of gas. Flatus consists of nitrogen, carbon dioxide, hydrogen and methane. Flatus is normally passed 13-20 times per day.

Diarrhoea and constipation

These are common complaints which are not usually due to serious disease. They are described in detail on pages 320 and 331 respectively.

A single episode of diarrhoea can be due to dietary indiscretion or anxiety. Watery stools of large volume are always due to organic disease. Bloody diarrhoea usually implies colonic disease.

Acute diarrhoea lasting 2-5 days is often due to an infective cause, and stool cultures are necessary.

Patients often consider themselves constipated if their bowels are not open on most days. The difficult passage of hard stool is also regarded as constipation, irrespective of stool frequency.

Abdominal pain

Pain is stimulated mainly by the stretching of smooth muscle or organ capsules. Severe acute abdominal pain can be due to a large number of gastrointestinal conditions, and normally presents as an emergency (p. 340). An 'acute abdomen' can occasionally be due to referred pain from the chest, as in pneumonia, or to metabolic causes, such as diabetic ketoacidosis.

In patients with abdominal pain the following should be ascertained:

- the site, intensity, character, duration and frequency of the pain
- the aggravating and relieving factors
- associated symptoms, including non-gastrointestinal symptoms.

Upper abdominal pain

Epigastric pain is very common; it is often a dull ache, but sometimes sharp and severe. Its relationship to food intake should be ascertained. It is a common feature of peptic ulcer disease, but also occurs in functional dyspepsia. In biliary tract disease, the pain is often epigastric.

Right hypochondrial pain is usually from the gall bladder or biliary tract. Hepatic congestion (e.g. in hepatitis) and sometimes peptic ulcer can present with pain in the right hypochondrium. Chronic, often persistent, pain in the right hypochondrium is a frequent symptom in healthy females suffering from functional bowel disorders. This chronic pain is not due to gall bladder disease (p. 399).

Lower abdominal pain

Acute pain in the left iliac fossa is usually colonic in origin (e.g. acute diverticulitis). *Chronic pain* is most commonly associated with functional bowel disorders.

In females, lower abdominal pain occurs in a number of gynaecological disorders and the differentiation from GI disease is often difficult.

Persistent pain in the right iliac fossa over a long period is not due to chronic appendicitis.

Proctalgia is a severe pain deep in the rectum that comes on suddenly but lasts only for a short time. It is not due to organic disease. ■ -

Abdominal wall pain

Recurrent localized abdominal pain with local tenderness can very rarely arise from the abdominal wall itself. Causes are thought to include nerve entrapment, external hernias and entrapment of internal viscera (commonly omentum) within traumatic ruptures of abdominal wall musculature.

Weight loss

This is due to anorexia (loss of appetite) and is a frequent accompaniment of all gastrointestinal disease. Anorexia is also common in systemic disease and may be seen in psychiatric disorders, particularly anorexia nervosa. Anorexia often accompanies carcinoma but it is a late symptom and not of diagnostic help. Weight loss with a normal or increased dietary intake occurs with hyperthyroidism. Malabsorption is never so severe as to cause weight loss without anorexia. Weight loss should be assessed objectively as patients often 'think' they have lost weight. Appetite and satiety are described on page 253.

CLINICAL EXAMINATION

A general examination is performed, with particular emphasis on the examination of all lymph nodes and noting the presence of anaemia or jaundice. Detailed examination of the gastrointestinal tract starts with the mouth and tongue, before examining the abdomen with the patient lying flat.

EXAMINATION OF THE ABDOMEN

Inspection

Abdominal distension, whether due to flatus, fat, fetus, fluid or faeces, must be looked for. Lordosis may give the appearance of a distended abdomen; it is a common feature of the 'abdominal distension' seen in functional bowel disorders.

Palpation

The abdominal organs may be felt in some normal subjects (Fig. 6.2) but this is not common and such organs are usually only just palpable. A Reidel's lobe is an extension of the lateral portion of the right lobe of the liver and can occasionally be palpated. Figure 6.3 shows a normal CT scan at the T12 level.

Any palpable mass is carefully felt to decide which organ is involved and also to evaluate its size, shape and consistency and whether it moves with respiration.

The hernial orifices should be examined if intestinal obstruction is suspected.

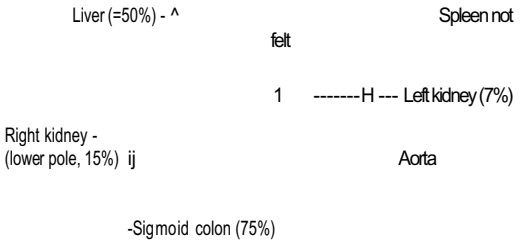

Fig. 6.2 **The organs sometimes palpable in thin subjects.**

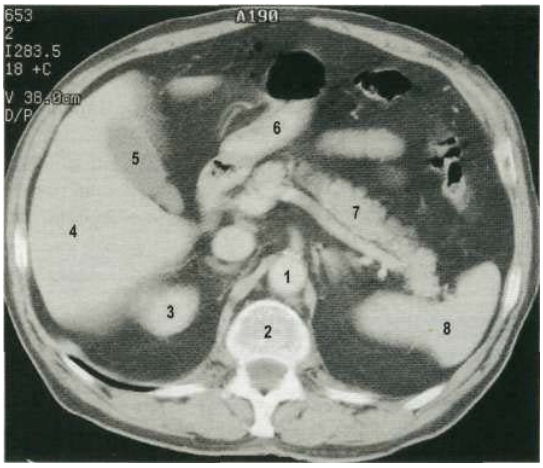

Fig. 6.3 **CT scan of the normal abdomen at the level of T12.** 1, aorta; 2, spine; 3, top of right kidney; 4, liver; 5, gall bladder; 6, stomach (containing air); 7, pancreas; 8, spleen.

A succussion splash suggests gastric outlet obstruction if the patient has not drunk for 2-3 hours; the splash of fluid in the stomach can be heard with a stethoscope laid on the abdomen when the patient is moved.

Percussion

This is performed in the usual way to detect the area of dullness caused by the liver and spleen, and possibly bladder enlargement. The presence of fluid in the peritoneal cavity (i.e. ascites) is detected by shifting dullness. The percussion note changes from resonance to dullness when the patient is moved from one side to the other. It is a good physical sign, but 1-2 L of fluid must be present to elicit it. A large ovarian cyst can sometimes produce an enlarged abdomen, but the dullness is more centrally placed than in ascites.

Auscultation

Auscultation is not of great value in gastrointestinal disease, apart from in the evaluation of the acute abdomen (see p. 341). Abdominal bruits are often present in normal subjects, but these are not clinically significant.

EXAMINATION OF THE RECTUM AND SIGMOID COLON

Digital examination of the rectum should be performed in all patients with a change in bowel habit and rectal bleeding.

Rigid sigmoidoscopy (Practical box 6.1) should, in hospital, be part of the routine examination in all cases of diarrhoea and in patients with lower abdominal symptoms such as a change in bowel habit or rectal bleeding.

Proctoscopy (Practical box 6.1) is performed in all patients with a history of bright red blood per rectum; the narrow sigmoidoscope does not distend the lumen and haemorrhoids can be missed.

Flexible sigmoidoscopy

The rigid sigmoidoscope allows inspection of only the lower 20-25 cm of the bowel. A 60 cm flexible sigmoidoscope can be readily used in the outpatient department after minimal bowel preparation (a disposable enema). Specialist nurse practitioners use this technique in many outpatient clinics. At least 50% of colonic neoplasms occur within the range of the flexible sigmoidoscope (see Fig. 6.42).

Practical Box 6.1 **Sigmoidoscopy and proctoscopy**

Sigmoidoscopy

- The technique using a 25 cm rigid sigmoidoscope is easy to learn, provides valuable information and is safe in competent hands.
- No bowel preparation is required.
- Explain to the patient the nature of the procedure.
- The technique is relatively painless. In the irritable bowel syndrome, the patient's pain is often reproduced by air insufflation

1. Rectal examination is initially performed.
2. The sigmoidoscope is passed into the anus, pointing towards the symphysis pubis. The obturator is removed, and the instrument passed under direct vision to the rectosigmoid junction and beyond if possible (using air insufflation).
3. The mucosa of the anus and rectum is inspected. The normal mucosa is shiny with superficial vessels and no contact bleeding.
4. Biopsies can be taken of any lesions that are seen or from apparently normal-looking mucosa, which occasionally shows histological evidence of inflammation.

Proctoscopy

1. The proctoscope is passed into the anus directed towards the symphysis pubis and the obturator is removed.
2. The patient strains down as the proctoscope is removed.
3. Haemorrhoids are seen as purplish veins in the left lateral, right posterior or right anterior positions.
4. Fissures may also be seen, but pain often prevents the procedure from being performed.

It is used to biopsy lesions in the sigmoid area seen on barium enema and for the follow-up of patients with distal colitis. It is useful as an initial test for patients with left-sided colonic symptoms and rectal bleeding but a full colonoscopy will be needed if no pathology is found.

Stool examination

This can be useful occasionally to confirm the patient's symptoms (e.g. passing of blood or steatorrhoea). The shape and size may be helpful (e.g. rabbity stools in the irritable bowel syndrome). Stool charts for recording volume and frequency of defecation are useful in inpatients to follow the progress of diarrhoea.

INVESTIGATIONS

Radiology and endoscopy are the principal investigations. These are usually preceded by routine haematology and biochemistry. The investigation of small bowel disease is discussed in more detail on page 299. Manometry is mainly used in oesophageal disease (p. 274) and rectal disorders (p. 320).

Barium contrast studies (Box 6.1)

Most examinations are performed after **an** overnight fast. The radiologist should be given sufficient clinical information and directed to the particular area under suspicion. X-rays should be reviewed with the radiologist, if possible.

- **Barium swallow.** The oesophagus is visualized as barium is swallowed in both the upright and prone positions. Motility abnormalities as well as anatomical lesions can then be observed. Reflux, as demonstrated by the retrograde flow of barium from the stomach into the oesophagus, is best observed with the patient tipped head down. It can be more effectively demonstrated by asking the patient to drink water (water siphon test) or by distension of the stomach with gas by an effervescent agent. Swallowing a lump of bread or a marshmallow coated in barium can be useful in evaluating patients with dysphagia.
- **Double-contrast barium meal.** This is performed to examine the stomach and duodenum. A small amount of barium is given together with effervescent granules to produce carbon dioxide so that a double contrast between air and barium is obtained. This test has a high accuracy rate for the detection of significant pathology - ulcers and cancer - but requires good technique to achieve high-quality pictures. Gastroscopy is a more sensitive test for small superficial mucosal lesions and for bleeding and enables biopsy of any suspicious area.
- **Small bowel follow-through.** This is used to examine the small bowel and ideally should be performed separately from **a** barium meal as a different technique is employed. Barium is swallowed and X-rays are

Box 6.1 **The use of barium contrast studies**

Barium contrast study	Main use	Comments
Barium swallow	Dysphagia Epigastric pain	Particularly useful in motility disorders
Barium meal	Vomiting	Gastroscopy has replaced barium meal in most centres as biopsy and histology is possible for *Helicobacter pylori* and carcinoma Only practical way of studying gross small bowel anatomy
	Diarrhoea Abdominal pain	
Small bowel follow-through	Altered bowel habit Abdominal pain	
Barium enema		Colonoscopy has largely replaced this examination for rectal bleeding, inflammatory bowel disease and polyp follow-up

taken as the barium passes through the jejunum and ileum into the right colon, which usually takes about 1 hour. The fold pattern and calibre of the small bowel can be assessed, and specific views of the terminal ileum are obtained using compression to separate the loops of bowel and particularly to identify early changes in patients with suspected Crohn's disease.

- **Small bowel enema (enteroclysis).** A tube is passed through the duodenum and a large volume of dilute barium is introduced. In some centres this is the exam ination of choice for the assessment of small bowel disease. It is particularly useful when there is suspicion of intermittent bowel obstruction to demonstrate strictures or adhesions.
- **Barium enema.** Patients are given a low-fibre diet for 3 days and the colon thoroughly cleansed with oral laxative preparations. Barium and air are insufflated via a rectal catheter and double-contrast views obtained of the entire colon. Rectal examination and sigmoid-oscopy should precede this examination. Some patients find the examination rather difficult to tolerate - particularly the elderly, frail or immobile in whom other tests such as CT should be used. An 'instant' barium enema involving no bowel preparation is very occasionally used in colitis .

Plain X-rays

Plain X-rays of the chest and abdomen **are** chiefly used in the investigation of an acute abdomen (see p. 341) including patients presenting with acute colitis (p. 317). Analysis of gas shadows gives information about the bowel. Areas of calcification can be seen in chronic pancreatitis. Faecal loading is seen in constipation.

Ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI)

These techniques are used to define the intra-abdominal organs (e.g. liver, spleen, pancreas) but also to detect thickened bowel, masses, abscesses or fistulae. Ultra-sound is often performed first as it is cheap and easy to perform although very operator dependent.

- **Ultrasound.** This involves no exposure to radiation and is the first-line investigation for the liver, gall bladder, spleen and pancreas. It will show dilated fluid-filled loops of bowel where there is obstruction, and thickening of the bowel wall when inflamed or infiltrated. It is valuable when ascites is suspected or when there is suspicion of abscess when it can be used to guide percutaneous drainage. In the acute abdomen, ultrasound can diagnose cholecystitis, appendicitis, enlarged mesenteric glands and other inflammatory conditions.

Endoscopic ultrasound (EUS). A gastroscope incorporating a high-frequency ultrasound probe at the tip is used to assess abnormalities arising in the oesophageal or gastric wall. It is particularly valuable in the detailed staging of oesophageal/ gastric cancer, including detection of local lymph nodes. It is also a sensitive technique for detection of small pancreatic tumours.

Endoanal ultrasonography involves the passage of a transducer into the rectum. It is used to define the anatomy of the anal sphincters (p. 323), to detect perianal disease and to stage rectal carcinomas.

Computed tomography. CT, particularly thin-section spiral CT, gives excellent anatomical definition. Modern multi-slice fast scanners are also able to evaluate the vascularity of an abnormality using intravenous contrast. The bowel wall and mesentery are well seen, together with the retroperitonal structures. It is used as a first-line investigation for the acute abdomen in many centres. Small volumes of gas from a perforated viscus can be detected as well as leakage of contrast from the gut lumen. Abscesses, appendicitis, diverticulitis, Crohn's disease and its complications can be demonstrated as well as the presence and cause of high-grade bowel obstruction. It is widely used in cancer staging and as guidance for fine-needle biopsy of tumour or lymph nodes. CT pneumocolon/CT colonography (virtual colonoscopy) involves air insufflation into the colon after colon preparation and provides a valuable alter-native for evaluation of colon mass lesions. It is being used as a screening test for colon cancer with sensiti-vities of over 90% for > 10 mm polyps (see p. 334)

Magnetic resonance imaging. MRI has the advantage of using no ionizing radiation. It is particularly useful in the evaluation of abscesses and fistulae in tiae perianal region and its use is evolving in the evalu-ation of luminal gut disease. MRI is used more in hepatobiliary and pancreatic disease (see p. 354).

Positron emission tomography (PET) after fludeoxyglucose F18 is used for staging oesophageal, gastric and colorectal cancer and in the detection of metastatic and recurrent disease.

Radioisotope imaging

Radionuclides are used to a varying degree depending on local enthusiasm and expertise. Indications are:

- to demonstrate oesophageal reflux using [^{99m}Tc] technetium-sulphur colloid
- to determine the rate of gastric emptying using [^{99m}Tc] technetium-sulphur colloid or ^{m}In-DTPA (indium-labelled diethylene triamine penta-acetic acid)
- to demonstrate a Meckel's diverticulum using [^{99m}Tc] pertechnetate, which has an affinity for gastric mucosa
- to show the extent of inflammation and the presence of any inflammatory collections in inflammatory bowel disease using ^{99m}Tc HMPAO (hexamethylpropylene amine oxime) labelled white cells
- neuroendocrine tumours using radiolabelled octreotide and whole-body scanning.

Isotopes can also be used for assessing:

- gastrointestinal loss of red cells by giving ^{51}Cr red cells and measuring radioactivity in the faeces, or by labelling red cells with ^{99m}Tc and scanning the abdomen, e.g. Meckel's diverticulum
- albumin loss in the stools in protein-losing enteropathy by giving $^{51}CrCl_3$ intravenously (p. 306)
- bile salt malabsorption by whole-body scanning and counting the activity in the faeces following oral $^{7:>}$Se-homochoyl taurine (SeHCAT)
- urea breath test (p. 248)
- bacterial overgrowth by measuring $^{14}CO_2$ in the breath following ^{14}C glycocholic acid orally.

EndQSCOpy (Practical box 6.2)

Video endoscopes have largely replaced the old fibreoptic types. They have three chips (for blue, green and red light) mounted at the tip of the instrument. These chips relay colour images via an image processor to a television monitor. A permanent record of the procedure can be obtained.

The tip of the endoscope can be angulated in all directions. Channels are present in the endoscope for air insufflation, water injection, suction and for the passage of biopsy forceps or brushes for obtaining tissue. These latter channels can also be used for other therapeutic interventions (e.g. injection of varices).

- **Oesophagogastroduodenoscopy (OGD).** This is often used as the investigation of choice for upper GI disorders by gastroenterologists because of easy access, the possibility of interventional therapy and obtaining mucosal biopsies. Relative contraindications include severe chronic obstructive pulmonary disease, a recent myocardial infarction, or instability of the atlanto-axial joints. The mortality for diagnostic endoscopy is 0.001% with significant complications in 1:1000, usually when performed as an emergency (e.g. GI haemorrhage).

Practical **Gastroscopy and colonoscopy**

» Explain to the patient the nature of the procedure (pamphlets are available).
- Get written consent.
- Tell the patient that i.v. sedation may be given.

Gastroscopy

1. The patient is fasted for at least 4 hours.
2. The throat is sprayed with lidocaine.
3. Intravenous sedation is usually not given except to the very anxious patient or for additional procedures.
4. Oxygen saturation is monitored.
5. Oxygen via nasal prongs is given to elderly patients.
6. The instrument is passed into the pharynx under direct vision, then down the oesophagus into the stomach and duodenum.
7. The patient must be 'nil by mouth' for approximately 1V$_2$ hours following the procedure and may complain of a sore throat and abdominal discomfort.
8. Complications include local perforation and aspiration pneumonia.

Colonoscopy

1. *Two days before* the procedure, start a low-residue diet.
2. *One day before* the procedure:
   « Light lunch followed by clear fluids only. «
   In the morning take one sachet of sodium picosulfate with 1 pint of water.
   In the afternoon take second sachet of sodium picosulfate with water.
   In the evening take bisacodyl tablets with 1 pint of water.
3. *Day of procedure* take clear fluids only early morning, then nothing until after the test.
4. *Procedure:*
   - Intravenous sedation with a benzodiazepine and pethidine is required. Oxygen saturation is monitored.
     The instrument is passed under direct vision and manoeuvred around to the caecum and into the terminal ileum.
     Observation is required for approximately 2 hours following the procedure.
     Complications include perforation or haemorrhage following a biopsy or polypectomy.

Colonoscopy. This allows good visualization of the whole colon and terminal ileum. Biopsies can be obtained and polyps removed. The success rate for reaching the terminal ileum is approximately 90%. Perforation occurs in 1 : 2500 examinations and in 2% after polypectomy. The mortality is 0.02% for diagnostic colonoscopy.

Enteroscopy. The small bowel from the duodenum to the ileum can be visualized by enteroscopes. The indications for this technique are limited (mainly gastrointestinal blood loss); the instruments are expensive, and consequently they are used only in a few centres.

■ Wireless capsule endoscopy is now being used for the evaluation of gastroscopy- and colonoscopy-negative GI bleeding and for the detection of small bowel tumours.

colonoscopy. *New England Journal of Medicine* 349: 2191-2201.

THE MOUTH

The oral cavity extends from the lips to the pharynx and contains the tongue, teeth and gums. Its primary functions are mastication, swallowing and speech.

Problems in the mouth are extremely common and, although they may be trivial, they can produce severe symptoms. Poor dental hygiene is often a factor.

Stomatitis is inflammation in the mouth from any cause, such as ill-fitting dentures. Angular stomatitis is inflammation of the corners of the mouth.

The burning mouth syndrome consists of a burning sensation with a clinically normal oral mucosa. It occurs more commonly in middle-aged and elderly females. It is probably psychogenic in nature. Halitosis is a common symptom; causes are shown in Box 6.2.

Oral ulceration

Recurrent ulceration

Recurrent aphthous ulceration of unknown aetiology is a common oral mucosa disorder affecting 20% of the population. It consists of recurrent bouts of one or more rounded, shallow, painful ulcers recurring at intervals of days to a few months.

Minor aphthous ulcers are the most common. They are less than 10 mm diameter, have a grey/white centre with a thin erythematous halo and heal within 14 days without scarring. *Major aphthous ulcers* are larger (more than 20 mm diameter), often persist for weeks or months and heal with scarring.

Most patients with recurrent ulcers are otherwise well. Various nutritional deficiencies of iron, folic acid or vitamin B_{12} (with or without gastrointestinal disorders) are occasionally found.

There are no specific, effective therapies. Corticosteroids may lessen the duration and severity of the attacks. Chlorhexidine gluconate mouthwash, dapsone, colchicine, systemic steroids and azathioprine have all been used with variable effect.

Box 6.2 Causes of halitosis

- Poor oral hygiene
- Anxiety when halitosis is more imaginary than real
- Rare causes:
  - oesophageal stricture
  - pulmonary sepsis

Ulceration associated with systemic disorders

Oral ulceration is seen in gastrointestinal disorders, such as Crohn's disease, ulcerative colitis and coeliac disease in approximately 10-20% of cases. Other diseases associated with oral ulceration include lupus erythematosus (systemic and discoid), Behcet's disease, neutropenia (p. 464) and immunodeficiency disorders. In Reiter's disease, ulceration occurs in approximately 25-30% of patients.

Ulceration associated with dermatological disorders

These include erythema multiforme major, toxic epidermal necrolysis, lichen planus, pemphigus vulgaris, bullous pemphigoid, 'epidermolysis bullosa' and dermatitis herpetiformis.

Ulceration associated with viral infection

Herpes simplex virus. Primary herpes simplex (usually type I but rarely type II) presents with fever and widespread confluent painful ulcers. After resolution, the virus remains latent and recurs as herpes labialis ('cold sores', see p. 44).

Coxsackie. Hand, foot and mouth disease and herpangina, due to a different Coxsackie A, or rarely B, infection are described on page 50.

Other viruses. Herpes zoster and cytomegalovirus are among many viruses that can produce mouth ulceration, usually during the acute infective phase.

Ulceration associated with bacterial infection

Syphilis and tuberculosis can rarely cause oral ulcerations and are seen mainly in developing countries.

Ulceration associated with drugs

Certain drugs can cause oral lichenoid eruptions. They include antimalarials, methyldopa, tolbutamide, penicillamine and gold salts.

Trauma

Traumatic ulcers may be due to ill-fitting dentures, tooth brushing or lacerations by sharp teeth.

Neoplastic lesions (squamous cell carcinoma)

Malignant tumours of the mouth account for 1% of all malignant tumours in the UK. The majority develop on the floor of the mouth or lateral borders of the tongue. Early tumours may be painless, but advanced tumours are easily recognizable as indurated aphthous ulcers with raised and rolled edges. Aetiological agents include tobacco, heavy alcohol consumption and the areca nut. Intra-oral lesions which undergo malignant transformation include leucoplakia, lichen planus, submucous fibrosis and erythroplakia (a red patch). The previous

male predominance has declined. Treatment is by surgical excision and/or radiotherapy.

Oral white patches

White lesions may be transient or persistent. Transient white patches are either due to *Candida* infection or are very occasionally seen in systemic lupus erythematosus. Oral candidiasis in adults is seen in seriously ill or immunocompromised patients, or following therapy with broad-spectrum antibiotics or inhaled steroids.

Local causes include mechanical, irritative or chemical trauma from drugs (e.g. aspirin).

Leucoplakia describes white patches for which no local cause can be found. It is associated with alcohol and (particularly) smoking, and is regarded as a premalignant condition. A biopsy should always be undertaken; histology shows alteration in the keratinization and dysplasia of the epithelium; aneuploidy is associated with a very high risk of cancer. Treatment is unsatisfactory. Isotretinoin possibly reduces disease progression. Oral *lichen planus* presents as white striae.

Oral pigmented lesions

Non-neoplastic lesions

Racial pigmentation is scattered and symmetrically distributed. Amalgam tattoo is the most common form of localized oral pigmentation and consists of blue-black macules involving the gingivae and results from the dental amalgam sequestering into the tissues. Diseases causing pigmentation include Peutz-Jeghers syndrome, Addison's disease and lichen planus. Heavy metals, such as lead, bismuth and mercury, and drugs (e.g. phenothiazines and antimalarials) all cause gingival pigmentation.

Neoplastic lesions

These include melanotic naevi on the hard palate and buccal mucosa. These are rarer in the mouth than on the skin. Malignant melanomas are rare, more common in males, and occur mainly on the upper jaw. The 5-year survival is only 5%.

The tongue

The tongue may be involved in a generalized stomatitis with similar lesions to those described above. *Glossitis* is a red, smooth, sore tongue seen in anaemia due to B_{12}, folate or iron deficiency. It is also seen in infections due to *Candida* and in riboflavin and nicotinic acid deficiency.

A *black hairy tongue* is due to a proliferation of chromogenic microorganisms causing brown-staining of elongated filiform papillae. The causes are unknown, but heavy smoking and the use of antiseptic mouthwashes have been implicated. A *geographic tongue* is an idiopathic condition occurring in 1-2% of the population and may be familial. There are erythematous areas surrounded by well-defined, slightly raised irregular margins. The lesions are usually painless and the patient should be reassured.

The gums

The gingivae consist of the mucous membranes covering the alveolar process of the mandible and the maxilla.

Chronic gingivitis is the most common cause of bleeding gums and is an inflammation following the accumulation of bacterial plaque. It resolves when the plaque is removed.

Acute (necrotizing) ulcerative gingivitis (Vincent's gingivitis) is characterized by the proliferation of spirochaete and fusiform bacteria. Young male smokers with poor oral hygiene are predominantly affected. It responds to oral metronidazole 200 mg three times daily for 3 days, used with chlorhexidine gluconate mouthwash.

Desquamatous gingivitis is a clinical description of smooth, red atrophic gingivae caused by lichen planus or mucous membrane pemphigoid. The diagnosis is confirmed by biopsy.

Gingival swelling is due to fibrous hyperplasia or is a result of inflammatory changes. Fibrous gingival hyperplasia is a result of hereditary gingival fibromatosis or associated with drugs (e.g. phenytoin, ciclosporin, nifedipine). Inflammatory swellings are seen in pregnancy, gingivitis and scurvy. Swelling due to infiltration is seen in acute leukaemia and Wegener's granulomatosis.

The teeth

Streptococcus mutans is the main bacterial cause of dental caries in man. These bacteria are cariogenic only in the presence of dietary sugar. Dental caries can progress to pulpitis and pulp necrosis, and spreading infection can cause dentoalveolar abscesses. If there is soft tissue swelling, antibiotics (e.g. amoxicillin or metronidazole) should be prescribed prior to dental intervention. Erosion of the teeth can also result from exposure to acid (e.g. in bulimia nervosa - p. 1311) or, very occasionally, in patients with gastro-oesophageal reflux disease.

Oral manifestations of HIV infection

In the UK, 60% of HIV-infected patients have characteristic oral lesions. Lesions strongly associated with HIV infection include candidiasis (with erythema and/or white exudates), erythematous candidiasis, oral hairy leucoplakia, Kaposi's sarcoma, non-Hodgkin's lymphoma, necrotizing ulcerative gingivitis, and necrotizing ulcerative periodontitis.

Oral hairy leucoplakia is almost pathognomonic of HIV infection and may be an early sign. It is more common in HIV-infected homosexual men than in any other high-risk group. It is characterized by white vertical corrugations on the lateral borders of the tongue, and immunostaining shows Epstein-Barr virus (p. 47).

Kaposi's sarcoma presents as a red, purple or blue macule or nodule, most commonly on the palate. It is diagnostic of AIDS. The lesion is associated with herpesvirus 8 (p. 48).

All lesions are much less common since the introduction of HAART (p. 143).

THE SALIVARY GLANDS

Ptyalism (excessive salivation)

Ptyalism occurs prior to vomiting, but may be secondary to other intra-oral pathology. It can be psychogenic.

Xerostomia (dry mouth)

This can result from:

- Sjogren's syndrome
- drugs (e.g. antimuscarinic, antiparkinsonian, antihistamines, lithium, monoamine oxidase inhibitors, tricyclic and related antidepressants, and clonidine)
- radiotherapy
- psychogenic causes
- dehydration, shock and renal failure.

The principles of management are to preserve what flow remains, stimulate flow and replace saliva (glycerine and lemon mouthwash and artificial saliva).

Sialadenitis

Acute sialadenitis is due to mumps (parotitis) or bacteria. Bacteria include *Staphylococcus aureus, Streptococcus pyogenes* and *Strep, pneumoniae.* There is an ascending infection, usually secondary to secretory failure. Pus can be expressed from the affected duct.

Salivary duct obstruction due to calculus

Obstruction to salivary flow is usually due to a calculus. There is a painful swelling of the submandibular gland after eating and stones can sometimes be felt in the floor of the mouth. Sialography and plain X-ray films will show the calculus. Removal of the obstruction gives complete relief.

Sarcoidosis can involve the major salivary glands and forms part of Heerfordt's syndrome (parotitis, uveitis, low-grade fever). When combined with lacrimal gland enlargement it is known as the Mikulicz syndrome.

Neoplasms

Salivary gland neoplasms account for 3% of all tumours world-wide. The majority occur in the parotid gland. The pleomorphic adenoma is the most common and 15% of these undergo malignant transformation. Recurrence following surgical excision is common. Malignant tumours classically result in 7th cranial nerve lower motor neurone signs.

THE PHARYNX AND OESOPHAGUS

Structure and function

The oesophagus is a muscular tube, approximately 25 cm long, connecting the pharynx to the stomach. The muscle coat has two layers - an outer longitudinal layer and an inner circular layer of fibres. In the upper portion both muscle layers are striated. They gradually change to smooth muscle in the lower oesophagus, where they are continuous with the muscle layer of the stomach. The oesophagus joins to the stomach, just below the diaphragm after a short intra-abdominal segment (the gastro-oesophageal junction).

The oesophagus is lined by stratified squamous epithelium; the squamo-columnar junction lies 2 cm above the gastro-oesophageal junction and is recognized endoscopically by an irregular white Z line.

The oesophagus is separated from the pharynx by the *upper oesophageal sphincter,* which is normally closed by the continuous contraction of the cricopharyngeus muscle. The *lower oesophageal sphincter* (LOS) consists of an area of the distal end of the oesophagus that has a high resting tone and is largely responsible for the prevention of gastric reflux. The reduction in tone and relaxation of the LOS that occurs with swallowing is under the control of cholinergic excitatory neurones and non-adrenergic non-cholinergic (NANC) inhibitory neurones as well as hormonal mechanisms. The presynaptic neurotransmitter is acetylcholine. The postsynaptic neurotransmitter is nitric oxide (NO), with vasoactive intestinal peptide (VIP) and other peptides playing a role.

During swallowing, the bolus of food is moved from the mouth to the pharynx voluntarily. Immediately, the upper sphincter relaxes and food enters the oesophagus. A primary peristaltic wave starts in the pharynx at the onset of swallowing and sweeps down the whole oesophagus (Fig. 6.4). Secondary peristalsis occurs locally in response to direct stimulation (e.g. distension by the bolus) and helps to clear food residue from the oesophagus. Non-peristaltic, non-propulsive tertiary waves are frequent in the elderly. The LOS relaxes when swallowing is initiated, before the arrival of the peristaltic

Symptoms of oesophageal disorders

Major oesophageal symptoms are:

- dysphagia
- substernal discomfort/ heartburn
- acid regurgitation
- painful swallowing (odynophagia).

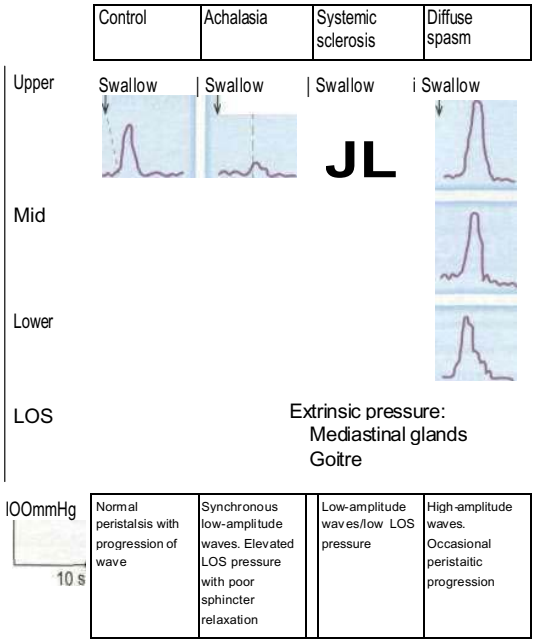

Fig. 6.4 **Oesophageal manometric patterns in normals and diseased states.** LOS, lower oesophageal sphincter. Dotted line shows peristaltic wave.

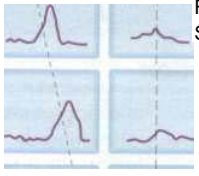
Dysphagia

This is difficulty in swallowing which is due to a local lesion or is part of a generalized disease. Patients will complain of something sticking in their throat or chest during swallowing or immediately afterwards. It is always a serious symptom and the cause must be found (Table 6.2); benign and malignant oesophageal strictures are the most common causes seen in hospital practice. *Globus* is described on page 337

Substernal discomfort/heartburn (see p. 275) This is a common symptom of acid reflux. It is usually a retrosternal burning pain that can spread to the neck, across the chest, and can be difficult to distinguish from the pain of ischaemic heart disease. It can occur at night when the patient lies flat or after bending or stooping.

Table 6.2 Causes of dysphagia



Intrinsic lesion:
- Foreign body
- Stricture:
  - benign - peptic, corrosive
  - malignant - carcinoma
- Lower oesophageal rings
- Oesophageal web
- Pharyngeal pouch
- Disease of mouth and tongue (e.g. tonsillitis)
- Neuromuscular disorders:
  - Pharyngeal disorders
  - Bulbar palsy (e.g. motor neurone disease)
  - Myasthenia gravis
- Oesophageal motility disorders:
  - Achalasia
  - Scleroderma
  - Diffuse oesophageal spasm
  - Presbyoesophagus
  - Diabetes mellitus
  - Chagas' disease
- Enlarged left atrium

Acid regurgitation

Acid regurgitation is the effortless reflux of gastric contents into the mouth and pharynx. It occurs infrequently in normal subjects but frequently in patients with gastro-oesophageal reflux disease.

Painful swallowing

Painful swallowing without real difficulty occurs with infections (p. 279). Ingestion of tablets such as bisphosphonates and potassium (slow release) will produce local ulceration if they lodge in the gullet when swallowed lying down and without water.

Signs of oesophageal disorders

There are very few signs associated with oesophageal disease, the main one being of weight loss as a consequence of dysphagia.

Investigation of oesophageal disorders

- **Barium swallow and meal.**
- **Oesophagoscopy.**
- **Manometry** (Fig. 6.4) is performed by passing a catheter through the nose into the oesophagus and measuring the pressures generated within the region of the lower oesophageal sphincter (LOS) and body of oesophagus either for a short fixed time period (static) or up to 24 hours (ambulatory).
- **pH monitoring** - 24-hour ambulatory monitoring using a pH-sensitive probe positioned in the lower oesophagus is used to identify reflux episodes (pH < 4) and when combined with manometry is a valuable means of correlating episodes of acid reflux and oesophageal dysmotility with patients' symptoms (see Fig. 6.6).
- **Radioisotope studies** with technetium-sulphur colloid incorporated into food can also be used to study reflux. It is not widely used in the UK.
- **The Bernstein test** (alternate dilute acid and alkali infused into the oesophagus to reproduce the pain) is hardly ever used. A positive test suggests oesophagitis, but there are many false negatives.

HIATUS HERNIA

This describes the 'herniation' of **part of the stomach into** the chest.

In a *sliding hiatus hernia,* the gastro-oesophageal junction 'slides' through the hiatus so that it lies above the diaphragm. This type of hernia occurs in approximately 30% of people of 50 years of age and by itself is of no diagnostic significance. It does not produce symptoms on its own; symptoms occur because of the presence of associated reflux (see below).

A *para-oesophageal or rolling hernia* is when a small part of the fundus of the stomach rolls up through the hernia alongside the oesophagus. The sphincter remains below the diaphragm and remains competent. Occasionally a rolling para-oesophageal hernia will produce severe pain and require surgical treatment for gastric volvulus or strangulation.

Box 6.3 Definitions in oesophageal disease

Hiatus hernia - anatomical abnormality with part of the stomach in the chest, usually asymptomatic. **Gastro-oesophageal reflux** - reflux of gastric contents which can occur normally with no symptoms.
Gastro-oesophageal reflux disease (GORD) - patient with reflux who has persistent symptoms. **Reflux oesophagitis** - inflammation of the lower oesophagus produced by persistent episodes of reflux. Patients may be asymptomatic. **Barrett's oesophagus** - presence of intestinal metaplastic columnar epithelium which has replaced squamous epithelium as a consequence of acid reflux.

GASTRO-OESOPHAGEAL REFLUX DISEASE (GORD)

Gastro-oesophageal reflux occurs as a normal event, and the clinical features of GORD occur only when the anti-reflux mechanisms fail sufficiently to allow gastric contents to make prolonged contact with the lower oesophageal mucosa. Definitions of terms used in oesophageal disease are shown in Box 6.3.

Antireflux mechanisms (Fig. 6.5)

The lower oesophageal sphincter (LOS) is formed by the distal 4 cm of oesophageal smooth muscle. It rapidly regains its normal tone (following relaxation to allow a bolus to enter the stomach) and thereby prevents reflux. It is capable of increasing tone in response to rises in intra-abdominal and intragastric pressures.

Other antireflux measures involve the intra-abdominal segment of the oesophagus, which acts as a flap valve, and the mucosal rosette formed by folds of the gastric mucosa also helps to occlude the gastro-oesophageal junctional lumen. In addition, contraction of the crural diaphragm exerts a 'pinchcock-like' action at the LOS.

The oesophagus is normally rapidly cleared of any reflux contents by secondary peristalsis.

Pathogenesis

The following mechanisms have been implicated:

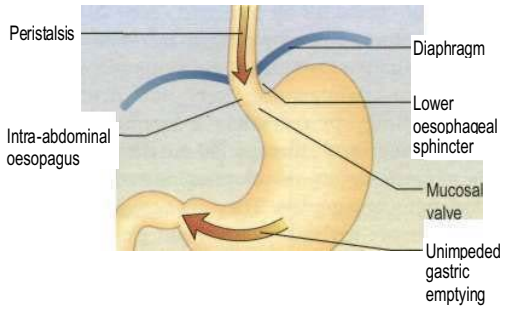


Fig. 6.5 **The main antireflux mechanisms.**

Table 6.3 Factors associated with gastro-oesophageal reflux

Pregnancy or obesity
Fat, chocolate, coffee or alcohol ingestion
Large meals
Cigarette smoking
Drugs - antimuscarinic, calcium-channel blockers, nitrates
Systemic sclerosis
After treatment for achalasia
Hiatus hernia

- Transient LOS relaxations.
- Low resting LOS tone which fails to increase when the patient is lying flat, as occurs normally.
- The LOS tone fails to increase when intra-abdominal pressure is increased by tight clothing or pregnancy.
- There is increased oesophageal mucosal sensitivity to acid.
- There is reduced oesophageal clearance of acid because of poor oesophageal peristalsis. The reduced acid clearance is exacerbated with a hiatus hernia, owing to trapping of acid within the hernial sac.
- A large hiatus hernia can impair the 'pinchcock' mechanism of the crural diaphragm.
- Delayed gastric emptying occurs, which may increase the chance of reflux.
- Prolonged episodes of gastro-oesophageal reflux occurring at night and postprandially.

Factors associated with increased gastro-oesophageal reflux are shown in Table 6.3. All or some of these features play a role in the individual patient and can occur whether or not a hiatus hernia is present. GORD often occurs without a hiatus hernia.

Clinical features

Heartburn is the major feature of GORD. Pain is mainly due to direct stimulation of the hypersensitive oesophageal mucosa, but is also partly due to spasm of the distal oesophageal muscle. The burning is aggravated by bending, stooping or lying down and may be relieved by antacids. The patient may complain of pain on drinking hot liquids or alcohol. The correlation between heartburn and oesophagitis is poor. Some patients have mild oesophagitis, but severe heartburn; others have severe oesophagitis without symptoms, and present with a haematemesis or an iron deficiency anaemia from chronic blood loss.

Regurgitation of food and 'acid' into the mouth occurs, particularly when the patient is bending or lying flat. Aspiration into the lungs, producing pneumonia, is unusual without an accompanying stricture, but cough and nocturnal asthma from regurgitation and aspiration can occasionally occur. The differential diagnosis of the retrosternal pain from angina can be difficult; 20% of cases admitted to a coronary care unit have GORD (Box 6.4).

***wjm Box 6.4* Features of gastro-oesophageal reflux ^^ and myocardial ischaemia**

Gastro-oesophageal reflux
Burning pain produced by bending, stooping or lying down
Pain seldom radiates to the arms Pain precipitated by drinking hot liquids or alcohol Relieved by antacids

Myocardial ischaemia
Gripping or crushing pain
Pain radiates into neck, shoulders and both arms
Pain produced by exercise
Accompanied by dyspnoea

Diagnosis and investigations

GORD is a clinical diagnosis and in many patients the diagnosis can be made without investigation. Under the age of 45 years, all patients should be treated initially without investigations, unless there are alarm symptoms (see p. 265).

Documenting reflux

- Barium swallow when combined with the water siphon test is a reliable way of assessing the potential severity of reflux. It will also show the presence of a hiatus hernia.
- 24-Hour intraluminal pH monitoring combined with manometry (see p. 274), which should always be performed to confirm GORD before considering surgery. There should be a good correlation between reflux (pH < 4.0) and symptoms (Fig. 6.6). It is also necessary to exclude oesophageal dysmotility as the cause of symptoms.
- Radiolabelled technetium (see p. 270) is used in some centres to demonstrate reflux.

Assessing oesophagitis (Fig. 6.7)

Fibreoptic oesophagoscopy is used to confirm the presence of oesophagitis, i.e. a red friable mucosa with ulceration in severe cases (erosive oesophagitis). The technique is also used to diagnose Barrett's oesophagus (p. 277).

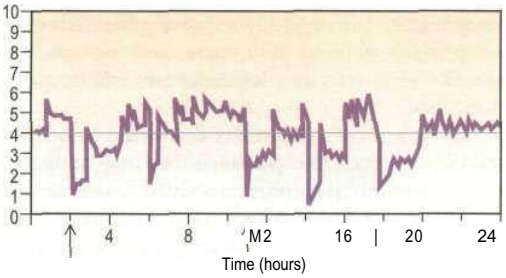

Fig. 6.6 **24-hour intraluminal pH monitoring.** Five reflux episodes (pH < 4) occurred, but only three gave symptoms (arrows).

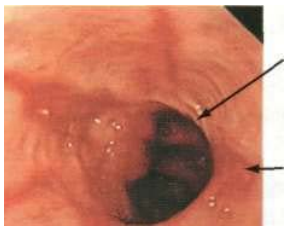

Fig. 6.7 **Endoscopic picture, showing oesophagitis.** Courtesy of Dr Geoff Smith.

Treatment

Many patients with reflux symptoms (approximately 50%) can be treated successfully with simple antacids, loss of weight, and raising the head of the bed at night. Precipitating factors should be avoided, with a reduction in alcohol consumption and cessation of smoking. These measures are simple to say, difficult to carry out, but are useful in mild cases.

Drugs

Simple antacids magnesium trisilicate and aluminium hydroxide are readily available and are often used initially by patients. The former tends to cause diarrhoea whilst the latter causes constipation. Many antacids contain sodium which may exacerbate fluid retention; aluminium hydroxide has less sodium than magnesium trisilicate.

Alginate-containing antacids (10 mL three times daily) are the most frequently prescribed agents for GORD. They form a gel or 'foam raft' with gastric contents and thereby reduce reflux. They are available over the counter and are often used by the patient before consultation.

H_2-receptor antagonists (e.g. cimetidine, ranitidine, famotidine and nizatadine) are used for acid suppression if the above measures fail and as they can be obtained over the counter in the UK they are frequently used.

Proton pump inhibitors (PPIs) (e.g. omeprazole, rabeprazole, lansoprazole, pantoprazole, esomeprazole) inhibit gastric hydrogen/potassium-ATPase (see Fig. 6.10). PPIs reduce gastric acid secretion by 90% and are the drugs of choice for all but mild cases. Patients with severe symptoms need prolonged treatment, often for years. Sometimes a lower dose, e.g. omeprazole 10 mg, is sufficient for maintenance. Rebound increased acid secretion lasting approximately 2 months occurs after 2 months' omeprazole therapy (40 mg daily).

The prokinetic agents metoclopramide and domperidone are dopamine antagonists. They are occasionally helpful as they enhance peristalsis and speed gastric emptying. Cisapride increases the QT_C interval and has been withdrawn because of the risk of arrhythmias.

Helicobacter pylori eradication in GORD has little effect on the symptoms but is usually advised (p. 285).

Using the above treatments, most patients can be kept symptom-free, but symptoms usually return when treatment is stopped and long-term therapy is then required.

Surgery

Surgery should never be performed for a hiatus hernia alone. The properly selected case with severe reflux symptoms confirmed by pH monitoring and with oesophagitis on oesophagoscopy responds well to surgery. Repair of the hernia and some sort of additional antireflux surgery (e.g. a modified Nissen fundoplication) is performed laparoscopically. Results show an improvement in symptoms in up to 80% of cases. The indications for surgery are not always clear as medical therapy with PPIs is so effective; the young patient needing years of drug treatment is one common indication.

Patients with oesophageal dysmotility unrelated to acid reflux tend to do less well as do those with underlying functional bowel disease.

Management of reflux oesophagitis

There is a poor correlation between GORD symptoms and the presence of endoscopic oesophagitis.

Many gastroenterologists treat severe oesophagitis (even in the absence of symptoms) with long-term PPIs with regular surveillance oesophagoscopy in an attempt to reduce the risk of complications. Long-term PPI therapy appears very safe.

Complications

Peptic Stricture usually occurs in patients over the age of 60. The symptoms are those of intermittent dysphagia over a long period. Treatment is by dilatation of the stricture and management of the reflux usually medically with a proton-pump inhibitor to achieve anacidity. Occasionally surgery is required.

Barrett's oesophagus. This occurs from long-standing reflux. It consists of columnar epithelium with intestinal metaplasia extending upwards into the lower oesophagus replacing normal squamous epithelium. It is seen in up to 20% of patients undergoing endoscopy for gastro-oesophageal reflux disease. Endoscopically, Barrett's may be seen as a continual sheet, a finger like projection extending upwards from the squamo-columnar junction or as islands of columnar mucosa interspersed in areas of residual squamous mucosa. It is very common in middle-aged men. Barrett's oesophagus (even a short segment < 3 cm) is premalignant for adenocarcinoma. An indocarmine spray down the endoscope can detect intestinal metaplasia and possibly dysplasia. The dysplasia is patchy, and biopsies from all four quadrants (every 2 cm) of the Barrett's segment must be performed. There is no evidence that treatment with PPIs or antireflux surgery leads to Barrett's regression. Surveillance - looking for severe dysplasia/cancer - is costly and subject to observer error. Current recommendations are still controversial but the consensus view is that patients without dysplasia do not require surveillance gastroscopy. With low-grade dysplasia, 6-monthly endoscopy for 1 year, followed by endoscopy at 2- to 3-yearly intervals (along with intensive medical therapy) has been suggested. There is much controversy over high-grade dysplasia, as approximately a quarter do not progress to cancer; oesophagectomy is associated with a mortality of 3-10% and high morbidity. There are no current randomized controlled trials for guidance but laser mucosal ablation and photodynamic therapy are being tried.

Adenocarcinoma. Patients with weekly reflux symptoms are nearly eight times more likely to develop adenocarcinoma compared with those without symptoms. The greater the frequency, severity and the duration of reflux symptoms, the greater the risk.

MOTILITY DISORDERS

Achalasia

Achalasia is a disease characterized by aperistalsis in the body of the oesophagus and failure of relaxation of the lower oesophageal sphincter on initiation of swallowing. In the majority of cases the aetiology is unknown (idiopathic). The disease can present at any age but is rare in childhood. The incidence is about 1 per 100 000 per year in all ages. A similar clinical picture is seen in chronic Chagas' disease (American trypanosomiasis, p. 101) where there is damage to the neural plexus of the gut.

Pathogenesis

Degenerative lesions are found in the vagus as well as a decrease in ganglionic cells in the myenteric nerve plexus of the oesophageal wall. NANC inhibitory neurones are affected more than the cholinergic nerves, and thus the relaxation of the sphincter is impaired in the absence of nitric oxide. Some patients have autoantibodies to a dopamine-carrying protein on the surface of the cells in the myenteric plexus.

Clinical features

Patients usually have a long history of intermittent dysphagia for both liquids and solids. Regurgitation of food from the dilated oesophagus may be induced by the patient or may occur spontaneously, particularly at night, and aspiration pneumonia can occur. Occasionally food gets stuck but patients often learn to overcome this by drinking large quantities, thereby increasing the head of pressure in the oesophagus and forcing the food through. Severe retrosternal chest pain occurs particularly in younger patients with vigorous non-peristaltic contraction of the oesophagus. The dysphagia in these patients can be mild and the pain misdiagnosed as cardiac in origin. Weight loss is usually not marked.

Investigations

- **Chest X-ray** may show a dilated oesophagus, sometimes with a fluid level seen behind the heart. The fundal gas shadow is not present.

- Barium swallow will show dilatation of the oesophagus, lack of peristalsis and often synchronous contractions. The lower end gradually narrows ('swan neck deformity'); this appearance is due to failure of the sphincter to relax (Fig. 6.8).
- Oesophagoscopy is necessary to exclude a carcinoma at the lower end of the oesophagus, as an intramucosal carcinoma can produce a similar X-ray appearance. When there is marked dilatation, extensive cleansing is necessary to remove food debris in order to obtain a clear view. In achalasia the oesophagoscope easily flops through the apparent narrowing without resistance.
- CT scan. This is helpful, particularly in detecting an intramucosal carcinoma.
- Manometry shows aperistalsis of the oesophagus as well as the failure of relaxation of the lower oesophageal sphincter (see Fig. 6.4).

Treatment

The treatment of choice is endoscopic dilatation of the LOS using a pneumatic bag (passed under X-ray control). This weakens the sphincter and is successful in 80% of cases. Endoscopic injection of botulinum toxin into the LOS has been used with variable success. If these measures fail, surgical division of the muscle at the lower end of the oesophagus (cardiomyotomy or Heller's operation) is performed laparoscopically. Reflux oesophagitis complicates all procedures and the aperistalsis of the oesophagus remains. In older patients, nifedipine (20 mg sublingually) or sildenafil can be tried initially.

Fig. 6.8 **Barium swallow showing achalasia** with atonic body of the oesophagus and a narrowed distal end. Note food residue in dilated oesophagus.

Complications

There is a slight increase in the incidence of squamous carcinoma of the oesophagus in both treated and untreated cases (7% after 25 years).

Systemic sclerosis (see also p. 577)

There is oesophageal involvement in 90% or more of patients with this disease. Diminished peristalsis, detected manometrically (see Fig. 6.4) or by barium swallow, is due to replacement of the smooth muscle layers by fibrous tissue. The lower oesophageal sphincter pressure is also decreased, allowing reflux; mucosal damage occurs as a consequence. Strictures may develop. Initially there are no symptoms, but dysphagia and heartburn occur as the oesophagus becomes severely involved.

Similar motility abnormalities may be found in other connective-tissue disorders, particularly if Raynaud's phenomenon is present. Treatment is as for reflux (see p. 276) and stricture formation.

Diffuse oesophageal spasm

This is a severe form of abnormal oesophageal motility that can sometimes produce retrosternal chest pain and dysphagia. It can accompany GORD. Swallowing is accompanied by bizarre and marked contractions of the oesophagus without propagation of the waves (see Fig. 6.4). On barium swallow the appearance may be that of a 'corkscrew'. However, changes in oesophageal motility 'dysmotility' are not infrequent, particularly in patients over the age of 60 years (presbyoesophagus). Care must therefore be taken that the symptoms, the manometry and X-ray findings of oesophageal spasm are not falsely correlated; functional dyspepsia is commoner than oesophageal spasm.

A variant of diffuse oesophageal spasm is the 'nutcracker' oesophagus, which is characterized by finding very high-amplitude peristalsis (pressures > 200 mmHg) within the oesophagus. Chest pain and dysphagia occur.

Treatment

True oesophageal spasm producing severe symptoms is uncommon and treatment is often difficult. When the spasm is due to GORD, acid suppression is given. Antispasmodics, nitrates, or calcium-channel blockers - such as sublingual nifedipine 10 mg three times daily - may be tried. Occasionally, balloon dilatation or even myotomy is necessary.

Miscellaneous motility disorders

Abnormalities of motility that are mostly asymptomatic but occasionally produce dysphagia are found in the elderly, in diabetes mellitus, myotonia dystrophica and

myasthenia gravis, as well as neurological disorders involving the brainstem.

OTHER OESOPHAGEAL DISORDERS

Oesophageal diverticulum

This is a pouch lined with epithelium that can produce dysphagia and regurgitation. It is usually asymptomatic and often detected accidentally on a barium swallow performed for other reasons. Diverticula can occur:

- immediately above the upper oesophageal sphincter (pharyngeal pouch) (p. 1161)
- near the middle of the oesophagus (traction diverticulum produced by extrinsic inflammation)
- just above the lower oesophageal sphincter (epiphrenic diverticulum).

Only when symptoms are severe should surgery be undertaken.

Rings and webs

A number of rings and webs have been described throughout the oesophagus.

Upper oesophageal web

This is a constriction near the upper oesophageal sphincter in the post-cricoid region and appears radiologically as a web. The web may be asymptomatic or may produce dysphagia. In the Plummer-Vinson syndrome (Paterson-Brown-Kelly syndrome) this web is associated with iron deficiency anaemia, glossitis and angular stomatitis. This rare syndrome affects mainly women and its aetiology is not understood. At oesophagoscopy the web may be difficult to see. Dilatation of the web is rarely necessary. Iron is given for the iron deficiency.

Cricopharyngeal dysfunction

There is poor relaxation of the cricopharyngeal muscle during swallowing so that a prominent indentation or 'bar' is seen on a barium swallow. It occurs in the elderly. Dysphagia is treated with dilatation but surgical myotomy may be necessary.

Lower oesophageal or Schatzki ring

This is a narrowing of the lower end of the oesophagus due to a ridge of mucosa or a fibrous membrane. The ring may be asymptomatic, but it can very occasionally produce dysphagia after swallowing a large bolus of bread or meat. A barium swallow (with the oesophagus well distended with barium) often shows the narrowing; barium-coated bread will lodge at the narrowing. Treatment is with reassurance and dietary advice, but dilatation is occasionally necessary.

Benign oesophageal stricture

Peptic stricture secondary to reflux is the most common cause of benign strictures (for treatment, see p. 277). They also occur after the ingestion of corrosives, after radiotherapy, after sclerosis of varices, and following prolonged nasogastric intubation. All strictures give rise to dysphagia. They are usually treated by dilatation, but occasionally surgery is necessary.

Oesophageal infections

Infection is a cause of painful swallowing and is seen particularly in immunosuppressed debilitated patients and patients with AIDS. Infection can occur with:

- *Candida*
- herpes simplex
- cytomegalovirus.

It is occasionally difficult to distinguish between these either on barium swallow or oesophagoscopy, as only widespread ulceration is seen. In candidiasis the characteristic white plaques on top of friable mucosa are frequently found but oral candidiasis is not always present. The diagnosis of *Candida* infection can be confirmed by examining a direct smear taken at endoscopy, but often infections are mixed and cultures and biopsies must be performed.

Treatment

Most patients on large doses of immunosuppressive agents are treated prophylactically with nystatin or amphotericin. Other antifungal or antiviral treatment is given appropriately (see Ch. 2).

The Mallory-Weiss syndrome

This is described on page 293.

Oesophageal perforation or rupture

Oesophageal perforation usually occurs at the time of endoscopic dilatation or very occasionally following insertion of a nasogastric tube. Patients with a malignant, corrosive or post-radiotherapy stricture are more likely to perforate than those with a benign peptic stricture.

Management usually involves placement of an oesophageal stent (p. 281), which dilates the usually malignant stricture and seals the hole. A water-soluble contrast X-ray is performed after 2-3 days to check the perforation has sealed.

Oesophageal rupture occurs with violent vomiting, producing severe chest pain and collapse. It may follow alcohol ingestion. A chest X-ray shows a hydropneumothorax. The diagnosis is made radiologically using water-soluble contrast. Treatment is surgical; mortality is high.

OESOPHAGEAL TUMOURS

Cancer of the oesophagus

This is the fifth most common cancer seen throughout the world. Approximately 40% occur in the middle third of

the oesophagus and are squamous carcinomas. Adenocarcinomas (approx 45%) occur in the lower third of the oesophagus and at the cardia. Tumours of the upper third are rare (15%).

Epidemiology and aetiological factors

Squamous cell carcinoma (SCC)

The incidence of this carcinoma varies throughout the world, being high in China, parts of Africa and in the Caspian regions of Iran (where the incidence is the highest observed for any type of cancer anywhere in the world). In the UK the incidence is 5-10 per 100 000 and represents 2.2% of all malignant disease. The variation in incidence throughout the world is greater than for any other carcinoma and is unusual in that sharp differences occur in regions very close to one another. The incidence of SCC is decreasing, in contrast to adenocarcinoma.

SCC of the oesophagus is more common in men (2 :1); risk factors are shown in Table 6.4. Monotonous diets very high in cereals and N-nitroso compounds in preserved food, possibly increase the risk. Diets high in carotenoids and vitamin C (vegetables and fruit) possibly decrease the risk.

Adenocarcinoma

These tumours arise in the columnar-lined epithelium of the lower oesophagus (Barrett's oesophagus, p. 277). This columnarization results from long-standing reflux, although some patients will have no preceding symptoms. This premalignant lesion increases the chances of developing an adenocarcinoma 30-40-fold. The incidence rate of this tumour is increasing (fivefold in Europe and the USA). Extension of an adenocarcinoma of the gastric cardia into the oesophagus can present with the same symptoms.

Clinical features

Carcinoma of the oesophagus occurs mainly in those aged 60-70 years, although it is now occurring in younger age groups. Dysphagia is the most common single symptom and is progressive and unrelenting. Initially there is difficulty in swallowing solids, but eventually dysphagia for liquids also occurs. Benign strictures, on the other hand, initially produce intermittent dysphagia. Impaction of food causes pain, but more persistent pain implies infiltration.

The lesion is usually ulcerative, extending around the wall of the oesophagus to produce a stricture. Direct invasion of the surrounding structures occurs rather than widespread metastases. Weight loss, due to the dysphagia as well as to anorexia, frequently occurs. The oesophageal obstruction eventually causes difficulty in swallowing saliva, and coughing and aspiration into the lungs is common.

Signs are often absent. Weight loss, anorexia and lymphadenopathy are occasionally found.

Table 6.4 **Risk factors for cancer of the oesophageal**

Squamous cell carcinoma	Adenocarcinoma
Tobacco smoking High alcohol intake Plummer-Vinson syndrome Achalasia Corrosive strictures Coeliac disease Breast cancer treated with radiotherapy Tylosis* Diet deficient in vitamins; high dietary carotenoids and vitamin C possibly decrease the risk	Long-standing weekly GORD Barrett's oesophagus Tobacco smoking Obesity Breast cancer treated with radiotherapy

* Tylosis is an autosomal dominant condition with hyperkeratosis of the palms and soles

Investigation

Diagnostic

Endoscopy/barium swallow. Many gastroenterologists like to go directly to oesophagoscopy, which provides histological or cytological proof of the carcinoma; 90% of oesophageal carcinomas can be confirmed with this technique. Barium swallow (Fig. 6.9a) is also a very sensitive technique and is useful in the younger patient with dysphagia where the differential diagnosis includes a motility disorder.

Staging for surgery

The TNM staging system is used (p. 490). Extent of tumour invasion (T), presence of tumour in lymph nodes (N) or metastases (M) are combined into stage categories.

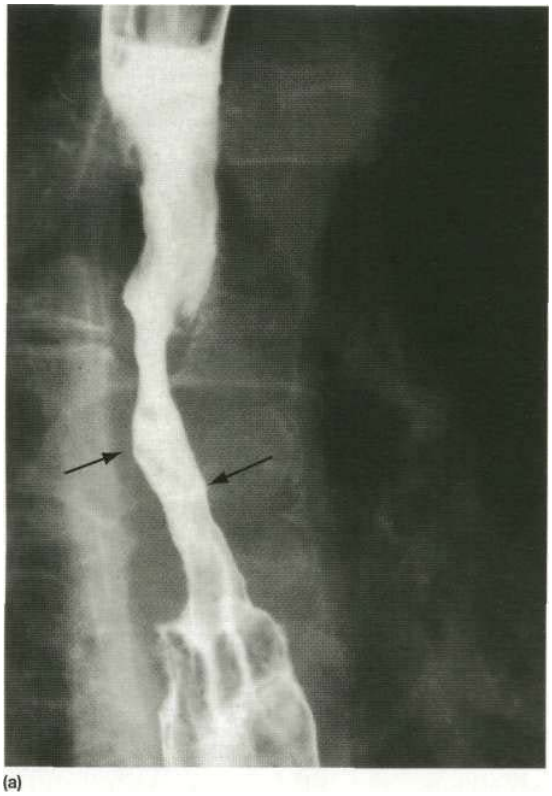
- **CT scan and MRI** of the thorax and upper abdomen will show the volume of the tumour, local invasion and lymph node involvement.
- **Endoscopic ultrasound** (Fig. 6.9b) has an accuracy rate of nearly 90% for assessing depth of tumour and infiltration and 80% for staging lymph node involvement.
- **Positron emission tomography (PET)** after fludeoxyglucose F18 is being used. Its specificity is high with a similar sensitivity to CT and MRI for distant metastases.

Treatment

This depends on the age and performance status of the patient and the stage of the disease. Five-year survival with stage 1 is 80% (T_1/T_2, N_o, M_o), stage 2 is 30%, stage 3 is 18% and stage 4 is 4%. Seventy per cent of patients present with stage 3 disease, so that overall survival is 27% at 1 year and 14% at 5 years. Management should be undertaken by multidisciplinary teams.

Surgery

Surgery provides the best chance of a cure and should be used only when imaging (see above) has shown that the tumour has not infiltrated outside the oesophageal wall. Surgery in this group shows an 80% 5-year survival rate if the postoperative pathology confirms the staging. The patients must be carefully evaluated preoperatively,



(a)

(b)

Fig. 6.9 **Carcinoma of the oesophagus, (a) Barium swallow,** showing an irregular narrowed area (arrows) at the lower end of the oesophagus, **(b) Endoscopic ultrasound.** The central concentric circles are the probe. The arrow points to a break in the muscle layer and the soft tissue mass of the carcinoma.

particularly with regard to performance status (p. 490), and surgery undertaken in designated units.

Radiotherapy

This is now seldom used on its own for squamous or adenocarcinoma except for palliation.

Chemotherapy/chemoradiation

5FU, cisplatinum and combined chemoradiation are being used for squamous carcinoma (see p. 521) before and after surgical resection (neo-adjuvant) in some centres, with some prolongation of survival.

Palliative therapy (see also p. 524)

This is often the only realistic possibility. Repeated dilatation or dilatation of the stricture with the insertion of an expanding metal stent to keep the oesophageal lumen open is performed via an endoscope. This allows liquids and soft foods to be eaten. Fizzy drinks are recommended to keep the tubes from blocking. Additional chemoradiation improved survival from 9 months to 14.9 months in one study. Brachytherapy has also been shown to give long-term relief.

Tumours can be photocoagulated using a laser beam delivered through an endoscope, or necrosed using alcohol injections. This relieves the dysphagia, but repeated treatments are necessary. Photodynamic therapy is being tried to reduce the tumour bulk.

Nutritional support, as well as support for the patient and their family, is vital in this distressing condition.

Other oesophageal tumours

Most other tumours are rare. Gastrointestinal stromal tumours (p. 290) are found usually by chance. Ten per cent cause dysphagia or bleeding. Surgical removal is performed for symptomatic lesions.

Kaposi's sarcoma is found in the oesophagus as well as the mouth (see p. 272) and hypopharynx in patients with AIDS.

THE STOMACH AND DUODENUM

Structure

The stomach, which varies considerably in size, is divided into a small area immediately distal to the oesophagus (the cardia), the upper region (the fundus which lies under the left diaphragm), the mid-region or body, and the antrum, which extends into the pyloric region.

There are two sphincters, the gastro-oesophageal sphincter and the pyloric sphincter; the latter is largely made up of a thickening of the circular muscle layer. The muscle wall of the stomach has three layers - an outer longitudinal, an inner circular, and an innermost oblique layer of smooth muscle.

The duodenum has outer longitudinal and inner smooth muscle layers. It is C-shaped and the pancreas sits in the concavity. It terminates in the jejunum at the duodenojejunal flexure.

The mucosal lining of the stomach, particularly in the greater curvature, is thrown into thick folds or rugae. The upper two-thirds of the stomach contains parietal cells, which secrete hydrochloric acid, and chief cells, which secrete pepsinogen (which initiates proteolysis). The junction between the body and the antrum of the stomach can often be seen macroscopically, but can be confirmed by measuring surface pH. The antrum contains mucus-secreting and G cells, which secrete gastrin. There are two major forms of gastrin, G17 and G34, depending on the number of amino-acid residues. G17 is the major form found in the antrum. Mucus-secreting cells are present throughout the stomach and secrete mucus and bicarbonate which is trapped in the mucus gel. The mucus is made of glycoproteins called mucins. Somatostatin is also produced by specialized antral cells (Dcells).

The mucosal barrier, made up of the surface membranes of mucosal cells and the mucus, protects the gastric epithelium from damage by, for example, alcohol, aspirin, NSAIDs, and bile salts. Prostaglandins stimulate secretion of mucus, and their synthesis is inhibited by aspirin and NSAIDs, which inhibit cyclo-oxygenase (see Fig.14.32).

The duodenal mucosa contains Brunner's glands, which secrete alkaline mucus. This, along with the pancreatic and biliary secretions, helps to neutralize the acid secretion from the stomach when it reaches the duodenum.

Function

The factors controlling acid secretion are shown in Figure 6.10. Secretion is under neural and hormonal control. Both stimulate acid secretion through the direct release of histamine on the parietal cell. Acetylcholine and gastrin also release histamine via the enterochromaffin cells. Somatostatin inhibits both histamine and gastrin release and therefore acid secretion.

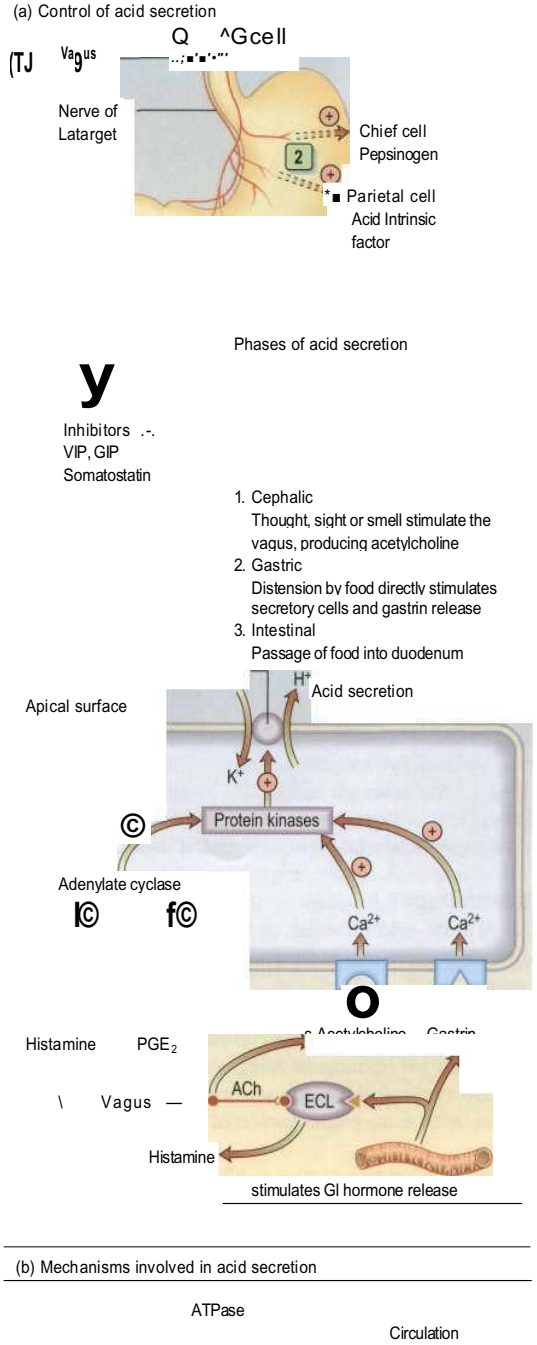

Fig. 6.10 **(a) Control of acid secretion, (b) Mechanisms involved in acid secretion.**

- *Gastrin* acts via the gastrin receptor, increasing the intracellular free calcium, and the ECL cell stimulating histamine.
- *Acetylcholine* (ACh) acts via the M_3 receptors and is vagally stimulated.
- ACh and gastrin also act via the enterochromaffin cell.
- *Histamine* stimulates G_s via the H_2 receptors and acts via cyclic AMP.
- *Prostaglandin* E_2 activates the G, protein and INHIBITS acid secretion.

G_s and G,, stimulating and inhibiting G-proteins; ECL, enterochromaffin cells.

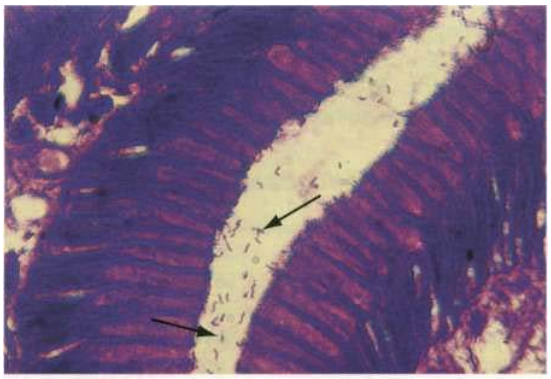
Other major gastric functions are:

- acting as a reservoir for food
- the emulsification of fat and mixing of gastric contents
- the secretion of intrinsic factor
- absorption (of only minimal importance).

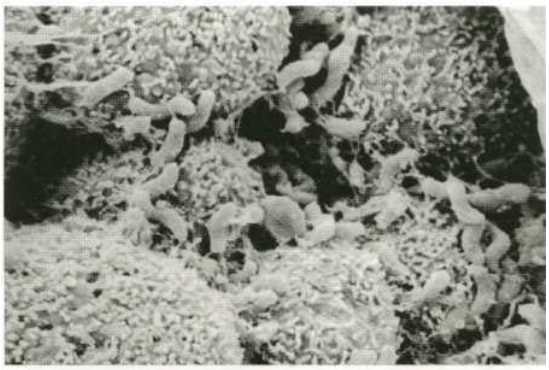
Gastric emptying depends on many factors. There are osmoreceptors in the duodenal mucosa that control gastric emptying by local reflexes and the release of gut hormones. In particular, intraduodenal fat delays gastric emptying by negative feedback through duodenal receptors.

HELICOBACTER PYLORI INFECTION

H. pylori is a spiral-shaped Gram-negative urease-producing bacterium (Fig. 6.11). Its complete genomic sequence is known. It is found in the gastric antrum and in areas of gastric metaplasia in the duodenum. *H. pylori* is found in greatest numbers under the mucus layers in gastric pits, where it adheres specifically to gastric epithelial cells.



(a)



(b)

Fig. 6.11 ***Helicobacter pylori.***
(a) Organisms (arrowed) are shown on the gastric mucosa (cresyl fast violet (modified Giemsa) stain). Courtesy of Dr Alan Phillips, Department of Paediatric Gastroenterology, Royal Free Hospital.
(b) Scanning electron microscopy, showing the spiral-shaped bacterium.

Colonization in the acid environment of the gastric mucosa occurs because:

- Sheathed flagella allow the organisms to move quickly from the acidic lumen of the stomach through the mucus layer where the pH is higher. (Mutant strains that are non-motile do not colonize.)
- Acute infection produces transient hypochlorhydria.
- *H. pylori* produces urease (see Fig. 6.12). The ammonia produced neutralizes the acid.
- It possesses a proton pump.

Epidemiology

The exact mode of transmission is unclear, but intrafamilial clustering suggests person-to-person spread, either oral-oral or faeco-oral mainly in childhood. The prevalence of *H. pylori* is high in developing countries (80-90% of the population) and its presence is associated with lower socio-economic status world-wide. Between one- and two-thirds of the western populations have this infection and the prevalence is high in the older population - presumably acquired in their childhood when hygiene was less good than today.

Pathogenesis

H. pylori infection produces a gastritis mainly in the antrum of the stomach. The mucosa appears reddened endoscopically, and histologically there is epithelial cell damage from local release of cytokines such as IL-6 and IL-8. This leads to recruitment and activation of an inflammatory infiltrate in the lamina propria. This consists of polymorphonuclear leucocytes, eosinophils, lymphocytes, monocytes and plasma cells.

In some individuals this chronic superficial gastritis can involve the body of the stomach and this leads to atrophic gastritis. Intestinal metaplasia, which is a premalignant pathological change, occurs in some of these areas (see Fig. 6.15).

Duodenal ulcer (DU) disease

H. pylori is causally associated with DU disease because in patients with DU:

- 95% are infected with *H. pylori*
- cure of the infection stops duodenal ulcer recurrence.

The precise mechanism of how duodenal ulceration occurs is unclear, as only 15% of patients infected with *H. pylori* (approximately 50-60% of the adult population world-wide) develop duodenal ulcers. Factors that have been implicated include:

- Increased acid secretion because of:
  - increased parietal cell mass
  - increased gastrin secretion.
- Smoking impairing gastric mucosal healing.
- Virulence factors: *H. pylori* produces toxins, Vac A (vacuolating toxin) and Cag A (cytotoxic associated protein) as well as urease and adherence factors. There is controversy over their role in producing duodenal ulcer disease.

Decreased inhibition of acid secretion; *H. pylori-induced* gastritis reduces somatostatin production in the antrum with loss of the negative feedback on gastrin secretion.

- Genetic susceptibility may play a role. DUs are more common in patients who have blood group O and are non-secretors of blood group substances in saliva.
- These factors lead to an increased acid load to the duodenum, which precipitates bile salts which would normally inhibit the growth of *H. pylori.*

Bicarbonate secretion is decreased in the duodenum by *H. pylori* inflammation and the damage and repair leads to gastric metaplasia which *H. pylori* colonizes, causing local release of cytokines and further damage.

Gastric ulcers (GU)

Gastric ulcers are associated with a gastritis affecting the body as well as the antrum of the stomach (pangastritis). Parietal cell damage occurs so that acid production is normal or low. The ulcers occur because of local epithelial damage by cytokines released by *H. pylori* and also because of abnormal mucus production.

Clinical syndromes

H. pylori gastritis

This is usually asymptomatic; whether *H. pylori* gastritis itself produces epigastric discomfort, i.e. functional dyspepsia, is controversial.

Peptic ulcer disease

Epidemiology

DUs are very common and are two to three times more common than gastric ulcers (GUs). Approximately 10-15% of the population will suffer from a DU.

Ulcer rates are declining rapidly for younger men and increasing for older individuals, particularly women. Both DUs and GUs are common in the elderly. There is a considerable geographical variation; for example, DUs are more common in northern England and Scotland than in other parts of the UK.

Pathology

Gastric ulcers are found in any part of the stomach, but are most commonly seen on the lesser curve. Most duodenal ulcers are found in the duodenal cap; the surrounding mucosa appears inflamed, haemorrhagic or friable (duodenitis). Erosions are superficial mucosal defects, whereas in a peptic ulcer there is a break in the superficial epithelial cells penetrating down to the muscularis mucosa at the site of the ulcer; there is a fibrous base and an increase in inflammatory cells. *H.* py/on'-induced gastritis is present, confined to the antrum in DU disease but also involving the body in gastric ulcer disease. Occasionally peptic ulcers are seen without *H. pylori,* e.g. Zollinger-Ellison syndrome (p. 416).

Clinical features

The characteristic feature is epigastric pain. It has been shown that if a patient points to the epigastrium as the site of the pain this has a high discriminatory value for diagnosis. The relationship of the pain to food is variable and on the whole not helpful in the diagnosis. The pain of a DU classically occurs at night (as well as during the day) and is worse when the patient is hungry. Both gastric and duodenal ulcers are helped by antacids.

Nausea may accompany the pain; vomiting is infrequent but often relieves the pain. Heartburn occurs owing to acid regurgitation. Anorexia and weight loss may occur, particularly with gastric ulcers. If the patient complains of persistent and severe pain, complications such as penetration into other organs may have occurred. Back pain suggests a penetrating posterior duodenal ulcer. Severe ulceration can occasionally be symptomless, as 50% of patients who have died from the complications of peptic ulceration were unaware of the diagnosis prior to the final event. Patients can present for the first time with either a haematemesis or melaena or a perforation.

Untreated, the symptoms of a DU are periodic with spontaneous relapses and remissions. The natural history is for the disease to remit over many years with the onset of atrophic gastritis and a decrease in acid secretion.

Examination. This is usually unhelpful; epigastric tenderness is quite common in non-ulcer dyspepsia.

Diagnosis of *Helicobacter pylori* infection

Non-invasive methods

- *^{13}C Urea breath test* (Fig. 6.12). This is a quick and easy way of detecting the presence of *H. pylori* and is used as a screening test. The measurement of $^{13}CO_2$ in the breath, after ingestion of ^{13}C urea, requires a mass spectrometer, which is expensive, but the test is very

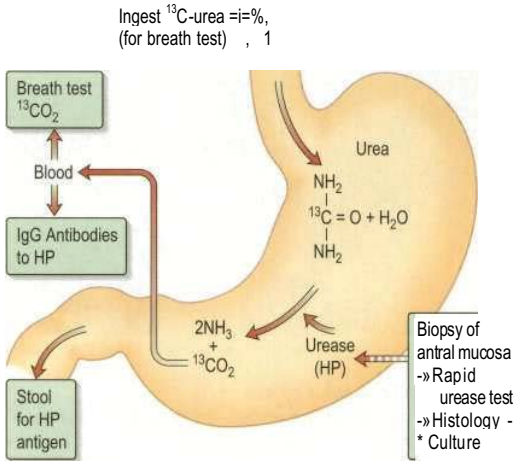


Fig. 6.12 **Metabolism of urea by *Helicobacter pylori* (HP), showing the different tests that are available for the detection of *H. pylori.***

sensitive (97%) and specific (96%). The breath test is also used to demonstrate eradication of the organism following treatment.

- *Serological tests* detect IgG antibodies and are reasonably sensitive (90%) and specific. They are used in the diagnosis and in epidemiological studies. IgG titres may take up to 1 year to fall by 50% after eradication therapy and therefore are not useful for confirming eradication or the presence of a current infection. Antibodies can also be found in the saliva, but tests are not as sensitive or specific as serology.
- *Stool test.* A specific immunoassay using monoclonal antibodies for the qualitative detection of *H. pylori* antigen is widely available. The overall sensitivity is 96% with a specificity of 97%. It is useful in the diagnosis of *H. pylori* infection and for monitoring efficacy of eradication therapy. (Patients should be off PPIs for 1 week but can continue with H_2 blockers.)

Invasive (endoscopy)

- *Rapid urease test.* Gastric biopsies are added to a urea solution containing phenol red. If *H. pylori* are present, the urease enzyme splits the urea to release ammonia which raises the pH of the solution and causes a rapid colour change.
- *Culture.* Biopsies obtained can be cultured on a special medium, and sensitivities to antibiotics can be ascertained.
- *Histology. H. pylori* can be detected histologically on routine (Giemsa) stained sections of gastric mucosa obtained at endoscopy.

Investigation of suspected peptic ulcer disease

- *Patients under 55 years of age* with typical symptoms of peptic ulcer disease who are *H. pylori* positive require no further investigation and can start eradication therapy.
- *In older patients,* confirmation of peptic ulcer is required. Endoscopy is the preferred investigation (Fig. 6.13). All gastric ulcers must be biopsied. A duodenal ulcer is shown in Figure 6.14.
- *In all patients* with 'alarm symptoms', (p. 265) endoscopy is required.

Eradication therapy

Current recommendations are that all patients with duodenal and gastric ulcers should have *H. pylori* eradication therapy.

Many patients, however, are tested for *H. pylori* (see above). Some of these patients will have incidental *H. pylori* infection with no gastric/duodenal lesion, and whether all such patients should have eradication therapy is controversial (see Functional dyspepsia, p. 337). There has been an increase in the prevalence of GORD and adenocarcinoma of the lower oesophagus in the last few years and some gastroenterologists thought this might be linked to eradication of *H. pylori.* This is unlikely and eradication of *H. pylori* is often advised in the hope that symptoms will be reduced and because of the link between *H. pylori* and gastric cancer.

Fig. 6.13 **Endoscopic picture of a benign gastric ulcer.** Courtesy of Dr RD. Fairclough.

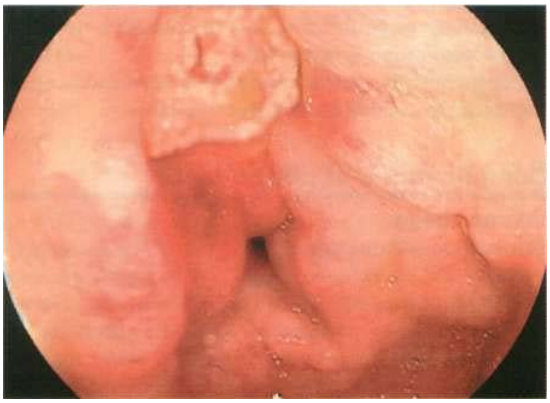

Fig. 6.14 **Duodenal ulcer.** Endoscopic view showing the ulcer with inflamed duodenal folds. Courtesy of Dr RD. Fairclough.

All eradication therapies are successful in approximately 90% of patients.

Reinfection is very uncommon (1%) in developed countries. In developing countries, where compliance with treatment may be poor and metronidazole resistance is high (> 50%) failure of eradication is common.

There are several regimens for eradication, but all regimens must take into account the following factors:

- the necessity of good compliance with the chosen treatment regimen
- the high incidence of antibiotic resistance to metronidazole (25%+)
- the side-effects of treatment with oral metronidazole
- bismuth chelate is unpleasant to take, even as tablets.

Currently favoured regimens are triple therapy with a PPI along with two antibiotics for 1 week. For example:

- omeprazole 20 mg + metronidazole 400 mg and clarithromycin 500 mg (all twice daily)
- omeprazole 20 mg + clarithromycin 500 mg and amoxicillin 1 g (all twice daily).

Resistance to amoxicillin has not yet been demonstrated.

Tripotassium dicitratobismuthate (bismuth chelate) binds to the ulcer crater and stimulates prostaglandin secretion. It is effective against *H. pylori* and is used in some eradication therapies with two antibiotics. It blackens the tongue and stools.

In some regimens, H_2-receptor antagonists, e.g. ranitidine or ranitidine bismuth citrate, are included instead of a PPI.

General measures

Stopping smoking should be strongly encouraged as smoking slows mucosal healing. Patients with peptic ulcers usually require 3-4 weeks' further treatment with a proton pump inhibitor after eradication therapy.

The effectiveness of treatment should be assessed symptomatically. If symptoms persist, a ^{13}C urea breath test or stool test for *H. pylori* should be performed to check eradication. Patients with complications, i.e. haemorrhage or perforation, should always be tested to be sure eradication is successful.

A patient with a gastric ulcer should be re-endoscoped at 6 weeks to exclude a malignant tumour.

Complications of peptic ulcer

Haemorrhage

This is discussed on page 291.

Perforation (Box 6.5; see also p. 342) The frequency of perforation of peptic ulceration is decreasing; this is partly attributable to better medical therapy. Duodenal ulcers perforate more commonly than gastric ulcers, usually into the peritoneal cavity; perforation into the lesser sac also occurs.

Management of perforation

Detailed management is described on page 342. Surgery is performed to close the perforation and drain the abdomen. Conservative management using nasogastric suction, intravenous fluids and antibiotics is occasionally used in elderly and very sick patients.

Gastric outlet obstruction

The obstruction may be prepyloric, pyloric or in the duodenum. The obstruction occurs either because of an active ulcer with surrounding oedema or because the healing of an ulcer has been followed by scarring.

***Box* 6.5 Suspected perforated peptic ulcer**

Look for:

other acute gastrointestinal conditions (e.g. cholecystitis, pancreatitis - check serum amylase) non-GI conditions (e.g. myocardial infarction) silent perforation in the elderly or patients on steroids.

Remember:

There is harm in leaving an undiagnosed perforation, i
Avoid laparotomy if pancreatitis is diagnosed.

Obstruction is now rare with peptic ulcer disease and gastric malignancy; Crohn's disease or external compression from a pancreatic carcinoma are more common causes. Adult hypertrophic pyloric stenosis is a rare cause.

The main symptom of this condition is vomiting, usually without pain as the characteristic ulcer pain has abated owing to healing.

Vomiting is projectile and huge in volume, and the vomitus contains particles of yesterday's food. On examination of the abdomen the patient may have a succussion splash.

Severe or persistent vomiting causes loss of acid from the stomach and a metabolic alkalosis occurs (see p. 720).

The diagnosis is made by endoscopy but can be suspected when large quantities of fluid are removed by gastric intubation in the fasting state. Fluid and electrolyte replacement is necessary, together with the regular removal of gastric contents via a nasogastric tube. In some patients the symptoms will settle with this regimen and acid suppression therapy. Endoscopic dilatation is useful and 70% of patients can be managed without surgery.

Surgical treatment and its long-term consequences

Surgery in peptic ulceration disease is used only for the complications:

- recurrent uncontrolled haemorrhage, when the bleeding vessel is ligated
- perforation, which is oversewn.

For both of these conditions no other procedure, such as a gastrectomy or vagotomy, is required. Two types of operation were performed:

- *partial gastrectomy*
- *vagotomy:* usually highly selective vagotomy or proximal gastric vagotomy, in which only the nerves supplying the parietal cells were transected, and therefore no drainage of the stomach was required.

Long-term complications of surgery are still seen occasionally.

- *A recurrent ulcer.* Check for *H. pylori*. Rule out the Zollinger-Ellison syndrome (see p. 416).
- *Dumping.* This is the term used to describe a number of upper abdominal symptoms (e.g. nausea and distension associated with sweating, faintness and palpitations) that occur in patients following gastrectomy or gastroenterostomy. It is due to 'dumping' of food into the jejunum, which is followed by rapid fluid dilution of the high osmotic load. A number of patients had mild symptoms of dumping but learned to cope with them. It was rare for it to be a clinical problem and, if it was, the symptoms had a functional element.
- *Diarrhoea.* This was chiefly seen after vagotomy with occasional urgency and recurrent severe episodes (1%). Treatment is with antidiarrhoeals.

Nutritional complications:

- anaemia - mainly iron deficiency due to poor absorption
- occasionally folate deficiency due to poor intake
- vitamin B_{12} deficiency due to intrinsic factor deficiency
- patients often fail to gain weight owing to anorexia after gastric surgery.

Other *H. pylori*-associated diseases

Gastric adenocarcinoma

The incidence of gastric cancer parallels that of *H. pylori* infection in countries with a high incidence of gastric cancer. Serological studies show that people infected with *H. pylori* have a higher incidence of gastric carcinoma. For further discussion, see page 288.

Gastric B cell lymphoma

Over 70% of patients with gastric B cell lymphomas (mucosal-associated lymphoid tissue - MALT) have *H. pylori*. *H. pylori* gastritis has been shown to contain the clonal B cell that eventually gives rise to the MALT lymphoma (p. 290).

GASTROPATHY AND GASTRITIS

Gastropathy is the term used when there is epithelial/endothelial damage in the mucosa but there is little or no accompanying inflammation. Erosions and subepithelial haemorrhage are most commonly seen at endoscopy.

Gastritis is inflammation of the gastric mucosa.

The terms are often used loosely, particularly at endoscopy when any redness of the gastric mucosa may be described as 'gastritis'. Gastritis (as opposed to gastropathy) can only be readily diagnosed histologically.

The Sydney classification of gastritis was introduced in 1990 but has not been widely adopted because of the poor correlation between histological and endoscopic findings.

The commonest cause of *gastropathy* is mucosal damage associated with the use of aspirin and other NSAIDs and alcohol.

The commonest cause of *gastritis* is *H. pylori* infection (80%) and this is fully discussed on page 283. Autoimmune gastritis is seen in 5% while the remaining causes include viruses (e.g. CMV and herpes simplex), disorders of duodenogastric reflux and specific causes, e.g. Crohn's.

Erosive and haemorrhagic gastropathy

Aspirin and other NSAIDs deplete mucosal prostaglandins by inhibiting the cyclo-oxygenase (COX) pathway, which leads to mucosal damage. Cyclo-oxygenase occurs in two main forms: COX-1, the constitutive enzyme, and COX-2, the inducible form which is produced by cytokine stimulation in areas of inflammation. NSAIDs more specific for COX-2 are still available but see page 550, and these drugs have less effect on the COX-1 enzyme in the gastric mucosa. They still produce gastric mucosal damage but less than with COX-1 drugs.

Fifty per cent of patients on regular NSAIDs will develop gastric mucosal damage and approximately 30% will have ulcers on endoscopy. Only a small proportion of patients have symptoms (about 5%) and only 1-2% have a major problem, i.e. GI bleed. Because of the large number of patients on NSAIDs including low-dose aspirin for vascular prophylaxis, this is still a significant problem, particularly in the elderly.

H. pylori and NSAIDs are independent risk factors for the development of ulcers. There is little evidence to suggest that *H. pylori* infection increases the risk of ulceration in NSAID users.

Alcohol in high concentration damages the gastric mucosal barrier and is associated with acute gastric mucosal erosions and subepithelial haemorrhage which can lead to upper GI bleeding.

Acute erosive/haemorrhagic gastropathy can also be seen after severe stress (stress ulcers) and secondary to burns (Curling ulcers), trauma, shock, renal or liver (called portal gastropathy) disease. The underlying mechanism for these ulcers is unknown but may be related to an alteration in mucosal blood flow.

Management

In patients who develop problems, NSAIDs or alcohol should be stopped. Patients who are found to have mucosal damage and continuing symptoms are usually given an H_2-receptor antagonist or a PPI as a therapeutic trial. For established ulcers, a PPI is the best treatment. There is a little evidence that *H. pylori* eradication is helpful but if found, eradication therapy is usually given.

In many patients with severe arthritis, stopping NSAIDs may not be possible. Use:

- an NSAID with low GI side-effects at lowest dose possible (p. 549)
- prophylactic cytoprotective therapy, e.g. PPI or misoprostol (a synthetic analogue of prostaglandin E_a) for all high-risk patients, i.e. over 65 years; those with a peptic ulcer history, particularly with complications, and patients on therapy with corticosteroids or anticoagulants

Autoimmune gastritis

This affects the fundus and body of the stomach (pangastritis), leading to atrophic gastritis with loss of parietal cells.

This leads to achlorhydria and intrinsic factor deficiency causing pernicious anaemia. Autoantibodies to

gastric parietal cells and intrinsic factor are found in the serum (see p. 432).

Menetrier's disease

This is a rare condition consisting of giant gastric folds, mainly in the fundus and the body of the stomach. Histologically there is hyperplasia of the gastric pits, atrophy of glands and an overall increase of mucosal thickness. Hypochlorhydria is usually present.

The patient may complain of epigastric pain and occasionally peripheral oedema may occur because of hypoalbuminaemia resulting from protein loss through the gastric mucosa. It is possibly premalignant. Treatment is unclear as some patients improve spontaneously. Anti-secretory drugs are usually given. A few patients will require surgery.

Management of dyspepsia in the community

Dyspepsia (or indigestion) is very common in the general population. Over-the-counter antacids and H_2-receptor antagonists are available and are widely used.

Some patients' history is very suggestive of gastro-oesophageal reflux disease (GORD) and this subgroup of dyspepsia patients should be treated (see p. 277).

In young people (< 45 years) with dyspepsia, significant gastrointestinal pathology is very uncommon. Investigation with endoscopy is therefore not necessary. Their *H. pylori* status can be assessed serologically and, if positive, eradication therapy instituted. Further investigation should be reserved for those who remain symptomatic after successful eradication (p. 285). Patients who are *H. pylori-negative* on testing should be treated as for functional dyspepsia (p. 337), which is much commoner than organic disease.

Older people (> 45 years) with new-onset dyspepsia and all patients with 'alarm symptoms' (p. 265) must be investigated with endoscopy to exclude significant organic disease. Even in this age group, functional dyspepsia is very common and management of symptoms must reflect life event problems.

Therapies

Antacids are described on page 276.

H_2-receptor antagonists have molecular structures that fit the H_2-receptors on the parietal cells. They can produce up to 80% reduction in nocturnal acid production. They are useful in the management of dyspepsia and are part of some *H. pylori* eradication regimens. There is little difference between the several H_2-receptor antagonists available, but some have side-effects and cross-react with other medication, such as warfarin.

Proton pump inhibitors (p. 276) are also widely used. They are very effective for reflux symptoms and are also used in functional dyspepsia despite their cost, as many find them helpful.

GASTRIC TUMOURS

Adenocarcinoma

Carcinoma of the stomach (see Fig. 6.17) is the eighth most common fatal cancer in the UK. The frequency varies throughout the world, being high in Japan and Chile and relatively low in the USA.

In the UK, 15 per 100 000 males are affected per year. Although the overall world-wide incidence of gastric carcinoma appears to be falling, even in Japan, proximal gastric cancers are increasing in the West. The incidence increases with age (peak incidence 50-70 years), being rare under the age of 30 years, and more men than women are affected.

Epidemiology and pathogenesis

There is a strong link between *H. pylori* infection and gastric cancer. *H. pylori* infection results in chronic gastritis which eventually leads to atrophic gastritis and intestinal metaplasia - a premalignant pathological change (Fig. 6.15). Much of the earlier epidemiological data (i.e. the increase of cancer in lower socio-economic groups) can be explained by the intrafamilial spread of *H. pylori*. *H. pylori* is recognized by WHO as a Class 1 gastric carcinogen.

Dietary factors may still be involved, as both initiators and promoters may have separate roles in carcinogenesis. Diets high in salt probably increase the risk. Dietary nitrates can be converted into nitrosamines by bacteria at neutral pH, and nitrosamines are known to be carcinogenic in animals. Nitrosamines are also present in the stomach of patients with achlorhydria, who have an increased cancer risk. Consumption of diets high in vegetables and

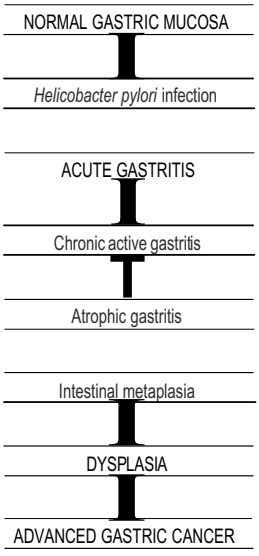

Fig. 6.15 **Flow diagram showing the development of gastric cancer associated with *H. pylori* infection.**

fruits, and low in salt, protect against cancer. Smoking is also associated with an increased incidence of stomach cancer.

The commonest genetic abnormality is a loss of heterozygosity (LOH) of tumour suppressor genes such as *p53* (in 70% of cancers as well as in pre-cancerous states) and the *APC* gene (in over a third of gastric cancers). These abnormalities are similar to those found in colorectal cancers (see p. 392). Some families with diffuse gastric cancer have been shown to have mutations in the E-cadherin gene. There is a higher incidence of gastric cancer in blood group A patients. First-degree relatives of patients with gastric cancer have two- to three-fold increased relative risk of developing the disease.

Benign gastric ulcers (see Fig. 6.13) have not been shown to develop into gastric cancer. It can, however, be difficult to differentiate a benign ulcer from a malignant ulcer, as even malignant ulcers can partially heal on medical treatment. For these reasons it was originally thought that gastric ulcers could become malignant.

Pernicious anaemia carries a small increased risk of developing gastric carcinoma. Atrophic gastritis present in the body and fundus of the stomach of these patients may be a precancerous lesion.

There is an increased risk of gastric cancer after a partial gastrectomy (postoperative stomach) whether performed for a gastric or a duodenal ulcer. This may be a reflection of *H. pylori* causing the original ulceration.

Screening

Gastric cancer has an appalling prognosis despite treatment, and earlier diagnosis has been advocated in an attempt to improve this. Screening is discussed on page 488; it has had no effect on overall mortality in gastric cancer. Similarly, early investigation of dyspepsia has had little effect on mortality.

Early gastric cancer

In Japan, mass screening with mobile X-ray units has increased the proportion of early gastric cancers diagnosed. Early gastric cancer is defined as a carcinoma that is confined to the mucosa or submucosa. It is associated with 5-year survival rates of approximately 90%. In a large series of patients with gastric cancer from the UK, only 0.7% were identified as having early gastric cancer and they are usually detected by chance (Fig. 6.16).

Pathology

Most gastric cancers occur in the antrum and are almost invariably adenocarcinomas. The common type is 'intestinal' and the tumours are polypoid or ulcerating lesions with heaped-up, rolled edges. Intestinal metaplasia is seen in the surrounding mucosa, often with *H. pylori*. The diffuse type is composed of scattered or small clusters of cells, often with extensive submucosal spread which may result in the picture of Tinitis plastica', where the stomach appears rigid on X-ray.

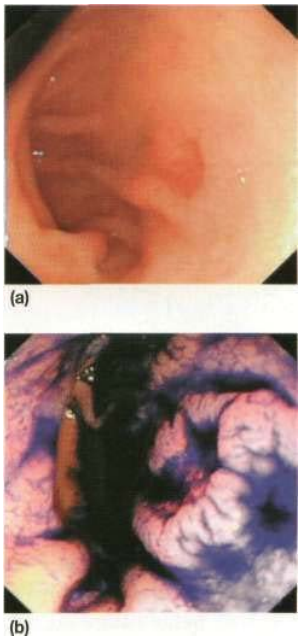

Fig. 6.16 **Early gastric cancer:** **(a)** endoscopic view - showing subtle changes in mucosa; (b) same view following an ink spray. By courtesy of Dr Peter Fairdough.

Clinical features

Symptoms

The most common symptom is epigastric pain, which is indistinguishable from the pain of peptic ulcer disease, both being relieved by food and antacids. The pain can vary in intensity, but may be constant and severe. Most patients with carcinoma of the stomach have advanced disease at the time of presentation, and also have nausea, anorexia and weight loss. Vomiting is frequent and can be severe if the tumour is near the pylorus. Dysphagia can occur with tumours involving the fundus. Gross haematemesis is unusual, but anaemia from occult blood loss is frequent. No pattern of symptoms is suggestive of early gastric cancer.

Patients can present with metastases causing abdominal swelling due to ascites or jaundice due to liver involvement. Metastases also occur in bone, brain and lung, producing appropriate symptoms.

Signs

Nearly 50% of patients have a palpable epigastric mass with abdominal tenderness. Often weight loss is the only feature. A palpable lymph node is sometimes found in the supraclavicular fossa (Virchow's node) and signs of metastases are present in up to one-third of patients. Carcinoma of the stomach is the cancer most frequently associated with dermatomyositis (p. 580) and acanthosis nigricans.

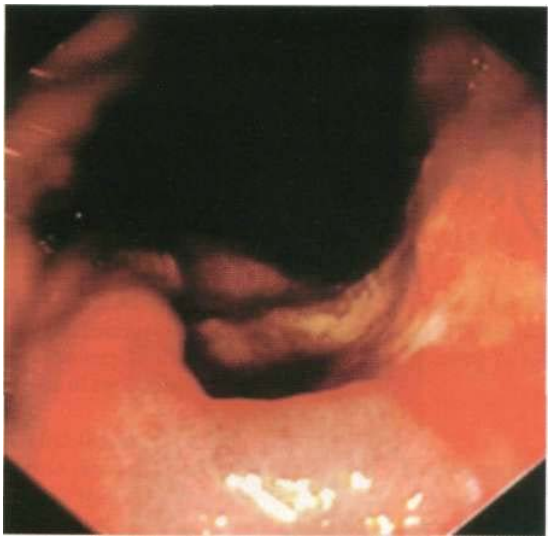

Fig. 6.17 Carcinoma of the stomach. Endoscopic picture showing a large irregular ulcer with rolled edges.

Investigations

- **Routine full blood count and liver biochemistry.**
- **Gastroscopy** (Fig. 6.17). Gastroscopy is usually performed as the primary procedure and has the advantage that biopsies can be performed for histological assessment and to exclude lymphoma. Positive biopsies can be obtained in almost all cases of obvious carcinoma, but a negative biopsy does not necessarily rule out the diagnosis. For this reason, 8-10 biopsies should be taken from around the ulcer margin and its base. Superficial brushings for cytology will further improve the diagnostic rate.
- **Barium meal.** This has largely been replaced by gastroscopy; however, a good-quality double-contrast barium meal has a diagnostic accuracy of up to 90%. The carcinoma is usually seen as a filling defect or an irregular ulcer with rolled edges. With a diffuse (linitis plastica) infiltrating type, the X-ray may show a rigid stomach.

Staging

Imaging. CT can demonstrate gastric wall thickening, but has limited value in determining tumour invasion into adjacent tissues. Ultrasound can demonstrate masses and wall thickening. Liver secondaries can be detected. Endoscopic ultrasound can demonstrate the penetration of the cancer through the gastric wall and extension into lymph nodes. It complements CT and ultrasound.

The TNM classification is used (p. 490). The tumour (T) indicates depth of tumour invasion, N denotes the presence or absence of lymph nodes, M indicates presence or absence of metastases.

TNM classification is then combined with stage categories 0^. At presentation, two-thirds of patients are at stage 3 or 4, i.e. advanced disease.

Treatment

The 5-year survival rate of patients operated on for early gastric cancer (EGC) in Japan is 90%, but outside Japan EGC is rare. Surgery remains the best form of treatment if the patient is operable. Better preoperative staging has reduced the numbers undergoing surgery and has improved the overall surgical 5-year survival rates to around 30%. Five-year survival rates in 'curative' operations are as high as 50%. Surgery and combined chemo-radiotherapy and treatment of advanced disease is described on page 521. Despite the improved results, the overall survival rate for a patient with gastric carcinoma has not dramatically improved, with a 10% 5-year survival. Palliative care with relief of pain, and counselling are essential, as described on page 524.

Stromal tumour

These tumours were known as leiomyomas or leiomyosarcomas. They are not of smooth muscle origin but are from the stroma and are thought to share a common ancestry with the interstitial cells of Cajal. They have a varying pattern of differentiation. There is a mutation in the cellular proto-oncogene *KIT* which leads to activation and cell-surface expression of the tyrosine kinase KIT (CD 117). They are usually asymptomatic and found by chance but they can occasionally ulcerate and produce a haematemesis.

Treatment is surgical. These tumours grow slowly and were thought to be benign, but histologically, tumours with more than 10 mitoses per 10 high-power fields are malignant and recurrences occur. Imatinib, a tyrosine kinase inhibitor, is being used for unresectable or metastatic disease. ; . ,

Primary lymphoma

Lymphoma of the stomach can account for 10% of **all** gastric malignancies in the developed world. It is a non-Hodgkin's lymphoma of the B cell type. Gastric lymphomas in mucosal-associated lymphoid tissue (MALT) are caused by *H. pylori* (p. 287). The clinical presentation is the same as with gastric carcinoma. Some lymphomas due to *H. pylori* can be treated successfully by eradication therapy. Chemotherapy ± radiotherapy is the usual treatment for other lymphomas (p. 512). Prognosis is good, with a 75% 5-year survival depending on the type of lymphoma.

Gastric polyps

These are uncommon and again are found usually by chance. They produce no symptoms. The most common are regenerative or hyperplastic polyps, which are often multiple and require no treatment. Rarely adenomatous polyps are found and endoscopic removal is recommended because of possible malignant potential. Most gastric cancers appear not to arise from pre-existing adenomas (in contrast to colonic carcinomas).

ACUTE AND CHRONIC GASTROINTESTINAL BLEEDING

This section should be read in conjunction with the descriptions of the specific conditions mentioned.

Acute upper gastrointestinal bleeding

Haematemesis is the vomiting of blood from a lesion proximal to the distal duodenum.

Melaena is the passage of black tarry stools; the black colour is due to blood altered by bacteria - 50 mL or more is required to produce this. Melaena can occur with bleeding from any lesion from areas proximal to and including the caecum. Following a massive bleed from the upper GI tract, unaltered blood (owing to rapid transit) can appear per rectum, but this is rare. The colour of the blood appearing per rectum is dependent not only on the site of bleeding but also on the time of transit through the gut.

Aetiology

Peptic ulceration is the commonest cause of serious and life threatening gastrointestinal bleeding. This and other causes are shown in Figure 6.18. The relative incidences of these causes vary depending on the patient population; overall the incidence has fallen. In the developing world; haemorrhagic viral infections (see Table 2.23) can cause significant gastrointestinal bleeding.

Drugs. Aspirin (even 75 mg a day) and other NSAIDs can produce gastric lesions. These agents are also responsible for GI haemorrhage from both duodenal and gastric ulcers, particularly in the elderly. Remember, these drugs are available over the counter and detailed questioning is necessary. Corticosteroids in the usual therapeutic doses probably have no influence on GI haemorrhage. Anticoagulants do not cause acute GI haemorrhage per se but bleeding from any cause is greater if the patient is anticoagulated.

Clinical approach to the patient

All cases with a recent (i.e. within 48 hours) significant

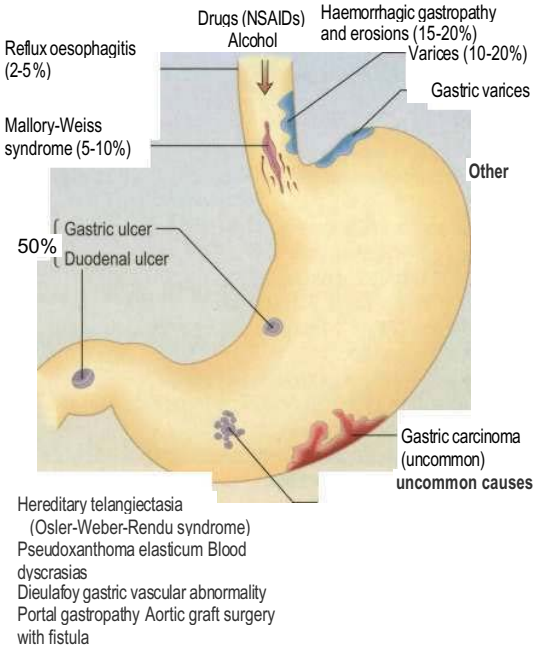

Fig. 6.18 **Causes of upper gastrointestinal haemorrhage.** The approximate frequency is also given.

gastrointestinal bleed should be seen in hospital. In many, no immediate treatment is required as often there has been only a small amount of blood loss and the patient's cardiovascular system can compensate for this. Approximately 85% of patients stop bleeding spontaneously within 48 hours.

The following factors affect the management:

- age (see below)
- the amount of blood lost, which may give some guide to the severity
- continuing visible blood loss
- signs of chronic liver disease on examination
- evidence of co-morbidity, e.g. cardiac failure, ischaemic heart disease, renal disease and malignant disease
- presence of the classical clinical features of shock (pallor, cold nose, tachycardia and low blood pressure - see Emergency box 6.1).

With liver disease, the bleeding is often severe and recurrent if it is from varices. Splenomegaly suggests portal hypertension but its absence does not rule out oesophageal varices. Liver failure can develop.

With shock, remember that the peripheral arterial constriction that occurs may keep the blood pressure falsely high.

Immediate management

a Rapid history and examination.

- Note age of patient.
- Rapid assessment of haemodynamic state.
- Look for evidence of co-morbidity.

Emergency Box 6.1
Management of acute gastrointestinal bleeding

History and examination.
Monitor the pulse and blood pressure half-hourly.
Take blood for haemoglobin, urea, electrolytes, grouping and crossmatching (2 units initially).
Establish intravenous access - central line if brisk bleed.
Give blood transfusion/colloid if necessary. *Indications for blood transfusion are:*
(a) SHOCK (pallor, cold nose, systolic PB below 100 mmHg, pulse > 100 b.p.m.)
(b) haemoglobin < 10 g/dL in patients with recent or active bleeding.
Oxygen therapy for shocked patients.
Urgent endoscopy in shocked patients/liver disease.
Continue to monitor pulse and BP.
Re-endoscope for continued bleeding/hypovolaemia.
Surgery if bleeding persists.

- Take blood for haemoglobin, urea, electrolytes, liver function, coagulation studies and for grouping and crossmatching.
- Stop drugs, e.g. NSAIDs, warfarin (see p. 481).

Urgent resuscitation is required in patients with large bleeds and the clinical signs of shock. Details of the management of shock are given in Figure 15.21. Many hospitals have multidisciplinary specialist teams with agreed protocols and these should be followed carefully. Such patients should be managed in high-dependency beds. Oxygen should be given by face mask and the patient should be kept nil by mouth until endoscopy has been performed.

Blood volume

The major principle is to rapidly restore the blood volume to normal. This can be best achieved by transfusion of whole blood via one or more large-bore intravenous cannulae; physiological saline is given until the blood becomes available (p. 974).

The rate of blood transfusion must be monitored carefully to avoid overtransfusion and consequent heart failure. The pulse rate and venous pressure are the best guides to transfusion rates. All patients with organ failure and requiring blood transfusion, as well as patients with severe hypotension, should have a central venous pressure line.

Anaemia does not develop immediately as haemodilution has not taken place, and therefore the haemoglobin level is a poor indicator of the need to transfuse. If the level is low (less than 10 g/dL) and the patient has either bled recently or is actively bleeding, transfusion may be necessary. In most patients the bleeding stops, albeit temporarily, so that further assessment can be made.

Endoscopy

Endoscopy should be performed within 24 hours in most patients. Early endoscopy helps to make a diagnosis and to make decisions regarding discharge from hospital, particularly in patients with minor bleeds and under 60 years of age. Clinical risk scores are used in some centres to identify patients at low risk who do not require endoscopy.

Urgent endoscopy (i.e. after resuscitation) should be performed in patients with shock, suspected liver disease or with continued bleeding. Endoscopy can detect the cause of the haemorrhage in 80% or more of cases. In patients with a peptic ulcer, if the stigmata of a recent bleed are seen (i.e. a spurting artery, active oozing, fresh or organized blood clot or black spots) the patient is more likely to re-bleed.

At first endoscopy:

- varices should be injected - see page 379 for management of varices
- all bleeding ulcers should be either injected with epinephrine (adrenaline), the vessel coagulated either with a heater probe or with laser therapy or metallic clips applied.

These methods reduce the incidence of re-bleeding, although they do not significantly improve mortality as re-bleeding still occurs in 20% within 72 hours. Intravenous omeprazole 80 mg followed by infusion 8 mg/h for 72 hours should be given to all patients in this group, as it reduces re-bleeding rates and the need for surgery.

Drug therapy

There is little evidence that H_2-receptor antagonists or proton-pump inhibitors (PPIs) affect the mortality rate of GI haemorrhage, but PPIs are usually given to all patients with ulcers because of their longer-term benefits. Somatostatin (which reduces the splanchnic blood flow as well as acid secretion) can be given as an infusion if the bleeding is difficult to stop, although a meta-analysis of clinical trials has shown no clear benefit.

Reassessment/risk factors

- Age is clearly significant. Below the age of 60 years mortality from GI bleeding is small, < 0.1%, but above the age of 80 the mortality is greater than 20%.
- Patients with recurrent haemorrhage have an increased mortality.
- Most re-bleeds (approximately 20% of all cases) occur within 48 hours.
- Co-morbidity invariably increases mortality.
- Melaena is usually less hazardous than haematemesis.
- Presence of shock at *any time* increases mortality.

Uncontrolled or repeat bleeding

Endoscopy should be repeated to assess the bleeding site and to treat, if possible. Surgery is necessary only if bleeding is persistent and/ or uncontrollable and should be limited to controlling the haemorrhage.

Discharge policy

The patient's age, diagnosis on endoscopy, co-morbidity and the presence or absence of shock should be taken into consideration. In general, all patients who are dynamically stable and have no stigmata of recent haemor-

rhage on endoscopy, can be discharged from hospital within 24 hours. All shocked patients and patients with co-morbidity need inpatient observation.

Specific conditions

Chronic peptic ulcer. Eradication of *H. pylori* is started as soon as possible (see p. 285). A proton-pump inhibitor is continued for 4 weeks to ensure ulcer healing. Eradication of *H. pylori* should always be checked in a patient who has bled. If necessary to control haemorrhage, surgery with ligation of **the** bleeding vessel is performed, but no other surgical procedure is **undertaken.**

Gastric carcinoma. Most patients do not have large bleeds with this condition but surgery is occasionally necessary for uncontrolled or repeat bleeding. Usually surgery can be delayed until the patient has been fully evaluated (p. 290).

Oesophageal varices. These are discussed on page 379.

Mallory-Weiss tear. This is a linear mucosal tear occurring at the oesophagogastric junction and produced by a sudden increase in intra-abdominal pressure. It often occurs **after** a bout of coughing or retching and is classically seen after an alcohol binge. There may, however, be no antecedent history of retching. The haemorrhage may be large but most patients stop spontaneously. Early endoscopy confirms diagnosis and allows early discharge from the hospital (within 24 hours). Rarely, surgery with oversewing of the tear will be required.

Prognosis

The mortality from gastrointestinal haemorrhage has not changed from 5 to 12% over the years, despite many changes in management, mainly because more patients are elderly and have more co-morbidity. The lowest mortality rates are achieved in dedicated medical/surgical GI units. Early therapeutic endoscopy has not so far reduced the mortality, although bleeding episodes are reduced.

Acute lower gastrointestinal bleeding

Massive bleeding **from the lower GI tract** is rare. On the other hand, small bleeds from haemorrhoids occur very commonly. Massive bleeding is usually due to diverticular disease or ischaemic colitis. The causes of lower gastrointestinal bleeding are shown in Figure 6.19.

Management

Most acute lower GI bleeds start spontaneously. The few patients that continue bleeding and are haemodynamically unstable need resuscitation using the same principles as for upper GI bleeding (p. 291). Surgery is rarely required. A diagnosis is made using the history, and the following investigations as appropriate:

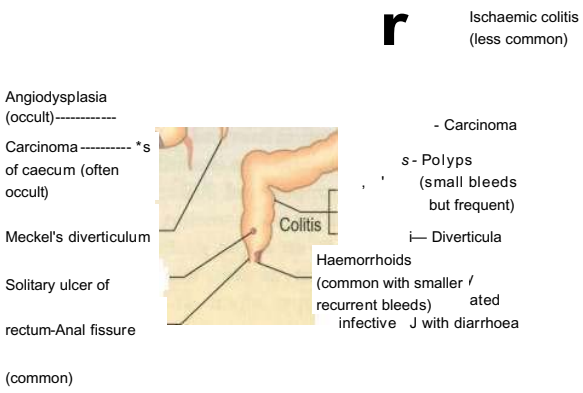

Fig. 6.19 **Causes of lower gastrointestinal bleeding.** The sites shown are illustrative - many of the lesions can be seen in other parts of the colon.

- rectal examination (e.g. carcinoma)
- proctoscopy (e.g. anorectal disease, particularly haemorrhoids)
- sigmoidoscopy (e.g. inflammatory bowel disease)
- barium enema - ischaemic colitis
- colonoscopy - for any mucosal lesion and removal of polyps
- angiography - vascular abnormality (e.g. angiodysplasia, which can be sometimes treated with argon plasma coagulation).

Isolated episodes of rectal bleeding in the young (< 45 years) only require rectal examination and sigmoidoscopy. Colorectal cancer is rare in this age group without a strong family history.

Individual lesions are treated as appropriate.

Chronic gastrointestinal bleeding

Patients with chronic bleeding usually present with iron-deficiency anaemia (see Ch. 8).

Chronic blood loss producing iron deficiency anaemia in all men and all women after the menopause is always due to bleeding from the gastrointestinal tract, often from a right-sided colonic neoplasm which must be excluded. Occult blood tests are not necessary (Box 6.6).

Box 6.6 **Measurement of faecal occult blood**

This is frequently performed *unnecessarily*. It is *only* of value in:

premenopausal women - if a history of menorrhagia is uncertain and the cause of iron deficiency is unclear mass population screening for large bowel malignancy.

Advantages: cheap and easy to perform.

Disadvantages: high false-positive rate, leading to unnecessary investigations.

Diagnosis

Chronic blood loss can occur with any lesion of the gastrointestinal tract that produces acute bleeding (see Figs 6.18 and 6.19). It is, however, usual for oesophageal varices to bleed severely and rarely to present as chronic blood loss. It should be remembered that, world-wide, hookworm is the most common cause of chronic gastrointestinal blood loss.

History and examination may indicate the most likely site of the bleeding, but if no clue is available it is usual to investigate both the upper and lower gastrointestinal tract endoscopically at the same session ('top and tail').

For practical reasons an upper gastrointestinal endoscopy is performed first as this takes only minutes, followed by colonoscopy when any lesion can be removed or biopsied. A barium enema is performed only if colonoscopy is unavailable.

A small bowel follow-through is the next investigation, but the diagnostic yield is very low.

Following negative investigations, a coeliac axis and mesenteric angiography may show the site of bleeding, although the yield is low. Occasionally, intravenous technetium-labelled colloid may be used to demonstrate the bleeding site in a Meckel's diverticulum. Endoscopes to visualize the whole of the small bowel (enteroscopy) are available at specialist centres. Wireless capsule endoscopy is useful, particularly with melaena of obscure origin (90% of causes were found in a recent study).

Treatment

The cause of the bleeding should be treated, if found. Oral iron is given to treat anaemia (see p. 429).

THE SMALL INTESTINE

Structure

The small intestine extends from the duodenum to the ileocaecal valve. It is approximately 6 m in length, the upper 40% - the jejunum; the remainder - the ileum. Its surface area is enormously increased by mucosal folds. In addition, the mucosa has numerous finger-like projections called villi and the surface area is further increased by microvilli (Fig. 6.20). Each villus consists of a

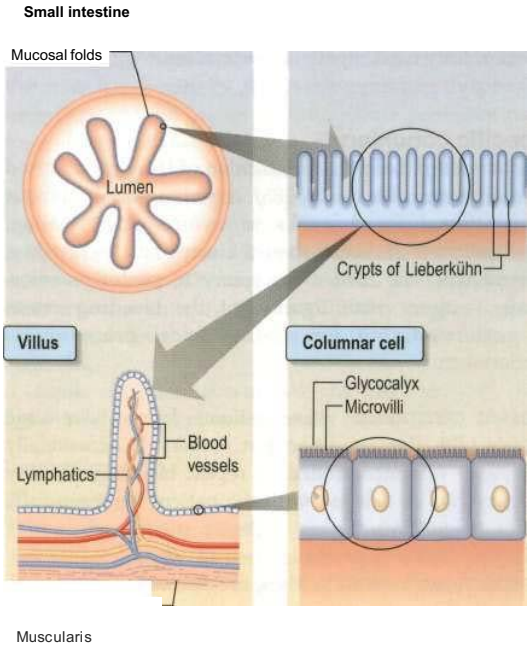

Fig. 6.20 **Structure of the small intestine.**

core containing blood vessels, lacteals (lymphatics) and cells (e.g. plasma cells and lymphocytes), and is covered by epithelial columnar cells that are absorptive. The crypts of Lieberkiihn open into the lumen, between the villi.

The epithelial cells are formed at the bottom of these crypts and migrate to the tops of the villi, from where they are shed. This process takes 3^ days. On its luminal side the epithelial cell has a brush border of microvilli that is covered by the glycocalyx. The lamina propria contains plasma cells, lymphocytes, macrophages, eosinophils and mast cells. Scattered throughout the gut are peptide-secreting cells.

Most of the blood supply to the small intestine is via branches of the superior mesenteric artery. The terminal branches are end arteries - there are no local anastomotic connections.

The *enteric nervous system* is linked to the central nervous system via the autonomic. The nerve plexuses in the mucosa, submucosa and muscularis propria are of three types:

- cholinergic parasympathetic (with muscarinic or nicotinic receptors)
- adrenergic sympathetic (with both a and (3 receptors)
- non-cholinergic non-adrenergic (NANC).

For NANC, the transmitters are thought to be either cyclic nucleotides and ATP (the purinergic system) or intestinal hormones (e.g. VIP - the peptidergic hypothesis) or nitric oxide. . . . . .

Functions (Table 6.5)

The epithelial cells form a physical barrier permeable to ions, small molecules and macromolecules. The small

Table 6.5 Functions of the small intestine

acquired (see p. 204)
Neuroendocrine peptide production
Motor function - transit of nutrients

intestine is concerned with the digestion and absorption of nutrients, salt and water. Digestive enzymes (e.g. proteases, disaccharidases) are produced by intestinal cells; some of these enzymes are membrane-bound whilst others (e.g. lipases produced by the pancreas) are associated with the glycocalyx. Nutrients can be absorbed throughout the small intestine, but vitamin B_{12} and bile salts have specific receptors in the terminal ileum.

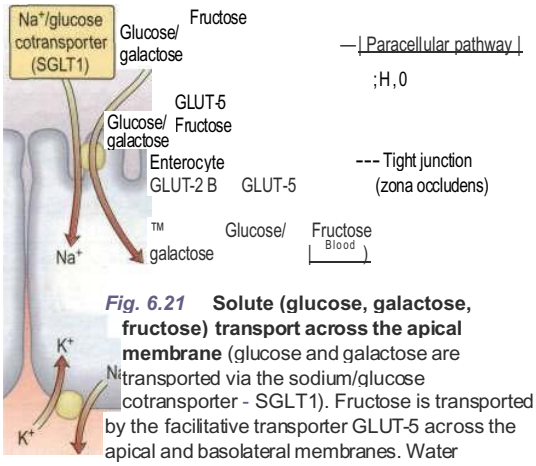

Fig. 6.21 **Solute (glucose, galactose, fructose) transport across the apical membrane** (glucose and galactose are transported via the sodium/glucose cotransporter - SGLT1). Fructose is transported by the facilitative transporter GLUT-5 across the apical and basolateral membranes. Water absorption is mainly cellular but paracellular absorption also occurs. The tight junction is a network of strands and is a dynamic structure. The sodium/potassium-ATPase pump is located in the basolateral membrane.

General principles of absorption

Simple diffusion

This process requires no energy and takes place if there is a concentration gradient from the intestinal lumen (high concentration) to the bloodstream (low concentration).

Active transport

This requires energy and can work against a concentration gradient. A carrier protein is required and the process in the enterocyte is sodium-dependent. For example, glucose enters the enterocyte on the luminal side via a sodium-dependent carrier molecule (sodium/glucose cotransporter I, SGLTI) and leaves on the serosal side via a sodium-independent carrier (GLUT-2) that is found in the basolateral membrane. A Na^+ gradient is maintained across the membrane by an energy-dependent sodium pump (Na^+/K^+-ATPase) that keeps the intracellular sodium concentration low (Fig. 6.21).

Facilitated diffusion

This is an energy-independent carrier-mediated transport system (GLUT-5) that allows a faster absorption rate than simple diffusion (e.g. fructose absorption). GLUT-5 has a very low affinity for glucose.

Absorption in the small intestine

Carbohydrate

Dietary carbohydrate consists mainly of starch with some sucrose and a small amount of lactose. Starch is a polysaccharide made up of numerous glucose units. Its hydrolysis begins in the mouth by salivary amylase. The majority of hydrolysis takes place in the upper intestinal lumen by pancreatic amylase. This hydrolysis is limited by the fact that amylases have no specificity for some glucose-glucose branching links.

The breakdown products of starch digestion, together with sucrose and lactose, are hydrolysed on the brush border membrane by their appropriate oligo- and disaccharidases to form the monosaccharides glucose, galactose and fructose. These monosaccharides are transported into the cells (Fig. 6.21).

Protein

Dietary protein is digested by pancreatic enzymes prior to absorption. These proteolytic enzymes are secreted by the pancreas as proenzymes and transformed to active enzymes in the lumen. The presence of protein in the lumen stimulates the release of enterokinase, which activates trypsinogen to trypsin, and this in turn activates the other proenzymes, chymotrypsin and elastase. These enzymes break down protein into oligopeptides. Some di- and tripeptides are absorbed intact by a carrier-mediated process, while the remainder are broken down into free amino acids by peptidases on the microvillus membranes of the cell, prior to absorption in a similar way to disaccharides. These amino acids are transported into the cell by a variety of carrier systems.

Fat (Fig. 6.22)

Dietary fat consists mainly of triglycerides with some cholesterol and fat-soluble vitamins. Emulsification of fat occurs in the stomach and is followed by hydrolysis of triglycerides in the duodenum by pancreatic lipase to yield fatty acids and monoglycerides.

Bile enters the duodenum following gall bladder contraction. Bile contains phospholipids and bile salts, both of which are partially water-soluble and act as detergents.

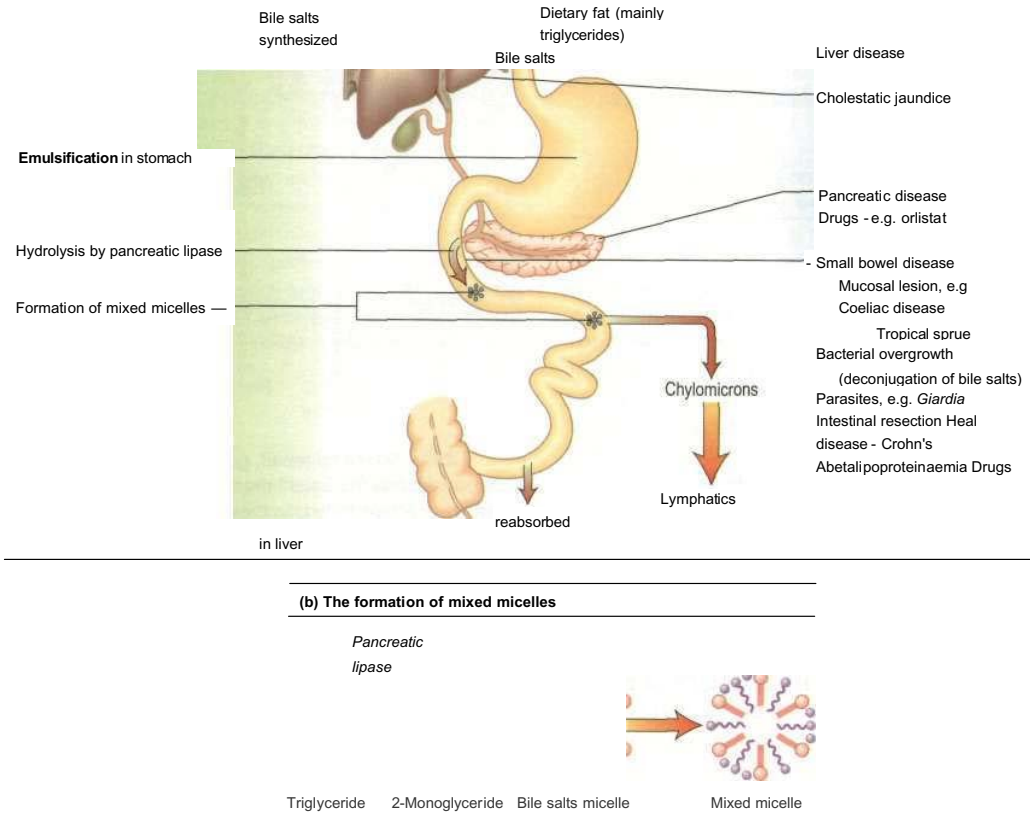

Fig. 6.22 (a) The pathophysiology of fat absorption, (b) Diagram showing the formation of mixed micelles.

They aggregate together to form micelles with their hydrophilic ends on the outside. Trapped in the hydrophobic centre of the micelles are the monoglycerides, fatty acids and cholesterol; these are then transported to the intestinal cell membrane.

At the cell membrane the lipid contents of the micelles are absorbed, while the bile salts remain in the lumen. Inside the cell the monoglycerides and fatty acids are re-esterified to triglycerides. The triglycerides and other fat-soluble molecules (e.g. cholesterol, phospholipids) are then incorporated into chylomicrons to be transported into the lymph.

Medium-chain triglycerides (which contain fatty acids of chain length 6-12) as well as a small amount of long-chain fatty acids are transported via the portal vein.

Bile salts are not absorbed in the jejunum, so that the intraluminal concentration in the upper gut is high. They pass down the intestine to be absorbed in the terminal ileum and are transported back to the liver. This enterohepatic circulation prevents excess loss of bile salts (see p. 351).

The pathophysiology of fat absorption is shown in Figure 6.22. Interference with absorption can occur at all stages, as indicated, giving rise to steatorrhoea (> 17 mmol (6 g) of fat per day).

Water and electrolytes

A large amount of water and electrolytes, partly dietary, but mainly from intestinal secretions, are absorbed coupled with monosaccharides, amino acids and bicarbonate in the upper jejunum. Water and electrolytes are also absorbed paracellularly down electrochemical and osmotic gradients. Additional water and electrolytes are absorbed in the ileum and right side of the colon, where active sodium transport occurs that is not coupled to solute absorption. Intestinal secretion also takes place and abnormalities of this mechanism cause secretory diarrhoea (see p. 331).

Water-soluble vitamins, essential metals and trace elements

These are all absorbed in the small intestine. Vitamin B_{12} (see p. 431) is the only substance other than bile salts that is specifically absorbed in the terminal ileum, and malabsorption of both these substances will always occur following ileal resection.

Calcium absorption

Calcium absorption is discussed on page 592.

Iron absorption

Iron absorption is discussed on page 426.

Defence against antigens (see also p. 197)

Several strategies are used by the small bowel to prevent pathogenic invasion:

- the *physical barrier,* e.g. the epithelial and mucous layers
- *innate and adaptive immune mechanisms* - these interact to ensure maximum protection while at the same time tolerating harmless commensal organisms and dietary antigens.

All cell populations in the GI tract, including enterocytes, goblet cells and myofibroblasts, actively participate in the innate immune response. Enzymes such as lysozyme and phospholipase A_2 secreted by the goblet cells help ensure an infection-free environment in the gut, even in the presence of commensal bacteria. Antimicrobial peptides (e.g. defensins) are secreted in response to pathogenic bacteria, enterocytes and Paneth cells. These peptides exhibit potent activity against various classes of pathogens including Gram-positive and -negative bacteria, fungi and viruses. Enterocytes and Paneth cells also secrete cytokines (including IL-1 and TNF) critical for activating innate immune mechanisms.

The secretory immunoglobulin (slg) system plays a major role in mucosal immunity. There are approximately 10^{10} Ig-producing immunocytes (plasma cells and plasmablasts) per metre of human small bowel, of which 70-90% are IgA immunocytes. Dimeric and polymeric IgA (plgA), which contains a disulphide-linked polypeptide called '}' (or 'joining') chain, and IgM are transported through the glandular epithelium via the transmembrane pig receptor called 'secretory component' (SC) into the gut lumen. These antibodies are the first-line defence antigens in the lumen and may also take part in maintaining immunological homeostasis within the mucosa (e.g. damping T-cell-mediated hypersensitivity responses against harmless absorbed luminal antigens). SC expression can be upregulated by cytokines, including IFN-y and TNF-a, secreted by activated T cells and macrophages respectively, thus promoting the transport of IgA and IgM into the lumen.

An additional source of long-term host defence is provided by T lymphocytes that initiate, activate and regulate adaptive immune responses. Intestinal T cells occur principally in three major compartments: (a) organized gut-associated lymphoid tissue (GALT) such as the Peyer's patches; (b) the mucosal lamina propria and (c) the surface epithelium where they are referred to as intraepithelial lymphocytes (IELS) (Fig. 6.23). GALT is the major site of antigen priming as it is dominated by a population of naive T and B cells. Specialized epithelial cells above the Peyer's patches (called 'M' or 'membrane' cells) lack digestive enzymes and SC but express class II molecules and allow non-selective inward transport of luminal antigens and presentation of antigen to Peyer's patch T cells. Antigen is also transported to mesenteric lymph nodes by mucosal dendritic cells where T cell priming is initiated. Antigens may also be taken up by other class II expressing epithelial cells (expressing HLA-DR) and may subsequently be presented to primed (memory) T lymphocytes.

In contrast to GALT, the lamina propria and the surface epithelium are effector compartments that receive primed T cells. $CD4^+$ T cells dominate in the lamina propria where they are significant secretors of cytokines. $CD8^+$ T cells including significant populations of gamma/

SC, secretory component; HLA-DR, human lymphocyte antigen-DR; TNF, tumour necrosis factor; IFN-y, gamma-interferon; M cells, membrane cells.

delta TCR$^+$ cells predominate in the latter where they have a cytotoxic role. At present, identification of the exact function of various T cell subsets in the pathogenesis of inflammatory gut diseases is being actively pursued.

Neuroendocrine peptide production

The hormone-producing cells of the gut are scattered diffusely throughout its length and also occur in the pancreas. The cells that synthesize hormones are derived from neural ectoderm and are known as APUD (amine precursor uptake and decarboxylation) cells. Many of these hormones have very similar structures. Although they can be detected by radioimmunoassay in the circulation, their action is often local.

Table 6.6 shows some gut neuroendocrine peptides and their possible physiological actions. Many are also found in other tissues, particularly the brain. A number do not act as true hormones but act as neurotransmitters or have local effects on adjacent cells only (paracrine effects).

The exact physiological role of these peptides continues to be evaluated. They may be secreted in excess, particularly in neuroendocrine tumours of the pancreas (see p. 416).

Trefoil peptides

The trefoil factor family (TFF) of small proteins each consist of a three-loop structure. They help to protect the lining of the gastrointestinal tract by stabilizing the mucus in normal conditions and by upregulating and stimulating the repair process (e.g. epithelial restitution) in acute injury. TFF1 is produced predominantly by mucin-secreting cells of the stomach, small and large intestine. TFF2 is produced by mucus-producing cells of the stomach and by Brunner's glands and goblet cells in the small intestine, and is absent in the colon. TFF3 is absent from the stomach but secreted in the small intestine and colon. All three trefoil peptides can also be secreted ectopically in the cells around damaged areas (e.g. in inflammatory bowel disease and peptic ulceration).

Gut motility

The contractile patterns of the small intestinal muscular layers are primarily determined by integrated neural circuits within the gut wall - the enteric nervous system. The CNS and gut hormones also have a modulatory role on motility. The interstitial cells of Cajal lie within the smooth muscle. These mesenchymal cells appear to govern rhythmic contractions. During fasting, a distally migrating sequence of motor events termed the migrating motor complexes (MMC) occurs in a cyclical fashion. The MMC consists of a period of motor quiescence (phase I) followed by a period of irregular contractile activity (phase II), culminating in a short (5-10 min) burst of regular phasic contractions (phase III). Each MMC cycle lasts for approximately 90 minutes. In the duodenum, phase III is associated with increased gastric, pancreatic and biliary secretions. The role of the MMC is unclear, but the strong phase III contractions propel secretions, residual food and desquamated cells towards the colon, acting as an 'intestinal housekeeper'.

After a meal, the MMC pattern is disrupted and replaced by irregular contractions. This seemingly chaotic-fed pattern lasts typically for 2-5 hours, depending on the size and nutrient content of the meal. The irregular contractions of the fed pattern have a mixing function, moving intraluminal contents to and fro, aiding the digestive process.

Presenting features of small bowel disease

Regardless of the cause, the common presenting features of small bowel disease are:

- *Diarrhoea.* This is a common feature of small bowel disease but approximately 10-20% of patients will have no diarrhoea or any other gastrointestinal symptoms. Steatorrhoea is occasionally present (Box 6.7).
- *Abdominal pain and discomfort.* Abdominal distension can cause discomfort and flatulence. The pain has no specific character or periodicity and is not usually severe.
- *Weight loss.* Weight loss is due to the anorexia that invariably accompanies small bowel disease. Although malabsorption occurs, the amount is small relative to intake.
- *Nutritional deficiencies.* Deficiencies of iron, B_{12}, folate or all of these, leading to anaemia, are the only common deficiencies. Occasionally malabsorption of other vitamins or minerals occurs, causing bruising (vitamin K deficiency), tetany (calcium deficiency), osteomalacia (vitamin D deficiency), or stomatitis, sore tongue and aphthous ulceration (multiple vitamin deficiencies). Ankle oedema may be seen and is partly nutritional and partly due to intestinal loss of albumin.

Physical signs of small bowel disease

These are few and non-specific. If present they are associated with anaemia and the nutritional deficiencies described above.

Abdominal examination is often normal, but sometimes distension and, rarely, hepatomegaly or an abdominal mass are found. In the severely ill patient, gross malnutrition with muscle wasting is seen. A neuropathy, not always due to B_{12} deficiency, can be present.

Box 6.7 Steatorrhoea

The stools:
- are pale, bulky, offensive and contain fat (> 17 mmol/day)
- float in the lavatory pan because of their increased air content
- are difficult to flush away.

Table 6.6 **Gut regulatory peptides**

Hormone	Physiological action	Main gut localization
Gastrin/cholecystokinin family		
Cholecystokinin (CCK)	Stimulates gall bladder contraction and has trophic effects on duodenum and pancreas Pancreatic secretion (minor role) Role in satiety Stimulates acid secretion Trophic	Duodenum and jejunum (I cells) Enteric nerves

Investigation of small bowel disease

(Fig. 6.24) -.-.-.

Blood tests

- **Full blood count and film.** Anaemia can be microcytic (low mean corpuscular volume - MCV) or macrocytic (high MCV). The blood film may therefore be dimorphic and also show other abnormal cells (e.g. Howell-Jolly bodies which are seen in splenic atrophy associated with coeliac disease).

If the MCV is low, serum ferritin and the serum soluble transferrin receptor are measured (p. 428). *If the MCV is high,* serum B_{12}, and serum and red cell folate are measured. However, with mixed deficiencies, the MCV may be normal. The red cell folate is a good indicator of the presence of small bowel disease. It is frequently low in both coeliac disease and Crohn's disease, which are the two most common causes of small bowel disease in developed countries.

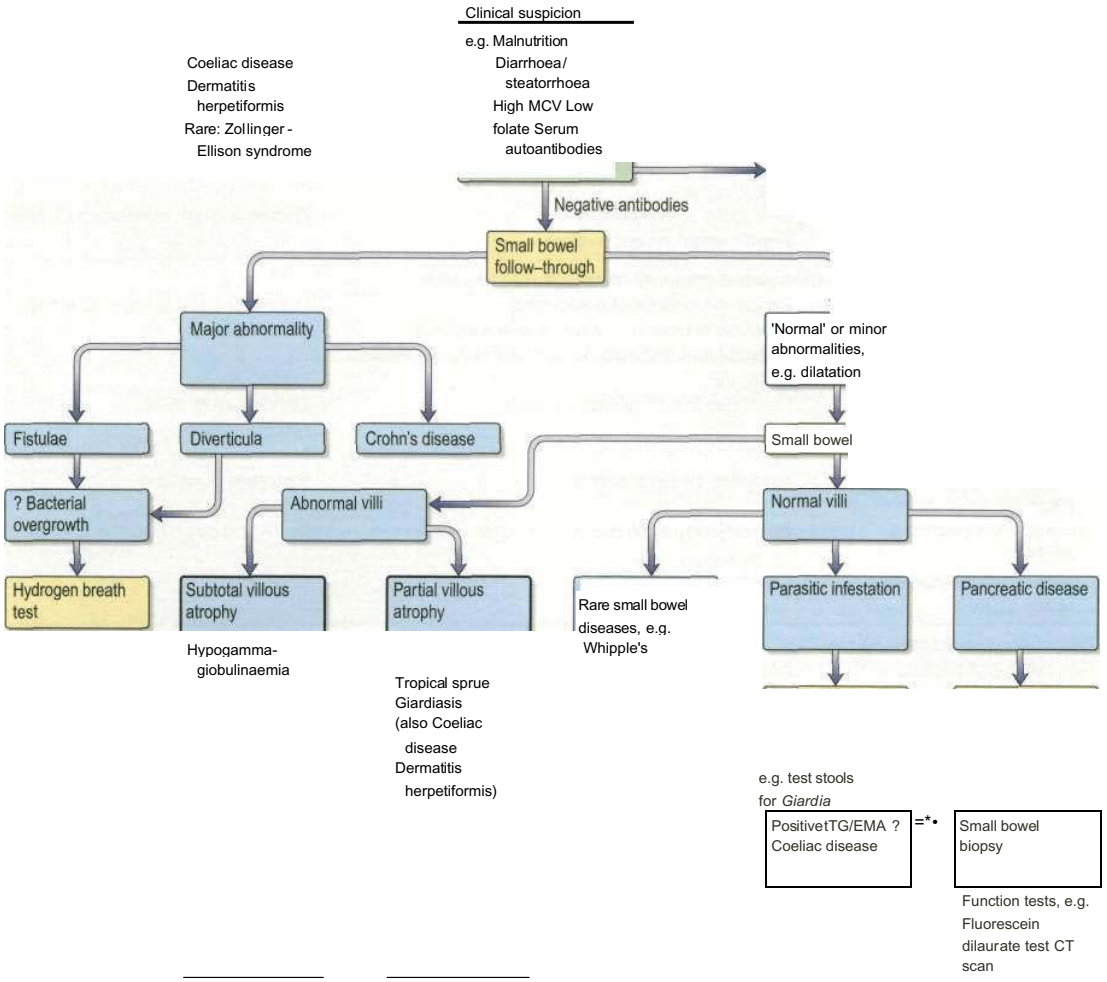

Fig. 6.24 Flow diagram for investigation of patients with suspected small bowel disease. EMA, endomysial antibody; tTG, tissue transglutaminase.

- **Serum albumin** gives some indication of the nutritional status.
- **Low serum calcium and raised alkaline phosphatase.** These may indicate the presence of osteomalacia.
- **Autoantibodies.** Measurement in the serum of antibodies to endomysium and tissue transglutaminase are useful for the diagnosis of coeliac disease.

Small bowel anatomy

The macroscopic and microscopic appearances of the small bowel are studied unless the diagnosis has already been made (e.g. the presence of endomysial antibodies in coeliac disease).

- **Small bowel follow-through** (see p. 268). This detects gross anatomical defects such as diverticula, strictures and Crohn's disease. Dilatation of the bowel and a changed fold pattern may suggest malabsorption but, as these are not specific findings, the diagnosis should not be based on these alone. Gross dilatation is seen in myopathic pseudo-obstruction.
- **Small bowel biopsy.** This is used to assess the micro-anatomy of the small bowel. Biopsies are usually obtained via an endoscope passed into the duodenum using large forceps and should be well-orientated for correct evaluation. The histological appearances are described in the sections on individual diseases.

A smear of the jejunal juice or a mucosal impression can also be made and is helpful in the diagnosis of *Giardia intestinalis* (see p. 105).

Tests of absorption

These are required only in *complicated* cases.

- **Fat malabsorption.** The confirmation of the presence of steatorrhoea is only occasionally necessary. Three-day faecal fat analysis, breath tests and serum (3 carotene are now rarely performed. In the rare cases when it is really necessary to confirm steatorrhoea, Sudan **III** staining of a faecal sample can be used.
- **Lactose tolerance test.** This involves the oral ingestion of 50 g of lactose and the measurement of blood glucose. The test is of little use in adults as lactose intolerance is not a clinical problem since these patients avoid milk by choice. There is a high incidence of lactase deficiency in many parts of the world (e.g. the Mediterranean countries, and parts of Africa and Asia). It should be remembered that a glass of milk contains only approximately 11 g of lactose.

- **B_{12} absorption studies** are no longer performed in the UK (see p. 432).

Other tests

- **Hydrogen breath test.** This is frequently used as a screening test to detect bacterial overgrowth. Oral lactulose or glucose is metabolized by bacteria with the production of hydrogen. An early rise in the breath hydrogen will indicate bacterial breakdown in the small intestine. Rapid transit of the lactulose to the large intestine will also produce a rise in breath hydrogen. As bacteria are present in the oral cavity, the mouth should be rinsed out with an antiseptic mouthwash prior to the test being performed. This test is simple to perform and it does not involve radioisotopes. However, interpretation is often difficult with a low sensitivity and specificity.
- **^{14}C-glycocholic acid breath test.** This was performed to look for bacterial overgrowth. Bacteria deconjugate the bile salts, releasing [^{14}C]-glycine, which is metabolized and appears in the breath as $^{14}CO_2$. It has largely been replaced by the hydrogen breath test.
- **Direct intubation.** Aspiration of intestinal juices is another method by which bacterial contamination can be detected, but is seldom used. Bacterial counts are performed on aerobic and anaerobic cultures. Chromatography of bile salts can also be performed on the aspirate to detect evidence of deconjugation by bacteria.
- **Pancreatic tests** (see p. 408). These are used in the differential diagnosis of steatorrhoea.
- **Other blood tests.** Serum immunoglobulins are measured to exclude immune deficiencies. Gut peptides (e.g. vasoactive intestinal peptide - VIP) are measured in high-volume secretory diarrhoea, and chromogranins A and B are raised in endocrine tumours.
- **Test for protein-losing enteropathy.** Intravenous radioactive chromium chloride ($^{51}CrCl_3$) is used to label circulating albumin. In excess gastrointestinal protein loss, the faeces will contain radioactivity. This test is rarely required unless a low serum albumin is a major clinical feature.
- **Bile salt loss.** This can be demonstrated by giving oral ^{75}Se-homocholyl taurine (SeHCAT - a synthetic taurine conjugate) and measuring the retention of the bile acid by whole-body counting at 7 days.

MALABSORPTION

In many small bowel diseases, malabsorption of specific substances occurs, but these deficiencies do not dominate the clinical picture. An example is Crohn's disease, in which malabsorption of vitamin B_{12} can be demonstrated, but this is not usually a problem and diarrhoea and general ill-health are the major features.

Steatorrhoea - malabsorption of fat - is discussed on page 298.

The major disorders of the small intestine that cause malabsorption are shown in Table 6.7.

Table 6.7 **Disorders of the small intestine causing malabsorption**

Coeliac disease
Dermatitis herpetiformis
Tropical sprue
Bacterial overgrowth
Intestinal resection
Whipple's disease
Radiation enteritis
Parasite infestation (e.g. *Giardia intestinalis)*

Coeliac disease (gluten-sensitive enteropathy)

Coeliac disease is a condition in which there is an inflammation of the jejunal mucosa that improves when the patient is treated with a gluten-free diet and relapses when gluten is reintroduced. Gluten is contained in the cereals wheat, rye and barley. Pure oats are not harmful.

It is closely related to dermatitis herpetiformis, a skin disorder that has an associated gluten-sensitive enteropathy (see below).

Incidence

Coeliac disease is common in Northern Europe and epidemiological studies have shown a prevalence of 1 in 100 to 1 in 6500 in different temperate countries. It occurs throughout the world, but is rare in the black African.

There is an increased incidence of coeliac disease within families but the exact mode of inheritance is unknown; 10-15% of first-degree relatives will have the condition, although it may be asymptomatic. DQ2 (DQA*0501, DQBl*0201) and DQ8 (DQAl*0301, DQBl*0302) are associated with coeliac disease. Over 90% of patients will have DQ2, compared with 20-30% of the general population. Non-HLA regions linked to coeliac disease are chromosome 5q31-33, possibly llq, and others are being identified. However, the fact that not all patients have these haplotypes, and that as many as 30% of identical twins are discordant for the condition, suggests an additional factor, e.g. environmental.

Aetiology

Gluten is a high-molecular-weight, heterogeneous compound that can be fractionated to produce a-, (5-, y- and co-gliadin peptides. a-Gliadin is the main damaging peptide to the small intestinal mucosa although the other smaller peptides are also 'toxic'. T cells play a central role in the aetiopathogenesis and react with the enzyme tissue transglutaminase (the main antigen of the endomysial antibody). This enzyme is one of the targets of the autoimmune response; it modifies gliadin and enhances gliadin-specific T cell response in genetically predisposed individuals. An environmental factor, such as a viral infection, may play a role (e.g. adenovirus 12 which shows a sequence homology with gliadin). There are many other immunological abnormalities that revert to normal on treatment.

Pathology

The mucosa of the proximal small bowel is predominantly affected, the mucosal damage decreasing in severity towards the ileum as the gluten is digested into smaller 'non-toxic' fragments.

There is an absence of villi, making the mucosal surface flat. Histological examination shows crypt hyperplasia with chronic inflammatory cells in the lamina propria and villous atrophy (Marsh type III) (Fig. 6.25). The lesion is described as subtotal villus atrophy, although true atrophy of the mucosa is not present because the crypt hyperplasia compensates for villus atrophy and the total mucosal thickness remains normal. A partial villus atrophy (Marsh type II) can also be found.

The surface cells become cuboidal. There is an increase in the number of intraepithelial lymphocytes (IELs) which show an increased expression of the y/8 T-cell receptor, instead of the a/p receptor, and this is specific to coeliac disease and remains after treatment. In the lamina propria there is an increase in lymphocytes and plasma cells. A few patients just show an increase in IELs (latent coeliac disease Marsh type 0 and I) and others, e.g. relatives, a coeliac-like antibody pattern (potential coeliac disease). The most severe form with atrophy and hypoplasia (Marsh type IV) is thought to be associated with non-response to a gluten-free diet and its complications (p. 303).

Clinical features

Coeliac disease can present at any age. In infancy it appears after weaning on to gluten-containing foods. The peak incidence in adults is in the fifth decade, with a female preponderance. The symptoms are very variable and often non-specific with tiredness and malaise often associated with an anaemia. Many patients are asymptomatic (silent) and picked up on incidental findings, e.g. a raised MCV. Common GI symptoms include diarrhoea or steatorrhoea, abdominal discomfort, bloating or pain and weight loss. Mouth ulcers and angular stomatitis are frequent and can be intermittent. Infertility and neuropsychiatric symptoms of anxiety and depression occur. Osteoporosis is common and occurs even in patients on long-term gluten-free diets. Rare complications include tetany, osteomalacia, or gross malnutrition with peripheral oedema. Neurological symptoms such as paraesthesia, ataxia (due to cerebellar calcification), muscle weakness or a polyneuropathy occur; the prognosis for these symptoms is variable.

There is an increased incidence of atopy and autoimmune disease, including thyroid disease, insulin-dependent diabetes, primary biliary cirrhosis and Sjogren's syndrome. Other associated diseases include inflammatory bowel disease, chronic liver disease, fibrosing allergic alveolitis and epilepsy. IgA deficiency is more common than in the general population.

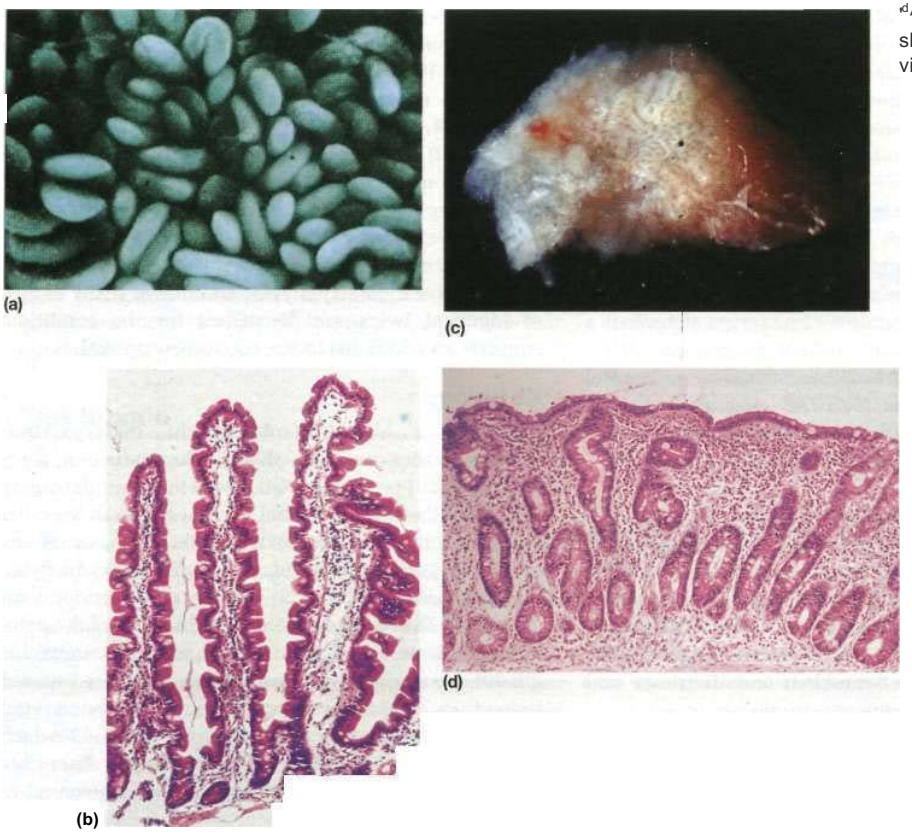

Fig. 6.25 **Small bowel mucosal appearances - macroscopic and microscopic, (a)** Normal mucosa under the dissecting microscope (DM). **(b)** Normal mucosal histology, (c) Coeliac disease (DM) - flattened mucosa. **(d)** Coeliac disease - showing subtotal villous atrophy.

Physical signs are usually few and non-specific and are related to anaemia and malnutrition.

Investigations

- **Endomysial (EMA) and tissue transglutaminase (tTG) antibodies (IgA).** These antibodies have a high sensitivity and specificity for the diagnosis of untreated coeliac disease and can also be used as screening tests. They are the investigation of first choice. An immunofluorescent test. for endomysial antibodies (EMA) can be performed on umbilical cord tissue or monkey oesophagus and the antigen for EMA is tissue transglutaminase. Anti-tissue trans glutaminase antibodies are measured using an ELISA. In the presence of a typical clinical picture and the presence of these antibodies, a confirmatory small bowel biopsy may not always be required although most doctors prefer to have one performed.
- **Anti-reticulin antibodies (ARA)** are also very sensi tive but not so specific, as they are seen in other gastrointestinal conditions (e.g. Crohn's disease). Anti-gliadin antibodies (AGA) are less sensitive and are not used.
- **Duodenal/jejunal biopsy.** The mucosal appearance (Fig. 6.25) of a small bowel biopsy specimen is diagnostic and regarded as the 'gold standard' although errors occur, particularly with poorly orientated specimens. Other causes of a flat mucosa in adults are rare and are shown in Figure 6.24. At endoscopy, the duodenal folds look effaced and a dye can be sprayed on to the duodenal mucosa to accentuate the smoothness of the mucosa (positive dye test) before the biopsy is taken.
- Haematology. A mild or moderate anaemia is present in 50% of cases. Folate deficiency is almost invariably present in coeliac disease, giving rise in most instances to a high MCV. B_{12} deficiency is rare but iron deficiency due to malabsorption of iron and increased loss of desquamated cells is common. A blood film may therefore show microcytes and macrocytes as well as hypersegmented polymorphonuclear leucocytes and Howell-Jolly bodies due to splenic atrophy found in most patients.
- **Absorption tests** are often abnormal (see p. 300) but are seldom performed.
- **Radiology.** A small bowel follow-through may show dilatation of the small bowel with a change in fold pattern. Folds become thicker and in the severer forms total effacement is seen. Radiology is now mainly used when a complication, e.g. lymphoma, is suspected.
- **Wireless capsule endoscopy** (p. 271) is used to look for gut abnormalities when a complication is suspected.
- **Bone densitometry** (DXA) should be performed on all patients because of the risk of osteoporosis.
- **Biochemistry.** *In the severely ill patient,* biochemical abnormalities, e.g. hypoalbuminaemia, low calcium and high phosphate (osteomalacia) are seen.

Treatment and management

Treatment with a gluten-free diet usually produces a rapid clinical and morphological improvement. Replacement haematinics, e.g. iron, folic acid, calcium, are given initially to replace body stores. The usual cause for failure to respond to the diet is poor compliance. Dietary adherence can be monitored by serial tests for EMA and tTG. If clinical progress is suboptimal then a repeat intestinal biopsy should be taken. If the diagnosis is equivocal a gluten challenge, i.e. reintroduction of gluten with evidence of jejunal morphological change, confirms the diagnosis, but is only performed if the diagnosis is equivocal. A transient gluten intolerance can occur in early childhood.

Despite advice, many patients do not keep to a strict diet but nevertheless maintain good health. The long-term effects of this low gluten intake are uncertain but osteoporosis is seen even in the treated case.

Patients should have pneumococcal vaccinations (because of splenic atrophy) once every 5 years (p. 457).

Complications

A few patients do not improve on a strict diet (unresponsive 'coeliac disease'). Often no cause for this is found, but intestinal lymphoma, ulcerative jejunitis or carcinoma are sometimes responsible. The incidence of enteropathy-associated T-cell lymphoma (EATCL) (see p. 309) is increased in coeliac disease. Ulcerative jejunitis may present with fever, abdominal pain, perforation and bleeding. Diagnosis for these conditions is with barium studies but laparotomy with full-thickness biopsies is often required. Steroids and immunosuppressive agents, e.g. azathioprine, are used. Carcinoma of the small bowel and oesophagus as well as extragastrointestinal cancers are also seen. Malignancy seems to be unrelated to the duration of the disease but the incidence is reduced by a gluten-free diet.

Dermatitis herpetiformis (see also p. 1348)

This is an uncommon blistering subepidermal eruption of the skin associated with a gluten-sensitive enteropathy. Rarely there may be gross malabsorption, but usually me jejunal morphological abnormalities are not as severe as in coeliac disease. The inheritance and immunological abnormalities are the same as for coeliac disease. The skin condition responds to dapsone but both the gut and the skin will improve on a gluten-free diet.

Tropical sprue

This is a condition presenting with malabsorption that occurs in residents or visitors to a tropical area where the disease is endemic.

Malabsorption of a mild degree, sometimes following an enteric infection, is quite common and is usually asymptomatic. This is sometimes called tropical mal-absorption. The term tropical sprue is reserved for severe malabsorption (of two or more substances) that is usually accompanied by diarrhoea and malnutrition. Tropical sprue is endemic in most of Asia, some Caribbean islands, Puerto Rico and parts of South America. Epidemics occur, lasting up to 2 years, and in some areas

repeated epidemics occur at varying intervals of up to 10 years.

Aetiology

The aetiology is unknown, but is likely to be infective because the disease occurs in epidemics and patients improve on antibiotics.

A number of agents have been suggested but none has been shown to be unequivocally responsible. Different agents could be involved in different parts of the world.

Clinical features

These vary in intensity and consist of diarrhoea, anorexia, abdominal distension and weight loss. The onset is sometimes acute and occurs either a few days or many years after being in the tropics. Epidemics can break out in villages, affecting thousands of people at the same time. The onset can also be insidious, with chronic diarrhoea and evidence of nutritional deficiency.

The clinical features of tropical sprue vary in different parts of the world, particularly as different criteria are used for diagnosis.

Diagnosis

Acute infective causes of diarrhoea must be excluded (see p. 333), particularly *Giardia,* which can produce a syndrome very similar to tropical sprue.

Malabsorption should be demonstrated, particularly of fat and B_{12}.

The jejunal mucosa is abnormal, showing some villous atrophy (partial villous atrophy). In most cases the lesion is less severe than that found in coeliac disease, although it affects the whole small bowel. Mild changes can be seen in asymptomatic individuals in the tropics, so jejunal mucosal changes must be interpreted carefully.

Treatment and prognosis

Many patients improve when they leave the sprue area and take folic acid (5 mg daily). Most patients also require an antibiotic (usually tetracycline 1 g daily) to ensure a complete recovery; it may be necessary to give this for up to 6 months.

The severely ill patient requires resuscitation with fluids and electrolytes for dehydration; any nutritional deficiencies should be corrected. Vitamin B_{12} (1000 (ig) is also given to all acute cases.

The prognosis is excellent. Mortality is usually associated with water and electrolyte depletion, particularly in epidemics.

Bacterial overgrowth

The gut contains many resident bacteria with anaerobic bacteria, e.g. *Bacteroides,* bifidobacteria, being 100-1000 times more abundant than aerobic (facultative anaerobes), e.g. *Escherichia, Enterobacter, Enterococcus.* This gut microflora has major functions including metabolic, e.g. fermentation of non-digestible dietary residues into short chain fatty acids as an energy source in the colon. Bacteria also initiate vitamin K production. They control epithelial cell proliferation and are involved in the development and maintenance of the immune system. They protect the gut mucosa from colonization by pathogenic bacteria.

The upper part of the small intestine is almost sterile, containing only a few organisms derived from the mouth. Gastric acid kills most organisms and intestinal motility keeps the jejunum empty. The normal terminal ileum contains faecal-type organisms, mainly *Escherichia coli* and anaerobes and the colon has abundant bacteria

Bacterial overgrowth is normally only found associated with a structural abnormality of the small intestine, although it can occur occasionally in the elderly without such abnormality. *E. coli* and/or *Bacteroides,* both in concentrations greater than 10^6/mL are found as part of a mixed flora. These bacteria are capable of deconjugating and dehydroxylating bile salts, so that unconjugated and dehydroxylated bile salts can be detected in aspirates by chromatography. The *clinical features* are chiefly diarrhoea and steatorrhoea. Steatorrhoea (see p. 298) occurs as a result of conjugated bile salt deficiency.

The bacteria are able to metabolize vitamin B_{12} and interfere with its binding to intrinsic factor, thereby leading to B_{12} deficiency (p. 431). Conversely some bacteria produce folic acid giving a high serum folate.

Bacterial overgrowth has only minimal effects on other substances absorbed from the small intestine. The vitamin B_{12} deficiency is not so severe as to produce a neurological deficit. Confirmation of bacterial overgrowth is with the hydrogen breath test (p. 301); aspiration studies are not routinely performed.

Although bacterial overgrowth may be responsible for the presenting symptoms, it must be remembered that many of the symptoms may be due to the underlying small bowel pathology.

Treatment

If possible, the underlying lesion should be corrected (e.g. a stricture should be resected). With multiple diverticula, grossly dilated bowel, or in Crohn's disease, this may not be possible and rotating courses of antibiotics are necessary, such as metronidazole, a tetracycline, or ciprofloxacin.

Intestinal resection (Fig. 6.26)

Intestinal resection is usually well tolerated, but massive resection is followed by the short-bowel syndrome. The effects of resection depend on the extent and the areas involved. Because the gut is long, a 30-50% resection can usually be tolerated without undue problems. Residual jejunum shows less capacity for structural and functional adaptation than residual ileum.

Meal resection

The ileum has specific receptors for the absorption of bile salts and vitamin B_{12}, so that relatively small resections will lead to malabsorption of these substances. Removal of the ileocaecal valve increases the incidence of diarrhoea. The following occur in ileal resection:

Bile salts and fatty acids enter the colon and cause malabsorption of water and electrolytes leading to diarrhoea (p. 334).

Increased bile salt synthesis can compensate for loss of approximately one-third of the bile salts in the faeces. Greater loss than this results in decreased micellar formation and steatorrhoea, and lithogenic bile and gallstone formation.

Increased oxalate absorption is caused by the presence of bile salts in the colon. This gives rise to renal oxalate stones.

There is a low serum B_{12} and macrocytosis.

Glucagon-like peptide 2 (GLP-2) is low following ileal resection. GLP-2 is a specific growth hormone for the enterocyte and this deficiency may explain the lack of adaptation with an ileal resection.

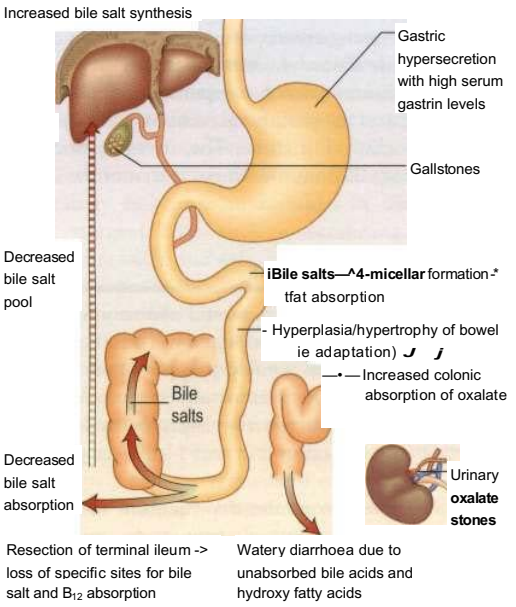

Fig. 6.26 The effects of resection of distal small bowel.

Investigations include a small bowel follow-through, measurement of B_{12}, bile salts and occasionally fat absorption (see p. 300). A hydrogen breath test will show rapid transit (p. 301). Many patients require B_{12} replacement and some need a low-fat diet if there is steatorrhoea. If diarrhoea is a problem, colestyramine, which binds bile salts, often helps.

Jejunal resection

The ileum can take over the jejunal absorptive function. Jejunal resection may lead to gastric hypersecretion with high gastrin levels; the exact mechanism of this is unclear. Structural and functional intestinal adaptation take place over the course of a year, with an increase in the absorption per unit length of bowel.

Massive intestinal resection (short-bowel syndrome)

This most often occurs following resection for Crohn's disease, mesenteric vessel occlusion (p. 307), radiation enteritis (see p. 306) or trauma. There are two types of short-bowel syndrome:

Shortened small intestine ending at a terminal stoma

The major problem is of sodium and fluid depletion and the majority of patients with 100 cm or less of jejunum remaining will require parenteral supplements of fluid and electrolytes, often with nutrients. Sodium losses can be minimized by increasing salt intake, restricting clear fluids between meals and administering oral glucose- electrolyte mixture with a sodium concentration > 90 mmol/L. Jejunal transit time can be increased and stomal effluent loss of fluids and electrolytes reduced by treatment with the somatostatin analogue octreotide, and to a much lesser extent, with loperamide, codeine phosphate or co-phenotrope. There is no benefit of a low-fat diet, but fat assimilation can be increased on treatment with colestyramine and synthetic bile acids.

Shortened small intestine in continuity with colon

Only a small proportion of these patients require parenteral supplementation of fluid, electrolytes and nutrients because of the absorptive capacity of the colon for fluid and electrolytes. Unabsorbed fat results in impairment of colonic fluid and electrolyte absorption so patients should be on a low-fat diet. A high carbohydrate intake is advised as unabsorbed carbohydrate is metabolized anaerobically to short-chain fatty acids (SCFAs). SCFAs are absorbed and act as an energy source (1.6 kcal/g) and stimulate fluid and electrolyte absorption in the colon. Patients are often treated with colestyramine, which binds dihydroxy bile acids which otherwise have a deleterious effect on colonic fluid and electrolyte absorption and increase colonic oxalate absorption to form renal stones.

Whipple's disease

This is a rare disease usually affecting males. It presents with steatorrhoea and abdominal pain along with systemic symptoms of fever and weight loss. Peripheral lymphadenopathy, arthritis and involvement of the heart, lung and brain may occur. Histologically, in the small bowel, the villi are stunted and contain diagnostic periodic acid-Schiff (PAS)-positive macrophages. On electron microscopy, bacilli can be seen 'within' the macrophages. The organism was identified by the polymerase chain reaction and can be cultured; it is classified as an actinobacterium and has been given the name *Tropheryma whippeii*. A dramatic improvement occurs with antibiotic therapy, which should include an antibiotic that crosses the blood—brain barrier (e.g. co-rrimoxazole) for 6 months.

Radiation enteritis

Radiation of more than 40 Gy will damage the intestine. The ileum and rectum are the areas most often involved, as pelvic irradiation is frequently used for gynaecological and urinary tract malignancies. There may be nausea, vomiting, diarrhoea and abdominal pain at the time of the irradiation. These symptoms usually improve within 6 weeks after completion of therapy. Chronic radiation enteritis is diagnosed if symptoms persist for 3 months or more. The prevalence is more than 15%. Many patients suffer from an increased bowel frequency.

Radiation produces muscle fibre atrophy, ulcerative changes due to ischaemia, and obstruction due to strictures produced by radiation-induced fibrosis. Abdominal pain is the main symptom due to the obstruction, which is usually partial but eventually may be complete. Malabsorption due to mucosal damage as well as bacterial overgrowth in dilated segments can occur. Treatment is symptomatic, although often unsuccessful in chronic enteritis. Surgery should be avoided if at all possible, being reserved for life-threatening situations such as complete obstruction or occasionally perforation. Radiation damage to the rectum produces a radiation proctitis with diarrhoea, with or without blood and tenesmus. Local steroids sometimes help initially. The telangiectasia that form and cause persistent bleeding can be treated with argon plasma coagulation or by placing a formalin-soaked swab in the rectum (for 2 min), both of which heal the lesions.

Parasite infestation

Giardia intestinalis (see p. 105) not only produces diarrhoea but can produce malabsorption with steatorrhoea. Minor changes are seen in the jejunal mucosa and the organism can be found in the jejunal fluid or mucosa.

Cryptosporidiosis (see p. 105) can also produce malabsorption.

Patients with HIV infection are particularly prone to parasitic infestation (see Table 6.20).

Other causes of malabsorption

- Drugs that bind bile salts (e.g. colestyramine) and some antibiotics (e.g. neomycin) produce steatorrhoea.
- Orlistat (p. 256) inhibits gastric and pancreatic lipase, reducing fat absorption. It is used in obesity; its side-effect is diarrhoea and steatorrhoea. Hence patients restrict their fat intake, which is the main reason why they lose weight.
- Diarrhoea, rarely with steatorrhoea, occurs in thyrotoxicosis owing to increased gastric emptying and increased motility. Steatorrhoea occurs in the Zollinger-Ellison syndrome (see p. 416).
- Intestinal lymphangiectasia produces diarrhoea and rarely steatorrhoea (see p. 308).
- Lymphoma that has infiltrated the small bowel mucosa causes malabsorption.
- In some patients with diabetes mellitus, diarrhoea, malabsorption and steatorrhoea occur, sometimes due to bacterial overgrowth from bowel stasis.
- Hypogammaglobulinaemia, which is seen in a number of conditions including lymphoid nodular hyperplasia, causes steatorrhoea due either to an abnormal jejunal mucosa or to secondary infestation with *Giardia intestinalis*.

MISCELLANEOUS INTESTINAL DISEASES

Protein-losing enteropathy

Protein-losing enteropathy is seen in many gastrointestinal and systemic conditions. Increased protein loss across an abnormal mucosa causes hypoalbuminaemia. Causes include inflammatory or ulcerative lesions (e.g. Crohn's disease), tumours, Menetrier's disease, coeliac disease and lymphatic disorders (e.g. lymphangiectasia). Usually protein-losing enteropathy forms a minor part of the generalized disorder, but occasionally hepatic synthesis of albumin cannot compensate for the hypoalbuminaemia, and the peripheral oedema produced may dominate the clinical picture. The investigations are described on page 301 and treatment is that of the underlying disorder.

Meckel's diverticulum

This is the most common congenital abnormality of the GI tract, affecting 2-3% of the population. The diverticulum projects from the wall of the ileum approximately 60 cm from the ileocaecal valve. It is usually symptomless, but 50% contain gastric mucosa that secretes hydrochloric acid. Peptic ulcers can occur and may bleed (see p. 291) or perforate.

Acute inflammation of the diverticulum also occurs and is indistinguishable clinically from acute appendicitis. Obstruction from an associated band rarely occurs. Treatment is surgical removal, often laparoscopically.

Tuberculosis

Tuberculosis (TB) can affect the intestine as well as the peritoneum (see p. 344).

Intestinal tuberculosis is due to reactivation of primary disease caused by *M. tuberculosis*. Bovine TB occurs in areas where milk is unpasteurized and is very rare in the UK. The ileocaecal area is most commonly affected, but the colon, and rarely other parts of the gastrointestinal tract, can be involved too.

Tuberculosis is being seen more frequently in patients with HIV infection.

Clinical features

These are chiefly diarrhoea and abdominal pain with generalized systemic manifestations, including fever, anorexia and weight loss. One-third of patients present acutely with intestinal obstruction or generalized peritonitis.

On examination, a mass may be palpable in the right iliac fossa and 50% have X-ray evidence of pulmonary tuberculosis.

Diagnosis

In the West, TB must be differentiated from Crohn's disease and should always be considered as a possible diagnosis in Asian immigrants. A caecal carcinoma can present with similar symptoms. A small bowel follow-through will show transverse ulceration, diffuse narrowing of the bowel with shortening of the caecal pole. An ultrasound or CT may show additional mesenteric thickening and lymph node enlargement. Histological verification and culture of tissue is highly desirable, but it is not always possible to obtain bacteriological confirmation, and treatment should be started if there is a high degree of suspicion. Specimens can be obtained by colonoscopy or laparoscopy but laparotomy is required in some cases.

Treatment

Drug treatment is similar to that for pulmonary TB - rifampicin, isoniazid and pyrazinamide (see p. 932) - but treatment should last 1 year.

Amyloid (see also p. 1147)

In systemic amyloidosis there is usually diffuse involvement that may affect any part of the GI tract. Occasionally amyloid deposits occur as polypoid lesions. The symptoms depend on the site of involvement; amyloidosis in the small intestine gives rise to diarrhoea.

Connective-tissue disorders

Systemic sclerosis (see p. 577) most commonly affects the oesophagus (p. 6.14), although the small bowel and colon are often found to be involved if the appropriate radiological studies are performed. Frequently there are no symptoms of this involvement, but diarrhoea and steatorrhoea can occur. This is usually due to bacterial overgrowth of the small bowel as a result of reduced motility, dilatation and the presence of diverticula.

In *rheumatoid arthritis* (p. 559) and systemic lupus erythematosus (p. 574), gastrointestinal symptoms may occur, but rarely predominate.

Intestinal ischaemia

Intestinal ischaemia results from occlusion of arterial inflow, occlusion of venous outflow or failure of perfusion; these factors may act singularly or in combination and usually occur in the elderly.

- *Arterial inflow occlusion:*
  - atheroma
  - thrombosis
  - embolus (cardiac arrhythmia) including cholesterol (p. 648)
  - aortic disease (occluding ostia of mesenteric vessels)
  - vasculitis (see p. 581), thromboangiitis and Takayasu's syndrome (p. 869)
  - neoplasia (occlusion of vessels - rare).
- Venous outflow occlusion: 5-15% of cases and usually occurs in sick patients with circulatory failure.
- Infarction without occlusion. Approximately one-third of patients dying with acute ischaemic necrosis of the small intestine have no demonstrable occlusion of a major vessel. Reduced cardiac output, hypotension and shock are the main causes of reduced intestinal blood flow leading to non-occlusive infarction.

Acute small intestinal ischaemia

Patients present with sudden abdominal pain and vomiting. An embolus from the heart in a patient with atrial fibrillation is the commonest cause, usually occluding the superior mesenteric artery. The abdomen is usually distended and tender, and bowel sounds are absent. The patient is hypotensive and ill. Treatment is surgical and gangrenous bowel is resected. Mortality is high (up to 90%) and is related to coexisting disease, the development of multiorgan failure (MOF) (p. 978) and massive fluid and electrolyte losses in the postoperative period. Survivors go on to develop nutritionally inadequate short-bowel syndrome (see p. 305).

Ischaemic colitis

See page 323.

Chronic small intestinal ischaemia

This is due to atheromatous occlusion or cholesterol emboli of the mesenteric vessels, particularly in the elderly. Such an occlusion does not always produce clinical effects because *ot* the *collateral circulation. The* characteristic symptom is abdominal pain occurring after food. This may be followed by acute mesenteric vascular occlusion. Loud bruits may be heard but, as these are heard in normal subjects, they are of doubtful significance. The diagnosis is made using angiography.

The term 'coeliac axis compression syndrome' has been used in young patients with chronic abdominal pain, bruits and minor angiographic changes. Despite its plausible title, it is not an organic syndrome. Its suggested existence results from the false correlation of pain and bruits.

Eosinophilic gastroenteritis

In this condition of unknown aetiology there is eosinophilic infiltration and oedema of any part of the gastrointestinal mucosa. The gastric antrum and proximal small intestine are usually involved either as a localized lesion (eosinophilic granuloma) or diffusely with sheets of eosinophils seen in the serosal and submucosal layers. An association with asthma, eczema and urticaria has been described.

The condition occurs mainly in the third decade. The clinical presentation depends on the site of gut involve-

ment. Abdominal pain, nausea and vomiting and upper GI bleeding occur. Eosinophilia occurs in only 20% of patients. Radiology or endoscopy will demonstrate the lesion. Steroids are used for the widespread infiltration, particularly if peripheral eosinophilia is present.

In some adults the condition appears to be allergic (allergic gastroenteritis) and is associated with peripheral eosinophilia and high levels of blood and tissue IgE.

Intestinal lymphangiectasia

Dilatation of the lymphatics may be primary or secondary to lymphatic obstruction, such as occurs in malignancy or constrictive pericarditis. In the rare primary form it may be detected incidentally as dilated lacteals on a jejunal biopsy or it can produce steatorrhoea of varying degrees. Hypoproteinaemia with ankle oedema is the other main feature. Serum immunoglobulin levels are reduced, with low circulating lymphocytes. Treatment is with a low-fat diet.

Abetalipoproteinaemia

In this rare condition, there is failure of apo B-100 synthesis in the liver and apo B-48 in the intestinal cell, so that chylomicrons are not formed. This leads to fat accumulation in the intestinal cells, giving a characteristic histological appearance to the jejunal mucosa. Clinical features include acanthocytosis (spiky red cells owing to membrane abnormalities), a form of retinitis pigmentosa, and mental and neurological abnormalities. The latter can be prevented by vitamin E injections.

GI problems in patients with HIV infection

See Table 6.20.

TUMOURS OF THE SMALL INTESTINE

The small intestine is relatively resistant to the development of neoplasia and only 3-6% of all GI tumours and fewer than 1% of all malignant lesions occur here. The reasons for the rarity of tumours is unknown. Explanations include the fluidity and relative sterility of small bowel contents and the rapid transit time, reducing the time of exposure to potential carcinogens. It is also possible that the high population of lymphoid tissue and secretion of IgA in the small intestine protect against malignancy.

Adenocarcinoma of the small intestine is rare and found most frequently in the duodenum (in the periampullary region) and in the jejunum. It is the most common tumour of the small intestine, accounting for up to 50% of primary tumours.

Lymphomas are most frequently found in the ileum. These are of the non-Hodgkin's type and must be distinguished from peripheral or nodal lymphomas involving the gut secondarily.

In developed countries, the most common type of lymphoma is the B-cell type arising from MALT (see p. 205). These lymphomas tend to be annular or polypoid masses in the distal or terminal ileum, whereas most T-cell lymphomas are ulcerated plaques or strictures in the proximal small bowel.

A tumour similar to Burkitt's lymphoma also occurs and commonly affects the terminal ileum of the children in North Africa and the Middle East.

Predisposing factors for adenocarcinoma and lymphoma

Coeliac disease

There is an increased incidence of lymphoma of the T-cell type and adenocarcinoma of the small bowel in coeliac disease, as well as an unexplained increase in all malignancies both in the GI tract and elsewhere. The reason for the local development of malignancy is unknown. It is now accepted that coeliac disease is a premalignant condition, but there is no association with the length of the symptoms. Treatment of coeliac disease with a gluten-free diet reduces the risk of both lymphoma and carcinoma.

Crohn's disease

There is a small increase in the incidence of adenocarcinoma of the small bowel in Crohn's disease.

Immunoproliferative small intestinal disease (IPSID)

IPSID is a B cell disorder in which there is proliferation of plasma cells in the lamina propria of the upper small bowel. These cells produce truncated monoclonal heavy chains, but lack associated light chains. The a heavy chains are found in the gut mucosa on immunofluorescence and can also be detected in the serum. IPSID occurs usually in countries surrounding the Mediterranean, but it has also been found in other developing countries in South America and the Far East. IPSID predominantly affects people in lower socio-economic groups in areas with poor hygiene and a high incidence of bacterial and parasitic infection of the gut. IPSID presents itself as a malabsorptive syndrome associated with diffuse lymphoid infiltration of the small bowel and neighbouring lymph nodes. This then progresses in some cases to a lymphoma. The condition has also been documented in the developed world.

Clinical features

Patients present with abdominal pain, diarrhoea, anorexia, weight loss and symptoms of anaemia.

There may be a palpable mass, and a small bowel follow-through will detect most lesions. Ultrasound and CT will show bowel wall thickening and the involvement of lymph nodes, which is common with lymphoma. Wireless capsule endoscopy is also being used.

Treatment

Adenocarcinoma. Most patients are treated surgically with a segmental resection. The overall 5-year survival

rate is 20-35%; this varies with the histological grade and the presence or absence of lymph node involvement. Radiotherapy and chemotherapy are used in addition.

IPSID. If there is no evidence of lymphoma, antibiotics, e.g. tetracycline, should be tried initially. In the presence of lymphoma, combination chemotherapy is used; in one series the 3- to 5-year survival was 58%.

Lymphoma. Most patients require surgery and radiotherapy with chemotherapy for more extensive disease. The prognosis varies with the type.

The 5-year survival rate for T-cell lymphomas is 25%, but is better for B-cell lymphomas, varying from 50% to 75%, depending on the grade of lymphoma.

Carcinoid tumours

These originate from the enterochromaffin cells (APUD cells) of the intestine. They make up 10% of all small bowel neoplasms, the most common sites being in the appendix, terminal ileum and the rectum. It is often difficult to be certain histologically whether a particular tumour is benign or malignant. Clinically most carcinoid tumours are asymptomatic until metastases are present. Ten per cent of carcinoid tumours in the appendix present as acute appendicitis, the inflammation being secondary to obstruction. Surgical resection of the tumour is usually performed.

Carcinoid syndrome occurs in only 5% of patients with carcinoid tumours and only when there are liver metastases. Patients complain of spontaneous or induced bluish-red flushing, predominantly on the face and neck. This can lead to permanent changes with telangiectasis. Gastrointestinal symptoms consist of abdominal pain and recurrent watery diarrhoea. Cardiac abnormalities are found in 50% of patients and consist of pulmonary stenosis or tricuspid incompetence. Examination of the abdomen reveals hepatomegaly.

The tumours secrete a variety of biologically active amines and peptides, including serotonin (5-hydroxytryptamine; 5-HT), bradykinin, histamine, tachykinins and prostaglandins.

The diarrhoea and cardiac complications are probably caused by 5-HT itself, but the cutaneous flushing is thought to be produced by one of the kinins, such as bradykinin, which is known to cause vasodilatation, bronchospasm and increased intestinal motility.

Diagnosis and treatment

Ultrasound examination confirms the presence of liver secondary deposits, and the major metabolite of 5-HT, 5-hydroxyindoleacetic acid (5-HIAA), is found in high concentration in the urine.

Octreotide and lanreotide are octapeptide somatostatin analogues that have been shown to inhibit the release of many gut hormones. They alleviate the flushing and diarrhoea and can control a carcinoid crisis. Octreotide is given subcutaneously in doses up to 200 ug three times daily initially; a depot preparation 30 mg every 4 weeks can then be used. Lanreotide 30 mg is given every 7-10 days, or as a gel 60 mg every 28 days.

Long-acting octreotide also sometimes inhibits tumour growth and, since its introduction, other therapy is usually unnecessary. Interferon and other chemotherapeutic regimens occasionally reduce tumour growth, but have not been shown to increase survival. Most patients survive for 5—10 years after diagnosis.

Peutz-Jeghers syndrome

This consists of mucocutaneous pigmentation (circumoral, hands and feet) and gastrointestinal polyps and has an autosomal dominant inheritance. The gene *LKB1* responsible for Peutz-Jeghers is a serine protein kinase and can be used for genetic analysis. The brown buccal pigment is characteristic of this condition. The polyps, which are hamartomas, can occur anywhere in the GI tract but are most frequent in the small bowel. They may bleed or cause small bowel obstruction or intussusception. The polyps can occasionally contain areas of epithelial dysplasia which can become malignant. Treatment is by individual polypectomy. Multiple polypectomies may have to be performed, but bowel resection should be avoided. Follow-up is every 2 years with X-ray and endoscopy.

Other tumours

Adenomas, lipomas and stromal tumours (p. 290) are rarely found and are usually asymptomatic and picked up incidentally. They occasionally present with iron deficiency anaemia. In familial adenomatous polyposis the upper gut, particularly the duodenum, is affected in one-third of patients.

INFLAMMATORY BOWEL DISEASE (IBD)

Two major forms of *non-specific* inflammatory bowel disease are recognized: Crohn's disease (CD), which can affect any part of the GI tract, and ulcerative colitis (UC), which affects only the large bowel.

There is overlap between these two conditions in their clinical features, histological and radiological abnormalities; in 10% of cases of colitis a definitive diagnosis of either *UC*

or CD is not possible. Currently it is necessary to distinguish between these two conditions because of certain differences in their management. However, it is possible that these conditions represent two aspects of the same disease.

Three additional forms of non-specific inflammatory bowel disease are also recognized, namely microscopic ulcerative, microscopic lymphocytic and microscopic collagenous colitis (see p. 319).

Epidemiology

The incidence of Crohn's disease varies from country to country but is approximately 4-10 per 100 000 annually, with a prevalence of 27-106 per 100 000. The incidence of ulcerative colitis is stable at 6-15 per 100 000 annually, with a prevalence of 80-150 per 100 000.

Both conditions have a world-wide distribution but are more common in the West. The incidence is lower in the non-white races. Jews are more prone to inflammatory bowel disease than non-Jews, and the Ashkenazi Jews have a higher risk than the Sephardic Jews.

Crohn's disease is slightly commoner in females (M : F = 1:1.2) and occurs at a younger age (mean 26 years) than ulcerative colitis (M : F = 1.2 : 1; mean 34 years).

Aetiopathogenesis

Although the aetiology of IBD is unknown, it is becoming clear that IBD represents the outcome of three essential interactive co-factors: genetic susceptibility, environment and host immune response (Fig. 6.27), with the environmental factors representing both the local microenvironment (enteric microflora) and also the nutritional environment.

- *Familial.* Both Crohn's disease (CD) and ulcerative colitis (UC) are more common amongst relatives of patients than in the general population. Thus 6-10% of patients affected with CD or UC have one or more relatives with the disease. The risk of CD in first-degree relatives of a CD patient is 10-14 times higher than in the general population, with the risk of UC being about 8. In CD, but not UC, affected patients are more likely to be siblings than first-degree relatives. *Genetic. A* role for genetic factors in IBD was first suggested by epidemiological studies showing increased concordance for the disease (CD more than UC) in monozygotic twins in comparison with dizygotic twins who demonstrated familial aggregation. In 2001 three independent studies reported the identification of the first Crohn's disease susceptibility gene (IBD1) on chromosome 16ql2, originally known as *NOD2* but subsequently renamed *CAKD15* by the International Nomenclature Committee. In experimental studies, wild type *CARD15* protein activates NFκB in response to a bacterial peptidoglycan; this did not occur in a mutant form of *CARD15.* Three main independent mutations within *CARD15* have been found in association with CD. Ten to thirty per cent of CD patients are heterozygous for one of the three *CARD15* mutations, while 3—15% of patients are either homozygous or compound heterozygotes. The relative risks of developing CD from inheriting *CARD15* mutations can be estimated to be 1.5-3% in people carrying one mutation and 10^10% in people carrying two mutations. The contribution of *CARD15* mutations to disease susceptibility varies according to subpopulation, and they are not associated with CD in the Japanese population. While all clinically recognizable forms of CD can be found in patients with and without *CARD15* variants, *CARD15* variants are associated with younger age of onset, ileal (versus non-ileal) disease and a tendency to develop strictures. Since the *CARD15* mutations seem to account for less than 20% of CD, other candidate susceptibility genes have been searched for. Putative loci have been mapped to chromosome 12 (IBD2) 6 (IBD3) and 14 (IBD4).

  Apart from susceptibility, HLA genes on chromosome 6 also have a role in modifying the disease. For example, the DRBl*0103 allele, which is uncommon, produces extensive and more severe disease; DRBl*0103 as well as MICA*010 are associated with perianal disease, DRB1*O7O1 with ileal disease (in the absence of *CARD15* alleles); and uveitis with HLA-B27 and DRBl*0103.

  Environmental factors. Good domestic hygiene has been shown to be a risk factor for CD but not for UC - similarly *Helicobacter pylori* seroprevalence is reduced in CD but not in UC. In a 'clean' environment the intestinal immune system may not be exposed to pathogenic or non-pathogenic microorganisms, particularly helminthic parasites, and therefore be 'untrained' to confront minor infections without recruiting the full array of specific immune functions that lead to inflammation. Helminth infections are associated with a type 2 helper T cell response (Th_2), which would counterbalance the type-1 helper T cell response (Thj) that is characteristic of CD. If such a mechanism is operative, it would explain why there is a frequent association of a recent intestinal infection

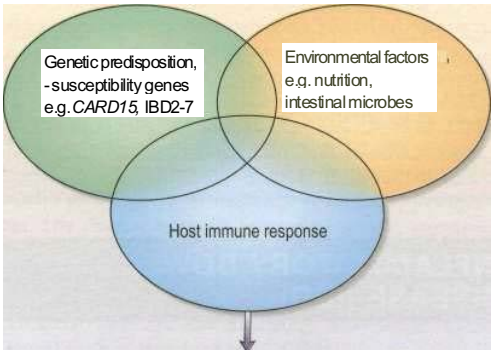

Fig. 6.27 **Inflammatory bowel disease.** Schematic diagram showing the aetiopathogenesis. Modified from Cashman KD, Shanahan F (2003) *European Journal of Gastroenterology and Hepatology* 15: 607-613, with permission.

with the first presentation and subsequent flare-ups of CD.

- *Nutritional factors.* Many foods and food components have been suggested to play a role in the aetiopathogenesis of IBD (e.g. high sugar and fat intake). Unfortunately the results of numerous studies have been equivocal so, as yet, there are no definitive data to support nutritional factors as a cause of either CD or UC.
- *Smoking.* Patients with CD are more likely to be smokers, and smoking has been shown to exacerbate CD. In contrast, there is an increased risk of UC in non- or ex-smokers and nicotine has been shown to be an effective treatment of UC.
- *Appendicectomy.* Appendicectomy is protective for the development of UC, particularly if performed before the age of 20 for appendicitis or mesenteric lymph adenitis. Appendicectomy also influences the clinical course of UC, with a lower incidence of colectomy and need for immunosuppressive therapy. In contrast, appendicectomy may increase the risk of development of CD and may result in more aggressive disease.
- *Intestinal microflora.* The gut is colonized by 10 times more bacterial organisms than there are host cells, there being 300-400 distinct bacterial species. Evidence now supports a hypothesis that IBD is characterized by an overaggressive immune response to luminal bacterial antigens and other products, occurring against a background of genetic susceptibility.
  - *Bacterial flora.* There is an alteration in the bacterial flora, with an increase in anaerobic bacteria in CD and an increase in aerobic bacteria in UC.
  - *Bacterial antigens.* Bacteria may exert their pro-inflammatory influence by producing toll-like receptor ligands such as peptidoglycan-polysaccharides (PG-PS), lipopolysaccharides (LPS), bacterial DNA motifs or formylated oligopeptides, e.g. N-formyl-methionyl leucyl-phenylalanine (FMLP), which interact in the normal intestine with surface toll-like receptors (TLR). The disruption in TLR signalling could prevent the mucosa withstanding bacterial insult.
  - *Intestinal mucosal invasion.* The intestinal wall in IBD patients is contaminated by adherent and invading bacteria.
  - *Defective chemical barrier or intestinal defensins.* These cationic antimicrobial peptides normally protect the mucosa against adherent and invading bacteria. Evidence suggests a decrease in human P defensin-1 (HBD-1) in both CD and UC and lack of induction of HBD-2 and HBD-3 in CD.
  - *Impaired mucosal barrier function* may explain the presence of unusual and potentially pathogenic bacteria, e.g. *Mycobacterium paratuberculosis* (MAP), *Listeria,* mucosal adherent £. *coli.* Their presence does not necessarily imply causation of the disease. However, MAP has recently been found in the blood of patients with Crohn's disease and further studies are awaited.
  - *Measles virus* has been implicated as it was found in the vascular epithelium with associated vascular injury and focal enteritis. However, RT-PCR did not detect the virus from intestinal biopsies from patients. There may be antigen mimicry. - *Butyrate.* Sulphate-producing bacteria increase luminal levels of hydrogen sulphide (H_2S), which leads to a reduction of butyrate oxidation in colonic mucosa, producing an energy-deficient state and leading to mucosal inflammation. H_2S and methane-ethiol may produce the malodorous flatus that some patients complain of prior to a flare-up.
- *Immunopathogenesis.* Many immunological abnormalities have been described. It is suggested that genetically susceptible patients with defective immunoregulation or barrier function/healing lack the ability to appropriately downregulate immune (antigen-specific) or antigen-non-specific inflammatory responses to endogenous luminal antigens. Specifically there is upregulation of macrophages and Thl lymphocytes in Crohn's disease. This produces an excess of cytokines, interleukin-l(3 (IL-1(3), IL-1 receptor antagonist (IL-1RA), IL-6, the chemokine IL-8 and TNF-oc. UC is a modified Th_2 response with IL-5 and IL-10. Nuclear factor kappa B (NFκB) plays a central regulatory role by controlling the transcription of genes for these pro-inflammatory cytokines. There is also activation of other cells (eosinophils, mast cells, neutrophils and fibroblasts) which leads to excess production of chemokines (lymphokines, arachidonic acid metabolites, neuropeptides and free oxygen radicals), all of which can lead to tissue damage.

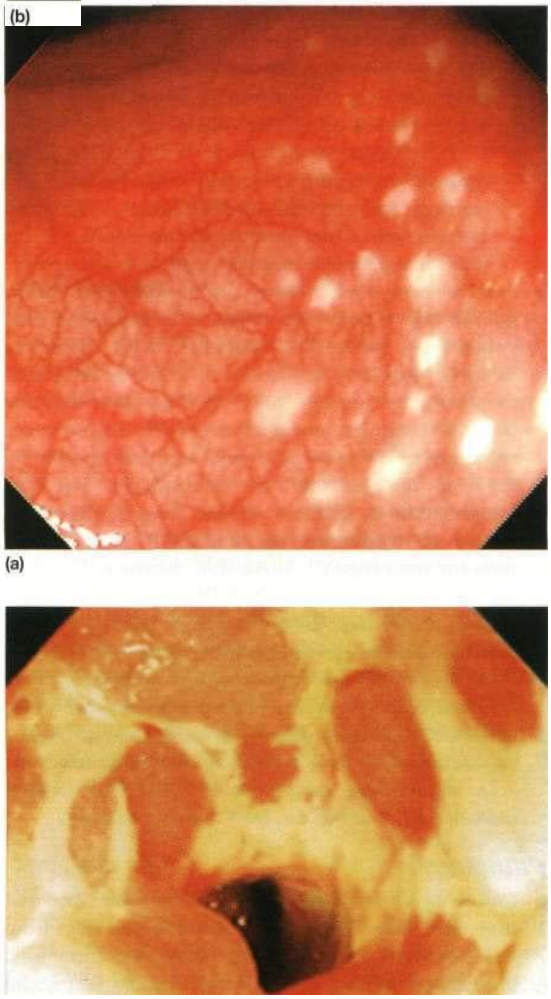
Pathology

- *Crohn's disease* is a chronic inflammatory condition that may affect any part of the gastrointestinal tract from the mouth to the anus (see Table 6.10) but has a particular tendency to affect the terminal ileum and ascending colon (ileocolonic disease). The disease can involve one small area of the gut such as the terminal ileum, or multiple areas with relatively normal bowel in between (skip lesions). It may also involve the whole of the colon (total colitis) sometimes without small bowel involvement.
- *Ulcerative colitis* can affect the rectum alone (proctitis), can extend proximally to involve the sigmoid and descending colon (left-sided colitis), or may involve the whole colon (total colitis). In a few of these patients there is also inflammation of the distal terminal ileum (backwash ileitis).

Macroscopic changes

In *Crohn's disease* the involved small bowel is usually thickened and narrowed. There are deep ulcers and fissures in the mucosa, producing a cobblestone appearance. Fistulae and abscesses may be seen in the colon. An early feature is aphthoid ulceration, usually seen at colonoscopy (Fig. 6.28); later, larger and deeper ulcers appear in a patchy distribution, again producing a cobblestone appearance.

In *ulcerative colitis* the mucosa looks reddened, inflamed and bleeds easily. In severe disease there is



A

Fig. 6.28 **Crohn's disease.** Colonoscopic appearances of (a) aphthoid ulcers typical of Crohn's disease, (b) cobblestone appearance.

extensive ulceration with the adjacent mucosa appearing as inflammatory polyps.

In fulminant colonic disease of either type, most of the mucosa is lost, leaving a few islands of oedematous mucosa (mucosal islands), and toxic dilatation occurs. On healing, the mucosa can return to normal, although there is usually some residual glandular distortion.

Microscopic changes

In *Crohn's disease* the inflammation extends through all layers (transmural) of the bowel, whereas in ulcerative colitis a superficial inflammation is seen. In Crohn's disease there is an increase in chronic inflammatory cells and lymphoid hyperplasia, and in 50-60% of patients granulomas are present. These granulomas are non-caseating epithelioid cell aggregates with Langhans' giant cells.

In *ulcerative colitis* the mucosa shows a chronic inflammatory cell infiltrate in the lamina propria. Crypt abscesses and goblet cell depletion are also seen.

The differentiation between these two diseases can usually be made not only on the basis of clinical and radiological data but also on the histological differences seen in the rectal and colonic mucosa obtained by biopsy (Table 6.8).

It is occasionally not possible to distinguish between the two disorders, particularly if biopsies are obtained in the acute phase, and such patients are considered to have an indeterminate inflammatory colitis. Serological testing may be of value in differentiating the two conditions (p. 314).

Table 6.8 **Histological differences between Crohn's disease and ulcerative colitis**

	Crohn's disease	Ulcerative colitis
Inflammation	Deep (transmural)	Mucosal
	Patchy	Continuous
Granulomas	++	Rare
Goblet cells	Present	Depleted
Crypt abscesses	+	++

Extragastrointestinal manifestations

These occur with both diseases. Joint complications are commonest, and the peripheral arthropathies are now classified as type 1 (pauci-articular) and type 2 (polyarticular). Type 1 attacks are acute, self-limiting (< 10 weeks) and occur with IBD relapses; they are associated with other extraintestinal manifestations of IBD activity. Type 2 arthropathy lasts longer (months to years), is independent of IBD activity and usually associated with uveitis. The incidence of joint and other extragastrointestinal manifestations is shown in Table 6.9. This is an association HLA DRB1*0103 with pauci-articular large joint arthritis in UC and CD and small joint symmetrical arthritis with HLA-B44. HLA B27 is associated with sacroileitis.

Differential diagnosis

All causes of diarrhoea should be excluded (see Table 6.18) and stool cultures are always performed. Crohn's disease should be considered in all patients with evidence of malabsorption, e.g. megaloblastic anaemia, or malnourishment, as well as in children with small stature. Ileocolonic tuberculosis (p. 306) is common in developing countries, e.g. India, and makes a diagnosis of Crohn's disease difficult. Microscopy and culture for TB of any available tissue is essential in these countries. A therapeutic trial of antituberculosis therapy may be required.

Lymphomas can occasionally involve the ileum and caecum.

Table 6.9 **Extragastrointestinal manifestation of inflammatory bowel disease (percentage of cases)**

	Ulcerative colitis	Crohn's disease

Crohn's disease

i *mess*

Clinical features

The major symptoms are diarrhoea, abdominal pain and weight loss. Constitutional symptoms of malaise, lethargy, anorexia, nausea, vomiting and low-grade fever may be present and in 15% of these patients there are no gastrointestinal symptoms. Despite the recurrent nature of this condition, many patients remain well and have an almost normal lifestyle. However, patients with extensive disease often have frequent recurrences, necessitating multiple hospital admissions.

The clinical features are very variable and depend partly on the region of the bowel that is affected. The disease may present insidiously or acutely. The abdominal pain can be colicky, suggesting obstruction but it usually has no special characteristics and sometimes in colonic disease only minimal discomfort is present. Diarrhoea is present in 80% of all cases and in colonic disease it usually contains blood, making it difficult to differentiate from ulcerative colitis. Steatorrhoea can be present in small bowel disease.

Crohn's disease can present as an emergency with acute right iliac fossa pain mimicking appendicitis. If laparotomy is undertaken, an oedematous reddened terminal ileum is found. There are other causes of an acute ileitis (e.g. infections such as *Yersinid)*. Up to 30% of patients presenting with acute ileitis turn out eventually to have Crohn's disease. Crohn's disease can be complicated by anal and perianal disease and this is the presenting feature in 25% of cases, often preceding colonic and small intestinal symptoms by many years (Table 6.10).

Enteric fistulae, e.g. to bladder or vagina, occur in 20-40% of cases, equally divided between internal and external fistulae; the latter usually occurring after surgery.

Examination

Physical signs are few, apart from loss of weight and general *ill-health. Aphtfrous* criVeratiorr o/ rfte rrtuuilV is often seen. Abdominal examination is often normal although tenderness and a right iliac fossa mass are occasionally found. The mass is due either to inflamed loops of bowel that are matted together or to an abscess. The anus should always be examined to look for oedematous anal tags, fissures or perianal abscesses.

Extragastrointestinal features of inflammatory bowel disease should be looked for (Table 6.9).

Sigmoidoscopy should always be performed in a patients with Crohn's disease. With small bowel involvement the rectum may appear normal, but a biopsy must be taken as non-specific histological changes can

Table 6.10 **Anal and perianal complications of Crohn's disease**

Fissure in ano (multiple and indolent)
Haemorrhoids
Skin tags
Perianal abscess
Ischiorectal abscess
Fistula in ano (may be multiple)
Anorectal fistulae

sometimes be found in the mucosa. Even with extensive colonic Crohn's disease the rectum may be spared and be relatively normal, but patchy involvement with an oedematous haemorrhagic mucosa can be present.

Investigations

Blood tests

- Anaemia is common and is usually the normocytic, normochromic anaemia of chronic disease. Deficiency of iron and/or folate also occurs. Despite terminal ileal involvement in Crohn's disease, megaloblastic anaemia due to B_{12} deficiency is unusual, although serum B_{12} levels can be below the normal range.
- Raised ESR and CRP and a raised white cell count.
- Hypoalbuminaemia is present in severe disease.
- Liver biochemistry may be abnormal.
- Blood cultures are required if septicaemia is suspected.
- Serological tests. *Saccharomyces cerevisiae* antibody is usually present while p-ANCA antibody is negative. The reverse is true in UC but the clinical value of these tests is limited.

Stool cultures

These should always be performed on presentation if diarrhoea is present.

Radiology and imaging

A barium follow-through examination should always be performed in patients suspected of having Crohn's disease. The findings include an asymmetrical alteration in the mucosal pattern with deep ulceration, and areas of narrowing or stricturing. Although commonly confined to the terminal ileum (Fig. 6.29), other areas of the small bowel can be involved and skip lesions with normal bowel are seen between affected sites.

Imaging of the small bowel may also be performed by magnetic resonance enteroclysis. Colonoscopy is performed if colonic involvement is suspected except in patients presenting with severe acute disease. The findings vary from mild patchy superficial (aphthoid) ulceration to more widespread larger and deeper ulcers producing a cobblestone appearance (see Fig. 6.28).

In patients presenting acutely with colonic symptoms plain abdominal X-ray, ultrasound or CT is used to outline the colon as for UC (p. 317).

High-resolution ultrasound and *spiral CT scanning* are both helpful techniques in defining thickness of the bowel wall and mesentery as well as intra-abdominal and para-intestinal abscesses. Rectal ultrasound and MRI are used to evaluate perianal disease.

Radionuclide scans with gallium-labelled polymorphs or indium- or technetium-labelled leucocytes are used in some centres to identify small intestinal and colonic disease and to localize extraintestinal abscesses.

Disease activity

This can be assessed using simple parameters such as Hb, white cell count, inflammatory markers (raised ESR, CRP and platelet count) and serum albumin. Formal clinical activity indices (e.g. Crohn's disease activity index) are used in research studies. Calprotectin is a calcium-binding protein and accounts for 60% of cytosolic protein of neutrophils. Faecal calprotectin has the potential as a simple cheap non-invasive marker of disease activity in IBD and may be of value in predicting response to and failure of treatment.

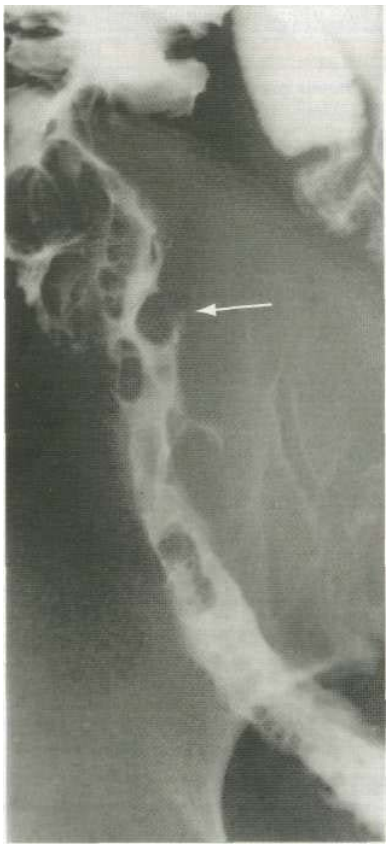

Fig. 6.29 **Terminal ileum on small bowel follow-through in Crohn's disease,** showing narrowing and ulceration of the terminal ileum (arrow). Note the presence of deep 'rose thorn' type ulcers and 'cobblestoning' in the terminal ileum.

Medical management of Crohn's disease

(Box 6.8)

The aim of management is to induce and then maintain a remission. Patients with mild symptoms may require only symptomatic treatment. Cigarette smoking should be stopped. Diarrhoea can be controlled with loperamide, codeine phosphate or co-phenotrope. Diarrhoea in long-standing inactive disease may be due to bile acid malabsorption (p. 334) and should be treated with colestyramine. Anaemia, if due to vitamin B_{12}, folic acid or iron deficiency, should be treated with the appropriate haematinics. Anaemia in more active disease is usually normochromic and normocytic (anaemia of chronic disease, p. 430) and will usually improve as the patient gets

***Box 6.8* Options for medical treatment of Crohn's disease**

Induction of remission

- Oral or i.v. glucocorticosteroids
- Enteral nutrition
- Oral glucocorticosteroids + azathioprine or 6 mercaptopurine (6MP)

Maintenance of remission

- Aminosalicylates
- Azathioprine, 6MP, mycophenolate mofetil

Treatment of glucocorticosteroid/immunosuppressive therapy-resistant disease

- Methotrexate
- Intravenous ciclosporin
- Infliximab (TNF-a antibody)
- New biological agents

Perianal disease

- Ciprofloxacin and metronidazole

better. Patients with active (moderate/ severe) attacks may have to be admitted to hospital. Patients with moderate to severe total *Crohn's colitis* are treated as for UC (p. 317).

Glucocorticosteroids are commonly used to induce remission in moderate and severe attacks of Crohn's disease (oral prednisolone 30-60 mg/day). In patients with ileocaecal, but not colonic, Crohn's disease, slow-release formulations of budesonide are as efficacious as oral prednisolone. Budesonide has high topical potency and because of its extensive hepatic inactivation has low systemic availability, which induces less suppression of endogenous cortisol and reduces frequency and intensity of steroidal side-effects. Overall remission/response rates vary from 60% to 90% depending on type, site and extent of disease.

Enteral nutrition is an underutilized means of inducing remission in moderate and severe attacks of Crohn's disease, and efficacy is independent of nutritional status. If enteral diets with a low fat (1.3% of total calories) and a low linoleic acid content are administered as the sole source of nutrition for 28 days, rates of induction of remission are similar to those obtained with steroids. Relapse rates are high, however, particularly in those with colonic involvement.

Flare-ups commonly occur after steroid dosages are tapered and/or enteral nutrition stopped, and alternative treatment strategies have to be introduced, e.g. steroid dosage may have to be temporarily increased, to re-induce and maintain remission. Aminosalicylates are particularly useful in Crohn's colitis. The immuno-suppressive agents azathioprine (AZA) and its metabolite 6-mercaptopurine (6MP) are both effective in inducing and maintaining remission and have steroid-sparing properties. Mycophenolate mofetil, which suppresses the proliferation of T and B lymphocytes, is also effective in maintaining remission.

Long-term treatment with AZA and 6MP is necessary as the rate of relapse on discontinuation of treatment is high (70%). Regular blood counts should be performed after commencing treatment as the key enzyme involved in AZA and 6MP metabolism (thiopurine methyltransferase, TPMT) has significant genetic variation in the population, with deficiencies resulting in high levels of active thioguanine nucleotides which result in immune and bone marrow suppression. Assays for TPMT are now available in some centres and early detection of a deficiency will alert clinicians to the potential dangers of AZA and 6MP therapy. In unresponsive patients, remission is sometimes induced and maintained by raising the dose of AZA to levels that make patients leucopenic.

In patients with corticosteroid/immunosuppressive therapy-resistant Crohn's disease, methotrexate or i.v. (but not oral) ciclosporin has been shown to be effective in inducing remission, but not in maintaining it. Biological treatments directed against specific inflammatory mediators, e.g. anti TNF-a antibody (infliximab), are now being used and the results of the first maintenance trials have been reported (Box 6.9). A single infusion of this agent has been shown to be effective in producing clinical improvement in up to 60% of patients with steroid-resistant disease.

In the future, other anti TNF-a agents currently under assessment may be approved for clinical use (e.g. CDP571, CDP870) as will other biological agents (e.g. natalizumab, basiliximab, visilizumab, RDP 58, MLN-02). Anti-interleukins, e.g. Anti-IL-12, are also being tested.

Surgical management of Crohn's disease

Approximately 80% of patients will require an operation at some time during the course of their disease. Nevertheless, surgery should be avoided if possible and only minimal resections undertaken, as recurrence (15% per year) is almost inevitable. The indications for surgery are:

***Box 6.9* Tumour necrosis facfor-a (I *fiF-af* in Crohn's disease**

TNF-a is a pro-inflammatory cytokine.
It has a major role in the pathogenesis of Crohn's disease.
Infliximab - a chimeric anti-TNF-a monoclonal antibody - binds with high affinity to TNF-a and neutralizes its biological activity.
Infliximab 5 mg/kg i.v. as a single infusion can induce remission in patients with moderately to severely active Crohn's disease.
Responders without fistulizing disease are more likely to remain in remission if repeat infusions are administered at weeks 2 and 6, and then every 8 weeks until week 46 (ACCENT I trial).
Infliximab 5 mg/kg at 0, 2 and 6 weeks closes fistulae in patients with fistulizing Crohn's disease, with a median duration of response of 12 weeks.
Added maintenance treatment (5 mg/kg) 8-weekly until week 46 increases the chances of not having a draining fistula at week 54 (36% vs placebo 19%; ACCENT II trial).
Side-effects include the detection of antibodies to infliximab, anti-dsDNA and ANA and the development of lupus-like syndrome. Infusion reactions, serum sickness-like reactions and infections (e.g. tuberculosis) in up to a third of patients have been reported.

failure of medical therapy, with acute or chronic symptoms producing ill-health
- complications (e.g. toxic dilatation, obstruction, perforation, abscesses, enterocutaneous fistula)
- failure to grow in children.

In patients with small bowel disease, some strictures can be widened (stricturoplasty), whereas others require resection and end-to-end anastomosis.

When colonic Crohn's disease involves the entire colon and the rectum is spared or minimally involved a subtotal colectomy and ileorectal anastomosis may be performed. An eventual recurrence rate of 60-70% in the ileum, rectum or both is to be expected; however, two-thirds of these patients retain a functional rectum for 10 years. If the whole colon and rectum are involved a panproctocolectomy with an end ileostomy is the standard operation. In this operation the colon and rectum are removed and the ileum is brought out through an opening in the right iliac fossa and attached to the skin. The patient wears an ileostomy bag, which is stuck on to the skin over the ileostomy spout. The bag needs to be emptied once or twice daily, so this is compatible with a near-normal lifestyle. Stoma care therapists are readily available with help and advice. Crohn's disease patients are not suitable for a pouch operation (p. 318) as recurrence in the pouch is high.

Problems associated with ileostomies include:

- mechanical problems
- dehydration, particularly in hot climates
- psychosexual problems
- infertility in men
- recurrence of Crohn's disease.

Ulcerative colitis

Clinical features

The major symptom in ulcerative colitis is diarrhoea with blood and mucus, sometimes accompanied by lower abdominal discomfort. General features include malaise, lethargy and anorexia. Aphthous ulceration in the mouth is seen. The disease can be mild, moderate or severe, and in most patients runs a course of remissions and exacerbations. Ten per cent of patients have persistent chronic symptoms, while some patients may have only a single attack.

When the disease is confined to the rectum (proctitis), blood mixed with the stool, urgency and tenesmus are common. There are normally few constitutional symptoms, but patients are nevertheless greatly inconvenienced by the frequency of defecation.

In an acute attack of UC, patients have bloody diarrhoea, passing up to 10-20 liquid stools per day. Diarrhoea also occurs at night, with urgency and incontinence that is severely disabling for the patient. Occasionally blood and mucus alone are passed.

The definition of a severe attack is given in Table 6.11. The patient is often very ill and needs urgent treatment in hospital.

Table 6.11 Definition of a severe attack of ulcerative colitis

Stool frequency	> 6 stools per day with blood +++
Fever	> 37.5°C
Tachycardia	> 90 per minute
ESR	> 30 mm per hour
Anaemia	< 10 g/dL haemoglobin
Albumin	< 30 g/L

Examination

In general there are no specific signs in ulcerative colitis. The abdomen may be slightly distended or tender to palpation. The anus is usually normal. Rectal examination will show the presence of blood. Rigid sigmoidoscopy is usually abnormal, showing an inflamed, bleeding, friable mucosa. Very occasionally rectal sparing occurs, in which case sigmoidoscopy will be normal.

Investigations

Blood tests

- In moderate to severe attacks an iron deficiency anaemia is commonly present and the white cell and platelet counts are raised.
- The ESR and CRP are often raised; liver biochemistry may be abnormal, with hypoalbuminaemia occurring in severe disease.
- pANCA may be positive. This is contrary to Crohn's disease, where pANCA is usually negative (p. 345).

Stool cultures

These should always be performed to exclude infective causes of colitis.

Imaging

A plain abdominal X-ray with an *abdominal ultrasound* are the key investigations in moderate to severe attacks. The extent of disease can be judged by the air distribution in the colon and the presence of colonic dilatation can be noted. Thickening of the colonic wall can be detected on ultrasound, as can the presence of free fluid within the abdominal cavity. CT is also valuable in acute attacks. An instant *unprepared barium enema* is sometimes performed.

Colonoscopy

A colonoscopy should not be performed in severe attacks of disease for fear of perforation. In more long-standing and chronic disease it is useful in defining extent and activity of disease, and in patients with total ulcerative colitis of 10 years' duration or more, *colonoscopy* and multiple biopsies should be performed to exclude dysplasia and carcinoma.

Radionuclide scans

These can be used to assess colonic inflammation (p. 270).

Medical management of ulcerative colitis (UC)

Wherever possible, patients with ulcerative colitis and Crohn's disease should be managed in patient-focused

inflammatory bowel disease clinics. All patients with ulcerative colitis should be treated with an aminosalicylate. The active moiety of these drugs is 5-aminosalicylic acid (5-AS A). 5-ASA is absorbed in the small intestine (and may be nephrotoxic) so the design of the various aminosalicylate preparations is based on the binding of 5-ASA by an azo bond to sulfapyridine (sulfasalazine), 4-aminobenzoyl-|3-alanine (balsalazide) or to 5-ASA itself (olsalazine), coating with a pH-sensitive polymer (Asacol) or packaging of 5-ASA in microspheres (Pentasa).

The azo bonds are broken down by colonic bacteria to release 5-ASA within the colon. The pH-dependent forms are designed to release 5-ASA in the terminal ileum. Luminal pH profiles in patients with inflammatory bowel disease are abnormal and in some patients capsules of 5-ASA coated with pH-sensitive polymer may pass through into the faeces intact. 5-ASA is released from microspheres throughout the small intestine and colon. The mode of action of 5-ASA in inflammatory bowel disease is unknown, but the aminosalicylates have been shown to be effective in inducing remission in mild to moderately active disease and maintaining remission in all forms of disease. Sulfasalazine is being used less frequently because of its wider side-effect profile.

Proctitis

Oral aminosalicylates plus a local rectal steroid preparation (10% hydrocortisone foam; prednisolone 20 mg enemas or foam) are the first-line treatment. Mesalazine enemas and budesonide enemas can be tried. Some cases of proctitis can be 'resistant' to treatment. In these, oral corticosteroids alone or in combination with azathioprine are used and in rare cases short-chain fatty acid enemas may help. . - ■ ■ . .

Left-sided proctocolitis

Oral aminosalicylates plus local rectal steroid preparations may be effective but in moderate to severe attacks oral prednisolone will be required. If patients do not respond within 2 weeks they should be admitted to hospital.

Total colitis (moderate to severe attacks) (Table 6.11) Patients should be admitted to hospital and treated initially with hydrocortisone 100 mg i.v. 6-hourly with oral aminosalicylates. Full investigations (see above) should be performed initially and full supportive therapy administered (i.v. fluids, nutritional support via the enteral (not parenteral) route if required).

Patients who have been previously admitted within 2-3 years with moderate to severe attacks of total colitis can be started on azathioprine if not already on this treatment, as it takes time to work. The clinical status of patients should subsequently be monitored carefully (fever, tachycardia, abdominal signs) and daily FBC, ESR, CRP, electrolytes and urea, tests of liver function, including serum albumin, straight abdominal X-ray, and stool weights should be performed. Success or failure of medical treatment of a severe attack of ulcerative colitis must be judged by an experienced gastroenterologist.

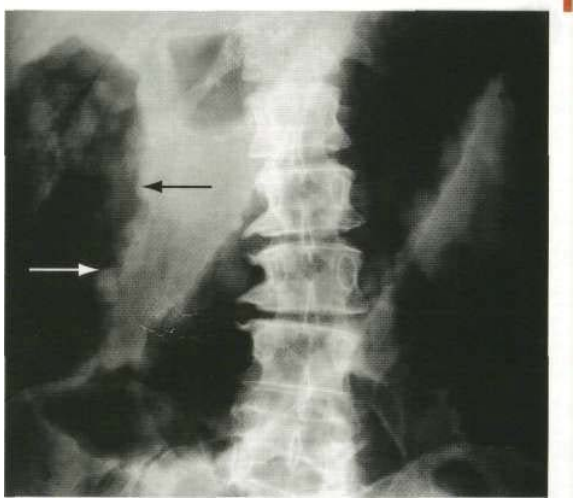

Fig. 6.30 Plain abdominal X-ray, showing toxic dilatation in ulcerative colitis. The arrows indicate mucosal islands.

A persistent fever, tachycardia, falling Hb, rising white cell count, falling potassium, falling albumin and persistently raised stool weights (> 500 g/day) with loose blood-stained stool are all signs that the patient is not responding to treatment and that surgery may be indicated.

Toxic dilatation of the colon in which the plain abdominal X-ray shows a dilated thin-walled colon with a diameter of more than 5 cm that is gas filled and contains mucosal islands (Fig. 6.30) is a particularly dangerous stage of advanced disease with impending perforation and high mortality (15-25%). Urgent surgery is required in all patients in whom toxic dilatation has not resolved within 48 hours.

In patients responding to i.v. hydrocortisone treatment, oral prednisolone therapy should be substituted and doses slowly tailed off (5-10 mg weekly). Maintenance of remission is with aminosalicylates. In patients in whom it is not possible to reduce the dose of prednisolone without flare-up, azathioprine is used.

Surgical management of ulcerative colitis

While the treatment of ulcerative colitis remains primarily medical, surgery continues to have a central role because it may be life-saving, is curative and eliminates the long-term risk of cancer. The main indication for surgery is for a severe attack which fails to respond to medical therapy. Other indications are listed in Box 6.10.

In acute disease, subtotal colectomy with end ileostomy and preservation of the rectum is the operation of choice. At a later date a number of surgical options are available. These include proctectomy with a permanent ileostomy. To avoid a permanent ileostomy, ileorectal anastomosis can be performed; annual biopsies of the rectal mucosa must be carried out to exclude dysplasia, a

Box 6.10 **Indications for surgery in ulcerative colitis**

Fulminant acute attack
Failure of medical treatment Toxic dilatation Haemorrhage . Perforation

Chronic disease
- Incomplete response to medical treatment
- Excessive steroid requirement
- Non-compliance with medication
- Risk of cancer

Box 6.11 **Probiotic use in inflammatory bowel disease**

Probiotics are live microorganisms which when ingested can modify the composition of enteric microflora. Commonly used probiotics are lactobacilli, bifidobacteria, non-pathogenic £ *coli.*

Rationale for use

Germ-free animals are susceptible to gastrointestinal infections and inflammation. ■ Pseudomembranous colitis due to *C. difficile* follows antibiotic therapy.

In vitro isolates of normal bacteria inhibit growth of pathogenic bacteria. « Regulatory signals between bacterial flora and intestinal epithelial cells maintain mucosal integrity.

Use

Pouchitis (p. 318) - they can prevent onset and maintain a remission, possibly by increasing tissue levels of IL-10 and reducing TH-1 cytokine production as well as normalizing colonic bacterial function. May be useful in maintaining remissions in ulcerative colitis.

histological change that precedes the development of a rectal stump carcinoma. With an ileo-anal anastomosis (Fig. 6.31), a pouch of ileum is formed that acts as a reservoir. The pouch is anastomosed to the anus at the dentate line following endoanal excision of the mucosa of the distal rectum and anal canal. Continence is usually achieved. A third of patients, however, will experience 'pouchitis' in which there is inflammation of the pouch mucosa with clinical symptoms of diarrhoea, bleeding, fever and at times exacerbation of extracolonic manifestations (Fig. 6.32). The incidence of pouchitis is twice as high in patients with primary sclerosing cholangitis. Two-thirds of pouchitis cases will recur either as acute relapsing or chronic unremitting forms. Treatment is not always satisfactory and includes topical and oral 5-ASA, corticosteroids, metronidazole and ciprofloxacin. Probiotics (four strains of lactobacillus, three strains of bifidobacterium and one of streptococcus) have been shown to prevent the onset of pouchitis and to maintain remission in pouchitis patients. Probiotics have also been used as maintenance therapy in UC (Box 6.11). Finally, short-chain fatty acid enemas and alicaforsen (a selective inhibitor of intercellular adhesion molecule-1, ICAM-1, expression) enemas have shown promise in the treatment of pouchitis.

Course and prognosis

A third of patients with distal inflammatory proctitis due to ulcerative colitis will develop more proximal disease, with 5-10% developing total colitis. A third of patients with ulcerative colitis will have a single attack and the others will have a relapsing course. A third of patients with ulcerative colitis will undergo colectomy within 20 years of diagnosis.

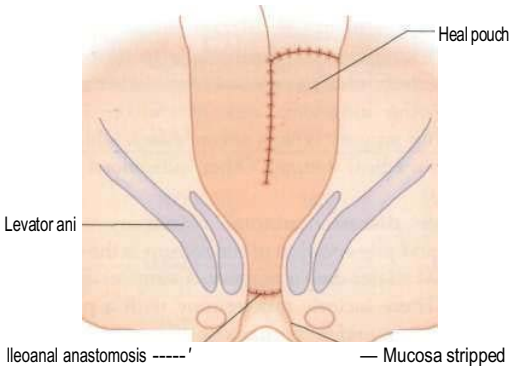

Fig. 6.31 **An ileo-anal pouch for ulcerative colitis.**

Cancer in inflammatory bowel disease

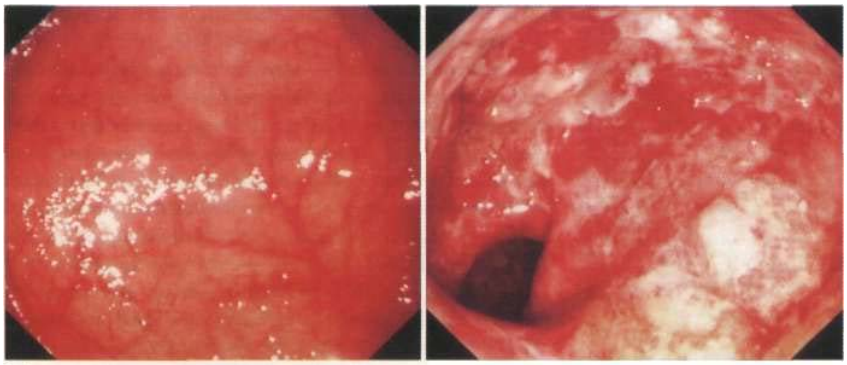
Patients with extensive ulcerative colitis of more than 10 years' duration are at an increased risk of developing colorectal cancer. (Cumulative risk 5% after 20 years, 12% at 25 years.) Although patients with Crohn's colitis are also at risk, this is lower than with ulcerative colitis. Many centres recommend that colonoscopy and multiple biopsies should be undertaken at 1- to 2-year intervals in patients with extensive ulcerative colitis of more than 10 years' duration, and those with evidence of high-grade dysplasia should undergo colectomy. There is, however, no supportive evidence for this strategy. There is as yet insufficient evidence to support the use of a surveillance program in patients with Crohn's colitis.

Pregnancy and inflammatory bowel disease

Women with inactive IBD have normal fertility. Fertility, however, may be reduced in those with active disease, and patients with active disease are twice as likely to suffer spontaneous abortion than those with inactive disease.

Although the risk of an exacerbation of IBD is not increased in pregnancy, when exacerbations occur they do so most commonly in the first trimester and during the immediate postpartum period.

Aminosalicylates, steroids and azathioprine are safe at the time of conception and during pregnancy. The sulfapyiridine moiety of sulfasalazine impairs spermatogenesis, so the partners of women trying to conceive should be treated with an alternative aminosalicylate.



(a) (b)

Fig. 6.32 Pouchitis. Fibreoptic sigmoidoscopic appearances. (a) Mild changes. (b) Severe haemorrhagic ulceration.

Mortality in inflammatory bowel disease

Population based studies demonstrate a mortality in UC similar to that in the general population. The two exceptions are patients with severe colitis who have a slightly higher mortality in the first year after diagnosis and patients aged over 60 at the time of diagnosis. Although currently it is unclear whether there is a slightly higher overall mortality in patients with CD or not, those with extensive jejunal and ileal disease and those with gastric and duodenal disease have been shown to have a higher relative mortality.

Microscopic inflammatory colitis

Patients with this group of disorders present with chronic or fluctuating watery diarrhoea. Although the macroscopic features on colonoscopy are normal, the histopathological findings on biopsy are abnormal. There are three distinct forms of microscopic inflammatory colitis:

- microscopic ulcerative colitis
- microscopic lymphocytic colitis
- microscopic collagenous colitis.

In *microscopic ulcerative colitis,* there is a chronic inflammatory cell infiltrate in the lamina propria, with deformed crypt architecture, and goblet cell depletion with or without crypt abscesses. *Treatment* is as for ulcerative colitis; many patients respond to treatment with aminosalicylates alone.

In *microscopic lymphocytic colitis* there is surface epithelial injury, prominent lymphocytic infiltration in the surface epithelium and increased lamina propria mononuclear cells. It affects males and females equally and is associated with a high prevalence of antibiotic use.

In *microscopic collagenous colitis* there is a thickened subepithelial collagen layer (> 10)im) adjacent to the basal membrane with increased infiltration of the lamina propria with lymphocytes and plasma cells and surface epithelial cell damage. It is predominantly a disorder of middle-aged or elderly females, and is associated with a variety of autoimmune disorders (arthritis, thyroid disease, CREST syndrome and primary biliary cirrhosis). The prevalence of collagenous colitis has been shown to be $15.7/10^5$ population with an annual incidence of $1.8/10^5$ population. There are a number of reports linking drugs to the development of collagenous colitis (non-steroidal anti-inflammatory drugs, simvastatin, H_2-receptor antagonists).

There are no controlled clinical trials of treatment in microscopic lymphocytic or collagenous colitis. Treatment is usually with aminosalicylates, budesonide, bismuth-containing preparations (tripotassium, dicitrato-bismuthate, peptobismol), prednisolone and azathioprine in that order. In general, patients with microscopic collagenous colitis are easier to treat than those with the lymphocytic form of the disease.

THE COLON AND RECTUM

Structure

The large intestine starts at the caecum, on the posterior medial wall of which is the appendix. The colon is made

up of ascending, transverse, descending and sigmoid parts, which join the rectum at the rectosigmoid junction.

The muscle wall consists of an inner circular layer and an outer longitudinal layer. The outer layer is incomplete, coming together to form the taenia coli, which produce the haustral pattern seen in the normal colon.

The mucosa of the colon is lined with epithelial cells with crypts but no villi, so that the surface is flat. The mucosa is full of goblet cells. A variety of cells, mainly lymphocytes and macrophages, are found in the lamina propria.

The blood supply to the colon is from the superior and inferior mesenteric vessels. Generally there are good anastomotic channels, but the caecum and splenic flexure are areas where ischaemia can occur. The colon is innervated mainly by the enteric nervous system with input from the parasympathetic and sympathetic pathways. Spinal afferent neurones from the dorsal root ganglia innervate the entire colon.

The rectum is about 12 cm long. Its interior is divided by three crescentic circular muscles producing shelf-like folds. These are the rectal valves that can be seen at sigmoidoscopy. The anal canal has an internal and an external sphincter.

Physiology of the colon

The main roles of the colon are the absorption of water and electrolytes (Table 6.12) and the propulsion of contents from the caecum to the anorectal region. Approximately 1.5-2 L of fluid pass the ileocaecal valve each day. Absorption is stimulated by short-chain fatty acids which are produced predominantly in the right colon by the anaerobic metabolism of dietary fibre by bacterial polysaccharidase enzyme systems. Colonic contents are mixed, aiding absorption by non-propagative segmenting muscular contractions. High-amplitude propagative colonic contractions cause propulsion. Peristalsis is induced by the release of serotonin (5-HT) from neuroendocrine cells in response to luminal distension. Serotonin activates the HT_4 receptors, which in turn results in the activation of sensory (calcitonin gene-related peptide (CGRP)) neurones. Normal colonic transit time is 24^8 h with normal stool weights of up to 250 g/day.

Table 6.12 **Input and output of water and electrolytes in the gastrointestinal tract over 24 hours**

	Water (mL)	Sodium (mmol)	Potassium (mmol)
Input			
Diet	1500	150	80
GI secretions	7500	1000	40
Totals	9000	1150	120
Output			
Faeces	150	5	12
Ileostomy (adapted)	500-1000	60-120	4

Physiology of defecation

The role of the rectum and anus in defecation is complex. The rectum is normally empty. Stool is propelled into the rectum by propagated colonic contractions. Sensation of fullness, a desire to defecate and urgency to defecate are experienced with increasing volumes of rectal content (threshold 100 mL). The sensations are associated with rectal contraction and a relaxation of the internal anal sphincter, both of which serve to push the stool down into the proximal anal canal. This increases the defecatory urge, which can only be suppressed by vigorous contraction of the external sphincter and puborectalis. If conditions are appropriate for defecation the subject sits or squats, contracts the diaphragm and abdominal muscles and relaxes the pelvic floor muscles, including the puborectalis, and the anal sphincter muscles.

CONSTIPATION

'Constipation' is a very common symptom, particularly in women and the elderly. It is often more of a perception than a real entity. A consensus definition used in research (The Rome II criteria) defines constipation as having two or more of the following for at least 12 weeks: infrequent passage of stools (< 3/week), straining > 25% of time, passage of hard stools, incomplete evacuation and sensation of anorectal blockage. According to these definitions 'constipation' affects more than 1 in 5 of the population.

Many symptoms are attributed by patients to constipation and include headaches, malaise, nausea and a bad taste in the mouth. Other symptoms include abdominal bloating and/ or discomfort (undistinguishable from the irritable bowel syndrome) as well as local and perianal pain. The causes of constipation are shown in Table 6.13.

Assessment of constipation

This relies on the history. When there has been a recent change in bowel habit in association with other symptoms (e.g. rectal bleeding) a barium enema or colonoscopy is indicated. A barium enema should always be preceded by a rectal examination and rigid sigmoidoscopy to exclude anorectal lesions that can otherwise be missed. By these means, gastrointestinal causes such as colorectal cancer and narrowed segments due to diverticular disease (Table 6.13) can be excluded.

Constipation can be classified into three broad categories but there is much overlap:

- normal transit through the colon (59%)
- defecatory disorders (25%)
- slow transit (13%).

Defecatory disorders with slow transit can occur together (3%).

Normal-transit constipation

In normal-transit constipation, stool traverses the colon at a normal rate, the stool frequency is normal and yet patients believe they are constipated. This is likely to be

Table 6.13 Causes of constipation

Large rectocele
Pelvic floor dyssynergia/anismus
Megarectum

Fig. 6.33 **Slow-transit constipation.** Straight abdominal X-ray taken on day 6 after ingestion of capsules each containing 20 radio-opaque shapes, which were administered daily on days 1, 2 and 3. All the markers are retained, confirming the diagnosis of severe slow-transit constipation.

due to perceived difficulties of evacuation or the passage of hard stools. Patients may complain of abdominal pain or bloating.

Normal-transit constipation can be distinguished from slow-transit constipation by undertaking marker studies of colonic transit. Capsules containing 21 radio-opaque shapes are swallowed on days 1, 2 and 3 and an abdominal X-ray obtained 120 hours after ingestion of the first capsule. Each capsule contains shapes of different configuration and the presence of more than 4 shapes from the first capsule, 6 from the second and 12 from the third denotes moderate to severe slow transit (Fig. 6.33).

Slow-transit constipation

Slow-transit constipation occurs predominantly in young women who have infrequent bowel movements (usually less than once a week). The condition often starts at puberty and the symptoms are usually an infrequent urge to defecate, bloating, abdominal pain and discomfort, which can make the condition difficult to distinguish from constipation-predominant irritable bowel syndrome. Some patients with severe slow-transit constipation have delayed emptying of the proximal colon and others a failure of 'meal-stimulated' colonic motility. Histopathological abnormalities have been demonstrated in the colons of some patients with severe slow-transit constipation, and some patients have coexisting disorders of small intestinal motility, consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (p. 343).

Defecatory disorders

A 'paradoxical' contraction rather than the normal relaxation of the puborectalis and external anal sphincter and associated muscles during straining may prevent evacuation (pelvic floor dyssynergia, anismus). These are mainly due to dysfunction of the anal sphincter and pelvic floor. An anterior rectocele is a common problem where there is a weakness of the rectovaginal septum, resulting in protuberance of the anterior wall of the rectum with trapping of stool if the diameter is > 3 cm. In some patients the mucosa of the anterior rectal wall prolapses downwards during straining (see p. 326)

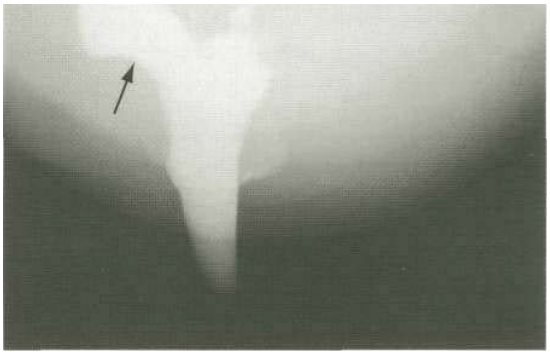

Fig. 6.34 **Evacuating proctogram** showing the presence of an anterior rectocele (arrowed).

impeding the passage of stool, whilst in others there may be a higher mucosal intussusception.

In some patients the rectum can become unduly sensitive to the presence of small volumes of stool, resulting in the urge to pass frequent amounts of small-volume stool and the sensation of incomplete evacuation..

The defecatory disorders can often be characterized by performing evacuation proctography (Fig. 6.34) and tests of anorectal physiology.

Treatment

Any underlying cause should be treated. In patients with normal and slow-transit constipation the main focus should be directed to increasing the fibre content of the diet in conjunction with increasing fluid intake. Fibre intake should be increased by dietary means rather than by prescribing commercially available fibre sources in order to avoid substrate inducibility of colonic bacterial polysaccharidase enzyme systems. These patients should therefore be referred to a dietitian.

The use of laxatives should be restricted to severe cases. Types of laxatives available are listed in Box 6.12. Osmotic laxatives act by increasing colonic inflow of fluid and electrolytes; this acts not only to soften the stool but to stimulate colonic contractility. Magnesium sulphate 5-10 g dissolved in a glass of hot water should be taken before breakfast; it works in 2-4 hours. The polyethylene glycols (Macrogols) have the advantage over the synthetic disaccharide lactulose in that they are not fermented anaerobically in the colon to gas which can distend the colon to cause pain. The osmotic laxatives are preferred to the stimulatory laxatives, which act by stimulating colonic contractility and by causing intestinal secretion. The use of irritant suppositories can be helpful in some patients with defecatory disorders. The use of enemas should be restricted to the management of elderly, infirm and immobile patients and those with neurological disorders.

Sox 6.*12* Laxatives and enemas

Bulking-forming laxatives
Dietary fibre
Wheat bran
Methylcellulose
Mucilaginous gums - sterculia
Mucilaginous seeds and seed coats, e.g. ispaghula husk

Stimulant laxatives (stimulate motility and intestinal secretion) Phenolphthalein Bisacodyl
Anthraquinones - senna and dantron (only for the terminally ill)
Docusate sodium

Osmotic laxatives
Magnesium sulphate
Lactulose
Macrogols

Suppositories
Bisacodyl
Glycerol

Enemas
Arachis oil Docusate
sodium Hypertonic
phosphate Sodium citrate

Patients with defecatory disorders should be referred to a specialist centre as surgery may be indicated for, for example, anterior rectocele or internal anal mucosal intussusception. Anterior mucosal prolapse can be treated by injection, and those with pelvic floor dyssynergia (anismus) can benefit from biofeedback therapy.

MISCELLANEOUS COLONIC CONDITIONS

Megacolon

The term 'megacolon' is used to describe a number of congenital and acquired conditions in which the colon is dilated. In many instances it is secondary to chronic constipation and in some parts of the world Chagas' disease is a common cause.

All young patients with megacolon should have Hirschsprung's disease excluded. In this disease, which presents in the first years of life, an aganglionic segment of the rectum (megarectum) gives rise to constipation and subacute obstruction. Occasionally Hirschsprung's disease affecting only a short segment of the rectum can be missed in childhood. A preliminary rectal biopsy is performed and stained with special stains for ganglion cells in the submucosal plexus. In doubtful cases full-thickness biopsy, under anaesthesia, should be obtained.

A frozen section is stained for acetylcholinesterase, which is elevated in Hirschsprung's disease. Manometric studies show failure of relaxation of the internal sphincter, which is diagnostic of Hirschsprung's disease. This disease can be successfully treated surgically.

Treatment of other causes of a megacolon is similar to that of slow-transit constipation, but saline washouts and manual removal of faeces are sometimes required.

Faecal incontinence

Seven per cent of the healthy population over the age of 65 experience incontinence at least weekly. Incontinence occurs when the intrarectal pressure exceeds the intra-anal pressure and is classified as minor (inability to control flatus or liquid stool, causing soiling) or major (frequent and inadvertent evacuation of stool of normal consistency). The common causes of incontinence are shown in Table 6.14. Obstetric injury is a common cause and sphincter defects have been found in up to 30% of primiparous women. A faecal incontinence rate of over 25% has been described and this gets more severe with increasing age. Endoanal ultrasonography with enhancing per vaginal views is the investigation of choice in the assessment of anal sphincter damage (Fig. 6.35). Neurophysiological investigation of pudendal nerve function, anal sensation and anal sphincter function may be required to elicit the cause of the problem. In the future static and dynamic pelvic magnetic resonance imaging may become the investigation of choice in faecal incontinence.

Initial management of minor incontinence is bowel habit regulation. Loperamide is the most potent antidiarrhoeal agent which also increases internal sphincter tone.

Biofeedback is effective in some patients with faecal incontinence associated with impaired function of the puborectalis muscle and the external anal sphincter. Sacral spinal nerve stimulation has been shown to be effective in the treatment of patients with a functionally deficient but morphologically intact external anal sphincter.

Surgery may be required for anal sphincter trauma and should be carried out in specialist centres.

Ischaemic disease of the colon (ischaemic colitis)

Occlusion of branches of the superior mesenteric (SMA) or inferior mesenteric arteries (IMA), often in the older age group, commonly presents with sudden onset of abdominal pain and the passage of bright red blood per rectum, with or without diarrhoea. There may be signs of shock and evidence of underlying cardiovascular disease. The majority of cases affect the splenic flexure and left colon. This condition has also been described in women taking the contraceptive pill and in patients with thrombophilia (p. 477) and small- or medium-vessel vasculitis (p. 581).

On examination the abdomen is distended and tender. A straight abdominal X-ray often shows thumb-printing

(a characteristic sign of ischaemic disease) at the site of the splenic flexure.

The differential diagnosis is of other causes of acute colitis. A rigid sigmoidoscopy (normal mucosal appearances often with presence of blood) and a gentle instant enema is preferred to colonoscopy (to avoid perforation) in cases where the diagnosis is in doubt. A barium enema should be performed when the patient recovers, to exclude the formation of a stricture at the site of disease. Patients without evidence of underlying cardiovascular disease should be screened for thrombophilia and vasculitis.

Treatment

Most patients settle on symptomatic treatment. A few develop gangrene and perforation and require urgent surgery.

Pneumatosis cystoides intestinalis

This is a rare condition in which multiple gas-filled cysts are found in the submucosa of the intestine, chiefly the colon. The cause is unknown but some cases are associated with chronic obstructive pulmonary disease. Patients are usually asymptomatic, but abdominal pain and diarrhoea do occur and occasionally the cysts rupture to produce a pneumoperitoneum. This condition is diagnosed on X-ray of the abdomen, barium enema or sigmoidoscopy when cysts are seen.

Treatment is often unnecessary but continuous oxygen therapy will help to disperse the largely nitrogen-containing cysts. Metronidazole may help.

DIVERTICULAR DISEASE

Diverticula are frequently found in the colon and occur in 50% of patients over the age of 50 years. They are most frequent in the sigmoid, but can be present over the whole colon.

The term *diverticulosis* indicates the presence of diverticula; *diverticulitis* implies that these diverticula are inflamed. It is perhaps better to use the more general term *diverticular disease,* as it is often difficult to be sure whether the diverticula are inflamed. The precise mechanism of diverticula formation is not known. There is thickening of the muscle layer and, because of high intraluminal pressures, pouches of mucosa extrude through the muscular wall through weakened areas near blood vessels to form diverticula. An alternative explanation is cholinergic denervation with increasing age which leads to hypersensitivity and increased uncoordinated muscular contraction. Diverticular disease seems to be related to the low-fibre diet eaten in developed countries.

Diverticulitis occurs when faeces obstruct the neck of the diverticulum causing stagnation and allowing bacteria to multiply and produce inflammation. This can then lead to bowel perforation (peridiverticulitis), abscess formation, fistulae into adjacent organs, or even generalized peritonitis.

Clinical features and management

Diverticular disease is asymptomatic in 95% of cases and is usually discovered incidentally on a barium enema examination. No treatment other than dietary advice is required in those patients. In symptomatic patients intermittent left iliac fossa pain or discomfort and an erratic bowel habit commonly occur. In severe disease luminal narrowing can occur in the sigmoid colon, giving rise to severer pain and constipation. In the absence of clinical signs of acute diverticulitis a barium enema is the investigation of choice (Fig. 6.36), combined with an abdominal ultrasound scan to assess bowel wall thickness and to exclude paracolic inflammatory disease. Technically it is sometimes difficult to obtain adequate views of the sigmoid region in diverticular disease and if this is the case a fibreoptic sigmoidoscopy may be required. Treatment of uncomplicated symptomatic disease is with a well-balanced *(soluble* and *insoluble,* see p. 234) fibre diet (20 g/day) with smooth muscle relaxants if required.

Acute diverticulitis

This most commonly affects diverticula in the sigmoid colon. It presents with severe pain in the left iliac fossa, often accompanied by fever and constipation. These symptoms and signs are similar to appendicitis but on the left side. On examination the patient is often febrile with a tachycardia. Abdominal examination shows tenderness, guarding and rigidity on the left side of the abdomen. A palpable tender mass is sometimes felt in the left iliac fossa.

Investigations

- **Blood tests.** A polymorphonuclear leucocytosis is often present. The ESR and CRP are raised.
- **Spiral CT of the lower abdomen** (Fig. 6.37) will show colonic wall thickening, diverticula and often pericolic collections and abscesses. There is usually a streaky increased density extending into the immediate pericolic fat with thickening of the pelvic fascial planes. These findings are diagnostic of acute diverticulitis and differ from those of malignant disease.

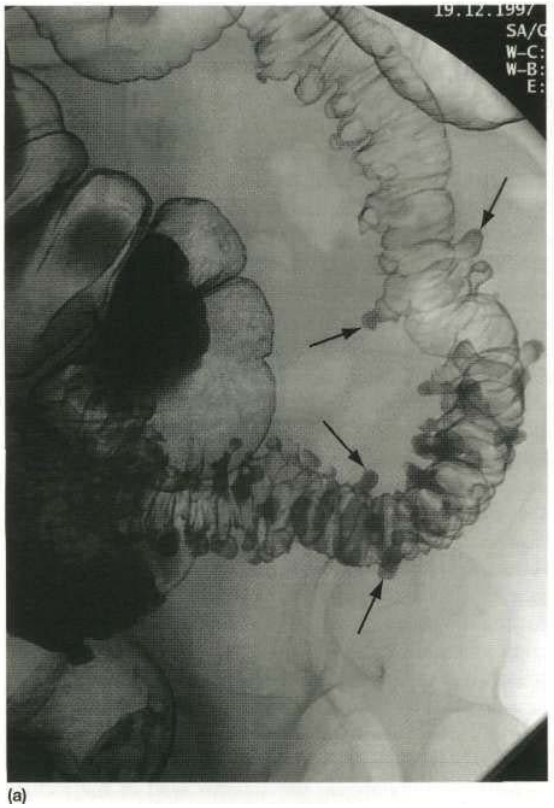
Ultrasound examination is often more readily available and is cheaper. It can demonstrate thickened bowel and large pericolic collections, but is less sensitive than CT.

Treatment

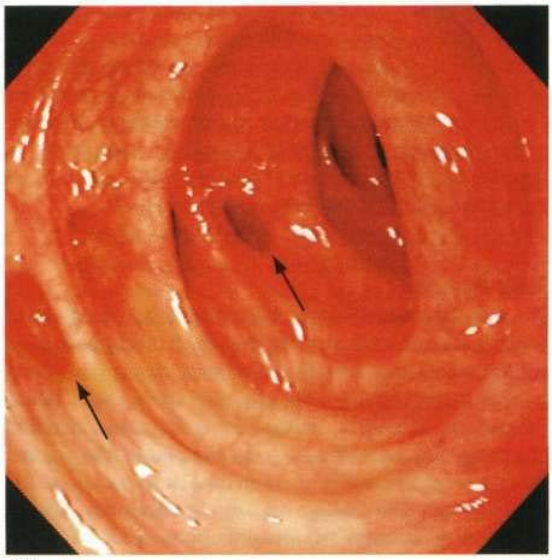
Acute attacks can be treated on an outpatient basis using a cephalosporin and metronidazole. Patients who are more ill will require admission for bowel rest, intravenous fluids and antibiotic therapy (e.g. gentamicin, or a cephalosporin) and metronidazole.

Complications of diverticular disease

- Perforation, which usually, but not always, occurs in association with acute diverticulitis, can lead to formation of a paracolic or pelvic abscess *or* generalized peritonitis. Surgery is usually required.



(a)



(b)

Fig. 6.36 Diverticular disease, (a) Double-contrast enema showing diverticular (arrows). The barium is black on these films, (b) Diverticula (arrows) seen on colonoscopy.

- Fistula formation into the bladder, causing dysuria or pneumaturia, or into the vagina, causing discharge.
- Intestinal obstruction (see p. 343) usually after repeated episodes of acute diverticulitis.

• Bleeding, which is sometimes massive. In most cases the bleeding stops and the cause of the bleeding can be established by colonoscopy and sometimes angiography. In rare cases emergency segmental colectomy is required.

- Mucosal inflammation in areas of diverticula occurs, giving the appearance of a segmental colitis at endoscopy.

Fig. 6.37 Spiral CT of lower abdomen, showing acute diverticulitis (arrow). The bowel wall is thickened and there is loss of clarity of the pericolic fat. A narrow segment of bowel is seen to the left of the diseased segment.

ANORECTAL DISORDERS

Pruritus ani

Pruritus ani, or an itchy bottom, is common. Perianal excoriation results from scratching. Usually the condition results from seepage from haemorrhoids or overactivity of sweat glands. Treatment consists of salt baths, keeping the area dry with powder; the use of all creams should be avoided. Secondary causes include threadworm *(Enterobius vermicularis)* infestation, fungal infections (e.g. candidiasis) and perianal eczema, which should be treated appropriately.

Haemorrhoids

Haemorrhoids (primary, internal, second degree, prolapsing, third degree prolapsed) usually cause rectal

bleeding, discomfort and pruritus ani. Patients may notice red blood on their toilet paper and blood on the outside of their stools. They are the most common cause of rectal bleeding (see Fig. 6.19). *Diagnosis* is made by inspection, rectal examination and proctoscopy. If symptoms are minor no treatment is required; depending on severity of symptoms, treatment is with injection of sclerosant, rubber band ligation or surgery.

Anal fissures

An anal fissure is a tear in the sensitive skin-lined lower anal canal distal to the dentate line which produces pain on defecation. It can be an isolated primary problem in young to middle-aged adults or occur in association with Crohn's disease or ulcerative colitis, in which case perianal abscesses and anal fistulae can complicate the fissure. Diagnosis can usually be made on the history alone and the fissures can be seen usually posteriorly. Rectal examination is often not possible because of pain and sphincter spasm. The spasm not only causes pain but impairs wound healing. In severe cases proctoscopy and sigmoidoscopy should be performed under anaesthesia to exclude other anorectal disease. Initial treatment is with local anaesthetic gel and stool softeners. Use of 0.2% glyceryl trinitrate and 2% diltiazem ointments are of benefit. Botulinum toxin is used in chronic fissures but lateral subcutaneous internal sphincterotomy may be required in severe cases.

Fistula in ano

Subcutaneous, low and high anal fistulae are the commonest types (Fig. 6.38). Anorectal fistulae are rarer forms. The fistulae usually present as abscesses and heal after the abscess is incised. In other cases a small discharging sinus may be noted by the patient. Endoanal ultrasonography magnetic resonance and/or examination under anaesthetic is usually required to define the primary and any secondary tracks and detect any associated disease. Management is usually surgical with approximately 90% of fistulae being laid open or excised.

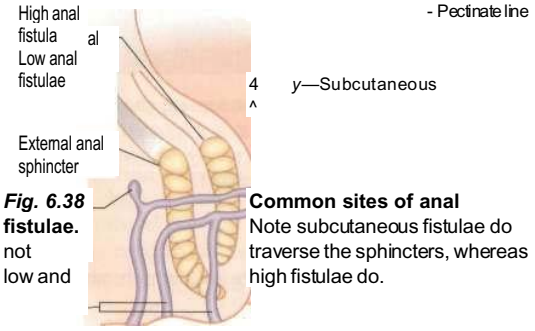

Fig. 6.38 **Common sites of anal fistulae.** Note subcutaneous fistulae do not traverse the sphincters, whereas high and low fistulae do.

Anorectal abscesses

Anorectal abscesses are a common cause of admission to hospital. They are two to three times commoner in men, particularly in homosexual men who indulge in penetrative anal sex. They may be the first manifestation of Crohn's disease, ulcerative colitis and tuberculosis. Perianal and ischiorectal abscess, the commonest forms, present with painful, tender swellings and discharge. Examination under anaesthetic, MRI and endoanal ultrasound are used for evaluation. Treatment is with surgical incision and drainage with antibiotics.

Rectal prolapse, intussusception and solitary rectal ulcer syndrome (SRUS)

All these conditions are thought to be related, with rectal prolapse being the unifying pathology. Some patients with SRUS do not have prolapse but strain excessively and ulcerate the anterior rectal wall, which is forced into the anus during futile straining efforts.

Rectal prolapse starts as an intussusception of the upper rectum which passes into the lower part of the viscus, and progression results in its protrusion through the anal canal to emerge as an external prolapse. Constipation and chronic straining are the likely causes. In addition, the presence of an intussuscepting rectum will mimic presence of stool in the rectum and lead to straining efforts to evacuate the prolapse. In some patients repeated straining leads to traumatic ulceration of the mucosa and formation of SRUS, commonly on the anterior wall of the rectum within 13 cm of the anal verge. Sometimes difficult to distinguish from cancer and Crohn's disease during endoscopic examination, SRUS has typical histological features of non-specific inflammatory changes with bands of smooth muscle extending into the lamina propria.

Patients commonly present with slight bleeding and mucus on defecation, tenesmus and sensation of anal obstruction. Asymptomatic SRUS should not be treated. Symptomatic patients should be advised to stop straining and measures taken to soften the stool. If rectal prolapse can be demonstrated during defecation, this should be repaired; in severe cases surgical treatment by resection rectopexy may be indicated. Surgical treatment for complete rectal prolapse is also required.

COLONIC TUMOURS

Colon polyps and polyposis syndromes

A polyp is an elevation above the mucosal surface. The majority of colorectal polyps are adenomas with malignant potential. Polyps range in size from a few millimetres to several centimetres in diameter. They may be single or multiple and in the polyposis syndromes hundreds may be found.

Larger polyps in the rectum and 70-80% of all polyps in the colon are adenomas, and 5% of these may contain invasive carcinoma at discovery. Most polyps are asymptomatic and found by chance when patients are investigated for pain, altered bowel habit, rectal bleeding or some other cause.

Table 6.15 Classification of colorectal polyps

Type of polyp	Pathogenesis	Polyposis syndrome
Adenoma	Neoplastic	Familial adenomatous polyposis

Metaplastic	Unknown	Metaplastic polyposis
Lymphoid	Hyperplasia	Lymphoid polyposis
Inflammatory	Inflammation	Inflammatory polyposis

Classification of colorectal polyps (Table 6.15)

Non-neoplastic polyps

Hamartomatous polyps are commonly large and stalked.

Juvenile polyps (occurring in children and teenagers) are confined mainly to the colon and histologically show mucus retention cysts. *Juvenile polyposis* (more than 10 colonic polyps) is inherited in an autosomal dominant fashion and the relevant gene has been identified (Box 6.13). The polyps are a cause of bleeding and intussusception in the first decade of life. There is also an increased risk of colonic cancer, and surveillance and removal of polyps must be undertaken.

Peutz-Jeghers syndrome is considered on page 309.

Cowden syndrome is an autosomal dominant disease associated with skin stigmata and intestinal polyps regarded as hamartomas but with a mixture of cell types. These patients have an increased risk of various extra-intestinal malignancies (thyroid, breast, uterine and ovarian).

Metaplastic polyps. These are frequently found in the rectum and sigmoid colon. These pale, sessile mucosal nodules usually measure < 5 mm and are non-neoplastic lesions without significant malignant potential. *Metaplastic polyposis* is defined as the presence of more than 10 colonic metaplastic polyps. These phenotypes are rare but appear to exhibit an increased risk of colon cancer.

Neoplastic polyps

Posrt-mortem studies have shown the incidence of adenomas to be 30^10% in western populations, and most colorectal cancers develop from sporadic adenomatous polyps. Flat adenomas, which were first described in Japan, may be difficult to detect at endoscopy (see below).

Polyps rarely produce symptoms and most are diagnosed on X-ray or on colonoscopy performed for other reasons. Large polyps (Fig. 6.39) may bleed intermittently and cause anaemia. Large sessile villous adenomas of the rectum can present with profuse diarrhoea and hypokalaemia.

Several factors influence the risk of cancer developing in an adenoma (see Box 6.14). Flat adenomas were thought to account for 10% of all adenomas but using dye spraying and extra magnification at colonoscopy, many more are being detected. The natural history is unclear but some of these flat lesions show malignant progression without any polyp formation. This increases the problem of surveillance and screening.

Once a polyp has been found it is usually possible to remove it endoscopically. The National Polyp Study conducted in the USA showed that colonoscopic polypectomy with surveillance reduced colorectal cancer incidence by 76-90%. Recent guidelines recommend a surveillance colonoscopy following polypectomy at 3 years in patients with 1-3 polyps > 1 cm. Screening at 1 year is recommended for more than 4 polyps and 5 years for small polyps < 1 cm. If any doubt exists about

the excision margins of any polyp then an earlier repeat examination is suggested.

Familial adenomatous polyposis (FAP) arises from germline mutations of the *APC* gene located on chromosome 5q and is inherited in an autosomal dominant fashion. The disease is characterized by the presence of hundreds to thousands of colorectal adenomas. The mean age of adenoma development is 16 years, whereas the average age for developing colorectal cancer is 39 years. Tracing and screening of relatives is essential (usually after 12 years of age) and affected individuals should be offered a prophylactic colectomy, often before the age of 20. Surgical options include colectomy and ileorectal anastomosis, which requires life-long surveillance of the rectal stump or a restorative proctocolectomy or pouch procedure.

Attenuated FAP may be missed as it presents in later life (44 years average age) and has fewer polyps (< 100), which tend to occur more on the right side of the colon than on the left; it may be indistinguishable from sporadic cases but the gene mutation is in the *APC* germ line. A recessive form of FAP has recently been described due to a mutation in the MutY homologue *(MUTYH)* gene in a patient with multiple colonic adenomas.

Gastric fundic gland polyps and duodenal adenomas are frequently found in FAP, as well as other extra-intestinal lesions such as osteomas, epidermoid cysts and desmoid tumours. *Congenital hypertrophy of the retinal pigment epithelium* (CHRPE) occurs in many families with FAP. Other cancers that are observed in FAP include thyroid, pancreatic and hepatoblastomas.

APC gene mutations can be found on screening in about 80% of families with FAP. Once the disease-causing mutation has been identified in an index case known to have FAP, other family members can be tested for the mutation and screening can then be directed at mutation carriers. If a mutation cannot be found in a known FAP case, then all family members should undergo clinical screening with regular endoscopy.

Colorectal carcinoma

Colorectal cancer (CRC) is the second most common cause of cancer death in the UK. Each year over 30 000 new cases are diagnosed in England and Wales (68% colon, 32% rectal cancer) and it is registered as the underlying cause of death in about half this number. The prevalence rate per 100 000 (all ages) is 53.5 for men and 36.7 for women. The incidence increases with age, the average age at diagnosis being 60-65 years. The disease is much more common in westernized countries than in Asia or Africa. Increased risk:

- Western diets are low in dietary fibre which increase faecal bulk and reduce transit time.
- Fat and meat consumption correlates with risk of CRC.

Decreased risk:

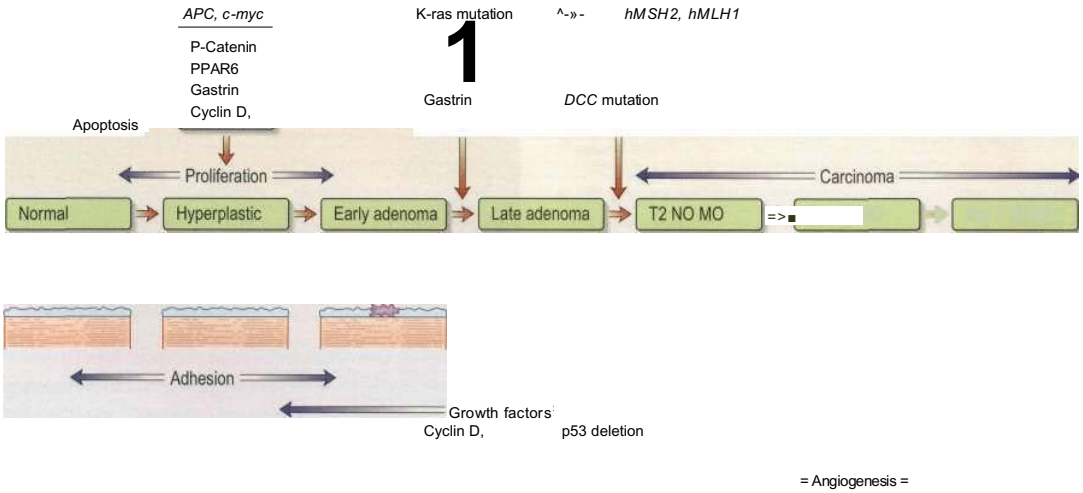
- Fruit and vegetables consumption has a protective effect.
- Increase fibre intake in the diet.
- Exercise reduces the risk of CRC.
- Aspirin and other NSAIDs reduce the risk of develop ing both adenomas and cancers.
- Hormone-replacement therapy (combined oestrogen and progesterone) may reduce the risk of colorectal cancer.

Genetics

Most colorectal cancers develop as a result of a stepwise progression from normal mucosa to adenoma to invasive cancer. This progression is controlled by the accumulation of alterations or mutations in a number of critical growth-regulating genes. Germline mutations of the *APC* gene are responsible for FAP (see above), but inactivation of this tumour suppressor gene and (J-catenin (a transcription activator) is also seen in up to 70% of sporadic colorectal cancers. A cytoplasmic complex consisting of the APC protein, f3-catenin, connexon/axin and glycogen synthase kinase-3P (GSK-3J3) ensures the tight control of fi-catenin. GSK-3|3 is a serine-threonine kinase which destroys (3-catenin. Other factors which regulate fi-catenin include cyclin Dj, gastrin and peroxisome, proliferator-activated receptor |3 (PPARJ3) which mediates transcription of prostaglandins and fatty acids. Inactivation of *APC* appears to occur at an early stage in the development of an adenoma, which has led to it being described as a 'gatekeeper' gene. The sequence is usually followed by K-ras mutations which appear to facilitate the growth of adenomatous tissue and then by *DCC* (deleted in colon cancer) and *p53* gene mutations which occur around the adenoma-carcinoma transition (Fig. 6.40). The exact order of these mutations may vary. Around 15% of sporadic colorectal cancers appear to follow a different pathway. In these there are insertions or deletions of nucleotides within repeated sequences *of DNA* - rnicrosafeMife *instability* (MSI) due to defective repair of mismatched nucleotides. Sporadic rumours with MSI tend to occur on the right side of the colon, have greater lymphocytic infiltration and are often poorly differentiated. MSI seems to be associated with increased survival. Revised Bethesda guidelines for patients who should be tested for MSI are available.

Cancer families

A family history of colon cancer confers an increased risk to relatives. Family history is, next to age, the most common risk factor for colon cancer. FAP (Fig. 6.41) is the best-recognized syndrome predisposing to colorectal cancer but represents less than 1% of all colorectal cancers. *Hereditary non-polyposis colorectal cancer* (HNPCC) arises from germline mutations in any one of five mismatch repair (MMR) genes. Mutations in two of these, *hMLHl* and *hMSH2,* account for > 95% of HNPCC families. Mutations in these genes lead to genomic instability in the tumours of affected individuals. Other cancers frequently occur in HNPCC, including endo-metrial, gastric, biliary tract, urinary tract, ovarian and small bowel malignancies. Diagnostic criteria, based on family history, were devised to help identify those affected and have subsequently been modified to include non-colonic tumours (Box 6.15).



F/cy. 6.40 Genetic model for colorectal tumorigenesis, showing the progression from adenoma to carcinoma. The stages are shown at which mutations occur in the genes: *APC* (adenomatous poiyposis coli), K-ras, *DCC, p53, hMSH2,* and *hMLHL*

Patients with HNPCC tend to develop right-sided cancers at an early age, and regular surveillance with colonoscopy is recommended.

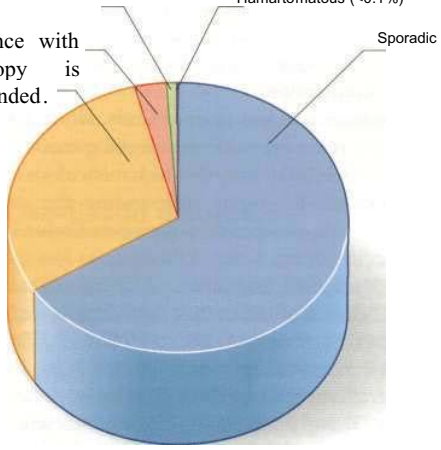


***Fig. 6.41* Percentages of colon cancer according to family risk.** HNPCC, hereditary non-polyposis colorectal cancer; FAR familial adenomatous poiyposis.

©

***Box 6.15* Modified Amsterdam Criteria for hereditary non-polyposis colorectal cancer**

There are more cases of colorectal cancer in a minimum of two generations.
One affected individual must be a first-degree relative of the other two (or more) cases.
One case must be diagnosed at age < 50.
Colorectal cancer can be replaced by endometrial or small bowel cancer.
Familial adenomatous poiyposis (FAP) should be excluded.
Tumours should be verified by pathological examination.

In addition to the above syndromes are some colon cancers that arise, at least in part, from an inherited predisposition, so-called *familial risk* (Table 6.16). Estimates of their frequency range from 10% to 30% of all CRC but the genes involved have yet to be identified. The risk of CRC can be estimated from a careful family history matched with empirical risk tables so that appropriate advice regarding screening can then be offered.

Most colorectal cancers are, however, sporadic and occur in individuals without a strong family history. Approximately half these familial cancers arise in the rectosigmoid area (Fig. 6.42) but there is evidence to suggest that there is an increase in right-sided tumours.

Pathology

CRC, which is usually a polypoid mass with ulceration, spreads by direct infiltration through the bowel wall. It involves lymphatics and blood vessels with subsequent spread, most commonly to the liver. Synchronous tumours are present in 2% of cases. *Histology* is adenocarcinoma with moderately to well differentiated glandular epithelium with mucin production. 'Signet ring' cells in which mucin displaces the nucleus to the side of the cell are characteristic.

Clinical features

Alteration in bowel habit, with or without abdominal pain, is a common symptom of left-sided colonic lesions.

***Table 6.16* Lifetime risk of colorectal cancer in first-degree relatives of a patient with colorectal cancer**

Population risk	1 in 50
One first-degree relative affected (any age)	1 in 17
One first-degree and one second-degree relative affected	1 in 12
One first-degree relative affected (age < 45)	1 in **10**
Two first-degree relatives affected	1 in 6
Autosomal dominant pedigree	1 in 2

Houlston et al. (1990) *British Medical Journal* **301**: 366-368

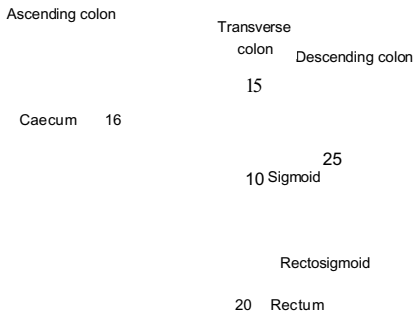

Fig. 6.42 **Distribution of sporadic colorectal cancer.** Only 60% are in the range of flexible sigmoidoscopy.

Rectal and sigmoid cancers often bleed, blood being mixed in with the stool. Cancers arising in the caecum and right colon are often asymptomatic and present as an iron deficiency anaemia. The elderly often present with intestinal obstruction.

Patients aged greater than 35-40 presenting with new large bowel symptoms should be investigated. *The alarm symptoms,* suggestive of colorectal cancer, include change in bowel habit, rectal bleeding, anorexia and weight loss, faecal incontinence, tenesmus and passing mucus per rectum.

Examination is usually unhelpful but a mass may be palpable. Hepatomegaly may be found with liver metastases. Digital examination of the rectum is essential and rigid sigmoidoscopy should be performed in all cases.

Investigations

- **Blood count and routine biochemistry.**
- **Serum carcinoembryonic antigen** level is related to outcome.
- **Colonoscopy** (Fig. 6.43) is the gold standard for investigation and allows biopsies and polypectomies to obtain specimens for histological examination.
- **Double-contrast barium enema** can visualize the large bowel but is now being superseded by CT pneumocolon.
- **Endoanal ultrasound and pelvic MRI** are used for staging rectal cancer.
- CT **and PET scanning** (p. 270) help to evaluate tumour size, local and secondary spread and hepatic metastases.

Faecal occult blood tests have been used for mass screening but are of no value in hospital practice.

Treatment

This should involve multidisciplinary teams working in designated centres. About 80% of patients with colorectal cancer undergo surgery, though fewer than half survive more than 5 years. The operative procedure depends on the cancer site and long-term survival relates to the stage

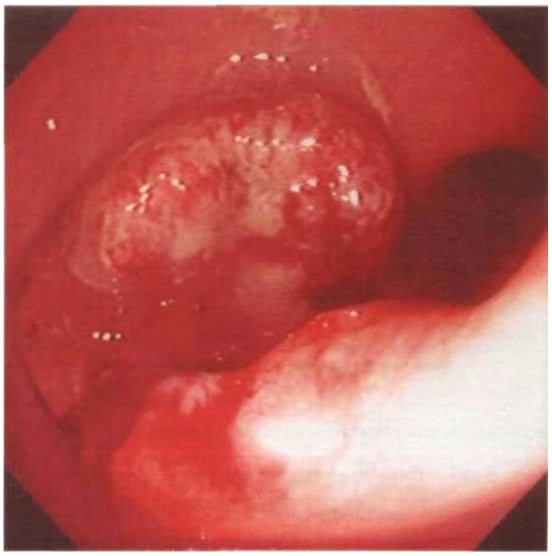

Fig. 6.43 **Colonoscopic appearance of a carcinoma in the ascending colon** - a large irregular ulcer. Courtesy of DrPD Fairclough.

of the primary tumour and the presence of metastatic disease (see Table 6.17). There has been a gradual move from using Dukes' classification to using the TNM classification system.

Long-term survival is only likely when the cancer is completely removed. Total mesorectal excision (TME) is an approach to rectal surgery in which meticulous care is taken to remove all the tissue surrounding the cancer. TME combined with preoperative chemo-radiotherapy reduces local recurrence rates in rectal cancer to less than 5% and improves survival. Radiotherapy for colonic cancers is not helpful because of difficulties delivering a sufficient dose without excess toxicity to the small bowel. Adjuvant post-operative chemotherapy will improve disease-free survival and overall survival in stage III (Dukes' C) colon cancer (p. 331). Those with Duke's B tumours with advanced features such as vascular invasion may also benefit.

Advanced colorectal cancer treatment is discussed on p. 521.

Follow-up

All patients who have surgery should have a colonoscopy performed before (or soon afterwards) to look for additional lesions. Patients with stage II or III disease should have serum carcinoembryonic antigen (CEA) measured every 3 months and colonoscopy every 3 years.

Prevention and screening

Healthcare agencies advocate a low-fat, high-fibre diet for the prevention of sporadic colorectal cancer, and endoscopic screening is a recommendation for high-risk patients with inherited syndromes (e.g. FAP, HNPCC). NSAIDs or aspirin may play a role in prevention. Faecal occult blood (FOB) tests have been studied as a screening test for

Table 6.17 **Staging and survival of colorectal cancers**

TNM classification			Modified Dukes' classification	5-Year survival (%)
Stage I (NO, MO)	Tumours invade submucosa Tumours invade muscularis propria	T1 T2		80-95 72-
Stage MA (NO, MO)	Tumours invade into subserosa	T3		85
MB	Tumours invade directly into other organs		T4	65-66 55-
Stage III (MO)	T1, T2 + 1-3 regional lymph nodes involved		N1	65
1MB	T3, T4 + 1-3 regional lymph nodes involved		NC D	35-42 25-
NIC	Any T + 4 or more regional lymph nodes		N	27
Stage IV	Any T, any N + distant metastases	M1		5-7

colorectal cancer. Several large randomized studies have demonstrated a reduction in cancer-related mortality of 15-33%. The disadvantage of screening with FOB is its relatively low sensitivity, which means many unnecessary colonoscopies. In a recent study of those who screened positive, 11.5% had cancer and 16.8% had large adenomas.

A once-only flexible sigmoidoscopy at 55-65 years has been shown to reduce overall CRC mortality by a third and is recommended in the USA. A multicentre trial of this strategy has been undertaken in the UK. Initial results suggest that such a screening regimen is acceptable, feasible and safe.

Colonoscopy is the gold-standard technique for the examination of the colon and rectum and is the investigation of choice for high-risk patients. Its expense, the need for full bowel preparation and sedation, and the small risk of perforation obviate its use as a population screening tool at present, though trials are underway in the USA. CT colonoscopy (or 'virtual colonoscopy') and the refinement of genetic testing may contribute to screening programmes. Universal screening strategies have been recommended in the USA. There are two large-scale pilot studies of FOB screening in the UK at present and it is anticipated that some form of colorectal screening will be introduced in the NHS in due

DIARRHOEA

Diarrhoea is a common clinical problem and there is no uniformly accepted definition of diarrhoea. Organic causes (stool weights > 250 g per day) have to be distinguished from 'functional causes', and is the first step in the assessment of the history. Sudden onset of bowel frequency associated with crampy abdominal pains, and a fever will point to an infective cause; bowel frequency with loose blood-stained stools to an inflammatory basis; and the passage of pale offensive stools that float, often accompanied by loss of appetite and weight loss, to steatorrhoea. Nocturnal bowel frequency and urgency usually point to an organic cause. Passage of frequent small-volume stools (often formed) points to a functional cause (see Functional gastrointestinal disorders, p. 335).

Mechanisms

Osmotic diarrhoea

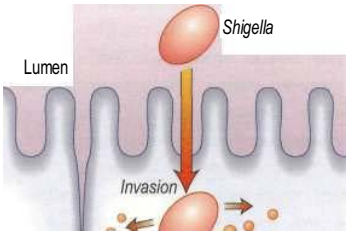
The gut mucosa acts as a semipermeable membrane and fluid enters the bowel if there are large quantities of non-absorbed hypertonic substances in the lumen. This occurs because:

- the patient has ingested a non-absorbable substance (e.g. a purgative such as magnesium sulphate or magnesium-containing antacid)
- the patient has generalized malabsorption so that high concentrations of solute (e.g. glucose) remain in the lumen
- the patient has a specific absorptive defect (e.g. disaccharidase deficiency or glucose-galactose malabsorption).

The volume of diarrhoea produced by these mechanisms is reduced by the absorption of fluid by the ileum and colon. The diarrhoea stops when the patient stops eating or the malabsorptive substance is discontinued.

Secretory diarrhoea

In this disorder, there is both active intestinal secretion of fluid and electrolytes as well as decreased absorption. The mechanism of intestinal secretion is shown in Figure 6.44a.



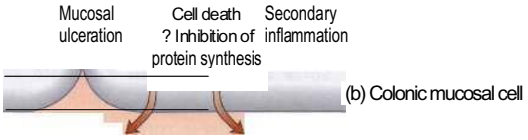


Fig. 6.44 **Mechanisms of diarrhoea.**
(a) Small intestinal secretion of water and electrolytes.

- *Cholera toxin* binds to its receptor (monosialoganglioside G,) via fimbria (toxin co-regulated pilus) on its fj subunit. This activates the a_s subunit (of the G_s protein), which in turn dissociates and activates cyclic AMP (cAMP). The increase in cAMP activates intermediates (e.g. protein kinase and Ca^{2+}) which then act on the apical membrane causing Cr secretion (with water) and inhibition of Na^+ and CI" absorption.
- *E. coli.* Heat-labile *E. coli* enterotoxin shares a receptor with cholera toxin. Heat-stable (HS) *E. coli* toxin binds to its own receptor and activates guanylate cyclase (cGMP), producing the same effect on secretion.
- *C. difficile* activates the protein kinases via $Ca^2$7calmodulin ($Ca^2$7CM).
- *Zona occludens toxin*. This toxin is the product of the *ZOT* gene, which is the gene required for the *CTX* gene which encodes for cholera toxin. It has enterotoxic activity, producing secretion.

Cholera and *E. coli* cause these effects without invasion of the cell. G, G protein consisting of subunits a, p, y; i, inhibitory; s, stimulatory; ATP, adenosine triphosphate; GTP, guanosine triphosphate; GMP, guanosine monophosphate; GC, guanyl cyclase; PKC, protein kinase C; VIP, vasoactive intestinal polypeptide.
(b) **Colonic mucosal cell.** This demonstrates one of the mechanisms by which an invasive pathogen (e.g. *Shigella)* acts. Following penetration, the pathogens generate cytotoxins which lead to mucosal ulceration and cell death.

Common causes of secretory diarrhoea are:

enterotoxins (e.g. cholera, E. *coli* - thermolabile or thermostable toxin)
hormones (e.g. vasoactive intestinal peptide in the Verner—Morrison syndrome, p. 416)
bile salts (in the colon) following ileal resection
fatty acids (in the colon) following ileal resection
some laxatives (e.g. docusate sodium).

Inflammatory diarrhoea (mucosal destruction)

Diarrhoea occurs because of damage to the intestinal mucosal cell so that there is a loss of fluid and blood (Fig. 6.44b). In addition, there is defective absorption of fluid and electrolytes. Common causes are infective conditions (e.g. dysentery due to *Shigella),* and inflammatory conditions (e.g. ulcerative colitis and Crohn's disease).

Abnormal motility

Diabetic, post-vagotomy and hyperthyroid diarrhoea are all due to abnormal motility of the upper gut. In many of these cases the volume and weight of the stool is not all that high, but frequency of defecation occurs; this therefore is not true diarrhoea.

Causes of diarrhoea are shown in Table 6.18. It should be noted that the irritable bowel syndrome, colorectal cancer, diverticular disease and faecal impaction with overflow in the elderly do not cause 'true' organic diarrhoea (i.e. > 250 g/day), even though the patients may complain of diarrhoea. World-wide, infection and infestation are a major problem and these are discussed under the causative organisms in Chapter 2.

Acute diarrhoea (excluding cholera, discussed on P_67) _____

Diarrhoea of sudden onset is very common, often short-lived and requires no investigation or treatment. This type of diarrhoea is seen after dietary indiscretions, but diarrhoea due to viral agents also lasts 24^8 hours (see p. 51). The causes of other infective diarrhoeas are shown on page 61. Travellers' diarrhoea, which affects people travelling outside their own countries, particularly to developing countries, usually lasts 2-5 days; it is discussed on page 70. Clinical features associated with the acute diarrhoeas include fever, abdominal pain and vomiting. If the diarrhoea is particularly severe, dehydration can be a problem; the very young and very old are at special risk from this. Investigations are necessary if the diarrhoea has lasted more than 1 week. Stools (up to three) should be sent immediately to the laboratory for culture and examination for ova, cysts and parasites. If the diagnosis has still not been made, a sigmoidoscopy and rectal biopsy should be performed and radiological studies should be considered.

Oral fluid and electrolyte replacement is of prime importance in the treatment. Special oral rehydration solutions (e.g. sodium chloride and glucose powder) are available for use in severe episodes of diarrhoea, particularly in infants. Antidiarrhoeal drugs are thought to impair the clearance of any pathogen from the bowel but may be necessary for short-term relief (e.g. codeine phosphate 30 mg four times daily, or loperamide 2 mg three times daily). Antibiotics are sometimes given (see p. 71) depending on the organism.

Table 6.18 **Causes of diarrhoea**

Infective causes
Bacterial, e.g.
- *Campylobacter jejuni*
- *Salmonella* sp.
- *Shigella*
- *Escherichia coli* (particularly enterohaemorrhagic *E. coli* 0157:H7)
- Staphylococcal enterocolitis
- *Bacillus cereus*
- *Clostridium perfringens*
- *Clostridium botulinum*
- gastrointestinal tuberculosis

Viral, e.g.
- rotavirus

Fungal, e.g.
- histoplasmosis

Parasitic, e.g.
- amoebic dysentery *(Entamoeba histolytica)*
- schistosomiasis
- *Giardia intestinalis*

Non-infective causes of diarrhoea
Inflammatory bowel disease
Pseudomembranous colitis
Radiation proctitis or colitis
Behcet's disease
Diverticular disease
Ischaemic colitis
Gastrointestinal lymphoma
Carcinoma of the colon (change in bowel habit)
Malabsorption
Gut resection
Bile acid malabsorption
Drugs - many, including
- laxatives
- metformin
- anticancer drugs Faecal impaction with overflow

Irritable bowel syndrome and functional diarrhoea

Endocrine
Zollinger—Ellison syndrome
Vipoma
Somatostatinoma
Glucagonoma
Carcinoid syndrome
Thyrotoxicosis
Medullary carcinoma of thyroid
Diabetic autonomic neuropathy

Factitious diarrhoea (4%)
Purgative abuse
Dilutional diarrhoea

Chronic diarrhoea

This always needs investigation. All patients should have a sigmoidoscopy and rectal biopsy. The flow diagram in Figure 6.45 is illustrative; whether the large or the small bowel is investigated first will depend on the clinical story of, for example, bloody diarrhoea or steatorrhoea. The investigations and treatment are described in detail under the individual diseases.

When difficulties exist in distinguishing between functional and organic causes of diarrhoea, hospital admission for a formal 72-hour assessment of stool weights is helpful and will also lead to the diagnosis of factitious causes of diarrhoea.

Antibiotic-associated diarrhoea (pseudomembranous colitis) (see p. 69)

Pseudomembranous colitis may develop following the use of any antibiotic. Diarrhoea occurs in the first few

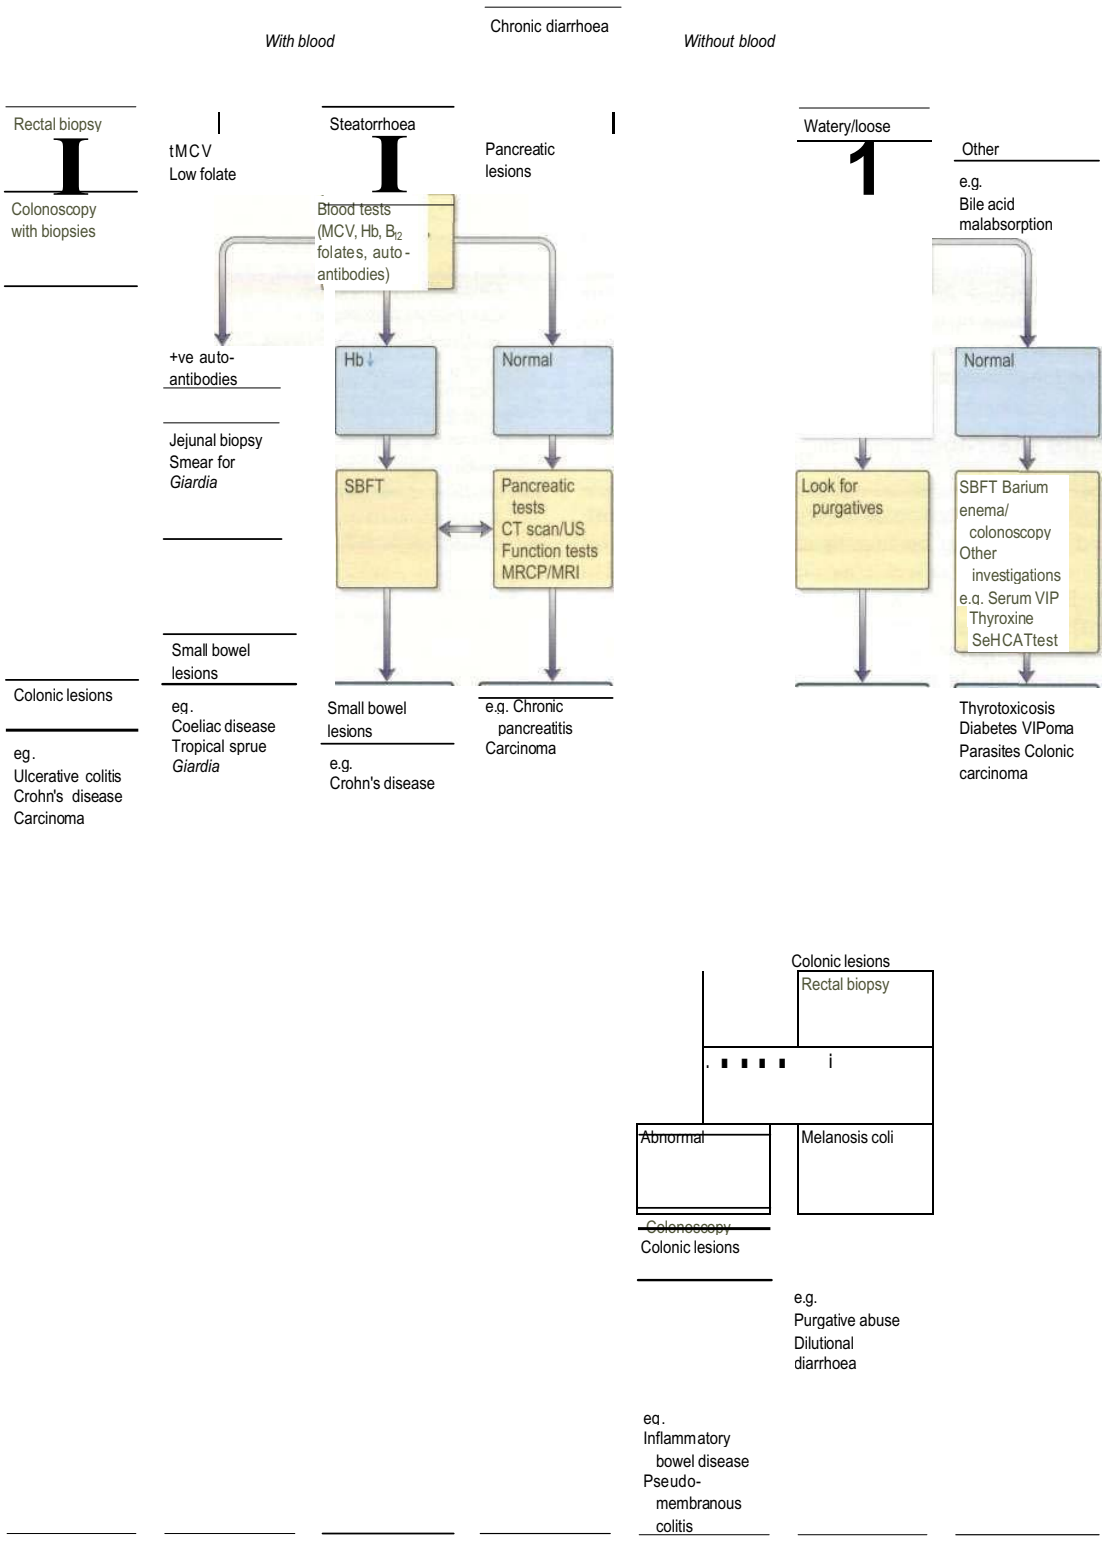

Fig. 6.45 **Flow diagram for the investigation of chronic diarrhoea.** NB: All patients should have had stool cultures. SBFT, small bowel follow-through; VIP, vasoactive intestinal polypeptide; ERCP, endoscopic retrograde cholangiopancreatography; SeHCAT, ^{75}Se-homochoyl taurine.

days after taking the antibiotic or even up to 6 weeks after stopping the drug. The causative agent is *Clostridium difficile* (p. 69).

Bile acid malabsorption

Diagnosis is made using the SeHCAT test in which a radiolabelled bile acid analogue is administered and percentage retention at 7 days calculated (< 19% retention abnormal). Treatment is with colestyramine, a resin which binds and inactivates the action of bile acids in the

Bile acid malabsorption is an underdiagnosed cause of chronic diarrhoea and many patients with this disorder are assumed to have irritable bowel syndrome. Bile acid diarrhoea occurs when the terminal ileum fails to reabsorb bile acids. Bile acids (particularly the dihydroxy bile acids - deoxycholate and chenodeoxycholate) when present in increased concentrations in the colon lead to diarrhoea by reducing absorption of water and electrolytes and, at higher concentrations, inducing secretion as well as increasing colonic motility. A variety of causes of bile acid malabsorption are recognized (Table 6.19).

Bile acid malabsorption should be considered not only in patients with chronic diarrhoea of unknown cause but also in patients with diarrhoea and associated disease who are not responding to standard therapy (e.g. patients with terminal ileal Crohn's disease, microscopic inflammatory colitis).

Table 6.19 **Causes of bile acid malabsorption**

- Increased small intestinal transit
- Ileal resection
- Ileal disease, e.g. active or inactive Crohn's disease
- Idiopathic or primary bile acid malabsorption (structurally normal ileum)
- Postinfective gastroenteritis
- Associated with:
  - post-cholecystectomy diarrhoea
  - diabetic diarrhoea
  - post-vagotomy diarrhoea
  - chronic pancreatitis
  - cystic fibrosis
  - coeliac disease
  - microscopic inflammatory colitis
  - drugs (e.g. colchicine, metformin)

colon. The best results of treatment are obtained in patients with a SeHCAT retention of < 5%.

Factitious diarrhoea

Factitious diarrhoea accounts for up to 4% of new patients with diarrhoea attending gastroenterology clinics.

Purgative abuse

This is most commonly seen in females who surreptitiously take high-dose purgatives and are often extensively investigated for chronic diarrhoea. The diarrhoea is usually of high volume (> 1 L daily) and patients may have a low serum potassium. Sigmoidoscopy may show pigmented mucosa, a condition known as melanosis coli. Histologically the rectal biopsy shows pigment-laden macrophages in patients taking an anthraquinone purgative (e.g. senna). Melanosis coli is also seen in people regularly taking purgatives in normal doses.

In advanced cases a barium enema may show a dilated colon and loss of haustral pattern.

Phenolphthalein laxatives can be detected by pouring an alkali (e.g. sodium hydroxide) on the stools, which then turn pink; a magnesium-containing purgative will give a high faecal magnesium content. Anthraquinones can also be measured in the urine. If the diagnosis is suspected, a locker or bed search (while the patient is out of the ward) is occasionally necessary. Management is difficult as most patients deny purgative ingestion. Purgative abuse often occurs in association with eating disorders and all patients needs psychiatric help.

Dilutional diarrhoea

In this condition raised stool weights occur as a consequence of patients deliberately diluting their stool with urine or tap water. The diagnosis is made by measuring stool osmolality and electrolyte concentrations in order to calculate the faecal osmolar gap. Measurement of stool creatinine content is helpful in excluding dilution of stools with urine, and early admission to hospital for formal assessment of stool weights may avoid unnecessary invasive investigations being carried out.

Diarrhoea in patients with HIV Infection

Chronic diarrhoea is a common symptom in HIV infection, but HIV's role in the pathogenesis of diarrhoea is unclear. *Cn/ptosporidium* (see p. 105) is the pathogen most commonly isolated. *Isospora belli* and microsporidia have also been found.

The cause of the diarrhoea is often not found and treatment is symptomatic. Table 6.20 shows the conditions affecting the gastrointestinal tract in patients with AIDS.

Table 6.20 Gastrointestinal problems in patients with AIDS

Site	Symptoms	Causes
Mouth/ oesophagus	Dysphagia Candidiasis Retrosternal discomfort Oral ulceration	Herpes simplex virus (HSV) Cytomegalovirus (CMV)
Small bowel/ colon	Chronic diarrhoea Steatorrhoea Weight loss	Parasites: *Entamoeba histolytica* *Giardia intestinalis* *Cryptosporidium* *Blastocystis hominis* *Isospora belli* Microsporidia *Cydospora cayetanensis* Viruses: CMV/HSV, adenovirus Bacteria: *Salmonella* *Campylobacter* *Shigella* *Mycobacterium avium-intracellulare* Non-infective enteropathy - cause unknown
Rectum/ colon	Bloody diarrhoea	Bacterial infection (e.g. *Shigella)*
Any	Weight loss Diarrhoea	Neoplasia: Kaposi's sarcoma Lymphoma Squamous carcinoma Infection - disseminated, e.g. *Mycobacterium avium-intracellulare* HAART therapy

FUNCTIONAL GASTROINTESTINAL DISORDERS I

There is a large group of gastrointestinal disorders that are termed 'functional' because symptoms occur in the absence of any demonstrable abnormalities in the digestion and absorption of nutrients, fluid and electrolytes and no structural abnormality can be identified in the gastrointestinal tract.

Table 6.21 lists some of the symptoms that are suggestive of a functional gastrointestinal disorder; modern classification systems (e.g. Rome II 1999, p. 338) are based on the premise that for each disorder there is a symptom cluster that 'breeds true' across clinical and population groups. There is inevitably overlap, with some symptoms being common to more than one disorder.

Table 6.21 Chronic gastrointestinal symptoms suggestive of a functional gastrointestinal disorder (FGID)

Nausea alone
Vomiting alone
Belching
Chest pain unrelated to exercise
Postprandial fullness
Abdominal bloating
Abdominal discomfort/pain (right or left iliac fossa)
Passage of mucus per rectum
Frequent bowel actions with urgency first thing in morning

Table 6.22 Common functional gastrointestinal disorders

Functional oesophageal disorders
Globus
Rumination syndrome
Chest pain of presumed oesophageal origin
Functional gastroduodenal disorders
Functional dyspepsia
Aerophagia
Vomiting
Functional bowel disorders
Irritable bowel syndrome (IBS)
Pain/gas/bloat syndrome
Functional diarrhoea

Table 6.22 lists the common functional gastrointestinal disorders. These conditions are extremely common world-wide, making up to 80% of patients seen in the gastroenterology clinic.

Pathophysiology and brain-gut interactions

People with functional gastrointestinal disorders (FGID), are characterized by having a greater gastrointestinal motility response to life events than normal subjects. There is, however, a poor association between measured gastrointestinal motility changes and pain in many of the FGIDs. Patients with FGID have been shown to have abnormalities in visceral sensation and have a lower pain threshold when tested with balloon distension (visceral hyperalgesia). Visceral hypersensitivity possibly relates to:

- altered receptor sensitivity at the viscus itself
- increased excitability of the spinal cord dorsal horn neurones
- altered central modulation of sensations.

Symptoms are likely to be generated as a consequence of disturbed gastrointestinal motility that leads to distension with visceral hyperalgesia accentuating the pain. In a group of patients who developed IBS symptoms following an acute enteric infection, inflammatory changes were demonstrated in the enteric mucosa with serotonin-producing enteroendocrine cell hyperplasia, the excessive release of serotonin being thought to contribute to symptom development.

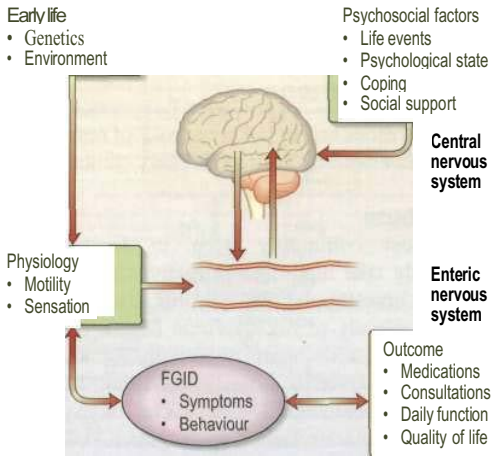

***Fig. 6.46* A biopsychosocial conceptualization of the pathogenesis and clinical expression of functional gastrointestinal disorders (FGID),** showing how genetic, environmental and psychological factors may interact to cause dysregulation of brain-gut function. Modified from *Gut* 45 (Suppl.) 1999.

The brain-gut axis describes a combination of intestinal motor, sensory and CNS activities (Fig. 6.46). Thus extrinsic (e.g. vision, smell) and intrinsic (e.g., emotion, thought) information can affect gastrointestinal sensation because of the neural connections from higher centres. Conversely, viscerotropic events can affect central pain perception, mood and behaviour.

Psychological stress can exacerbate gastrointestinal symptoms, and psychological disturbances are more common in patients with FGIDs. These disturbances alter attitude to illness, promote healthcare seeking, and often lead to a poor clinical outcome. They have psychosocial consequences with poor quality of life at home and work. Early in life, genetic and environmental influences (e.g. family attitudes towards bowel training, verbal or sexual abuse, exposure to an infection) may affect psychosocial development (susceptibility to life stress, psychological state, coping skills, development of social support) or the development of gut dysfunction (abnormal motility or visceral hypersensitivity).

FGID should be regarded as a dysregulation of brain-gut function.

FUNCTIONAL OESOPHAGEAL DISORDERS

The criteria for diagnosis rest mainly on compatible symptoms. However, *pathological gastro-oesophageal reflux and other causes may need full investigation,* particularly in the elderly with a short history.

Globus

Diagnostic criteria

- Persistent or intermittent sensation of a lump or foreign body in the throat.
- Occurrence of the sensation between meals.
- The absence of dysphagia and pain on swallowing (odynophagia).

Treatment

Reassurance and a trial of antireflux therapy are the mainstays of treatment.

Rumination syndrome

Diagnostic criteria

- Persistent or recurrent effortless regurgitation of recently ingested food into the mouth with subsequent re-mastication and re-swallowing.
- Absence of nausea and vomiting, abdominal discomfort, heartburn.
- Cessation of the process when the regurgitated material becomes acidic.

Central factors contribute significantly to the occurrence of rumination, and the disorder is common in individuals with learning difficulties. A range of medical, behavioural and nutritional approaches have been attempted in these patients, with varying success.

Functional chest pain, of presumed oesophageal origin

This is characterized by episodes of mainly midline chest pain, not burning in nature, that are potentially of oesophageal origin and which occur in the absence of a cardiological cause, gastro-oesophageal reflux and achalasia.

More than half of patients will respond to high-dose acid-suppression therapy in the first week; some will respond to nitrates and calcium-channel blockers. A history of psychiatric disorder is found in more than 60% of patients and low-dose antidepressant therapy, e.g. amitriptyline 10 mg, has been shown to be effective.

FUNCTIONAL GASTRODUODENAL DISORDERS

Functional dyspepsia

This is the second most common functional gastrointestinal disorder (after irritable bowel syndrome). Patients can present with a spectrum of symptoms including upper abdominal pain/discomfort, fullness, early satiety, bloating and nausea.

These patients have no structural abnormality as an explanation for their symptoms.

Functional dyspepsia subgroups

Two subgroups based on the predominant (or most bothersome) single symptoms are suggested:

- *Ulcer-like dyspepsia* with pain centred in the upper abdomen as the predominant (most bothersome) symptom.
- *Dysmotility-like dyspepsia* with an unpleasant or troublesome non-painful sensation (discomfort) centred in the upper abdomen being the predominant symptom. This sensation may be associated with upper abdominal fullness, early satiety, bloating and nausea.

There is considerable overlap between these two groups.

Investigations

Many young patients (< 50) require no investigation. Older patients or those with alarm symptoms require endoscopy (p. 265). Gastroscopy often shows gastritis but whether this is the cause of the symptoms is doubtful.

Treatment

The range of therapies prescribed for functional dyspepsia reflects the uncertain pathogenesis and the lack of satisfactory treatment options. Management is further confounded by high placebo response rates (20-60%). A proportion of patients will respond satisfactorily to reassurance, explanations and lifestyle changes, but antisecretory or prokinetic agents are used for patients with ulcer-like and dysmotility-like dyspepsia respectively. Reducing intake of fat, coffee, alcohol and cigarette smoking may help.

H. pylori eradication therapy is often used in functional dyspepsia but there is little evidence to recommend its use. Most gastroenterologists usually try such therapy if only for its possible long-term benefit.

In one study omeprazole produced symptomatic relief in patients with *H. pylori* and did not help *H. pylori-negative* patients.

Aerophagia

Aerophagia refers to a repetitive pattern of swallowing or ingesting air and belching. It is usually an unconscious act unrelated to meals. Usually no investigation is required. Explanation that the symptoms are due to swallowed air and reassurance are necessary, as is treatment of associated psychiatric disease.

Functional vomiting

Functional vomiting is a rare condition in clinical practice. Chronic nausea is a frequent accompaniment in all functional gastrointestinal disorders. Clinically functional vomiting is characterized by:

- frequent episodes of vomiting, occurring on at least 3 separate days in a week
- absence of criteria for an eating disorder, rumination, or major psychiatric disease

- absence of self-induced and medication-induced vomiting
- absence of abnormalities in the gut or central nervous system and metabolic disease to explain the recurrent vomiting.

Investigation is often not required but always exclude non-GI disorders (Table 6.1).

Treatment is with anti-nausea drugs and anti-depressants; behavioural and psychotherapy are helpful. Dietary changes occasionally help.

FUNCTIONAL BOWEL DISORDERS

Irritable bowel syndrome (IBS)

IBS is the commonest FGID. In western populations, up to 1 in 5 people report symptoms consistent with IBS. Only approximately 50% will consult their doctors and of these up to 30% will be referred by their GP to a hospital specialist. Up to 40% of all patients seen in specialist gastroenterology clinics will have IBS. Estimates in the UK put the annual cost of IBS to healthcare resources as £45.6 million; in the US the cost is higher at $8 billion. In the UK approximately a quarter of IBS patients lose time off work for periods ranging from 7 to 13 days each year. The factors that determine whether an IBS sufferer in the community seeks medical advice include the demonstration that consulters have higher illness attitude scores and higher anxiety and depression scores than non-consulters. Consulters perceive that their symptoms are severer than non-consulters, and consulting behaviour may be determined by the number of presenting symptoms. Female consulters outnumber male consulters by a factor of 2-3. Reasons for this include the fact that anxiety and depression scores are higher in women than in men and the gut may be more sensitive to various stimuli in women. It is likely that men and women perceive internal events in the abdomen differently and that women may be more focused on these events. Food and eating are of more special psychological significance for women, as evidenced by a much higher incidence of eating disorders in women. The whole pelvic region carries a more specific significance for women, being associated not only with defecation, urination and sexuality but additionally with menstruation, pregnancy and childbirth. Finally, women in western society in general seem more willing than men to seek medical attention for a whole variety of disorders.

IBS - a multisystem disorder

IBS patients suffer from a number of non-intestinal symptoms (Table 6.23). The non-intestinal symptoms of IBS can be more intrusive than the classical features of IBS. IBS coexists with chronic fatigue syndrome (see p. 1281), fibromyalgia (see p. 1282) and temporomandibular joint dysfunction.

The biopsychosocial conceptualization of the pathogenesis and clinical expression of FGIDs (Fig. 6.46) is particularly relevant to IBS and Box 6.16 lists some common factors that have been shown to trigger IBS symptoms. Infectious diarrhoea precedes the onset of IBS symptoms in 7-30% of patients. Whether this is a factor for all patients or just a small subgroup remains controversial. Risk factors in these patients have been shown to include female gender, severity and duration of diarrhoea, pre-existing life events and high hypochondriacal anxiety and neurotic scores at the time of the initial illness. Symptoms of anxiety and depression are more common in IBS patients and stress or life events often precedes the onset of chronic bowel symptoms.

Psychological trauma Sexual, physical, verbal abuse Mood disturbances Anxiety, depression Eating disorders
Food intolerance

Diagnostic criteria (Rome II 1999)

These criteria state that, in the preceding 12 months there should be at least 12 weeks (consecutive) of abdominal discomfort or pain that has two of three of the following features:

- relieved with defecation; and/or
- onset associated with a change in frequency of stool; and/ or
- onset associated with a change in form (appearance) of stool.

The following symptoms cumulatively support the diagnosis of IBS:

- abnormal stool frequency ('abnormal' may be defined as > 3/day and < 3/week)
- abnormal stool form (lumpy/hard or loose/watery stool)
- abnormal stool passage (straining, urgency, or feeling of incomplete evacuation)
- passage of mucus
- bloating or feeling of abdominal distension.

These symptoms can be used to subclassify patients into diarrhoea- and constipation-predominant forms of IBS. In practice a third subgroup of alternating IBS exists, in which constipation and diarrhoea alternate. The three forms have equal frequency. Many patients with constipation (p. 320) have abdominal discomfort or pain with bloating or distension so there is considerable overlap with constipation-predominant IBS.

The decision as to whether to investigate and if so what choice of investigations is required should be based on clinical judgement. Pointers to the need for thorough investigation are the presence of the above symptoms in association with rectal bleeding, nocturnal pain, fever and weight loss.

Treatment

Current strategies for treatment of IBS are based on the biopsychosocial conceptualization of IBS (Fig. 6.46) with targeting of central and end-organ therapies (Box 6.17). End-organ and central approaches to treatment should not be mutually exclusive and can be used in sequence and in combinations. Hydroxytryptamine (HT_3)-receptor antagonists for diarrhoea-predominant IBS, HT_4-receptor agonists for constipation-predominant IBS as well as kappa opioid agonists for use in patients in whom visceral hyperalgesia plays a predominant role in the pathogenesis of their symptoms may become available.

Pain/gas/bloat syndrome

There exist a group of patients with functional bowel disease whose abdominal pain and other clinical features are likely to occur as a consequence of disordered motility and visceral sensation that predominantly affects the small intestine or midgut. The symptom-based diagnostic criteria are *abdominal pain,* often exacerbated by eating and not relieved by opening the bowels and not associated with the passage of more frequent or looser stools than normal and not associated with constipation. Other symptoms include *abdominal distension.* Abdominal distension that is not restricted to the upper abdomen occurs, as well as postprandial fullness, nausea and, on occasions, anorexia and weight loss.

Some patients with pain/gas/bloat syndrome have particularly severe and chronic symptoms, that may also be nocturnal. A subgroup of these have been shown to have manometric features consistent with a diagnosis of chronic idiopathic intestinal pseudo-obstruction (CUP), and specifically of an enteric neuropathy. Full-thickness small intestinal biopsies have confirmed the diagnosis in some patients, while in others a deficiency of a actin staining in the inner circular layer of smooth muscle has been demonstrated.

Treatment of patients with pain/gas/bloat syndrome is not easy; and in some, pain can be chronic and severe. Narcotics should always be avoided. Central and end-organ targeted treatment approaches should be combined, e.g. selective serotonin reuptake inhibitor paroxetine combined with a prokinetic agent domperidone or smooth muscle relaxant, e.g. mepeverine. In the future, consideration should be given to treating these patients with a 5-HT_4-receptor agonist.

Box 6.17 **Approaches to management of irritable bowel syndrome**

End organ treatment	**Action**
Explore dietary triggers	Refer to dietitian
High-fibre diet ± fibre supplements for constipation	Refer to dietitian ± prescribe ispaghula husk
Anti-diarrhoeal drugs for bowel frequency	Loperamide Codeine phosphate Co-phenotrope
Smooth muscle relaxants for pain	Mebeverine hydrochloride Dicycloverine hydrochloride Peppermint oil
Central treatment	**Action**
Physiological explanation and symptoms	At consultation (leaflets with diagrams help)
Psychotherapy	Refer to clinical psychologist (see p. 1282)
Hypnotherapy	
Cognitive behavioural therapy	
Antidepressants	Clomipramine in functional diarrhoea; tricyclic group, e.g. nortriptyline 75 mg daily in diarrhoea-predominant IBS; selective serotonin reuptake inhibitors in constipation-predominant IBS, e.g. paroxetine 20 mg daily

Functional diarrhoea

In this form of functional bowel disease, symptoms occur in the absence of abdominal pain and commonly are:

- The passage of several stools in rapid succession usually first thing in the morning. No further bowel action may occur that day or defecation only after meals.
- The first stool of the day is usually formed, the later ones mushy, looser or watery.
- Urgency of defecation.
- Anxiety, uncertainty about bowel function with restriction of movement (e.g. travelling).
- Exhaustion after the 'morning rush'.

Chronic diarrhoea without pain is caused by many diseases indistinguishable by history from functional diarrhoea (p. 333). Features atypical for a functional disorder (e.g. large-volume stools, rectal bleeding, nutritional deficiency, and weight loss) call for more extensive studies of intestinal structure and function. In cases where it proves difficult to distinguish between functional and organic causes of diarrhoea, patients should be admitted to hospital for a formal 3-day analysis of stool weights and faecal fat estimation, and a purgative screen **together with** stool osmolality and creatinine contents to exclude factitious causes of diarrhoea (see p. 335). Outpatient analysis of stool weights is unreliable as brain-gut dysrhythmia may result in increased stool weights in the normal home environment.

Treatment of functional diarrhoea is usually with loperomide and a tricyclic antidepressant at night (e.g. clomipramine 10-30 mg).

THE ACUTE ABDOMEN

This section deals with the acute abdominal conditions that cause the patient to be hospitalized within a few hours of the onset of pain (Table 6.24). The diagnosis when made quickly reduces morbidity and mortality. Although a specific diagnosis should be attempted, the immediate problem in management is to decide whether an 'acute abdomen' exists and whether surgery is required.

Table 6.24 **Common causes of acute abdominal pain**

Diagnosis	No. of **patients**
Non-specific abdominal pain	466
Acute appendicitis	449
Renal colic	61
Gynaecological disorders	44
Intestinal obstruction	32
Urinary tract infection	30
Gall bladder disease	12
Perforated ulcer/dyspepsia	10
Diverticular disease	6
Other diagnoses	58
No diagnosis established	39

Data drawn from a series of 1204 patients reported by Dixon et al. 1991. *British Medical Journal* **302:** 386-388

History

This should include previous operations, any gynaecological problems and whether any concurrent medical condition is present.

Pain

The onset, site, type and subsequent course of the pain should be determined as accurately as possible. In general, the pain of an acute abdomen can either be constant (usually owing to inflammation) or colicky because of a blocked 'tube'. The inflammatory nature of a *constant pain* will be supported by a raised temperature, tachycardia and/or a raised white cell count. If these are normal, then other causes (e.g. musculoskeletal, aortic aneurysm) or rare causes (e.g. porphyria) should be considered. Colicky pain can be due to an obstruction of the gut, biliary system, urogenital system or the uterus. These will probably initially require conservative management along with analgesics. If a colicky pain becomes a constant pain, then inflammation of the organ may have supervened (e.g. strangulated hernia, ascending cholangitis or salpingitis). A *sudden onset of pain* suggests:

- a perforation (e.g. of a duodenal ulcer)
- a rupture (e.g. of an aneurysm)
- torsion (e.g. of an ovarian cyst)
- acute pancreatitis.

Back pain suggests:

- pancreatitis
- rupture of an aortic aneurysm
- renal tract disease.

Inflammatory conditions (e.g. appendicitis) produce a more gradual onset of pain. With peritonitis the pain is continuous and may be made worse by movement.

Vomiting

Vomiting may accompany any acute abdominal pain but, if persistent, it suggests an obstructive lesion of the gut. The character of the vomit should be asked - does it contain blood, bile or small bowel contents?

Other symptoms

Any change in bowel habit or of urinary frequency should be documented and, in females, a gynaecological history should be taken.

Physical examination

The general condition of the person should be noted. Does the patient look ill? Is he or she shocked? Large volumes of fluid may be lost from the vascular compartment into the peritoneal cavity or into the lumen of the bowel, giving rise to hypovolaemia, i.e. a pale cold skin, a weak rapid pulse and hypotension.

The abdomen

- **Inspection.** Look for the presence of scars, distension or masses.
- **Palpation.** The abdomen should be examined gently for sites of tenderness and the presence or absence of guarding. Guarding is involuntary spasm of the abdominal wall and it indicates peritonitis. This can be localized to one area or it may be generalized, involving the whole abdomen.
- **Bowel sounds.** Increased high-pitch tinkling bowel sounds indicate fluid obstruction; this occurs because of fluid movement within the large dilated bowel lumen. Absent bowel sounds suggest peritoneal involvement. In an obstructed patient, absent bowel sounds suggest strangulation ischaemia or ileus. It is essential that the hernial orifices be examined if intestinal obstruction is suspected.

Pelvic and rectal examination

Pelvic examination can be very helpful, particularly in diagnosing gynaecological causes of an acute abdomen (e.g. a ruptured ectopic pregnancy). Rectal examination is less helpful as localized tenderness may be due to any cause; it may show blood on the finger stall.

Sigmoidoscopy

If diarrhoea is present, sigmoidoscopy is indicated to aid exclusion of infective, inflammatory and ischaemic causes of acute pain. A specimen of stool should be taken for stool culture for bacterial pathogens (e.g. campylobacter, salmonella, shigella) when diarrhoea is present - stool should also be tested for *Clostridium difficile* toxin if antibiotic therapy precedes onset of diarrhoea and acute abdominal pain (see p. 69).

Other observations

- *Mouth.* The tongue is furred in some cases and a fetor is present.
- *Temperature.* Fever is more common in acute inflammatory processes.

Table 6.25 **Medical causes of acute abdomen**

Referred pain
Pneumonia
Myocardial infarction
Functional gastrointestinal disorders
Renal causes
Pelviureteric colic
Acute pyelonephritis
Metabolic causes
Diabetes mellitus
Acute intermittent porphyria
Lead poisoning
Haematological causes
Haemophilia and other bleeding disorders
Henoch-Schonlein purpura Sickle cell crisis
Polycythaemia vera
Vasculitis
Embolic

- *Urine.* Examine for:
  - blood - suggests urinary tract infection or renal colic
  - glucose and ketones — ketoacidosis can present with acute pain
  - protein and white cells - to exclude acute pyelonephritis.
- Think of medical causes (Table 6.25).

Investigations

- **Blood count.** A raised white cell count occurs in inflammatory conditions.
- **Serum amylase.** High levels (more than five times normal) indicate acute pancreatitis. Raised levels below this can occur in any acute abdomen and should not be considered diagnostic of pancreatitis.
- **Serum electrolytes.** These are not particularly helpful for diagnosis but useful for general evaluation of the patient.
- **Pregnancy.** A urine dipstick is used with women of child-bearing age.
- **X-rays.** A chest X-ray is useful to detect air under the diaphragm owing to a perforation. Dilated loops of bowel or fluid levels are suggestive of obstruction (supine abdominal X-ray).
- **Ultrasound.** This is useful in the diagnosis of acute cholangitis, cholecystitis and aortic aneurysm, and in expert hands is reliable in the diagnosis of acute appendicitis. Gynaecological and other pelvic causes of pain can be detected.
- **CT scan.** Spiral CT is the most accurate investigation in most acute emergencies. It should be used more often to avoid unnecessary laparotomies.
- **Laparoscopy.** This has *gained increasing importance* as a diagnostic tool prior to proceeding with surgery, particularly in men and women over the age of

50 years. In addition, therapeutic manoeuvres, such as appendicectomy, can be performed.

Acute appendicitis

This is the most common surgical emergency. It affects all age groups. Appendicitis should always be considered in the differential diagnosis if the appendix has not been removed.

Acute appendicitis mostly occurs when the lumen of the appendix becomes obstructed with a faecolith; however, in some cases there is only generalized acute inflammation. If the appendix is not removed at this stage, gangrene occurs with perforation, leading to a localized abscess or to generalized peritonitis.

Clinical features and management

Most patients present with abdominal pain; in many it starts vaguely in the centre of the abdomen, becoming localized to the right iliac fossa in the first few hours. Nausea, vomiting, anorexia and occasional diarrhoea can occur.

Examination of the abdomen usually reveals tenderness in the right iliac fossa, with guarding due to the localized peritonitis. There may be a tender mass in the right iliac fossa. Laboratory tests are unhelpful, except that the white cell count may be raised. An ultrasound scan is accurate for the detection of an inflamed appendix and will also indicate an appendix mass or other localized lesion. CT is highly sensitive and specific, and reduces the incidence of removing the 'normal' appendix.

Differential diagnosis

- Non-specific mesenteric lymphadenitis - may mimic appendicitis.
- Acute terminal ileitis due to Crohn's disease or *Yersinia* infection.
- Acute salpingitis - should be considered in women; there is usually a vaginal discharge and on vaginal examination, adnexal tenderness is found.
- Inflamed Meckel's diverticulum. .-■■
- Functional bowel disease.

It should be noted that 45% of women aged 15^5 years who have an appendicectomy have a normal appendix removed.

Treatment

The appendix is removed by open surgery or laparoscopically. If an appendix mass is present, the patient is usually treated conservatively with intravenous fluids and antibiotics. The pain subsides over a few days and the mass usually disappears over a few weeks. Interval appendicectomy is recommended at a later date to prevent further acute episodes.

Gynaecological causes

Ruptured ectopic pregnancy. The fallopian tube is the commonest extrauterine site of implantation. Delayed diagnosis is the major cause of morbidity. Most patients will present with recurrent low abdominal pain associated with vaginal bleeding. Diagnosis is usually made with abdominal and transvaginal ultrasound. Most patients can be managed by laparoscopic salpingostomy or salpingectomy.

Ovarian:

- Rupture of 'functional' ovarian cysts in the middle of the cycle (Mittelschmerz). ■

Torsion or rupture of ovarian cysts.

Acute salpingitis. Most cases are associated with sexually transmitted infection. Patients commonly present with bilateral low abdominal pain, a fever and vaginal discharge. In the Fitz-Hughes-Curtis syndrome the chlamydia infection tracks up the right paracolic gutter to cause a perihepatitis. Patients can present with acute right hypochondrial pain, fever and mildly abnormal liver biochemistry.

Acute peritonitis

Localized peritonitis

There is virtually always some degree of localized peritonitis with all acute inflammatory conditions of the gastrointestinal tract (e.g. acute appendicitis, acute cholecystitis). Pain and tenderness are largely features of this localized peritonitis. The treatment is for the underlying disease.

Generalized peritonitis

This is a serious condition resulting from irritation of the peritoneum owing to infection (e.g. perforated appendix), or from chemical irritation due to leakage of intestinal contents (e.g. perforated ulcer). In the latter case, superadded infection gradually occurs; E. *coli* and *Bacteroides* are the most common organisms.

The peritoneal cavity becomes acutely inflamed, with production of an inflammatory exudate that spreads throughout the peritoneum, leading to intestinal dilatation and paralytic ileus.

Clinical features and management

In perforation, the onset is sudden with acute severe abdominal pain, followed by general collapse and shock. The patient may improve temporarily, only to become worse later as generalized toxaemia occurs.

When the peritonitis is secondary to inflammatory disease, the onset is less rapid with the initial features being those of the underlying disease.

Investigations should always include an erect chest X-ray to detect free air under the diaphragm, and a serum amylase to diagnose acute pancreatitis, which is treated conservatively. Imaging with ultrasound and/or CT should also be performed for diagnosis.

Peritonitis is always treated surgically after adequate resuscitation with the re-establishment of a good urinary output. This includes insertion of a nasogastric tube,

intravenous fluids and antibiotics. Surgery has a twofold objective:

- peritoneal lavage of the abdominal cavity
- specific treatment of the underlying condition.

Complications

Any delay in treatment of peritonitis produces more profound toxaemia and septicaemia. In addition, local abscess formation occurs and should be suspected if a patient continues to remain unwell postoperatively with a swinging fever, high white cell count and continuing pain. Abscesses are commonly pelvic or subphrenic and can be localized and drained using ultrasound and CT scanning techniques.

Intestinal obstruction ^ ^ ^

Most intestinal obstruction is due to a mechanical block. Sometimes the bowel does not function, leading to a paralytic ileus. This occurs temporarily after most abdominal operations and with peritonitis. Some causes of intestinal obstruction are shown in Table 6.26.

Obstruction of the bowel leads to bowel distension above the block, with increased secretion of fluid into the distended bowel. Bacterial contamination occurs in the distended stagnant bowel. In strangulation the blood supply is impeded, leading to gangrene, perforation and peritonitis unless urgent treatment of the condition is undertaken.

Clinical features

The patient complains of abdominal colic, vomiting and constipation without passage of wind. In upper gut obstruction the vomiting is profuse but in lower gut obstruction it may be absent.

Examination of the abdomen reveals distension with increased bowel sounds. Marked tenderness suggests strangulation, and urgent surgery is necessary. Examination of the hernial orifices and rectum must be performed. X-ray of the abdomen reveals distended loops of bowel proximal to the obstruction. Fluid levels are seen in small bowel obstruction on an erect film. In large bowel obstruction, the caecum and ascending colon are distended. An instant water-soluble gastrografin enema without air insufflation may help to demonstrate the site of the obstruction. CT can localize the lesion accurately.

Table 6.26 **Some causes of intestinal obstruction**

Small intestinal obstruction
Adhesions (80% in adults)
Hernias
Crohn's disease
Intussusception
Obstruction due to extrinsic involvement by cancer
Colonic obstruction
Carcinoma of the colon
Sigmoid volvulus
Diverticular disease

Management

Initial management is by resuscitation with intravenous fluids (mainly isotonic saline with potassium) and decompression. Many cases will settle on conservative management, but an increasing temperature, raised pulse rate, increasing pain and a rising white cell count require exploratory laparotomy.

Laparotomy with removal of the obstruction will be necessary in some cases of *small bowel obstruction*. If the bowel is gangrenous owing to strangulation, gut resection will be required. A few patients (e.g. those with Crohn's disease) may have recurrent episodes of incomplete intestinal obstruction that can be managed conservatively. In *large bowel obstruction* due to malignancy, colorectal stents are being used, followed by elective surgery. In critically ill patients, a defunctioning colostomy may be required. Volvulus of the sigmoid colon can be managed by the passage of a flexible sigmoidoscope or a rectal tube to un-kink the bowel, but recurrent volvulus may require sigmoid resection.

Intestinal pseudo-obstruction

It is now recognized that a clinical picture mimicking mechanical obstruction may develop in patients who do not have a mechanical cause. Colonic pseudo-obstruction is the commonest form. In more than 80% of cases it complicates other clinical conditions, for example:

- intra-abdominal trauma, pelvic spinal and femoral fractures
- postoperatively (abdominal, pelvic, cardiothoracic, orthopaedic, neurosurgical)
- intra-abdominal sepsis
- pneumonia
- metabolic (e.g. electrolyte disturbances, malnutrition, diabetes mellitus, Parkinson's disease)
- drugs - opiates (particularly after orthopaedic surgery) antidepressants, antiparkinsonian drugs.

Patients present with rapid and progressive abdominal distension and pain. X-ray shows a gas-filled large bowel. Management is of the underlying problem (e.g. withdraw opiate analgesia) together with a trial of i.v. neostigmine therapy (Box 6.18). Patients should be monitored care-

Sox 6.*18* **Treatment of acute colonic pseudo-obstruction**

Neostigmine 2.0 mg i.v. over 3-5 min in presence of doctor with ECG monitor.
0.3-1 mg atropine if symptomatically bradycardic.
Nurse the patient supine for 60 min.
Monitor abdominal circumference and the diameter of the caecum, ascending, transverse and descending colon on straight abdominal X-ray.

fully and consideration should be given to surgery if the diameter of the caecum exceeds 14 cm.

Small intestinal pseudo-obstruction is a rare chronic condition that can occur in association with systemic sclerosis, systemic lupus erythematosus (SLE), Sjogren's syndrome, thyroid disease, amyloidosis and paraneoplastic syndromes. Primary myopathic and neuropathic forms also exist, with the former sometimes being familial. There are other patients with clinical and manometric features of small intestinal pseudo-obstruction who have normal full-thickness biopsies of smooth muscle but *a* actin deficiency in the inner circular layer of the smooth muscle. Myopathic forms can present with attacks of non-mechanical obstruction and/or functional small intestinal failure with dilated non-propulsive intestines and coexisting bacterial overgrowth. These patients are managed in specialist centres with facilities to manage home total parenteral nutrition (p. 259). The other patients, including those with enteric neuropathies, often present with a long history of abdominal pain and other intractable midgut symptoms. Many have extraintestinal symptoms, and a multidisciplinary approach to management is required, including, in a number, access to facilities to provide needle catheter jejunostomy enteral feeding as well as home TPN.

THE PERITONEUM

The peritoneal cavity is a closed sac lined by mesothelial cells, which produce surfactant that acts as a lubricant within the peritoneal cavity. The cavity contains less than 100 mL of serous fluid containing less than 30 g/L of protein.

The mesothelial cells lining the diaphragm have gaps that allow communication between the peritoneum and the diaphragmatic lymphatics. Approximately one-third of fluid drains through these lymphatics, the remainder through the parietal peritoneum. These mechanisms allow particulate matter to be removed rapidly from the peritoneal cavity.

Complement activation is an early defence mechanism followed rapidly by upregulation of the peritoneal mesothelial cells and migration of polymorphonuclear neutrophils and macrophages into the peritoneum.

Mast cells release potent mediators of inflammation and interact with T cells to generate an immune response.

The peritoneal-associated lymphoid tissue includes the omental milky spots, the lymphocytes within the peritoneal cavity and the draining lymph nodes. B cells with a unique $CD5^+$ are common. This defence system plays a major role in localizing peritoneal infection. Some conditions that can affect the peritoneum are shown in Table 6.27.

Table 6.27 **Disease of the peritoneum**

Infective (bacterial) peritonitis
Secondary to gut disease, e.g.
appendicitis
perforation of any organ Chronic peritoneal dialysis Spontaneous, usually in ascites with liver disease Tuberculosis

Neoplasia

Secondary deposits (e.g. from ovary, stomach)

Primary mesothelioma

Vasculitis
Connective tissue disease
Polyserositis (e.g. familial Mediterranean fever)

Peritonitis can be acute or chronic, as seen in tuberculosis. Most cases of infective peritonitis are secondary to gastrointestinal disease, but it occurs occasionally without intra-abdominal sepsis in ascites due to liver disease. Very rarely, fungal and parasitic infections can also cause primary peritonitis (e.g. amoebiasis, candidiasis). Peritonitis is discussed further on page 342.

The peritoneum can be involved by *secondary malignant deposits,* and the most common cause of ascites in a young to middle-aged woman is an ovarian carcinoma.

A *subphrenic abscess* is usually secondary to infection in the abdomen and is characterized by fever, malaise, pain in the right or left hypochondrium and shoulder-tip pain. An erect chest X-ray shows gas under the diaphragm, impaired movement of the diaphragm on screening and a pleural effusion. Ultrasound is usually diagnostic. Percutaneous catheter drainage inserted under CT or ultrasound guidance and antibiotics is highly successful therapy.

Ascites is associated with all diseases of the peritoneum. The fluid that collects is an exudate with a high protein content. It is also seen in liver disease. The mechanism, causes and investigation of ascites are discussed on page 381.

Retroperitoneal fibrosis (periaortitis)

This is a rare condition in which there is a marked fibrosis over the posterior abdominal wall and retroperitoneum. It is described on p. 656.

Tuberculous peritonitis

This is the second most common form of abdominal TB. Three subgroups can be identified: wet, dry and fibrous.

- In patients with the wet type, ascitic fluid should be examined for protein concentration (> 20 g/L) and tubercle bacilli (rarely found).
- In the dry form, patients present with subacute intestinal obstruction which is due to tuberculous small bowel adhesions.
- In the fibrous form, patients present with abdominal pain, distension and ill-defined irregular tender abdominal masses.

The diagnosis of peritoneal TB can be supported by findings on ultrasound or CT screening (mesenteric thickening and lymph node enlargement). A histological diagnosis is not always required before instituting treatment. In some patients careful laparoscopy (to avoid perforation) may have to be performed, and rarely laparotomy.

Treatment

Drug treatment is similar to that for pulmonary TB (see p. 932) and should be supervised by chest physicians who have experience in dealing with contacts.

Liver, biliary tract and pancreatic disease

7

In many countries alcohol is the major cause of liver disease, followed by hepatitis C virus infection. Hepatitis B virus is still a significant factor but widespread vaccination will reduce its prevalence. Health education and the improvement in public health should help to stop the spread of viral infections.

Imaging techniques enable the liver, biliary tree and pancreas to be visualized with precision, resulting in earlier diagnosis. Therapeutic endoscopy, laparoscopic and minimally invasive surgery are now widely available for biliary tract and pancreatic disease. Finally, liver transplantation is established therapy for both acute and chronic liver disease.

THE LIVER

STRUCTURE OF THE LIVER AND BILIARY SYSTEM

The liver

The liver is the largest internal organ in the body and is situated in the right hypochondrium. Functionally, it is divided into right and left lobes by the middle hepatic vein. The right lobe is larger and contains the caudate and quadrate lobes. The liver is further subdivided into a total of eight segments (Fig. 7.1) by divisions of the right, middle and left hepatic veins. Each segment receives its own portal pedicle, permitting individual segment resection at surgery.

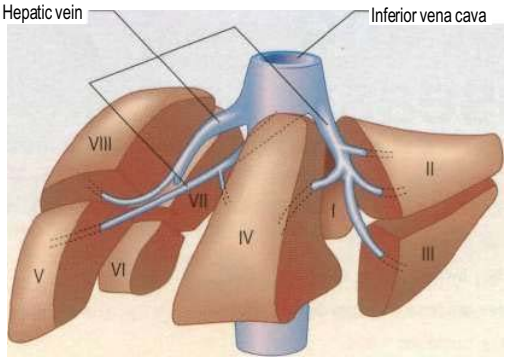

Fig. 7.1 **Segmental anatomy of the liver showing the eight hepatic segments.** I, caudate lobe; II—IV the left

The blood supply to the liver constitutes 25% of the resting cardiac output and is via two main vessels:

- The *hepatic artery,* which is a branch of the coeliac axis, supplies 25% of the total blood flow. Autoregulation of blood flow by the hepatic artery ensures a constant total liver blood flow.
- The *portal vein* drains most of the gastrointestinal tract and the spleen. It supplies 75% of the blood flow. The normal portal pressure is 5-8 mmHg; flow increases after meals.

Both vessels enter the liver via the hilum (porta hepatis). The blood from these vessels is distributed to the segments and passes into the sinusoids via the portal tracts.

Blood leaves the sinusoids, entering branches of the hepatic vein which join into three main branches before entering the inferior vena cava.

The caudate lobe is an autonomous segment as it receives an independent blood supply from the portal vein and hepatic artery, and its hepatic vein drains directly into the inferior vena cava.

Lymph, formed mainly in the perisinusoidal space, is collected in lymphatics which are present in the portal tracts. These small lymphatics enter larger vessels which eventually drain into the hepatic ducts.

The functional unit of the liver is the acinus. This consists of parenchyma supplied by the smallest portal tracts containing portal vein radicles, hepatic arterioles and bile ductules (Fig. 7.2). The hepatocytes near this triad (zone 1) are well supplied with oxygenated blood and are more resistant to damage than the cells nearer the terminal hepatic (central) veins (zone 3).

The sinusoids lack a basement membrane and are loosely surrounded by specialist fenestrated endothelial cells and Kupffer cells (phagocytic cells). Sinusoids are separated by plates of liver cells (hepatocytes). The sub-endothelial space that lies between the sinusoids and hepatocytes is the space of Disse, which contains a matrix of basement membrane constituents and stellate cells. , (See Fig. 7.21).

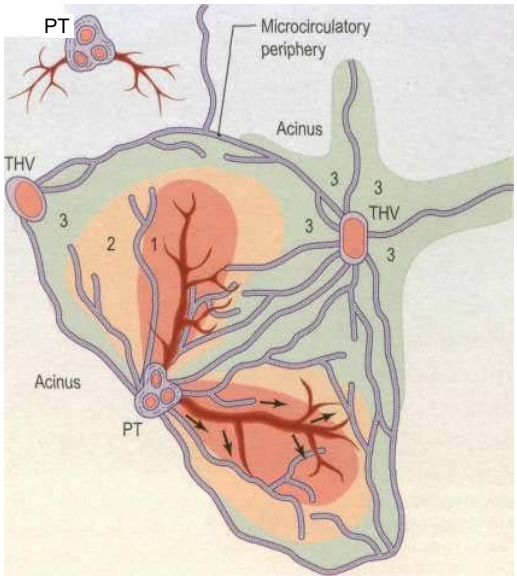

Fig. 7.2 **Diagram of an acinus.** Zones 1, 2 and 3 represent areas supplied by blood, with zone 1 being best oxygenated. Zone 3 is supplied by blood remote from afferent vessels and is in the microcirculatory periphery of the acinus. The perivascular area (star shaped green area around THV) is formed by the most peripheral parts of zone 3 of several adjacent acini and is the least well oxygenated. THV, terminal hepatic venule; PT, portal triad.

Stellate cells store retinoids in their resting state and contain the intermediate filament, desmin. When activated (to myofibroblasts) they are contractile and probably regulate sinusoidal blood flow. Endothelin and nitric oxide play a major role in modulating stellate cell contractility. Stellate cells, after activation, produce collagen types I, III and IV (see p. 375).

The biliary system

Bile canaliculi form a network between the hepatocytes. These join to form thin bile ductules near the portal tract, which in turn enter the bile ducts in the portal tracts. These then combine to form the right and left hepatic ducts that leave each liver lobe. The hepatic ducts join at the porta hepatis to form the common hepatic duct. The cystic duct connects the gall bladder to the lower end of the common hepatic duct. The gall bladder lies under the right lobe of the liver and stores and concentrates hepatic bile; it has a capacity of approximately 50 mL. The common bile duct is formed by the combination of the cystic and hepatic ducts and is approximately 8 mm in diameter, narrowing at its distal end to pass into the duodenum. The common bile duct and pancreatic duct open into the second part of the duodenum through a common channel at the ampulla of Vater. The lower end of the common bile duct contains the muscular sphincter of Oddi, which contracts rhythmically and prevents bile from entering the duodenum in the fasting state.

FUNCTIONS OF THE LIVER

Protein metabolism (see also p. 232)

Synthesis

The liver is the principal site of synthesis of all circulating proteins apart from γ-globulins, which are produced in the reticuloendothelial system. The liver receives amino acids from the intestine and muscles and, by controlling the rate of gluconeogenesis and transamination, regulates levels in the plasma. Plasma contains 60-80 g/L of protein, mainly in the form of albumin, globulin and fibrinogen.

Albumin has a half-life of 16-24 days and 10-12 g are synthesized daily. Its main functions are first to maintain the intravascular oncotic (colloid osmotic) pressure, and second to transport water-insoluble substances such as bilirubin, hormones, fatty acids and drugs. Reduced synthesis of albumin over prolonged periods produces hypoalbuminaemia and is seen in chronic liver disease and malnutrition. Hypoalbuminaemia is also found in hypercatabolic states (e.g. trauma with sepsis) and in diseases where there is an excessive loss (e.g. nephrotic syndrome, protein-losing enteropathy).

Transport or carrier proteins such as transferrin and caeruloplasmin, acute-phase and other proteins (e.g. a_r antitrypsin and α-fetoprotein) are also produced in the liver.

The liver also synthesizes all factors involved in coagulation (apart from one-third of factor VIII) - that is, fibrinogen, prothrombin, factors V, VII, IX, X and XIII, proteins C and S and antithrombin (see Ch. 8) as well as components of the complement system.

Degradation (nitrogen excretion)

Amino acids are degraded by transamination and oxidative deamination to produce ammonia, which is then converted to urea and excreted by the kidneys. This is a major pathway for the elimination of nitrogenous waste. Failure of this process occurs in severe liver disease.

Carbohydrate metabolism

Glucose homeostasis and the maintenance of the blood sugar is a major function of the liver. It stores approximately 80 g of glycogen. In the immediate fasting state, blood glucose is maintained either by glucose released from the breakdown of glycogen (glycogenolysis) or by newly synthesized glucose (gluconeogenesis). Sources for gluconeogenesis are lactate, pyruvate, amino acids from muscles (mainly alanine and glutamine) and glycerol from lipolysis of fat stores. In prolonged starvation, ketone bodies and fatty acids are used as alternative sources of fuel and the body tissues adapt to a lower glucose requirement (see Ch. 5).

Lipid metabolism

Fats are insoluble in water and are transported in the plasma as protein-lipid complexes (lipoproteins). These are discussed in detail on page 1135.

The liver has a major role in the metabolism of lipoproteins. It synthesizes very-low-density lipoproteins (VLDLs) and high-density lipoproteins (HDLs). HDLs are the substrate for lecithin-cholesterol acyltransferase (LCAT), which catalyses the conversion of free cholesterol to cholesterol ester (see below). Hepatic lipase removes triglyceride from intermediate-density lipoproteins (IDLs) to produce low-density lipoproteins (LDLs) which are degraded by the liver after uptake by specific cell-surface receptors (see Fig. 19.19).

Triglycerides are mainly of dietary origin but are also formed in the liver from circulating free fatty acids (FFAs) and glycerol and incorporated into VLDLs. Oxidation or de novo synthesis of FFA occurs in the liver, depending on the availability of dietary fat.

Cholesterol may be of dietary origin but most is synthesized from acetyl-CoA mainly in the liver, intestine, adrenal cortex and skin. It occurs either as free cholesterol or is esterified with fatty acids; this reaction is catalysed by LCAT. This enzyme is reduced in severe liver disease, increasing the ratio of free cholesterol to ester, which alters membrane structures. One result of this is the red cell abnormalities (e.g. target cells) seen in chronic liver disease. Phospholipids (e.g. lecithin) are synthesized in the liver.

The complex interrelationships between protein, carbohydrate and fat metabolism are shown in Figure 7.3.

Formation of bile

Bile secretion

Bile consists of water, electrolytes, bile acids, cholesterol, phospholipids and conjugated bilirubin. Two processes are involved in bile secretion across the canalicular membrane of the hepatocyte - a *bile salt-dependent* and a *bile salt-independent* process - each contributing about 230 mL per day. The remainder of the bile (about 150 mL daily) is produced by the epithelial cells of the bile ductules.

Bile formation requires firstly the uptake of bile acids and other organic and inorganic ions across the basolateral (sinusoidal) membranes by multiple transport proteins. This process is driven by Na^+-K^+-ATPase in the basolateral membrane. Intracellular transport across the hepatocyte is partly through microtubules and partly by cytosol transport proteins. The canalicular membrane contains additional transporters, mainly ATPase-dependent, which carry molecules into the biliary canaliculi against a concentration gradient. The canalicular multi-specific organic anion transporter (cMOAT) also known as multidrug-resistance protein 2 (MRP2) mediates transport of a broad range of compounds including

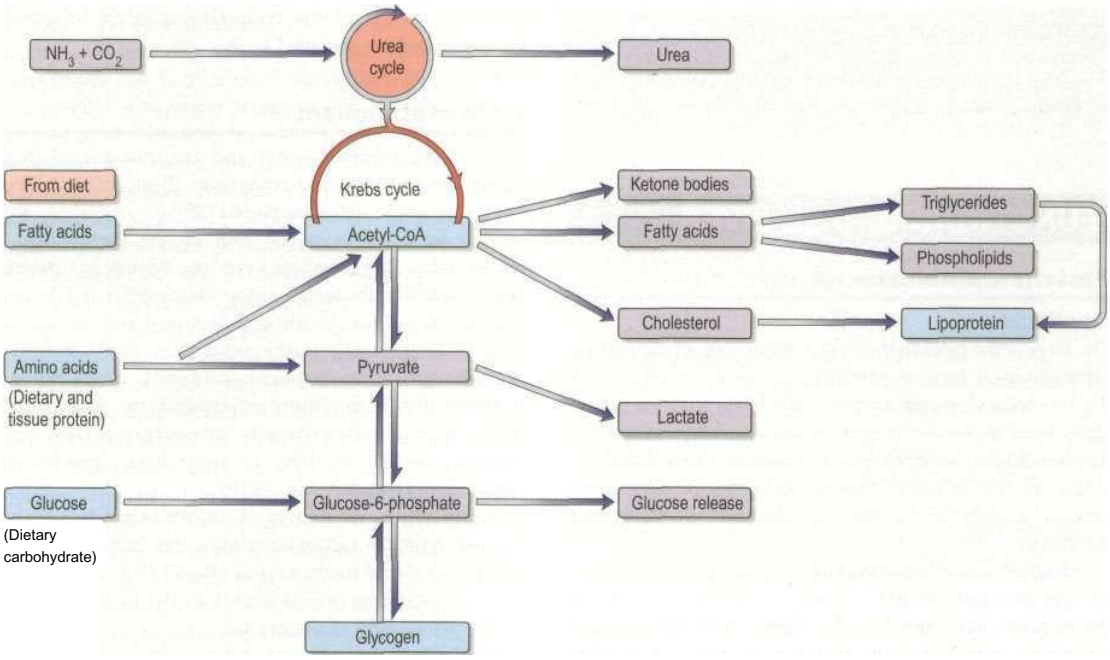

Fig. 7.3 Interrelationships of protein, carbohydrate and lipid metabolism in the liver.

bilirubin diglucuronide, glucuronidated and sulphated bile acids and other organic anions. Na^+ and water follow the passage of bile salts into the biliary canaliculus by diffusion across the tight junction between hepatocytes (a bile salt-dependent process). In the bile salt-independent process water flow is due to other osmotically active solutes such as glutathione and bicarbonate.

Secretion of a bicarbonate-rich solution is stimulated mainly by secretin and is inhibited by somatostatin. In this process several membrane proteins are involved, including the Cr/HCO_3~ exchanger and the cystic fibrosis transmembrane conductance regulator which controls Cr secretion, as well as water channels (aquaporins) in cholangiocyte membranes.

The average total bile flow is approximately 600 mL per day. In the fasted state half of the bile flows directly into the duodenum and half is diverted into the gall bladder. The mucosa of the gall bladder absorbs 80-90% of the water and electrolytes, but is impermeable to bile acids and cholesterol. Following a meal, cholecystokinin is secreted by the I cells of the duodenal mucosa and stimulates contraction of the gall bladder and relaxation of the sphincter of Oddi, so that bile enters the duodenum. An adequate bile flow is dependent on bile salts being returned to the liver by the enterohepatic circulation.

Bile acid metabolism

Bile acids are synthesized in hepatocytes from cholesterol. The rate-limiting step in their production is that catalysed by cholesterol-7oc-hydroxylase. They are excreted into the bile and then pass into the duodenum. The two primary bile acids — cholic acid and chenodeoxycholic acid (Fig. 7.4) - are conjugated with glycine or taurine (in a ratio of 3 : 1 in humans) and this process increases their solubility. Intestinal bacteria convert these acids into secondary bile acids, deoxycholic and lithocholic acid. Figure 7.5 shows the enterohepatic circulation of bile acids. Bile acids act as detergents; their main function is lipid solubilization. Bile acid molecules contain both a hydrophilic and a hydrophpbic end. In aqueous solutions they aggregate to form micelles, with their hydrophobic (lipid-soluble) ends in the centre. Micelles are expanded by cholesterol and phospholipids (mainly lecithin), forming mixed micelles.

Bilirubin metabolism

Bilirubin is produced mainly from the breakdown of mature red cells in the Kupffer cells of the liver and in the reticuloendothelial system; 15% of bilirubin comes from the catabolism of other haem-containing proteins, such as myoglobin, cytochromes and catalases.

Normally, 250-300 mg of bilirubin are produced daily. The iron and globin are removed from the haem and are reused. Biliverdin is formed from the haem and this is reduced to form bilirubin. The bilirubin produced is unconjugated and water-insoluble, and is transported to the liver attached to albumin. Bilirubin dissociates from albumin and is taken up by the hepatic cell membrane and transported to the endoplasmic reticulum by cytoplasmic proteins, where it is conjugated with glucuronic acid and excreted into bile. The microsomal enzyme, uridine diphosphoglucuronosyl transferase, catalyses the formation of bilirubin monoglucuronide and then diglucuronide. This conjugated bilirubin is water-soluble and is actively secreted into the bile canaliculi and excreted into the intestine within the bile (Fig. 8.5). It is not absorbed from the small intestine because of its large

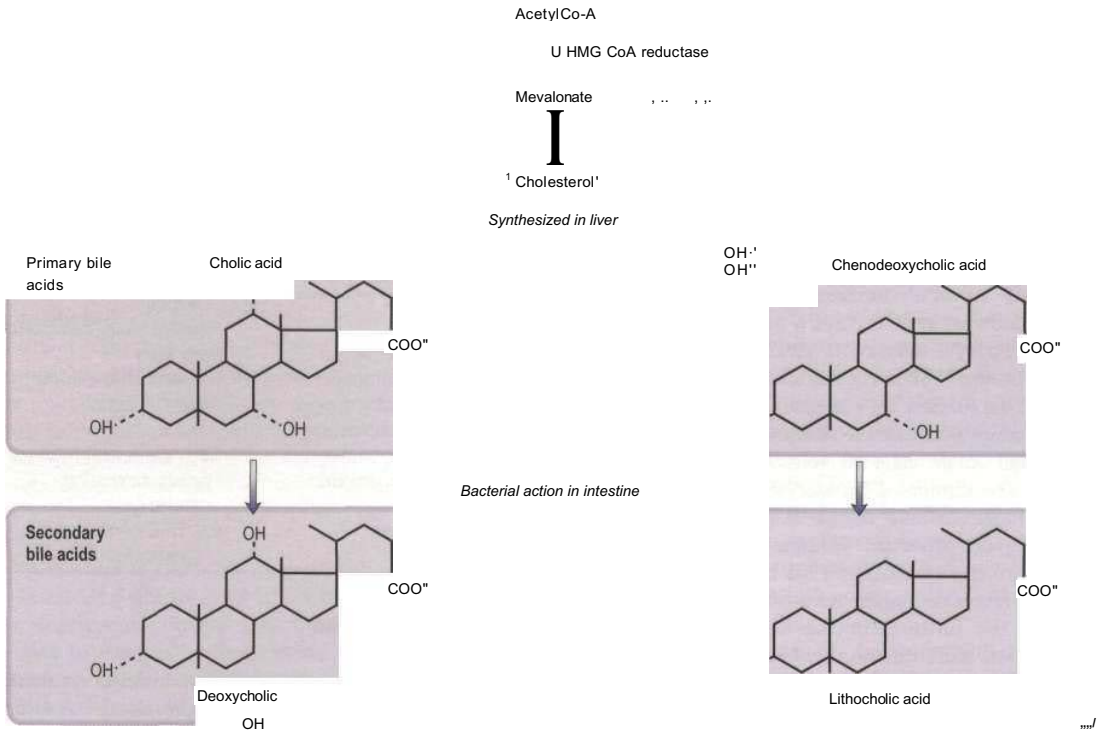

Fig. 7.4 **Cholesterol synthesis and its conversion to primary and secondary bile acids.** All bile acids are normally conjugated with glycine or taurine.

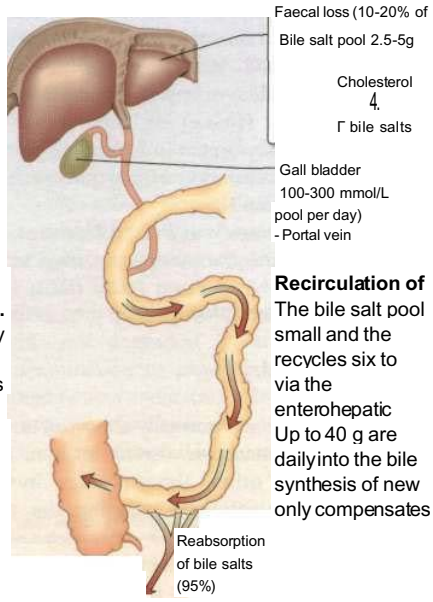

Fig. 7.5 **Recirculation of bile acids.** The bile salt pool is relatively small and the entire pool recycles six to eight times via the enterohepatic circulation. Up to 40 g are daily excreted into the bile and the synthesis of new bile acids only compensates for faecal loss.

molecular size. In the terminal ileum, bacterial enzymes hydrolyse the molecule, releasing free bilirubin, which is then reduced to urobilinogen. Some of this is excreted in the stools as stercobilinogen. The remainder is absorbed by the terminal ileum, passes to the liver via the enterohepatic circulation, and is re-excreted into the bile. Urobilinogen bound to albumin enters the circulation and is excreted in the urine via the kidneys. When hepatic excretion of conjugated bilirubin is impaired, a small amount of conjugated bilirubin is found strongly bound to serum albumin. It is not excreted by the kidneys and accounts for the continuing hyperbilirubinaemia for a short time after cholestasis has resolved.

Hormone and drug inactivation

The liver catabolizes hormones such as insulin, glucagon, oestrogens, growth hormone, glucocorticoids and parathyroid hormone. It is also the prime target organ for many hormones (e.g. insulin). It is the major site for the metabolism of drugs (see p. 993) and alcohol (see p. 262). Fat-soluble drugs are converted to water-soluble substances that facilitate their excretion in the bile or urine. Cholecalciferol is converted to 25-hydroxycholecalciferol.

Immunological function

The reticuloendothelial system of the liver contains many immunologically active cells. The liver acts as a 'sieve' for the bacterial and other antigens carried to it via the portal

tract from the gastrointestinal tract. These antigens are phagocytosed and degraded by Kupffer cells, which are macrophages attached to the endothelium. Kupffer cells have specific membrane receptors for ligands and are activated by several factors, such as infection. They secrete interleukins, tumour necrosis factor (TNF), collagenase and lysosomal hydrolases. Antigens are degraded without the production of antibody, as there is very little lymphoid tissue. They are thus prevented from reaching other antibody-producing sites in the body and thereby prevent generalized adverse immunological reactions. The reticuloendothelial system plays a role in tissue repair, T and B lymphocyte interaction, and cytotoxic activity in disease processes. Following stimulation by, for example, endotoxin, the Kupffer cells release IL-6, IL-8 and TNF-oc. These cytokines stimulate the sinusoidal cells, stellate cells and natural killer cells to release pro-inflammatory cytokines. The stimulated hepatocytes themselves express adhesion molecules and release IL-8, which is a potent neurrophil chemoattractant. Homing of mucosal lymphocytes (enterohepatic circulation) has been proposed. These exogenous leucocytes again release more cytokines - all damaging the function of the hepatocyte, including hepatocellular bile formation which leads to cholestasis. Cytokines also stimulate hepatic apoptosis.

INVESTIGATIONS

Investigative tests can be divided into:

- **Blood tests**
  - **(a)** Liver 'function' tests:
    - (i) serum albumin
    - (ii) prothrombin time
  - (b) Liver biochemistry:
    - (i) serum aspartate and alanine aminotransferases - reflecting hepatocellular damage
    - (ii) serum alkaline phosphatase, γ-glutamyl transpeptidase - reflecting cholestasis
    - (iii) total protein
  - (c) Viral markers
  - (d) Additional blood investigations; haematological, biochemical, immunological and genetic
- **Urine tests** - for bilirubin and urobilinogen
- **Imaging techniques** - to define gross anatomy
- **Liver biopsy** - for histology.

Most routine 'liver function tests' sent to the laboratory will be processed by an automated multichannel analyser to produce serum levels of bilirubin, aminotransferases, alkaline phosphatase, γ-glutamyl transpeptidase (γ-GT) and total proteins. These routine tests are markers of liver damage, but not actual tests of 'function' per se. Subsequent investigations are often based on these tests.

Blood tests

Useful blood tests for certain liver diseases are shown in Table 7.1.

Table 7.1 **Useful blood tests for certain liver diseases**

Test	Disease
Antimitochondrial antibody	Primary biliary cirrhosis
Antinuclear, smooth muscle (actin), liver/kidney microsomal antibody	Autoimmune hepatitis
Raised serum immunoglobulins: IgG	Autoimmune hepatitis
IgM	Primary biliary cirrhosis
Viral markers	Hepatitis A, B, C, D and others
a-Fetoprotein	Hepatocellular carcinoma
Serum iron, transferrin saturation, serum ferritin	Hereditary haemochromatosis
Serum and urinary copper, serum caeruloplasmin	Wilson's disease
ct]-Antitrypsin	Cirrhosis (± emphysema)
Antinuclear cytoplasmic antibodies	Primary sclerosing cholangitis
Genetic analyses	e.g. *HFE* gene (hereditary haemochromatosis)

Liver function tests *Serum albumin*

This is a marker of synthetic function and is a valuable guide to the severity of chronic liver disease. A falling serum albumin in liver disease is a bad prognostic sign. In acute liver disease initial albumin levels may be normal.

Prothrombin time (PT)

This is also a marker of synthetic function. Because of its short half-life, it is a sensitive indicator of both acute and chronic liver disease. Vitamin K deficiency should be excluded as the cause of a prolonged PT by giving an intravenous bolus (10 mg) of vitamin K. Vitamin K deficiency commonly occurs in biliary obstruction, as the low intestinal concentration of bile salts results in poor absorption of vitamin K.

Prothrombin times vary in different laboratories depending upon the thromboplastin used in the assay. The International Normalized Ratio (INR) is therefore used in many countries (see p. 480).

Liver biochemistry

Bilirubin

In the serum, bilirubin is normally almost all unconjugated. In liver disease, increased serum bilirubin is usually accompanied by other abnormalities in liver biochemistry. Determination of whether the bilirubin is conjugated or unconjugated is only necessary in congenital disorders of bilirubin metabolism (see below) or to exclude haemolysis.

Aminotransferases

These enzymes (often referred to as transaminases) are present in hepatocytes and leak into the blood with liver cell damage. Two enzymes are measured:

- *Aspartate aminotransferase* (AST) is primarily a **mitochondrial** enzyme (80%; 20% in cytoplasm) and is

also present in heart, muscle, kidney and brain. High levels are seen in hepatic necrosis, myocardial infarction, muscle injury and congestive cardiac failure. ■ *Alanine aminotransferase* (ALT) is a cytosol enzyme, more specific to the liver so that a rise only occurs with liver disease.

Alkaline phosphatase (ALP)

This is present in the canalicular and sinusoidal membranes of the liver, but is also present in many other tissues, such as bone, intestine and placenta. If necessary, its origin can be determined by electrophoretic separation of isoenzymes or bone-specific monoclonal antibodies. Alternatively, if there is also an abnormality of, for example, the γ-GT, the ALP can be presumed to come from the liver.

Serum ALP is raised in cholestasis from any cause, whether intrahepatic or extrahepatic disease. The synthesis of ALP is increased and this is released into the blood. In cholestatic jaundice, levels may be four to six times the normal limit. Raised levels may also occur in conditions with infiltration of the liver (e.g. metastases) and in cirrhosis, frequently in the absence of jaundice. The highest serum levels due to liver disease (> 1000IU/L) are seen with hepatic metastases and primary biliary cirrhosis.

y-Glutamyl transpeptidase

This is a microsomal enzyme that is present in many tissues as well as the liver. Its activity can be induced by such drugs as phenytoin and by alcohol. If the ALP is normal, a raised serum γ-GT is a good guide to alcohol intake and can be used as a screening test (see p. 1303). Mild elevation of the γ-GT is common even with a small alcohol consumption and does not necessarily indicate liver disease if the other liver biochemical tests are normal. In cholestasis the γ-GT rises in parallel with the ALP as it has a similar pathway of excretion. This is also true of the 5-nucleotidase, another microsomal enzyme that can be measured in blood.

Total proteins

This measurement, in itself, is of little value. Serum albumin is discussed above. The globulin fraction consists of many proteins that can be separated on electrophoresis. A raised globulin fraction, seen in liver disease, is usually due to increased circulating immunoglobulins and is polyclonal (see below).

Viral markers

Viruses are a major cause of liver disease. Virological studies have a key role in diagnosis; markers are available for most common viruses that cause hepatitis.

Additional blood investigations

Haematological

A full blood count is always performed. Anaemia may be present. The red cells are often macrocytic and can have abnormal shapes - target cells and spur cells - owing to membrane abnormalities. Vitamin B_{12} levels are normal or high, while folate levels are often low owing to poor dietary intake. Other changes are caused by the following:

- Bleeding produces a hypochromic, microcytic picture.
- Alcohol causes macrocytosis, sometimes with leucopenia and thrombocytopenia.
- Hypersplenism results in pancytopenia.
- Cholestasis can often produce abnormal-shaped cells and also deficiency of vitamin K.
- Haemolysis accompanies acute liver failure and jaundice.
- Aplastic anaemia is present in up to 2% of patients with acute viral hepatitis.
- A raised serum ferritin with transferrin saturation (> 60%) is seen in hereditary haemochromatosis.

Biochemical

- *a_1Antitrypsin.* A deficiency of this enzyme can produce cirrhosis.
- *a-Fetoprotein.* This is normally produced by the fetal liver. Its reappearance in increasing and high concentrations in the adult indicates hepatocellular carcinoma. Increased concentrations in pregnancy in the blood and amniotic fluid suggest neural-tube defects of the fetus. Blood levels are also slightly raised with regenerative liver tissue in patients with hepatitis, chronic liver disease and also in teratomas.
- Serum and urinary copper and serum caeruloplasmin - for Wilson's disease (see p. 387).

Immunological tests

There are no specific antibodies to the liver itself that are measured routinely.

Serum immunoglobulins

Increased γ-globulins are thought to be due to reduced phagocytosis by sinusoidal and Kupffer cells of the antigens absorbed from the gut. These antigens then stimulate antibody production in the spleen, lymph nodes and lymphoid and plasma cell infiltrate in the portal tracts. In primary biliary cirrhosis, the predominant serum immunoglobulin that is raised is IgM, while in autoimmune hepatitis it is IgG.

Serum autoantibodies

- *Antimitochondrial antibody* (AMA) is found in the serum in over 95% of patients with primary biliary cirrhosis (p. 385). Many different AMA subtypes have been described, depending on their antigen specificity. AMA is demonstrated by an immunofluorescent technique and is neither organ- nor species-specific. Some subtypes are occasionally found in autoimmune hepatitis and other autoimmune diseases.
- *Nucleic, smooth muscle (actin), liver/kidney microsomal antibodies* can be found in the serum in high titre in patients with autoimmune hepatitis. These antibodies can be found in the serum in other autoimmune conditions and other liver diseases.
- *Antinuclear cytoplasmic antibodies* (ANCA) are present in primary sclerosing cholangitis.

Genetic analysis
These tests are performed routinely for haemochromatosis *(HFE* gene). Markers are also available for Wilson's disease (see p. 387).

Bromsulphthalein (BSP) clearance test
This is now very rarely performed. The liver normally clears BSP from the blood. The level of BSP in the blood after an intravenous injection of BSP is a sensitive guide to hepatocellular damage. A second recirculation peak occurs in the congenital hyperbilirubinaemia of the Dubin-Johnson syndrome. Anaphylactic reactions may

Urine tests
Dipstick tests are available for bilirubin and urobilinogen. Bilirubinuria is due to the presence of conjugated (soluble) bilirubin. It is found in the jaundiced patient with hepatobiliary disease; its absence implies that the jaundice is due to increased unconjugated bilirubin. Urobilinogen in the urine is, in practice, of little value but suggests haemolysis or hepatic dysfunction of any cause.

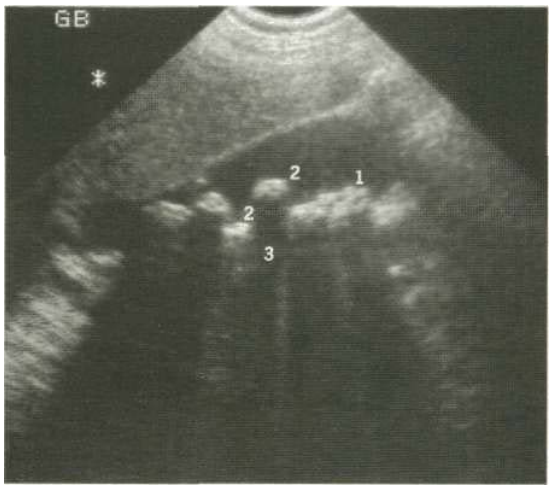

***Fig. 7.6* Gall bladder ultrasound with multiple echogenic gallstones causing well-defined acoustic shadowing.** 1, gall bladder; 2, gallstones; 3, echogenic shadow.

Imaging techniques

Ultrasound examination
This is a non-invasive, safe and relatively cheap technique. It involves the analysis of the reflected ultrasound beam detected by a probe moved across the abdomen. The normal liver appears as a relatively homogeneous structure. The gall bladder, common bile duct, pancreas, portal vein and other structures in the abdomen can be visualized. Abdominal ultrasound is useful in:

a jaundiced patient (p. 358) hepatomegaly/splenomegaly the detection of gallstones (Fig. 7.6) focal liver disease - lesions > 1 cm general parenchymal liver disease assessing portal and hepatic vein patency lymph node enlargement.

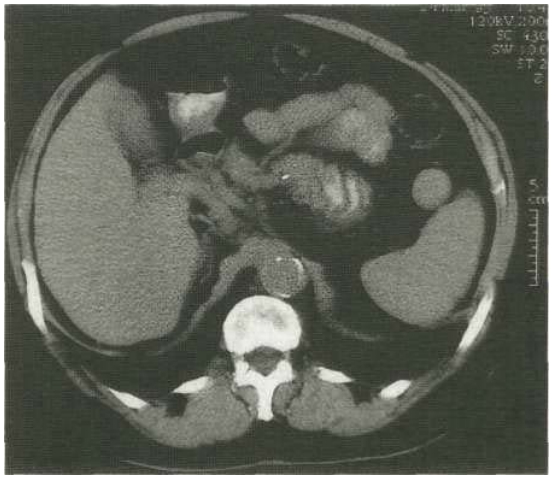
Other abdominal masses can be delineated and biopsies obtained under ultrasonic guidance. Colour Doppler ultrasound will demonstrate the vascularity of a lesion and the direction of blood flow in the portal and hepatic veins. The introduction of ultrasound contrast agents, most of which are based on the production of micro-bubbles within the flowing blood, may enhance the vascularity within a lesion, allowing abnormal circulation to be detected within liver nodules, giving a more specific diagnosis of hepatocellular carcinoma.

Computed tomography (CT) examination
This technique is complementary to ultrasound, which should usually be performed first. It provides excellent visualization of the liver, pancreas, spleen, lymph nodes and lesions in the porta hepatis. CT allows assessment of the size, shape and density of the liver and can characterize focal lesions in terms of their vascularity. CT is more sensitive in detecting calcification than plain X-rays. Ultrasound is usually more valuable for lesions in the bile duct and gall bladder, CT has advantages in obese subjects.

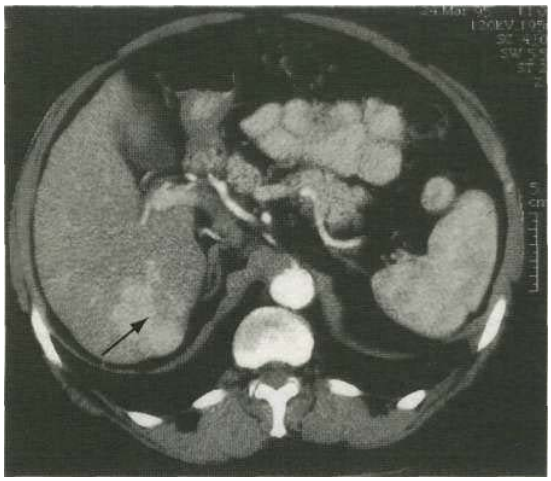
Spiral CT involves rapid acquisition of a volume of data during or immediately after i.v. contrast injection. Data can thus be acquired in both arterial and portal venous phases of enhancement, enabling more precise characterization of a lesion and its vascular supply (Fig. *7.7).* Retrospective analysis of data allows multiple overlapping slices to be obtained with no increase in the radiation dose. Multi-planar and three-dimensional reconstruction in the arterial phase can create a CT angiogram, often making formal invasive angiography unnecessary. CT also provides guidance for biopsy. In general lesions over 2 cm can usually be biopsied under ultrasound guidance, which is quicker and more cost-effective.

Magnetic resonance imaging **(MRI)**
(see also p. 1202)
MRI produces cross-sectional images in any plane within the body. Diffuse liver disease alters the Tl and T2 characteristics, and MRI is probably the most sensitive investigation of focal liver disease. Other fat-suppression modes such as STIR allow good differentiation between haemangiomas and other lesions. Contrast agents such as intravenous gadolinium allow further characterization of lesions, and are suitable for those with iodine allergy and provide angiography and venography of the splanchnic circulation. This has superseded direct arteriography.

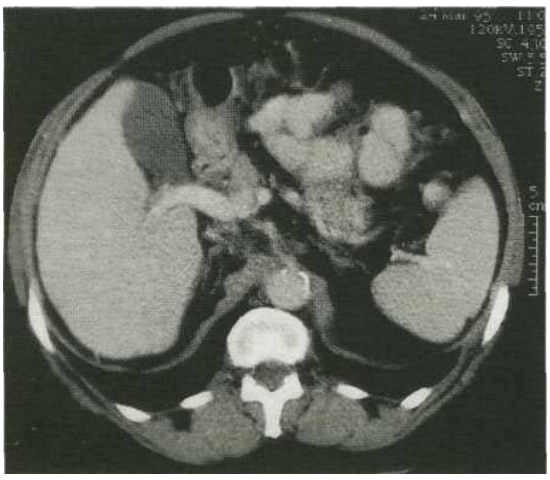
Magnetic resonance cholangiopancreatography (MRCP)
This technique involves the manipulation of a volume of data acquired by MRI. A heavily T2-weighted sequence



(a) Unenhanced.



(b) Arterial phase (note high density contrast in the aorta).



(c) Portal venous phase scan through the right lobe of the liver.

Fig. 7.7 **Use of contrast-enhanced spiral CT.**
There is an irregular mass (arrow) in the posterior aspect of the right lobe of the liver which is only well seen on the early arterial phase enhanced scan (b).

enhances visualization of the 'water-filled' bile ducts and pancreatic ducts to produce high-quality images of ductal anatomy. This non-invasive technique is replacing diagnostic (but not therapeutic) ERCP (see below).

Plain X-rays of the abdomen

These are rarely requested but may show:

- gallstones - 10% contain enough calcium to be seen
- air in the biliary tree owing to its recent instrumentation, surgery or to a fistula between the intestine and the gall bladder
- pancreatic calcification
- rarely, calcification of the gall bladder (porcelain gall bladder).

Cholecystogram

This test is rarely required as it has been almost universally replaced by ultrasound but may be useful as a test of gall bladder function. Oral iopanoic acid is absorbed from the gut, conjugated in the liver, secreted in bile and concentrated in the gall bladder, which opacifies homogeneously. A fatty meal is given to make the gall bladder contract. The dye is excreted by the liver via the same mechanism as bilirubin, so that non-visualization will occur in the jaundiced patient and in the patient with liver disease.

Radionuclide imaging - scintiscanning

In a technetium-99m (^{99m}Tc) colloid scan, the colloid is injected intravenously to be taken up by the reticulo-endothelial cells of the liver and spleen. In chronic liver disease there is poor intake in the liver and most of the colloid is taken up in the spleen and bone marrow. Ultrasound has largely replaced this technique.

In a ^{99m}Tc-Iodida scan, technetium-labelled iododiethyl IDA is taken up by the hepatocytes and excreted rapidly into the biliary system. Its main uses are in the diagnosis of:

- acute cholecystitis
- jaundice due to either biliary atresia or hepatitis in the neonatal period.

Endoscopy

Upper GI endoscopy is used for the diagnosis and treatment of varices, for the detection of portal hypertensive gastropathy, and for associated lesions such as peptic ulcers. Colonoscopy may show portal hypertensive colopathy.

Endoscopic ultrasound (EUS)

In this technique, a small high-frequency ultrasound probe is mounted on the tip of an endoscope and placed by direct vision into the duodenum. The close proximity of the probe to the pancreas and biliary tree permits high-resolution ultrasound imaging. It allows accurate staging of small, potentially operable, pancreatic tumours and offers a less-invasive method for bile duct imaging. It has a high accuracy in detection of small neuroendocrine

tumours of the pancreas. EUS-guided fine-needle aspiration of tumours provides cytological/histological tissue for confirmation of malignancy. EUS is also used to place transmural tubes to drain pancreatic and peri-pancreatic fluid collections.

Endoscopic retrograde cholangiopancreatography (ERCP)

This technique is used to outline the biliary and pancreatic ducts. It involves the passage of an endoscope into the second part of the duodenum and cannulation of the ampulla. Contrast is injected into both systems and the patient is screened radiologically. Contrast medium with a low iodine content of 1.5 mg/mL is used for the common bile duct so that gallstones are not obscured; a higher iodine content of 2.8 mg/mL is used for the pancreatic duct. In addition, other diagnostic and therapeutic procedures can be carried out:

- Common bile duct stones can be removed after a diathermy cut to the sphincter has been performed to facilitate their withdrawal (p. 403). Sphincterotomy has a serious morbidity rate of 3-5%: acute pancreatitis is the commonest, severe haemorrhage is rare. There is an overall mortality of 0.5-1%.
- The biliary system can be drained by passing a tube (stent) through an obstruction, or placement of a nasobiliary drain.
- Brachytherapy can be administered after placement at ERCP for therapy of cholangiocarcinoma.

The complication rate in diagnostic ERCP is 2-3%.

A raised serum amylase is often seen and pancreatitis is the most common complication. Cholangitis is also seen, and broad-spectrum antibiotics (e.g. 500 mg ciprofloxacin x 2) should be given prophylactically to all patients with suspected biliary obstruction, or a history of cholangitis.

Percutaneous transhepatic cholangiography (PTC)

Under a local anaesthetic, a fine flexible needle is passed into the liver. Contrast is injected slowly until a biliary radicle is identified and then further contrast is injected to outline the whole of the biliary tree. In patients with dilated ducts, the success rate is near 100%. ERCP is the preferred first investigation because therapy (e.g. stone removal) can be undertaken at the same time.

In difficult cases the two techniques are sometimes combined, PTC showing the biliary anatomy above the obstruction, with ERCP showing the more distal anatomy. If an obstruction in the bile ducts is seen, a bypass stent can sometimes be inserted, draining either externally or, for long-term use, internally. Contraindications are as for liver biopsy (see below). The main complications are bleeding and cholangitis with septicaemia, and prophylactic antibiotics should be given as for ERCP.

Angiography

This is performed by selective catheterization of the coeliac axis and hepatic artery. It detects the abnormal vasculature of hepatic tumours, but spiral CT and magnetic resonance angiography (MRA) have replaced this in many cases. The portal vein can be demonstrated with increased definition using subtraction techniques, and splenoportography (by direct splenic puncture) is rarely performed. In digital vascular imaging (DVI), contrast given intravenously or intra-arterially can be detected in the portal system using computerized subtraction analysis. Hepatic venous cannulation allows abnormal hepatic veins to be diagnosed in patients with Budd-Chiari syndrome and also serves as an indirect measurement of portal pressure. There is a 1:1 relationship of occluded (by balloon) hepatic venous pressure with portal pressure in patients with alcoholic or viral-related cirrhosis. The height of portal pressure has been shown to have prognostic value for survival and a reduced portal pressure 20% from baseline values has been associated with protection from rebleeding. Retrograde CO_2 portography is used when there is doubt about portal vein patency and can be combined with transjugular biopsy and hepatic venous pressure measurement.

Liver biopsy (see Practical box 7.1)

Histological examination of the liver is valuable in the differential diagnosis of diffuse or localized parenchymal disease. Liver biopsy can be performed on a day-case or overnight-stay basis. The indications and contra-indications are shown in Table 7.2. The mortality rate is less than 0.02% when performed by experienced operators.

Practical Box 7.1
Needle biopsy of the liver

This should be performed only by experienced doctors and with sterile precautions. Patient consent must be obtained following explanation of the procedure.

- The patient's coagulation status (prothrombin time, platelets) is checked.
- The patient's blood group is checked and serum saved for crossmatching.
- The patient lies on his back at the edge of the couch.
- The liver margins are delineated using percussion. *Alternatively* ultrasound examination can be used to confirm liver margins and position of the gall bladder.

B Local anaesthetic is injected at the point of maximum dullness in the mid-axillary line through the intercostal space during expiration. Anaesthetic (1% lidocaine), approximately 5 mL) should be injected down to the liver capsule.

- A tiny cut is made in the skin with a scalpel blade.
- A special needle (Menghini, Trucut or Surecut) is used to obtain the liver biopsy whilst the patient holds his breath in expiration.

m The biopsy is laid on filter paper and placed in 10% formalin. If a culture of the biopsy is required it should be placed in a sterile pot.

- The patient should be observed, with pulse and blood pressure measurements taken regularly for at least 6 h.

Table 7.2 **Indications and contraindications for liver biopsy**

Indications

Liver disease
- Unexplained hepatomegaly
- Some cases of jaundice
  - Persistently abnormal liver biochemistry
  - Occasionally in acute hepatitis
  - Chronic hepatitis
- Cirrhosis
- Drug-related liver disease
- Infiltrations
- Tumours: primary or secondary
- Infections (e.g. tuberculosis)
- Storage disease (e.g. glycogen storage)

Pyrexia of unknown origin

Usual contraindications to percutaneous needle biopsy

Uncooperative patient
Prolonged prothrombin time (by more than 3 s)
Platelets < 80×10^9/L
Ascites
Extrahepatic cholestasis

Liver biopsy guided by ultrasound or CT is also performed particularly when specific lesions need to be biopsied. Laparoscopy with guided liver biopsy is performed through a small incision in the abdominal wall under local anaesthesia (general anaesthesia is preferred in some centres). A transjugular approach is used when liver histology is essential for management but coagulation abnormalities prevent the percutaneous approach.

Most complications of liver biopsy occur within 24 hours (usually in the first 2 hours). They are often minor and include abdominal or shoulder pain which settles with analgesics. Minor intraperitoneal bleeding can occur, but this settles spontaneously. Rare complications include major intraperitoneal bleeding, haemothorax and pleurisy, biliary peritonitis, haemobilia and transient septicaemia. Haemobilia produces biliary colic, jaundice and melaena within 3 days of the biopsy.

SYMPTOMS OF LIVER DISEASE

Acute liver disease

This may be asymptomatic and anicteric. Symptomatic disease, which is often viral, produces generalized symptoms of malaise, anorexia and fever. Jaundice may appear as the illness progresses.

Chronic liver disease

Patients may be asymptomatic or complain of non-specific symptoms, particularly fatigue. Specific symptoms include:

- right hypochondrial pain due to liver distension
- abdominal distension due to ascites
- ankle swelling due to fluid retention
- haematemesis and melaena from gastrointestinal haemorrhage
- pruritus due to cholestasis - this is often an early symptom of primary biliary cirrhosis
- breast swelling (gynaecomastia), loss of libido and amenorrhoea due to endocrine dysfunction
- confusion and drowsiness due to neuropsychiatric complications (portosystemic encephalopathy).

SIGNS OF LIVER DISE

Acute liver disease

There may be few signs apart from jaundice and an enlarged liver. Jaundice is a yellow coloration of the skin and mucous membranes and is best seen in the conjunctivae and sclerae. In the cholestatic phase of the illness, pale stools and dark urine are present. Spider naevi and liver palms usually indicate chronic disease but they can occur in severe acute disease.

Chronic liver disease

The physical signs are shown in Figure 7.8. However, it is possible for the physical examination to be normal in patients with advanced chronic liver disease.

The skin

The chest and upper body may show spider naevi. These are telangiectases that consist of a central arteriole with radiating small vessels. They are found in the distribution of the superior vena cava (i.e. above the nipple line). They are also found in pregnancy. In haemochromatosis the skin may have a slate-grey appearance.

The hands may show palmar erythema, which is a non-specific change indicative of a hyperdynamic circulation; it is also seen in pregnancy, thyrotoxicosis or rheumatoid arthritis. Clubbing occasionally occurs, and a Dupuytren's contracture is often seen in alcoholic cirrhosis.

Xanthomas (cholesterol deposits) are seen in the palmar creases or above the eyes in primary biliary cirrhosis.

The abdomen

Initial hepatomegaly will be followed by a small liver in well-established cirrhosis. Splenomegaly is seen with portal hypertension.

The endocrine system

Gynaecomastia (occasionally unilateral) and resricuiar atrophy may be found in males. The cause of

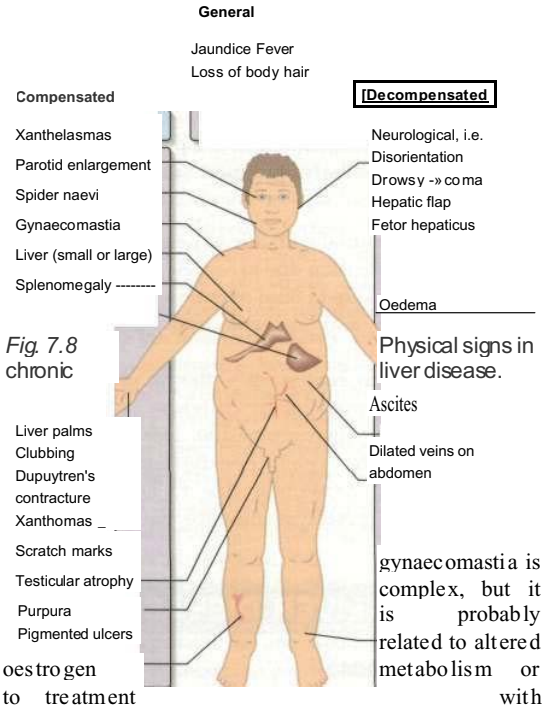

Fig. 7.8 Physical signs in chronic liver disease.

gynaecomastia is complex, but it is probably related to altered metabolism or oestrogen to treatment with spironolactone.

In decompensated cirrhosis, additional signs that can be seen are shown in Figure 7.8.

JAUNDI

Jaundice (icterus) is detectable clinically when the serum bilirubin is greater than 50 μmoI/L (3 mg/dL). The usual division of jaundice into prehepatic, hepatocellular and obstructive (cholestatic) is an oversimplification as in hepatocellular jaundice there is invariably cholestasis and the clinical problem is whether the cholestasis is intrahepatic or extrahepatic. Jaundice will therefore be considered under the following headings:

- haemolytic jaundice - increased bilirubin load for the liver cells
- congenital hyperbilirubinaemias - defects in conjugation
- cholestatic jaundice, including hepatocellular (parenchymal) liver disease and large duct obstruction.

Haemolytic jaundice

The increased breakdown of red cells (see p. 424) leads to an increase in production of bilirubin. The resulting jaundice is usually mild (serum bilirubin of 68-102 μmoI/L or 4-6 mg/dL) as normal liver function can easily handle the increased bilirubin derived from excess haemolysis.

Unconjugated bilirubin is not water-soluble and therefore will not pass into the urine; hence the term 'acholuric jaundice'. Urinary urobilinogen is increased.

The causes of haemolytic jaundice are those of haemolytic anaemia (p. 438). The clinical features depend on the cause; anaemia, jaundice, splenomegaly, gallstones and leg ulcers may be seen.

Investigations show features of haemolysis (p. 437). The level of unconjugated bilirubin is raised but the serum ALP, transferases and albumin are normal. Serum haptoglobulins are low. The differential diagnosis is from other forms of jaundice.

Congenital hyperbilirubinaemias (non-haemolytic)

Unconjugated

Gilbert's syndrome

This is the most common familial hyperbilirubinaemia and affects 2-7% of the population. It is asymptomatic and is usually detected as an incidental finding of a slightly raised bilirubin (17-102 μmoI/L or 1-6 mg/dL) on a routine check. All the other liver biochemistry is normal and no signs of liver disease are seen. There is a family history of jaundice in 5-15% of patients. Hepatic glucuronidation is approximately 30% of normal, resulting in an increased proportion of bilirubin monoglucuronide in bile. Most patients have reduced levels of UDP-glucuronosyl transferase (UGT-1) activity, the enzyme that conjugates bilirubin with glucuronic acid. Mutations occur in the gene *(HUG-Brl)* encoding this enzyme, with an expanded nucleotide repeat consisting of two extra bases in the upstream 5' promoter element. This abnormality appears to be necessary for the syndrome, but is not in itself sufficient for the phenotypic expression of the syndrome.

The major importance of establishing this diagnosis is to inform the patient that this is not a serious disease and to prevent unnecessary investigations. The raised unconjugated bilirubin rises on fasting and during a mild illness. The reticulocyte count is normal, excluding haemolysis and no treatment is necessary.

Crigler-Najjar syndrome

This is very rare. Only patients with type II (autosomal dominant) with a decrease rather than absence (type I - autosomal recessive) of UDP-glucuronosyl transferase can survive into adult life. Mutation of the *HUG-Brl* gene for UDP-glucuronosyl transferase has been demonstrated in the coding region. Liver histology is normal. Transplantation is the only effective treatment.

Conjugated

Dubin-Johnson (autosomal recessive) and *Rotor's* (possibly autosomal dominant) *syndromes* are due to defects in bilirubin handling in the liver. The prognosis is good in both. In the Dubin-Johnson syndrome there are mutations in both *MRP2* (p. 349) transporter genes. The liver is black owing to melanin deposition.

Recurrent familial intrahepatic cholestasis (FIC1), benign recurrent intrahepatic cholestasis

This is rare. Recurrent attacks of acute cholestasis occur without progression to chronic liver disease. Jaundice, severe pruritus, steatorrhoea and weight loss develop. Serum γ-GT is normal. The gene has been mapped to the FIC1 locus, but the precise relation to cholestasis is unclear.

Progressive familial intrahepatic cholestasis syndromes

These are autosomal recessive. In *type 1,* with cholestasis in infancy (previously known as Byler's disease), γ-GT is normal. The gene is also on the FIC1 locus, but has been mapped to a region encoding P type ATPases. *Type 2* has been mapped to the bile salt export pump gene *(BSEP).* The protein is located in the canalicular domain of the plasma membrane of the hepatocyte. The phenotypic expression frequently presents as a non-specific giant cell hepatitis progressing to cholestasis. *Type 3* is due to PGY3 gene mutation leading to deficient canalicular phosphatidylcholine transport and thus toxic bile causing liver damage. Liver transplantation is the only cure for these syndromes. ■

Intrahepatic cholestasis of pregnancy

This has been associated with mutations in the genes of the progressive familial intrahepatic cholestasis syndromes. It is described on page 393. : ■·„■··

Jansen PLM, Muller M (2000) The molecular genetics of familial intrahepatic cholestasis. *Gut* 47: 1—5.

Cholestatic jaundice (acquired)

This can be divided into extrahepatic and intrahepatic cholestasis. The causes are shown in Figure 7.9.

- Extrahepatic cholestasis is due to large duct obstruction of bile flow at any point in the biliary tract distal to the bile canaliculi.
- Intrahepatic cholestasis occurs owing to failure of bile secretion. A number of cellular mechanisms in cholestasis have been described in animal models, including inhibition of the Na^+-K^+-ATPase in the basolateral membranes, decreased fluidity of the sinusoidal plasma membrane, disruption of the microfilaments responsible for canalicular tone, and damage to the tight junctions. In addition, inflammatory change in ductular cells interferes with bile flow.

Clinically in both types there is jaundice with pale stools and dark urine, and the serum bilirubin is conjugated. However, intrahepatic and extrahepatic cholestatic jaundice must be differentiated as their clinical management is entirely different.

Differential diagnosis of jaundice

A careful history may give a clue to the diagnosis. Certain causes of jaundice are more likely in particular categories of people. For example, a young person is more likely to have hepatitis, so questions should be asked about drug and alcohol use, and sexual behaviour. An elderly person with gross weight loss is more likely to have a carcinoma. All patients may complain of malaise. Abdominal pain occurs in patients with biliary obstruction by gallstones and, sometimes with an enlarged liver there is pain resulting from distension of the capsule.

Questions should be appropriate to the particular situation, and the following aspects of the history should be covered.

- *Country of origin.* The incidence of hepatitis B virus (HBV) infection is increased in many parts of the world (p. 364).
- *Duration of illness.* A history of jaundice with prolonged weight loss in an older patient suggests malignancy. A short history, particularly with a prodromal illness of malaise, suggests a hepatitis.
- *Recent outbreak of jaundice.* An outbreak in the community suggests hepatitis A virus (HAV).

Types	HAEMOGLOBIN 4 BILIRUBIN 11	Causes
Prehepatic		Haemolysis
Cholestatic		
Intrahepatic	CONJUGATION	Viral hepatitis Drugs Alcoholic hepatitis Cirrhosis - any type Pregnancy Recurrent idiopathic cholestasis Some congenital disorders Infiltrations
Extrahepatic	GALL BLADDER	Common duct stones Carcinoma - bile duct - head of pancreas - ampulla Biliary stricture
	PANCREAS —	Sclerosing cholangitis Pancreatitis pseudocyst

Fig. 7.9 Causes of jaundice.

Recent consumption of shellfish. This suggests HAV infection.

- *Intravenous drug abuse, or recent injections or tattoos.* These all increase the chance of HBV and hepatitis C virus (HCV) infection.
- *Male homosexuality.* This increases the chance of HBV infection.
- *Female prostitution.* This increases the chance of HBV infection.
- *Blood transfusion or infusion of pooled blood products.* Increased risk of HBV and HCV. In developed countries all donors are screened for HBV and HCV.
- *Alcohol consumption.* A careful history of drinking habits should be taken, although many patients often understate the actual amount they drink.
- *Drugs taken* (particularly in the previous 2-3 months). Many drugs cause jaundice (see p. 396).
- *Travel.* Certain areas have an increased risk of HAV infection as well as hepatitis E (HEV) infection (this has a high mortality in pregnancy).
- *A recent anaesthetic.* Halothane (see p. 396) and occasionally enflurane, isoflurane, for example, may cause jaundice, particularly in those already sensitive to halogenated anaesthetics. The risk with desflurane appears remote.
- *Family history.* Patients with, for example, Gilbert's disease may have family members who get recurrent jaundice.
- *Recent surgery* on the biliary tract or for carcinoma.
- *Environment.* People engaged in recreational activities in rural areas, as well as farm and sewage workers, are at risk for leptospirosis.
- *Fevers or rigors.* These are suggestive of cholangitis or possibly a liver abscess.

Clinical features

The signs of acute and chronic liver disease should be looked for (p. 358). Certain additional signs may be helpful:

- **Hepatomegaly.** A smooth tender liver is seen in hepatitis and with extrahepatic obstruction, but a knobbly irregular liver suggests metastases. Causes of hepatomegaly are shown in Table 7.3.
- **Splenomegaly.** This indicates portal hypertension in patients when signs of chronic liver disease are present. The spleen can also be 'tipped' occasionally in viral hepatitis.
- Ascites. This is found in cirrhosis but can also be due to carcinoma (particularly ovarian) and many other causes (see Table 7.14).

A palpable gall bladder can suggest a carcinoma of the pancreas obstructing the bile duct. Generalized lymphadenopathy suggests a lymphoma.

Cold sores may suggest a herpes simplex virus hepatitis.

Investigations

Jaundice is not itself a diagnosis and the cause should always be sought. The two most useful tests are the viral markers for HAV, HBV and HCV (in high-risk groups), plus an ultrasound examination. Liver biochemistry confirms the jaundice and may help in the diagnosis.

***Table 7.3* Causes of hepatomegaly**

Apparent	**Haematological**
Low-lying diaphragm	Leukaemias
Reidel's lobe	Lymphoma
Cirrhosis (early)	Myeloproliferative disorders
	Thalassaemia
Inflammation	
Hepatitis	**Tumours: primary and secondary carcinoma**
Schistosomiasis	
Abscesses (pyogenic or amoebic)	**Venous congestion**
	Heart failure
Cysts	Hepatic vein occlusion
Hydatid	**Biliary obstruction**
Polycystic	**(particularly extrahepatic)**
Metabolic	
Fatty liver	
Amyloid	
Glycogen storage disease	

An ultrasound examination should always be performed to exclude an extrahepatic obstruction, and to diagnose any features compatible with chronic liver disease except when hepatitis A is strongly suspected in a young patient. Ultrasound will demonstrate:

- the size of the bile ducts, which are dilated in extra hepatic obstruction (Fig. 7.10)
- the level of the obstruction
- the cause of the obstruction in virtually all patients with tumours and in 75% of patients with gallstones.

The pathological diagnosis of any mass lesion can be made by fine-needle aspiration cytology (sensitivity approximately 60%) or by needle biopsy using a spring-loaded device (sensitivity approximately 90%).

A flow diagram for the general investigation of the jaundiced patient is shown in Figure 7.11.

Liver biochemistry

In hepatitis, the serum AST or ALT tends to be high early in the disease with only a small rise in the serum ALP. Conversely, in extrahepatic obstruction the ALP is high with a smaller rise in aminotransferases. These findings cannot, however, be relied on alone to make a diagnosis in an individual case. The prothrombin time (PT) is often prolonged in long-standing liver disease, and the serum albumin is also low.

Haematological tests

In haemolytic jaundice the bilirubin is raised and the other liver biochemistry is normal (p. 358). A raised white cell count may indicate infection (e.g. cholangitis). A leucopenia often occurs in viral hepatitis, while abnormal mononuclear cells suggest infectious mononucleosis and a Monospot test should be performed.

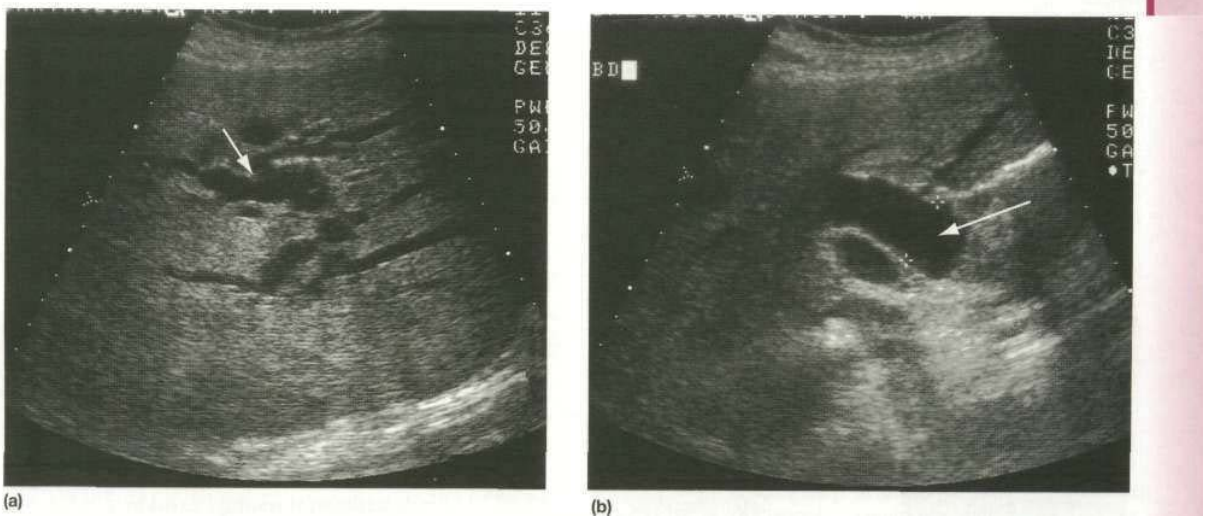

Fig. 7.10 Liver ultrasound showing (a) dilated intrahepatic bile ducts (arrow), (b) common bile duct (arrow). The normal bile duct measures 6 mm at the porta hepatis.

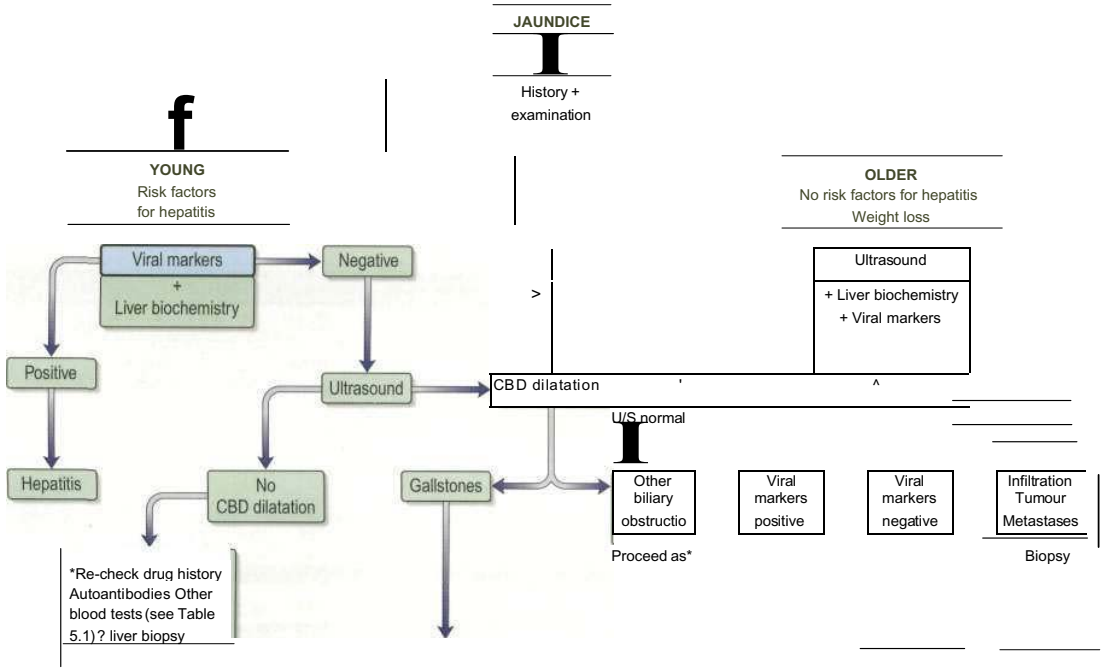

Fig. 7.11 Approach to patient with jaundice. ERCR endoscopic retrograde cholangiopancreatography; CBD, common bile duct; US, ultrasound; MRCP, magnetic resonance cholangiopancreatography.

Other blood tests

These include tests to exclude unusual causes of liver disease (e.g. cytomegalovirus antibodies), autoimmune antibodies, e.g. antimitochondrial antibodies (AMA) for the diagnosis of primary biliary cirrhosis, and α-fetoprotein for a hepatocellular carcinoma.

ACUTE HEPATITI

Acute parenchymal liver damage can be caused by many agents (Fig. 7.12).

Pathology

Although some histological features are suggestive of the aetiological factor, most of the changes are essentially

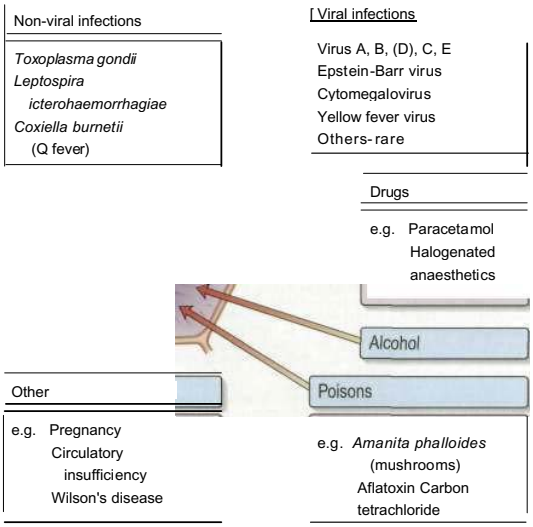

Fig. 7.12 **Some causes of acute parenchymal damage.**

similar whatever the cause. Hepatocytes show degenerative changes (swelling, cytoplasmic granularity, vacuolation), undergo necrosis (becoming shrunken, eosinophilic Councilman bodies) and are rapidly removed. The distribution of these changes varies somewhat with the aetiological agent, but necrosis is usually maximal in zone 3. The extent of the damage is very variable between individuals affected by the same agent: at one end of the spectrum, single and small groups of hepatocytes die (spotty or focal necrosis), while at the other end there is multiacinar necrosis involving a substantial part of the liver (massive hepatic necrosis) resulting in fulminant hepatic failure. Between these extremes there is limited confluent necrosis with collapse of the reticulin framework resulting in linking (bridging) between the central veins, the central veins and portal tracts, and between the portal tracts. The extent of the inflammatory infiltrate is also variable, but portal tracts and lobules are infiltrated mainly by lymphocytes. Other variable features include cholestasis in zone 3 and fatty change, the latter being prominent in hepatitis that is due to alcohol or certain drugs.

Management

This is discussed below under the individual aetiological factors.

The differing features of the common forms of viral hepatitis are summarized in Table 7.4.

Hepatitis A

Hepatitis A virus **(HAV)**

HAV is a picornavirus, having the structure shown in Figure 7.13. It has a single serotype as only one epitope is immunodominant. It replicates in the liver, is excreted in

Table 7.4 **Some features of hepatitis viruses**

		B			
Virus	RNA	DNA	RNA	RNA	RNA
	27 nm	42 nm	36 nm (with HBsAg coat)	approx. 50 nm	27 nm
	Picorna	Hepadna	Unclassified	Flavi	Calici

Immunization:					
Passive	Normal immunoglobulin serum i.m. (0.04-0.06 mlVkg)	Hepatitis B immunoglobulin (HBIg)	No	No	No
Active	Vaccine	Vaccine	HBV vaccine	No	No

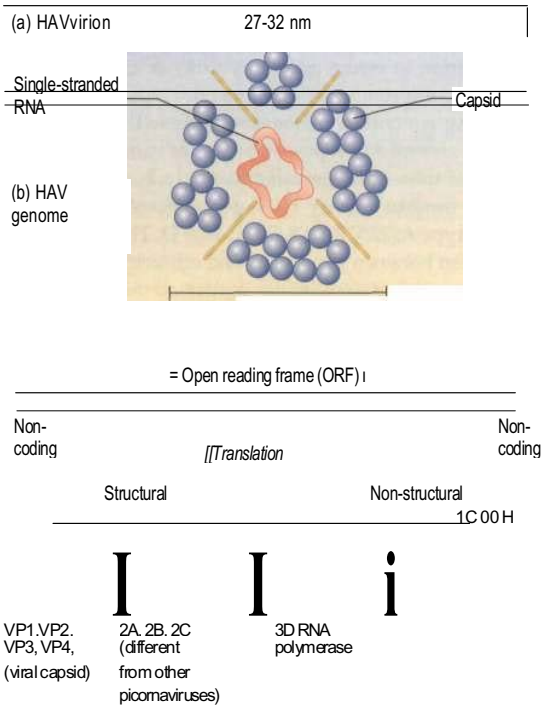

Fig. 7.13 (a) The hepatitis A (HAV) virion consists of four polypeptides (VP1-VP4) which form a tight protein shell, or capsid, containing the RNA. The major antigenic component is associated with VP1. (b) Arrangement of HAV genome.

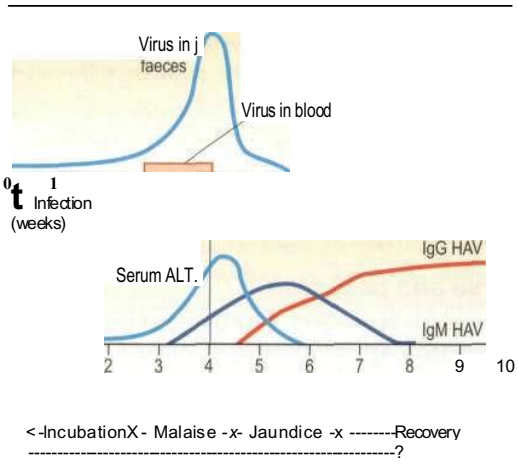

Fig. 7.14 **HAV - sequence of events after exposure.**

bile and is then excreted in the faeces of infected persons for about 2 weeks before the onset of clinical illness and for up to 7 days after. The disease is maximally infectious just before the onset of jaundice. HAV particles can be demonstrated in the faeces by electron microscopy.

Epidemiology

Hepatitis A is the most common type of viral hepatitis occurring world-wide, often in epidemics. The disease is commonly seen in the autumn and affects children and young adults. Spread of infection is mainly by the faeco-oral route and arises from the ingestion of contaminated food or water (e.g. shellfish). Overcrowding and poor sanitation facilitate spread. There is no carrier state. In the UK it is a notifiable disease.

Clinical features

The viraemia causes the patient to feel unwell with non-specific symptoms that include nausea, anorexia and a distaste for cigarettes. Many recover at this stage and remain anicteric.

After 1 or 2 weeks some patients become jaundiced and symptoms often improve. As the jaundice deepens, the urine becomes dark and the stools *pale* owing to intrahepatic cholestasis. The liver is moderately enlarged and the spleen is palpable in about 10% of patients.

Occasionally, tender lymphadenopathy is seen, with a transient rash in some cases. Thereafter the jaundice lessens and in the majority of cases the illness is over within 3-6 weeks. Extrahepatic complications are rare but include arthritis, vasculitis, myocarditis and renal failure. A biphasic illness occasionally occurs, with the return of jaundice. Rarely the disease may be very severe with fulminant hepatitis, liver coma and death. The typical sequence of events after HAV exposure is shown in Figure 7.14.

Investigations

Liver biochemistry

In the prodromal stage the serum bilirubin is usually normal. However, there is bilirubinuria and increased urinary urobilinogen. A raised serum AST or ALT, which can sometimes be very high, precedes the jaundice.

In the icteric stage the serum bilirubin reflects the level of jaundice. Serum AST reaches a maximum 1-2 days after the appearance of jaundice, and may rise above 500 IU/L. Serum ALP is usually less than 300 IU/L.

After the jaundice has subsided, the aminotransferases may remain elevated for some weeks and occasionally for up to 6 months.

Haematological tests

There is leucopenia with a relative lymphocytosis. Very rarely there is a Coombs'-positive haemolytic anaemia or an associated aplastic anaemia. The prothrombin time (PT) is prolonged in severe cases. The erythrocyte sedimentation rate (ESR) is raised.

Viral markers: antibodies to HAV

IgG antibodies are common in the general population over the age of 50 years, but an anti-HAV IgM means an *acute infection. In areas of high prevalence most children* have antibodies by the age of 3 years following asymptomatic infection.

that found in HAV infection, although the illness may be more severe. In addition, a serum sickness-like immunological syndrome may be seen. This consists of rashes (e.g. urticaria or a maculopapular rash) and polyarthritis affecting small joints occurring in up to 25% of cases in the prodromal period. Fever is usual. Extrahepatic immune complex-mediated conditions such as an arteritis or glomerulonephritis are occasionally seen.

Investigations

These are generally the same as for hepatitis A.

Specific tests

The markers for HBV are shown in Table 7.6. HBsAg is looked for initially; if it is found, a full viral profile is then performed. In acute infection, as HBsAg may be cleared rapidly, anti-HBc IgM is diagnostic. HBV DNA is the most sensitive index of viral replication and is found without e antigen in hepatitis due to mutants. HBV DNA has been shown to persist (using PCR techniques) even when the e antibody has developed.

Course

The majority of patients recover completely, fulminant hepatitis occurring in up to 1%. Some patients go on to develop chronic hepatitis (p. 370) and hepatocellular carcinoma (p. 394) or become asymptomatic carriers (Fig. 7.17). The outcome depends upon several factors, including the virulence of the virus and the immunocompetence and age of the patient as well as some genetic factors, while abnormalities in mannan-binding protein (p. 200) may alter host defence to HBV.

Treatment

There is no specific treatment apart from symptomatic therapy.

Prevention and prophylaxis

Prevention depends on avoiding risk factors, such as shared needles, multiple male homosexual partners, and prostitutes. Infectivity is highest in those with the e antigen and/or HBV DNA in their blood. These patients should be counselled about their infection. In developing countries, blood and blood products are still a hazard. Standard safety precautions in laboratories and hospitals must be enforced strictly to avoid accidental needle punctures and contact with infected body fluids.

Table 7.6 Significance of viral markers in hepatitis B

Antigens	
HBsAg	Acute or chronic infection
HBeAg	Acute hepatitis B Persistence implies: continued infectious state development of chronicity increased severity of disease
HBV DNA	Implies viral replication Found in serum and liver
Antibodies	
Anti-HBs	Immunity to HBV; previous exposure
Anti-HBe	Seroconversion
Anti-HBc	
IgM	Acute hepatitis B (high titre) Chronic hepatitis B (low titre)
IgG	Past exposure to hepatitis B (HBsAg-negative)

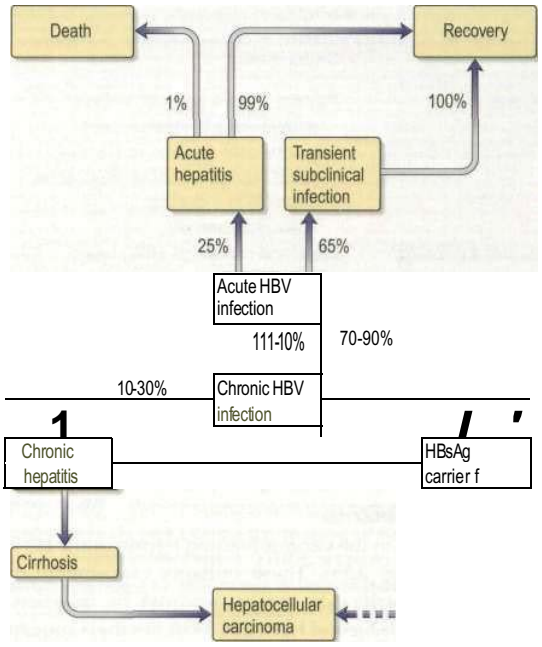

***Fig. 7.17* Clinical course of hepatitis B infection.**
*, percentage variable world-wide; † have normal liver biochemistry - a minority, having acquired infection at birth or in childhood, are HBeAg and HBV-DNA-positive. They may develop hepatitis as the immune system recognizes infected hepatocytes.

Passive and active immunization

Vaccination is universal in most developed countries as well as countries with high endemicity. Groups at high risk are: all healthcare personnel; members of emergency and rescue teams; morticians and embalmers; children in high-risk areas; people with haemophilia; patients in some psychiatric units; patients with chronic renal failure/on dialysis units; long-term travellers; homosexual and bisexual men and prostitutes; intravenous drug abusers.

Combined prophylaxis (i.e. vaccination and immunoglobulin) should be given to: staff with accidental needlestick injury; all newborn babies of HBsAg-positive mothers; regular sexual partners of HBsAg-positive patients, who have been found to be HBV-negative.

To adults give 500 IU of specific hepatitis B immunoglobulin (HBIG) (200 IU to newborns) and the vaccine i.m. at another site.

Active immunization

This is with a recombinant yeast vaccine produced by

insertion of a plasmid containing the gene of HBsAg into a yeast.

Dosage regimen. Three injections (at 0, 1 and 6 months) are given into the deltoid muscle; this gives short-term protection in over 90% of patients. People who are over 50 years of age or clinically ill and/or immunocompromised (including those with HIV infection or AIDS) have a poor antibody response; more frequent and larger doses are required. Antibody levels should be measured at 7-9 months after the initial dose in all at-risk groups. Antibody levels fall steadily after vaccination and booster doses may be required after approximately 3-5 years. It is not cost-effective to check antibody levels prior to active immunization. There are few side-effects from the vaccine; soreness at the site of injection may occur, with very occasionally a fever, rash or a 'flu-like' illness. Vaccines containing pre-S components which have a greater immunogenicity are being developed.

Chronic asymptomatic subjects with HBV

Following an acute HBV infection which may be subclinical, approximately 1-10% of patients will not clear the virus and most will become carriers of HBsAg. This occurs more readily with neonatal or childhood infection than when HBV is acquired in adult life. There is a vast geographical variation in the incidence of carriers. In the UK, asymptomatic carriers are usually discovered incidentally on blood tests, such as when they are screened for donating blood for transfusion or when attending genital medicine or antenatal clinics. Asymptomatic carriers have HBsAg in their serum and are HBeAg-negative, HBe antibody-positive with no HBV DNA in the serum. They have no evidence of active liver disease and are not highly infective. Most remain HBsAg-positive, but do not develop active liver disease; there is an annual spontaneous clearance rate of HBsAg of 1-2%. There are also asymptomatic people who have the e antigen and HBV DNA in the serum. They may have normal liver function tests for many years; liver disease develops when the immune balance changes, and lymphocytes recognize infected hepatocytes causing hepatitis. These patients need to be followed up.

Hepatitis D

This is caused by the hepatitis D virus (HDV or delta virus). It is an incomplete RNA particle enclosed in a shell of HBsAg. It is unable to replicate on its own but is activated by the presence of HBV. It is particularly seen in intravenous drug abusers but can affect all risk groups for HBV infection. Active HBV synthesis is reduced by delta infection and patients are usually negative for HBeAg and HBV DNA. Hepatitis D viral infection can occur either as a co-infection with HBV or as a superinfection in an HBsAg-positive patient.

Co-infection of HDV and HBV is clinically indistinguishable from an acute icteric HBV infection, but a biphasic rise of serum aminotransferases may be seen. *Diagnosis* is confirmed by finding serum IgM anti-delta in the presence of IgM anti-HBc. IgM anti-delta appears at 1 week and disappears by 5-6 weeks (occasionally 12 weeks) when serum IgG anti-delta is seen. The infection may be transient but the clinical course is variable.

Superinfection results in an acute flare-up of previously quiescent chronic HBV infection. A rise in serum AST or ALT may be the only indication of infection. Diagnosis is by finding serum IgM anti-delta at the same time as IgG anti-HBc; patients are usually negative for IgM anti-HBc.

Fulminant hepatitis can follow both types of infection but is more common after co-infection. HDV RNA in the serum and liver can be measured and is found in acute and chronic HDV infection.

Hepatitis C

Hepatitis C virus **(HCV)**

HCV is a single-stranded RNA virus of the Flaviviridae family. The RNA genome is approximately 10 Kb in length, encoding a polyprotein product consisting of structural (capsid and envelope) and non-structural viral proteins (Fig. 7.18). Comparisons of subgenomic regions, such as El, NS4 or NS5, have allowed variants to be classified into at least six genotypes. Variability is distributed throughout the genome with the non-structural gene of different genotypes showing only 65-70% nucleotide sequence similarity. Genotypes la or lb account for 70-80% of cases in the USA and Europe. There is a rapid change in envelope proteins, making it difficult to develop a vaccine. Antigens from the nucleocapsid regions have been used to develop enzyme-linked immunosorbent assays (ELISA). The current assay, ELISA-3, incorporates antigens NS3, NS4 and NS5 regions.

Epidemiology

The prevalence rate of infection in healthy blood donors is about 0.02% in Northern Europe, 1-3% in Southern Europe, possibly linked to intramuscular injections of vaccines or other medicines; 6% in Africa and with rates as high as 19% in Egypt, owing to parenteral antimony treatment for schistosomiasis. The virus is transmitted by blood and blood products and it is postulated that 80% of people with haemophilia in the UK may have been infected. The incidence in intravenous drug abusers is high, up to 90%. The low rate of HCV infection in high-

Fig. 7.18 **Hepatitis C virus.** Diagram showing a single-stranded RNA virus with viral proteins. C, core; NS, non-structural; E, envelope.

risk groups, such as homosexuals, prostitutes and attendees at STI clinics, suggests a limited role for sexual transmission. Vertical transmission from healthy mother to child can occur, but is very rare. Other routes of community-acquired infection (e.g. close contact) are unlikely. In 20% of cases the exact mode of transmission is unknown. An estimated 240 million people are infected with this virus world-wide.

Clinical features

Most acute infections are asymptomatic with about 10% of patients having a mild flu-like illness with jaundice and a rise in serum aminotransferases. Most patients will not be diagnosed until they present, years later, with evidence of abnormal transferase values at health checks or with chronic liver disease. Extrahepatic manifestations are seen, including arthritis, glomerulonephritis associated with cryoglobulinaemia, and porphyria cutanea tarda. There is a higher incidence of diabetes, and associations with lichen planus, sicca syndrome, and non-Hodgkin's lymphoma are under investigation.

Diagnosis

This is frequently by exclusion in a high-risk individual with negative markers for HAV, HBV and other viruses. A drug cause for hepatitis should be excluded if possible. HCV RNA can be detected 1 or 2 weeks after infection. Anti-HCV is usually positive 6 weeks from infection.

Treatment

Interferon has been used in acute cases to prevent chronic disease. Needle-stick injuries must be followed and treated early if there is evidence of HCV viraemia.

Course

At least 85% of patients go on to develop chronic liver disease (p. 372). Cirrhosis develops in about 15-20% within 10-30 years and of these patients between 7% and 15% will develop hepatocellular carcinoma. The course is adversely affected by alcohol consumption, which should be discouraged. Male patients and patients acquiring the infection over 40 years and those with genotype 1 or 4 have a more rapid development of fibrosis.

Hepatitis E

Hepatitis E virus (HEV) is an **RNA** virus (Calicivirus) (Fig. 7.19) which causes a hepatitis clinically very similar to hepatitis A. It is enterally transmitted, usually by contaminated water, with 30% of dogs, pigs and rodents carrying the virus. Epidemics have been seen in many developing countries. It has a mortality from fulminant hepatic failure of 1-2% which rises to 20% in pregnant women. There is no carrier state and it does not progress to chronic liver disease. An ELISA for IgG and IgM anti-HEV is available for diagnosis, although this ELISA is not always reliable. HEV RNA can be detected in the serum or stools by PCR (polymerase chain reaction). Prevention and control depend on good sanitation and hygiene; vaccination may soon be available.

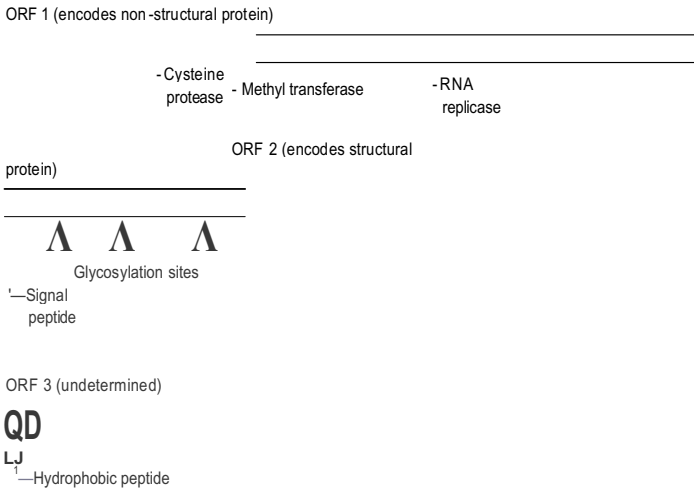

Fig. 7.19 **Hepatitis E genome - showing a single-stranded RNA genome with three open reading frames (ORF).**

Non-A-E hepatitis

Approximately 10-15% of acute viral hepatitides cannot be typed. GB agent (HGV hepatitis G virus) and TTV (transfusion-transmitted virus) agents have not been documented as causing disease in humans. Hepatitis non-A-E is the best term to label this cryptogenic group.

FULMINANT HEPATIC FAILURE (FHF)

This is defined as severe hepatic failure in which encephalopathy develops in under 2 weeks in a patient with a previously normal liver (occasionally in some patients with previous liver damage; e.g. D virus superinfection in a previous carrier of HBsAg and in Wilson's disease). Cases that evolve at a slower pace (2-12 weeks) are called subacute or subfulminant hepatic failure. FHF is a rare but often life-threatening syndrome that is due to acute hepatitis from many causes (Table *7.7*). The causes vary throughout the world; the majority are due to viral hepatitis, but paracetamol overdose is commonly implicated in the UK (50% of cases). HCV does not cause

Table 7.7 **Causes of fulminant hepatic failure**

Viruses	**Toxins**
A, B, (D), E	*Amanita* poisoning
Other viruses	Halohydrocarbons
Drugs (examples) Analgesics (e.g. paracetamol) Monoamine oxidase inhibitors Halogenated anaesthetics Antituberculosis (e.g. isoniazid) Antiepileptic (e.g. valproate) 'Social' drugs (e.g. 'Ecstasy')	Miscellaneous Wilson's disease Acute fatty liver of pregnancy Reye's syndrome Budd-Chiari syndrome Autoimmune hepatitis

FHF although exceptional cases have been reported from Japan.

Histologically there is multiacinar necrosis involving a substantial part of the liver. Severe fatty change is seen in pregnancy (p. 394), Reye's syndrome (p. 395), or following tetracycline administration intravenously.

Clinical features

Examination shows a jaundiced patient with a small liver and signs of hepatic encephalopathy. The mental state varies from slight drowsiness, confusion and disorientation (grades I and II) to unresponsive coma (grade IV) with convulsions. Fetor hepaticus is common, but ascites and splenomegaly are rare. Fever, vomiting, hypotension and hypoglycaemia occur. Neurological examination shows spasticity and extension of the arms and legs; plantar responses remain flexor until late. Cerebral oedema develops in 80% of patients with FHF but is far less common with subacute failure and its consequences of intracranial hypertension and brain herniation are the most common causes of death. Other complications include bacterial and fungal infections, gastrointestinal bleeding, respiratory arrest, renal failure (hepatorenal syndrome and acute tubular necrosis) and pancreatitis.

investigations

There is hyperbilirubinaemia, high serum aminotransferases and low levels of coagulation factors, including prothrombin and factor V. Aminotransferases are not useful indicators of the course of the disease as they tend to fall along with the albumin with progressive liver damage. An EEG is sometimes helpful in grading the encephalopathy. Ultrasound will define liver size and any evidence of underlying liver pathology.

Treatment

There is no specific treatment, but patients should be managed in a specialized unit. Transfer criteria to such units are shown in Box 7.1. Supportive therapy as for hepatic encephalopathy is necessary (see p. 383). When signs of raised intracranial pressure (which is sometimes measured directly) are present, 20% mannitol (1 g/kg bodyweight) should be infused intravenously; this dose may need to be repeated. Dexamethasone is of no value. Hypoglycaemia, hypokalaemia, hypomagnesaemia, hypophosphataemia and hypocalcaemia should be anticipated and corrected with 10% dextrose infusion (checked by 2-hourly Dextrostix testing), potassium, calcium, phosphate, and magnesium. Coagulopathy is managed with intravenous vitamin K, platelets, blood or fresh frozen plasma. Haemorrhage may be a problem and patients are given H_2-receptor antagonists to prevent gastrointestinal bleeding. Prophylaxis against bacterial and fungal infection is routine, and suspected infection should be treated immediately with suitable antibiotics. Renal and respiratory failure should be treated as necessary. Liver transplantation has been a major advance for patients with FHF. It is difficult to judge the timing or the necessity for transplantation, but there are guidelines based on validated prognostic indices of survival (see below).

Box 7.1 **Transfer criteria to specialized units for patients with acute liver injury**

- **fc** INR>3.0
- k Presence of hepatic encephalopathy
- ■ Hypotension after resuscitation with fluid
- ■ Metabolic acidosis
- ■ Prothrombin time (seconds) > interval (hours) from overdose (paracetamol cases)

Box 7.2 **Poor prognostic variables in fulminant hepatic failure indicating a need for liver transplantation**

Non-paracetamol (three of following five)

- \- Drug or non-A-E hepatitis
- t Age < 10 and > 40 years
- « Interval from onset of jaundice to encephalopathy > 7 days
- Serum bilirubin > 300 pmol/L
- Prothrombin time > 50 s (or > 100 s in isolation)

Paracetamol

Arterial pH < 7.3 (after resuscitation, 7.25 on N-acetylcysteine) Or

- Serum creatinine > 300 pmol/L and
- PT > 100 s and
- Grade III-IV encephalopathy

Course and prognosis

In mild cases (grades I and II encephalopathy with drowsiness and confusion), two-thirds of the patients will survive. The outcome of severe cases (grades III and IV encephalopathy with stupor or deep coma) is related to the aetiology. In special units, 70% of patients with paracetamol overdosage and grade IV coma survive, as do 30^10% patients with HAV or HBV hepatitis. Poor prognostic variables indicating a need to transplant the liver are shown in Box 7.2.

ACUTE HEPATITIS DUE TO OTHER VIRUSES

Infectious mononucleosis (see also p. 47) This is due to the Epstein-Barr (EB) virus. Mild jaundice associated with minor abnormalities of liver biochemistry is extremely common, but 'clinical' hepatitis is rare. Hepatic histological changes occur within 5 days of onset; the sinusoids and portal tracts are infiltrated with large mononuclear cells but the liver architecture is preserved. A Paul-Bunnell or Monospot test is usually positive, and atypical lymphocytes are present in the peripheral blood. Treatment is of the symptoms.

Cytomegalovirus (CMV) (see also p. 46) This can cause acute hepatitis, particularly in a patient with an impaired immune response. The virus may be isolated from the urine. The liver biopsy shows intranuclear inclusions and giant cells.

Yellow fever (see also p. 53)
This viral infection is carried by the mosquito *Aedes aegypti* and can cause acute hepatic necrosis. There is no specific treatment.

Herpes simplex (see also p. 43)
Very occasionally the herpes simplex virus causes a generalized acute infection, particularly in the immunosuppressed patient, and occasionally in pregnancy. Aminotransferases are usually massively elevated. Liver biopsy shows extensive necrosis. Aciclovir is used for treatment.

OTHER INFECTIOUS AGENTS

Abnormal liver biochemistry is frequently found in a number of acute infections. The abnormalities are usually mild and have no clinical significance.

Toxoplasmosis (see also p. 103)
This produces a clinical picture similar to that of infectious mononucleosis, with abnormal liver biochemistry, but the Paul-Bunnell test is negative.

CHRONIC HEPATITIS

Clinically this is defined as any hepatitis lasting for 6 months or longer. Chronic hepatitis is best classified according to the aetiology (Table 7.8):

- due to viral disease
- due to autoimmune disease
- drug-induced
- unknown cause.

Table 7.8 **Causes of chronic hepatitis**

Viral	**Hereditary**
Hepatitis B ± hepatitis D	Wilson's disease
Hepatitis C	**Others**
Autoimmune	Inflammatory bowel disease ■ ulcerative colitis
Drugs	Alcohol (rarely)
(e.g. methyldopa, isoniazid, ketoconazole, nitrofurantoin)	

Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis and hepatocellular carcinoma in the world.

Pathology

Chronic inflammatory cell infiltrates comprising lymphocytes, plasma cells and sometimes lymphoid follicles are usually present in the portal tracts. The amount of inflammation varies from mild to severe. In addition, there may be:

- loss of definition of the portal/periportal limiting plate - interface hepatitis (damage is due to apoptosis rather than necrosis)
- lobular change, focal lytic necrosis, apoptosis and focal inflammation
- confluent necrosis
- fibrosis which may be mild, bridging (across portal tracts) or severe cirrhosis.

The overall severity of the hepatitis is judged by the degree of the hepatitis and inflammation (grading) and the severity of the fibrosis or cirrhosis (staging) using various scoring systems.

Terms such as 'chronic persistent' or 'chronic active' hepatitis should no longer be used.

CHRONIC HEPATITIS DUE TO VIRAL DISEASE

Two main viruses (HBV and HCV) that cause chronic hepatitis (CH) can produce similar clinical features, biochemical abnormalities and histological characteristics, although some features are more suggestive of one virus than the other being involved.

Chronic hepatitis B infection

This is common in developing countries where vertical transmission still frequently occurs. In the UK it is mainly confined to high-risk groups (see p. 360) and immigrants from developing countries. The outcome of HBV infection is shown in Figure 7.17.

Pathogenesis

Cytotoxic T cells recognize the viral antigen via HLA class 1 molecules on the infected hepatocytes; Thl responses (interleukin-2, gamma-interferon) are thought to be associated with the clearance of the virus and Th2 (interleukins 4, 5, 6, 10, 13) responses with the development of chronic infection and severity of the disease. Viral persistence in patients with a very poor cell-mediated response leads to a healthy carrier state. A better response, however, results in continuing hepatocellular damage with the development of CH.

Chronic HBV infection goes through a replicative and an integrated phase. In the former there is active viral replication with hepatic inflammation and the patient is highly infectious with HBeAg and HBV DNA positivity. At some stage the viral genome becomes integrated into the host DNA and the viral genes are then transcribed

along with those of the host. At this stage, the level of HBV DNA in the serum is low and the patient is HBeAg-negative and HBe antibody-positive. The aminotransferases are now normal or only slightly elevated and liver histology shows little inflammation, often with cirrhosis. Hepatocellular carcinoma (HCC) develops in patients with this late-stage disease, but the mechanism is still unclear. Integration of the viral DNA with the host-cell chromosomal DNA does appear to have a major role in carcinogenesis. There is evidence to implicate inactivation of p53-induced apoptosis by protein X (Table 7.5), allowing accumulation of abnormal cells and, eventually, carcinogenesis.

Clinical features and investigations

Chronic hepatitis is more frequent in men and it is often not preceded by an acute attack. The condition may be asymptomatic or may present as a mild, slowly progressive hepatitis; 50% present with established chronic liver disease. Clinical relapses occur, sometimes associated with seroconversion (see below) of HBeAg to anti-HBe or vice versa.

Investigations show a moderate rise in aminotransferases and a slightly raised ALP. The serum bilirubin is often normal. HBsAg and HBV DNA are found in the serum, usually with HBe antigen, unless a mutant virus is involved (see p. 365).

Histologically, there is a full spectrum of changes from near normal with only a few lymphocytes and interface hepatitis to a full-blown cirrhosis. HBsAg may be seen as a 'ground-glass' appearance in the cytoplasm on haematoxylin and eosin staining, and this can be confirmed on orcein staining or more specifically with immunohistochemical staining. HBcAg can also be demonstrated in hepatocytes by appropriate immunohistochemical staining.

Treatment

Patients with HBsAg, HBeAg and HBV DNA in the serum with abnormal serum aminotransferases and chronic hepatitis on liver biopsy should be treated. Patients with normal aminotransferases and those with decompensated liver disease should not be treated with interferon (see below).

The main aim of treatment is to eliminate the HBeAg and HBV DNA from the serum with consequent reduction in inflammatory necrosis of the hepatocyte. This seroconversion occurs spontaneously at a rate of 10-15% per year, and this varies in different populations.

In patients in whom HBeAg disappears, remission is usually sustained. The patient remains a carrier with HBsAg present, although some will eventually become HBsAg-negative.

Antiviral agents

Interferon, lamivudine and adefovir dipivoxil (p. 144) have been shown to be effective. Pegylated oc-2b interferon (100 $\mu\xi$ once a week subcutaneously) gives response rates of 25^5% (depending on genotype - A and B respond best) after 6 months of treatment.

Side-effects of treatment are many, with an acute flu-like illness occurring 6-8 hours after the first injection. This usually disappears after subsequent injections, but malaise, headaches and myalgia, are common and depression, diarrhoea, reversible hair loss and bone marrow depression and infection may occur. The platelet count should be monitored. These drug reactions occur in up to 30% of patients, and the dose may have to be lowered; in 10% the treatment has to be discontinued.

Overall, the response rate with disappearance of HBeAg is 25-40%. The success rate depends on factors shown in Table 7.9.

Those with chronic hepatitis with no HBeAg (i.e. a mutant HBV, see p. 365) generally do not respond to interferon, and HDV-infected patients only respond with prolonged high-dose courses; patients with concomitant HIV infection also have a poor response. Patients with decompensated liver disease often have severe side-effects and should not be routinely treated with this drug but could be treated with lamivudine.

Lamivudine 100 mg/day can be given orally and is well-tolerated. It appears more effective than interferon, particularly in HBV-DNA-positive individuals who have acquired the infection perinatally or in childhood. At 1 year, 50—70% of patients have normalization of their serum ALT, 30% have lost their HBe antigen with seroconversion in 15-20%. However, there is a complication of a mutant escape virus (YMDD mutant—

Table 7.9 **Factors predictive of a sustained response to treatment in patients with chronic hepatitis**

	Chronic hepatitis B	Chronic hepatitis C
Duration of disease	Short	Short
Liver biochemistry	High serum aminotransferase concentrations	
Histology	Active liver disease	Absence of cirrhosis or minimal amounts of hepatic fibrosis
Viral levels	Low HBV DNA levels	Low HCV RNA levels Genotype 2 or 3
Other	Absence of immunosuppression Female gender Adult acquired Delta virus negative	Low hepatic iron stores Young age Non-obese Low body weight

tyrosine, methionine, aspartate), which in itself causes hepatitis (15% per year of therapy), but usually less severe than that due to the wild type infection. These mutants respond to adefovir dipivoxil lOmg/day. The latter is also effective in HBeAg-positive and HBeAg-negative naive patients. Adefovir mutants are to date extremely rare.

The duration of all treatment, and which combination of antivirals is optimal, is still being assessed. Currently, treatment is with alpha-interferon (4 months), lamivudine and adefovir (12 months).

Prognosis

The progression is slow and remission may occur. Established cirrhosis is associated with a poor prognosis. Hepatocellular carcinoma is a frequent association and is one of the most common carcinomas in HBV endemic areas such as the Far East. This incidence is being reduced by routine HBV vaccination of all children.

Chronic hepatitis C infection

(see also p. 367)

Pathogenesis

As with hepatitis B infection, cytokines in the Th2 phenotypes are profibrotic and lead to the development of chronic infection. A dominant CD4 Th2 response with a weak CD8 gamma-interferon response may lead to rapid fibrosis. Thl cytokines are anti-fibrotic and thus a dominant CD4 Thl and CD8 cytolytic response may cause less fibrosis. Variability may be related to the genetic phenotype; persistence of HCV infection has been shown to be associated with HLA-DRBl*0701 and DRB4*0101. Other factors also have an effect on the development of fibrosis, particularly fatty liver, and diabetes (p. 368).

Clinical features

Patients with chronic hepatitis C infection are usually asymptomatic, the disease being discovered only following a routine biochemical test when mild elevations in the aminotransferases (usually ALT) are noticed (50%). The elevation in ALT may be minimal and fluctuating, and some patients have a persistently normal ALT (25%) - the disease being detected by checking HCV antibodies (e.g. in blood donors).

Despite this, severe chronic hepatitis (25%) and even cirrhosis can be present with only minimal elevation in aminotransferases, but progression is very uncommon in those with a persistently normal ALT. Those with severe inflammation may have fatigue. A few patients present with the symptoms and signs found in cirrhosis.

Diagnosis

This is made by finding HCV antibody in the serum using third-generation ELISA-3 tests. HCV RNA should be assayed using quantitative HCV-RNA PCR. The viraemia is usually variable; less than 2 x 10^6 genome equivalents/mL signifies a greater likelihood of response to antiviral therapy.

The HCV genotype should be characterized in patients who are to be given treatment (see below).

Liver biopsy is indicated if active treatment is being considered. The changes on liver biopsy are highly variable. Sometimes only minimal inflammation is detected, but in most cases the features of CH are present, as previously described (p. 370). Lymphoid follicles are often present in the portal tracts, and fatty change is frequently seen.

Treatment (Fig. 7.20)

Treatment is appropriate for patients with chronic hepatitis on liver histology who have HCV RNA in their serum and who have raised serum aminotransferases for more than 6 months. Patients with persistently normal aminotransferases are also treated if they have abnormal histology. The presence of cirrhosis is not a contraindication, but therapeutic responses are less likely. Patients with decompensated cirrhosis should be considered for transplantation. The aim of treatment is to eliminate the HCV RNA from the serum in order to:

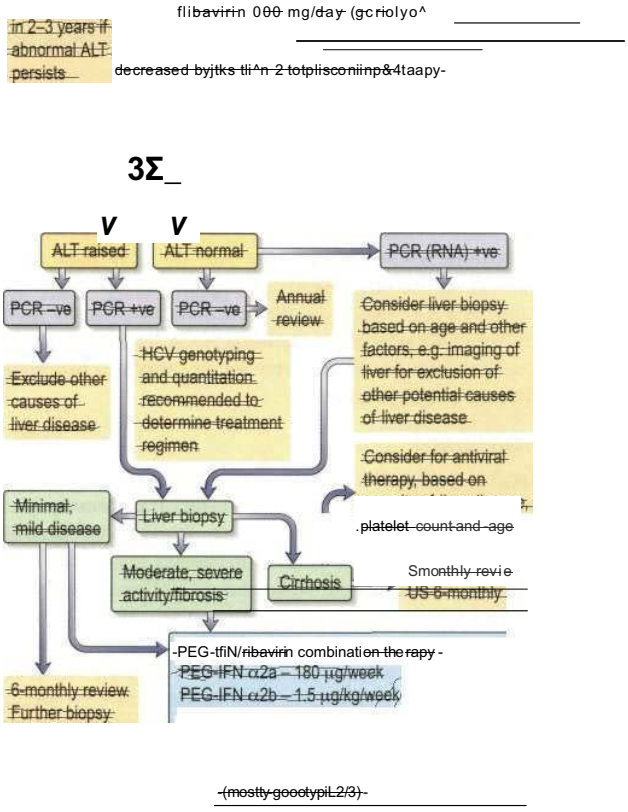

Fig. 7.20 **Approach to a patient with hepatitis C.** ALT, alanine aminotransferase; PCR, polymerase chain reaction. Adapted from Dhumeaux D et al. (2003) Treatment of hepatitis C. The 2002 French consensus. *Gut* 52.

- stop the progression of active liver disease
- prevent the development of hepatocellular carcinoma.

Antiviral agents

Current treatment is combination therapy with pegylated interferon, which is interferon with a polyethyleneglycol tail (a2a 180 µg/week or a2b 1.5 µg/kg/week) and ribavirin (1000-1200 mg/day for genotype 1, 800 mg/day for genotype 2 or 3); in divided doses for 12 months for genotype 1, and 6 months for other genotypes. Efficacy is also determined by viral load with HCV RNA > 2 x 10^6 genome equivalents per mL less likely to respond.

Side-effects of interferon. (p. 371) are less than for the treatment of HBV infection because of the lower dose. Ribavirin is usually well tolerated but side-effects include a dose-related haemolysis, pruritus and nasal congestion. Pregnancy should be avoided as it is teratogenic.

Monitoring results. The effects of treatment are monitored by measurement of the aminotransferases, with measurement of the PCR HCV RNA at 3 months. If the aminotransferases remain abnormal and HCV RNA is present in the serum above a 2 log drop in concentration from pre-treatment values, treatment is stopped because a response to further treatment is then unlikely.

A sustained response is achieved in 40-50% at 12 months with genotype 1 and 80% in genotype 2 or 3. Best results are obtained in patients with the predictive factors shown in Table 7.9. If PCR HCV RNA remains negative 6 months after the end of treatment relapse is unlikely and histological progression is halted.

Chronic D hepatitis

This is a relatively infrequent chronic hepatitis, but spontaneous resolution is rare. Between 60% and 70% of patients will develop cirrhosis and more rapidly than with HBV infection alone. In 15% the disease is rapidly progressive with development of cirrhosis in only a few years. The diagnosis is made by finding anti-delta antibody in a patient with chronic liver disease who is HBsAg-positive. It can be confirmed by finding HDV in the liver or HDV RNA in the serum by reverse transcription - polymerase reaction. Treatment is with alpha-interferon, usually at the high dose of 10M units three times weekly for 12 months, but response is poor. Lamivudine and adefovir appear to be unhelpful.

AUTOIMMUNE HEPATITIS

This condition occurs most frequently in women. In type I (see below) there is an association with other autoimmune diseases (e.g. pernicious anaemia, thyroiditis and Coombs'-positive haemolytic anaemia), and 60% of cases are associated with HLA, DR3, DR52a loci, HLADRB3*0101 and HLADRB*0401. In Asians, the condition is associated with HLADR4.

Pathogenesis

The cause is unknown. It is proposed, in a genetically predisposed person, that an environmental agent causes an autoimmune process to develop against liver antigens, producing a progressive necroinflammatory process which results in fibrosis and cirrhosis. In vitro observations have shown that there is a defect of suppressor (regulatory) T cells which may be primary or secondary. However, no clear mechanism causing the inflammation has been found.

Clinical features

There are two peaks in presentation. In the peri- and postmenopausal group, patients may be asymptomatic or present with fatigue, the disease being discovered by abnormalities in liver biochemistry or because of signs of chronic liver disease on routine examination. In the teens and early twenties the disease (often type II) presents as an acute hepatitis with jaundice and very high aminotransferases, which do not improve with time. This age group often has clinical features of cirrhosis with hepatosplenomegaly, cutaneous striae, acne, hirsuties, bruises and, sometimes, ascites. An ill patient can also have features of an autoimmune disease with a fever, migratory polyarthritis, glomerulonephritis, pleurisy, pulmonary infiltration or fibrosing alveolitis.

There are overlap syndromes with primary biliary cirrhosis and primary sclerosing cholangitis.

Investigations

Liver biochemistry

The serum aminotransferases are high, with lesser elevations in the ALP and bilirubin. The serum γ-globulins are high, frequently twice normal, particularly the IgG. The biochemical pattern is the same with all three types.

Haematology

A mild normochromic normocytic anaemia with thrombocytopenia and leucopoenia is present, even before portal hypertension and splenomegaly. The prothrombin time is often high.

Autoantibodies

Three types of autoimmune hepatitis have been recognized:

- Type I with antibodies:
  (a) antinuclear
  (b) anti-smooth muscle (anti-actin).
- Type II with antibodies: anti-liver/kidney microsomal (anti-LKMl). The main target is cytochrome P4502D6 (CYP2D6) on liver cell plasma membranes.
- Type III with soluble liver antigen (now designated anti SLP/LP) but this group behaves as type I.

Type II occurs most frequently in girls and young women. Approximately 13% of patients lack the above autoantibodies.

Liver biopsy

This shows the changes of CH described previously. The amount of interface hepatitis is variable, but tends to be high in untreated patients. Lymphoid follicles are less often seen than in hepatitis C, and plasma cell infiltration

is frequent. Approximately one-third of patients have cirrhosis at presentation.

Treatment

Prednisolone 30 mg is given daily for 2 weeks, followed by a slow reduction and then a maintenance dose of 10-15 mg daily; azathioprine should be added, 1-2 mg/kg daily, as a steroid-sparing agent and in some patients as sole long-term maintenance therapy. Mycophenalate, ciclosporin, and tacrolimus have been used in resistant cases.

Course and prognosis

Steroid and azathioprine therapy induce remission in over 80% of cases. The length of treatment is lifelong in most cases. Those with initial cirrhosis are more likely to relapse following treatment withdrawal and require indefinite therapy. Liver transplantation is performed if treatment fails, although the disease may recur.

JDRUG-INDUCED CHRONIC HEPATITIS _____

Several drugs can cause a CH which clinically bears many similarities to autoimmune hepatitis (see Table 7.8). Patients are often female, present with jaundice and hepatomegaly, have raised serum aminotransferases and globulin levels, and LE cells and anti-LKMl antibodies may be detected. Improvement follows drug withdrawal but exacerbations can occur with drug reintroduction. Isoniazid, amiodarone and methotrexate can lead to chronic histological changes. With rare exceptions patients with pre-existing chronic liver disease are not more susceptible to drug injury.

Chronic alcoholic liver disease can occasionally have histological appearances more like a chronic hepatitis.

NON-ALCOHOLIC FATTY LIVER DISEASE JNAFLD)

This is an increasingly recognized condition that can lead to cirrhosis (in 1%) and hepatocellular carcinoma. NAFLD progression accounts for the majority of cases of cryptogenic cirrhosis, and obesity is a risk factor for the development of hepatocellular carcinoma. The histological changes are similar to those of alcohol-induced hepatic injury and range from simple fatty change to fat and inflammation (steatohepatitis) and fibrosis. Inflammation can lead to fibrosis, probably via an oxidative stress injury leading to lipid peroxidation in the presence of fatty infiltrations; the latter causes insulin resistance, which in turn switches on connective tissue growth factor leading to fibrosis. Risk factors for NAFLD are obesity, hypertension, type 2 diabetes, hyperlipidaemia. NAFLD is estimated to affect 3-6% of the population in the USA and of these, 1-3% have steatohepatitis (NASH). Most patients are asymptomatic; hepatomegaly may be present. Mild increases in serum transferases are frequently the sole abnormality in the liver biochemistry. Liver biopsy allows staging the disease but when this should be performed is unclear. Most would biopsy if the ALT is persistently over twice normal. Currently weight loss, strict control of hypertension, diabetes, and lipid levels are the only treatments in the early stages, but the disease may still progress. Liver transplantation is reserved for end-stage cirrhosis, but the condition may recur. Regular follow-up is indicated, particularly for steatohepatitis.

CHRONIC HEPATITIS OF UNKNOWN CAUSE

As more and more people are having routine blood tests, mild elevations in the serum aminotransferases and γ-GT are found. Many of these patients have no symptoms and no evidence of liver disease clinically. All known aetiological agents should be excluded (see above), as well as tests to exclude primary biliary cirrhosis, primary sclerosing cholangitis, Wilson's disease, haemochromatosis and a,antitrypsin deficiency. Risk factors for NAFLD should be evaluated.

Liver biopsy should be performed if the elevation in the aminotransferases continues for over a year, to confirm the presence of chronic hepatitis, although this is often unhelpful.

CIRRHOSIS

Cirrhosis results from the necrosis of liver cells followed by fibrosis and nodule formation. The liver architecture is diffusely abnormal and this interferes with liver blood flow and function. This derangement produces the clinical features of portal hypertension and impaired liver cell function.

Aetiology

The causes of cirrhosis are shown in Table 7.10. Alcohol is now the most common cause in the West, but viral

Table 7.10 Causes of cirrhosis

Common	Others
Alcohol	Biliary cirrhosis: primary, secondary
Hepatitis B ± D	Autoimmune hepatitis
Hepatitis C ?	Hereditary haemochromatosis
Other viruses	Hepatic venous congestion Budd-Chiari syndrome
	Wilson's disease
	Drugs (e.g. methotrexate)
	o^-Antitrypsin deficiency
	Cystic fibrosis
	Non-alcoholic fatty liver disease (NAFLD)
	Galactosaemia
	Glycogen storage disease
	Veno-occlusive disease
	Idiopathic (cryptogenic)

infection is the most common cause world-wide. With the identification of HCV, idiopathic (cryptogenic) cirrhosis is diagnosed less commonly. Young patients with cirrhosis must be investigated carefully as the cause may be treatable (e.g. Wilson's disease).

Pathogenesis

Chronic injury to the liver results in inflammation, necrosis and, eventually, fibrosis (Fig. 7.21). Fibrosis is initiated by activation of the stellate cells (see p. 348). Kupffer cells seem to have a role in their activation, but hepatocytes and other cells are probably involved. Stellate cells are activated by many cytokines and their receptors, reactive oxygen intermediates and other paracrine and autocrine signals.

In the early stage of activation the stellate cells become swollen and lose retinoids with upregulation of receptors for proliferative and fibrogenic cytokines, such as platelet-derived growth factor (PDGF), and possibly transforming growth factor *fa* (TGF^). TGF-β! is the most potent fibrogenic mediator identified so far.

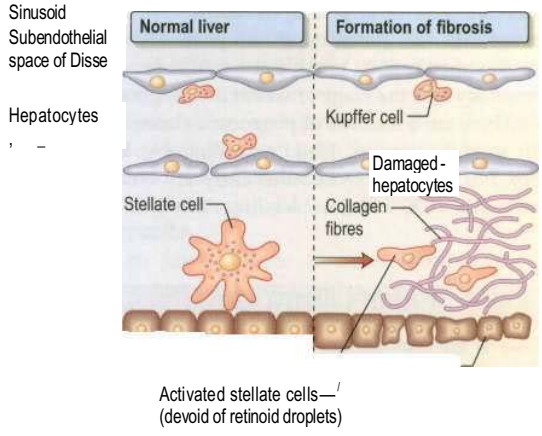

Fig. 7.21 **Pathogenesis of fibrosis.** Activation of the stellate cell is followed by proliferation of fibroblasts and the deposition of collagen.

In the space of Disse, the normal matrix is replaced by collagens, predominantly types 1 and 3, and fibronectin. Subendothelial fibrosis leads to loss of the endothelial fenestrations (ports), and this impairs liver function. Collagenases (matrix metalloproteinases, MMP) are able to degrade this collagen but are inhibited by tissue inhibitors of metalloproteinases (TIMPs), which are increased in human liver fibrosis. There is accumulating evidence that liver fibrosis is reversible.

Pathology

The characteristic features of cirrhosis are regenerating nodules separated by fibrous septa and loss of the normal lobular architecture within the nodules (Fig. 7.22a). Two types of cirrhosis have been described which give clues to the underlying cause:

- *Micronodular cirrhosis.* Regenerating nodules are usually less than 3 mm in size and the liver is involved uniformly. This type is often caused by ongoing alcohol damage or biliary tract disease.

Fig. 7.22 **(a) Pathology of cirrhosis.** Histological appearance showing nodules of liver tissue of varying size surrounded by fibrosis.
(b) CT scan showing an irregular lobulated liver. There is splenomegaly and enlargement of collateral vessels beneath the anterior abdominal wall (arrows) as a result of portal hypertension.

■ *Macronodular cirrhosis.* The nodules are of variable size and normal acini may be seen within the larger nodules. This type is often seen following previous hepatitis, such as HBV infection.

A mixed picture with small and large nodules is sometimes seen.

Symptoms and signs are described on page 357.

Investigations

These are performed to assess the severity and type of liver disease.

Severity

* **Liver function.** Serum albumin and prothrombin time are the best indicators of liver function: the outlook is poor with an albumin level below 28 g/L. The prothrombin time is prolonged commensurate with the severity of the liver disease (Box 7.3).
- **Liver biochemistry.** This can be normal depending on the severity of cirrhosis. In most cases there is at least a slight elevation in the serum ALP and serum aminotransferases. In decompensated cirrhosis all biochemistry is deranged.
- **Serum electrolytes.** A low sodium indicates severe liver disease due to a defect in free water clearance or to excess diuretic therapy.

In addition, serum α-fetoprotein if > 400 ng/mL is strongly suggestive of the presence of a hepatocellular carcinoma.

Type

This can be determined by:

viral markers serum
autoantibodies serum
immunoglobulins iron indices
and ferritin copper,
caeruloplasmin (p. 387)
Opantitrypsin (p. 388).

Serum copper and serum a,antitrypsin should always be measured in young cirrhotics. Total iron-binding capacity (TIBC) and ferritin should be measured to exclude hereditary haemochromatosis; genetic markers are also available (p. 386)

Imaging

m **Ultrasound examination.** This can demonstrate changes in size and shape of the liver. Fatty change and fibrosis produce a diffuse increased echogenicity. In established cirrhosis there may be marginal nodularity of the liver surface and distortion of the arterial vascular architecture. The patency of the portal and hepatic veins can be evaluated. It is useful in detecting hepatocellular carcinoma.
- CT scan (see p. 354). Figure 7.22b shows hepatosplenomegaly and dilated collaterals seen in chronic liver disease. Arterial phase-contrast-enhanced scans are useful in the detection of hepatocellular carcinoma.
- **Endoscopy** is performed for the detection and treatment of varices, and portal hypertensive gastropathy. Colonoscopy is occasionally performed for colopathy.
- **MRI scan.** This is useful in the diagnosis of benign tumours such as haemangiomas. MR angiography can demonstrate the vascular anatomy and MR cholangiography the biliary tree. However, intrahepatic bile duct damage is poorly identified by current MR technology.

Liver biopsy

This is necessary to confirm the severity and type of liver disease. The core of liver often fragments and sampling errors may occur in macronodular cirrhosis. Special stains may be required for iron and copper, and various immunocytochemical stains can identify viruses, bile ducts and angiogenic structures. Chemical measurement of iron and copper are necessary to confirm diagnosis of iron overload or Wilson's disease.

Management

Management is that of the complications seen in decompensated cirrhosis. Patients should have 6-monthly ultrasound and serum oc-fetoprotein measurements to detect the development of a hepatocellular carcinoma as early as possible (see p. 394), as all therapeutic strategies work best with small and single tumours.

There is no treatment that will arrest or reverse the cirrhotic changes although progression may be halted by correcting the underlying cause (see below). Patients with compensated cirrhosis should lead a normal life. The only dietary restriction is to reduce salt intake. Aspirin and NSAIDs should be avoided. Alcohol should be avoided, although if the cirrhosis is not due to alcohol and not due to viral hepatitis, small amounts not taken on a regular basis are probably not harmful.

Course and prognosis

This is extremely variable, depending on many factors, including the aetiology and the presence of complications. Poor prognostic indicators are given in Table 7.11. Development of any complication usually worsens the prognosis. In general, the 5-year survival rate is approximately 50%, but this also varies depending on the aetiology and the stage at which the diagnosis is made.

There are a number of prognostic classifications based on modifications of Child's grading (A, B and C; see Box 7.3). Surgical procedures carry an overall operative mortality of 30% in non-bleeding cirrhotics.

LIVER TRANSPLANTATION

This is an established treatment **for a** number of liver diseases. Shortage of donors is a major problem in all developed countries and in some such as Japan living related donors form the majority of transplant operations where there has been only one donor death, but in Europe, mortality has been between 0.4 to 0.9%.

Table 7.11 **Poor prognostic indicators in cirrhosis**

Blood tests
Low albumin (< 28 g/L)
Low serum sodium (< 125 mmol/L)
Prolonged prothrombin time > 6 seconds above normal value Raised creatinine > 160 μmol/L.

Clinical
Persistent jaundice
Failure of response to therapy
Ascites
Haemorrhage from varices, particularly with poor liver function Neuropsychiatric complications developing with progressive liver failure
Small liver
Persistent hypotension Aetiology (e.g. alcoholic cirrhosis, if the patient continues drinking)

Box 7.3 **Modified Child's-Pugh classification**

Score	1	2	3
Ascites	None	Mild	Moderate/severe
Encephalopathy	None	Mild	Marked
Bilirubin (μmol/L)	< 34	34-50	> 50
Albumin (g/L)	**> 35**	28-35	< 28
Prothrombin time (seconds over normal)	< 4	4-6	>6

Add above scores for your patient for survival figures below

	% survival Grade		
(scores)	**1 year**	**5 years**	**10 years**
Child's A (< 7)	82	45	25
Child's B (7-9)	62	20	7
Child's C (10+)	42	20	0

Indications include the following:

Acute liver disease. Patients with fulminant hepatic failure of any cause, including acute viral hepatitis (p. 362), may be considered.

Chronic liver disease. The indications for transplantation vary and the timing of the transplant is often difficult. All patients with end-stage (Child's grade C) cirrhosis should be referred to a transplant centre and also those with debilitating symptoms.

- *Primary biliary cirrhosis.* Patients with this disease should be transplanted when their serum bilirubin is persistently > IOOμmol/L or symptoms such as itching are intolerable.
- *Chronic hepatitis B if HBV-DNA-negative.* Following transplantation, recurrence of the hepatitis can occur despite use of hepatitis B immunoglobulin and lamivudine, because of escape mutants (see p. 365).
- *Chronic hepatitis C.* In end-stage disease the 5-year prognosis of the graft is good, despite universal HCV reinfection. However, cirrhosis occurs in 10-20% at 5 years and there is progressive disease. Antiviral agents may delay this progression and trials continue.
- *Autoimmune hepatitis.* In patients who have failed to respond to medical treatment or have major side-effects of corticosteroid therapy. It can reoccur.
- *Alcoholic liver disease.* Well-motivated patients who have stopped drinking without improvement of liver disease are offered a transplant.
- *Primary metabolic disorders.* Examples are Wilson's disease, hereditary haemochromatosis and α_1 antitrypsin deficiency.
- *Other conditions,* such as sclerosing cholangitis.

Contraindications

Absolute contraindications include active sepsis outside the hepatobiliary tree, malignancy outside the liver, liver metastases (except neuroendocrine), and if the patient is not psychologically committed.

Relative contraindications are mainly anatomical considerations that would make surgery more difficult, such as extensive splanchnic venous thrombosis. With exceptions, patients aged 65 years or over are not usually transplanted. In hepatocellular carcinoma the recurrence rate is high unless there are fewer than three small (< 3 cm) lesions, or a solitary nodule of < 5 cm.

Surgical procedure

Pretransplant work-up includes confirmation of the diagnosis, ultrasound and cross-sectional imaging, radiological demonstration of the hepatic arterial and biliary tree as well as assessment of cardiorespiratory and renal status. Because of the ethical and financial implications of this operation, regular psychosocial support is vital, and psychiatric counselling may be necessary in some cases.

The donor should be ABO-compatible. He or she should ideally be under 50 years of age and have no evidence of sepsis, malignancy, HIV, HBV or HCV infection. The liver is cooled and stored on ice; its preservation time can be up to 20 hours. The recipient operation takes approximately 8 hours and may require a large blood transfusion, but sometimes none at all.

The operative mortality is low. Most postoperative deaths occur in the first 3 months. Sepsis and haemorrhage can be serious complications. Opportunistic infections (see p. 29) are still a problem owing to immunosuppression. Various immunosuppressive agents have been used, but microemulsified ciclosporin, tacrolimus in combination with either azathioprine or mycophenolate mofetil, steroids and sirolimus are the most common. A pretransplant serum creatinine above 160 μmol/L (2 mg/dL) is the best predictor of post-transplant death.

Rejection

Acute or cellular rejection is usually seen 5-10 days post-transplant; it can be asymptomatic or there may be a fever. Histologically, there is a pleomorphic portal infiltrate with prominent eosinophils, bile duct damage

and endothelialitis of the blood vessels. This type of rejection responds to immunosuppressive therapy.

Chronic ductopenic rejection is seen from 6 weeks to 9 months post-transplant, with disappearing bile ducts (vanishing bile duct syndrome, VBDS) and an arteriopathy with narrowing and occlusion of the arteries. Early ductopenic rejection may rarely be reversed by immunosuppression, but often requires retransplantation.

Graft-versus-host disease is extremely rare.

Prognosis

Elective liver transplantation in low-risk patients has a 90% 1-year survival. Five-year survivals are as high as 70-85% largely owing to the introduction of ciclosporin and tacrolimus. Patients require lifelong immunosuppression, although the doses can be reduced over time without significant problems.

COMPLICATIONS AND EFFECTS OF CIRRHOSIS

These are shown in Table 7.12.

Portal hypertension

The portal vein is formed by the union of the superior mesenteric and splenic veins. The pressure within it is normally 5-8 mmHg with only a small gradient across the liver to the hepatic vein in which blood is returned to the heart via the inferior vena cava. Portal hypertension can be classified according to the site of obstruction:

- *prehepatic* - due to blockage of the portal vein before the liver
- *intrahepatic* - due to distortion of the liver architecture, which can be presinusoidal (e.g. in schistosomiasis) or postsinusoidal (e.g. in cirrhosis)
- *posthepatic* - due to venous blockage outside the liver (rare).

As portal pressure rises above 10-12 mmHg, the compliant venous system dilates and collaterals occur within the systemic venous system. The main sites of the collaterals are at the gastro-oesophageal junction, the rectum, the left renal vein, the diaphragm, the retroperitoneum and the anterior abdominal wall via the umbilical vein.

The collaterals at the gastro-oesophageal junction (varices) are superficial in position and tend to rupture. Portosystemic anastomoses at other sites seldom give rise to symptoms. Rectal varices are found frequently (30%) if carefully looked for and can be differentiated from haemorrhoids, which are lower in the anal canal.

Table 7.12 Complications and effects of cirrhosis

Portal hypertension and gastrointestinal haemorrhage
Ascites
Portosystemic encephalopathy
Renal failure
Hepatocellular carcinoma
Bacteraemias, infections
Malnutrition

Pathophysiology

Portal vascular resistance is increased in chronic liver disease. During liver injury, stellate cells are activated (see p. 348) and transform into myofibroblasts. In these cells there is de novo expression of the specific smooth muscle protein α-actin. Under the influence of mediators, such as endothelin, nitric oxide or prostaglandins, the contraction of these activated cells contributes to abnormal blood flow patterns and increased resistance to blood flow. In addition the balance of fibrogenic and fibrolytic factors is shifted towards fibrogenesis. This increased resistance leads to portal hypertension and opening of portosystemic anastomoses in both precirrhotic and cirrhotic livers. Patients with cirrhosis have a hyperdynamic circulation. This is thought to be due to the release of mediators, such as nitric oxide and glucagon, which leads to peripheral and splanchnic vasodilatation. This effect is followed by plasma volume expansion due to sodium retention (see the discussion on ascites, p. 381), and this has a significant effect in maintaining portal hypertension.

Causes (see Table 7.13)

The most common cause is cirrhosis. Other causes include the following.

Prehepatic causes

Exrrahepatic blockage is due to portal vein thrombosis. The cause is often unidentified, but some cases are due to portal vein occlusion secondary to congenital portal venous abnormalities or neonatal sepsis of the umbilical vein. Many are due to inherited defects causing prothrombotic conditions, e.g. factor V Leiden. Patients usually present with bleeding, often at a young age. They have normal liver function and, because *of this, their* prognosis following bleeding is excellent. The portal vein blockage can be identified by ultrasound or Doppler imaging. Splenectomy is only performed if there is isolated splenic vein thrombosis. Treatment is usually repeated endoscopic therapy or non-selective beta-blockade.

Table 7.13 Causes of portal hypertension

Prehepatic	Posthepatic
Portal vein thrombosis	Budd-Chiari syndrome
Intrahepatic	Veno-occlusive disease
Cirrhosis	Right heart failure (rare)
Hepatitis (alcoholic) Idiopathic non-cirrhotic portal hypertension	Constrictive pericarditis
Schistosomiasis Partial nodular transformation Congenital hepatic fibrosis Myelosclerosis (extramedullary haemopoiesis)	
Granulomata	

Intrahepatic causes

Although cirrhosis is the most common intrahepatic cause of portal hypertension, there are other causes:

- *Non-cirrhotic portal hypertension.* Patients present with portal hypertension and variceal bleeding but without cirrhosis. Histologically, the liver shows mild portal tract fibrosis. The aetiology is unknown, but arsenic, vinyl chloride and other toxic agents have been implicated. A similar disease is found frequently in India. The liver lesion does not progress and the prognosis is therefore good.
- *Schistosomiasis* with extensive pipe-stem fibrosis is the commonest cause, but is confined to endemic areas such as Egypt and Brazil. However, often there may be concomitant liver disease such as HCV infection.
- Other causes include congenital hepatic fibrosis, nodular regenerative hyperplasia, and partial nodular transformation. The last two conditions are rare. They share the common features of hyperplastic liver cell growth in the form of nodules, but in contrast to cirrhosis, fibrosis is typically absent. A wedge liver biopsy is usually required to establish the diagnosis. In none of these conditions are hormones implicated in aetiology or progression.

Posthepatic causes

Prolonged severe heart failure with tricuspid incompetence and constrictive pericarditis can both lead to portal hypertension. The Budd-Chiari syndrome is described on page 390.

Clinical features

Patients with portal hypertension are often asymptomatic and the only clinical evidence of portal hypertension is splenomegaly. Clinical features of chronic liver disease are usually present (see p. 357). Presenting features may include:

- haematemesis or melaena from rupture of gastro-oesophageal varices or portal hypertensive gastropathy
- ascites
- encephalopathy.

Variceal haemorrhage

Approximately 90% of patients with cirrhosis will develop gastro-oesophageal varices, over 10 years, but only one-third of these will bleed from them. Bleeding is likely to occur with large varices, red signs on varices (diagnosed at endoscopy) and in severe liver disease.

Management

Management can be divided into the active bleeding episode, the prevention of rebleeding, and prophylactic measures to prevent the first haemorrhage. Despite all the therapeutic techniques available, the prognosis depends on the severity of the underlying liver disease, with an overall mortality from variceal haemorrhage of 25% - reaching 50% in Child's grade C.

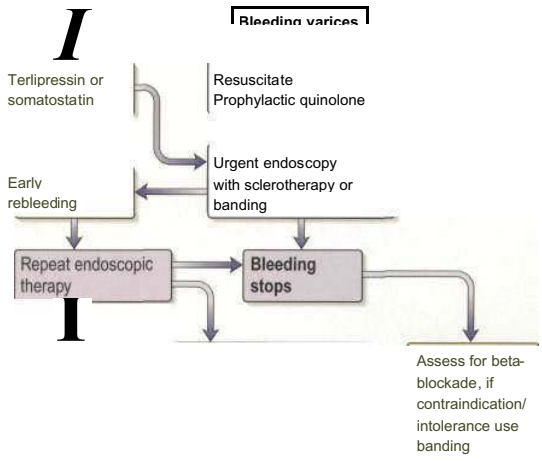

Fig. 7.23 Management of gastrointestinal haemorrhage due to oesophageal varices. TIPS, transjugular intrahepatic portosystemic shunt.

Initial management of acute variceal bleeding

(Fig. 7.23)

See also the discussion of the general management of gastrointestinal haemorrhage on page 291.

Resuscitation

- Assess the general condition of the patient - pulse and blood pressure.
- Insert an intravenous line and obtain blood for grouping and crossmatching, haemoglobin, PT/INR, urea, electrolytes, creatinine, liver biochemistry and blood cultures.
- Restore blood volume with plasma expanders or, if possible, blood transfusion. These measures are discussed in more detail in the treatment of shock (p. 972). Prompt correction of hypovolaemia is necessary in patients with cirrhosis as their baroreceptor reflexes are diminished.
- Ascitic tap.
- Monitor for alcohol withdrawal. Give thiamine.

Urgentendoscopy

Endoscopy should be performed to confirm the diagnosis of varices (Fig. 7.24) and to exclude bleeding from other sites (e.g. gastric ulceration). Portal hypertensive (or congestive) gastropathy is the term used for chronic gastric

congestion, punctate erythema and gastric erosions and is a source of bleeding. Varices may or may not be present. Propranolol (see below) is the best treatment for this.

Injection sclerotherapy or variceal banding

The varices should be injected with a sclerosing agent that may arrest bleeding by producing vessel thrombosis. A needle is passed down the biopsy channel of the endoscope and a sclerosing agent is injected into the varices. Alternatively, the varices can be banded by mounting a band on the tip of the endoscope, sucking the varix just

Fig. 7.24 Endoscopic picture of oesophageal varices, showing blood spurting from a varix.

into the end of the scope and dislodging the band over the varix using a trip-wire mechanism.

Acute variceal sclerotherapy and banding are the treatment of choice; they arrest bleeding in 80% of cases and reduce early rebleeding. Between 15% and 20% of bleeding comes from gastric varices and here results of endoscopic therapy are poor.

Other measures available

Vasoconstrictor therapy

The main use of this is for emergency control of bleeding whilst waiting for endoscopy and in combination with endoscopic techniques. The aim of vasoconstrictor agents is to restrict portal inflow by splanchnic arterial constriction.

- *Terlipressin.* This is the only vasoconstrictor which has been shown to reduce mortality, albeit in small trials. Dose is 2 mg 6-hourly, reducing to 1 mg 4-hourly after 48 hours if a prolonged dosage regimen is used. It should not be given to patients with ischaemic heart disease. The patient will complain of abdominal colic, will defecate and have facial pallor owing to the generalized vasoconstriction.
- *Somatostatin.* This drug has few side-effects. An infusion of 250-500 µg/h appears to reduce bleeding, but has no effect on mortality. It should be used if there are contraindications to terlipressin, although the data on efficacy are less convincing than with terlipressin.

Balloon tamponade

This procedure is used mainly to control bleeding if endoscopic therapy or vasoconstrictor therapy has failed or is contraindicated or if there is exsanguinating haemorrhage. The tube should be left in place for up to 12 hours and removed in the endoscopy room prior to the endoscopic procedure. The usual tube is a four-lumen Sengstaken-Blakemore. The tube is passed into the stomach and the gastric balloon is inflated with air and pulled back. It should be positioned in close apposition to the gastro-oesophageal junction to prevent the cephalad variceal blood flow to the bleeding point. The oesophageal balloon should be inflated only if bleeding is not controlled by the gastric balloon alone.

This technique is successful in up to 90% of patients and is very useful in the first few hours of bleeding. However, it can have serious complications such as aspiration pneumonia, oesophageal rupture and mucosal ulceration, which lead to a 5% mortality. The procedure is very unpleasant for the patient.

Additional management of acute episode

- *Prophylactic antibiotics.* These have been shown to reduce infection and reduce mortality. Both oral and intravenous quinolones are used, e.g. ciprofloxacin 500 mg twice daily.
- *Measures to prevent encephalopathy.* Portosystemic encephalopathy (PSE) can be precipitated by a large bleed (since blood contains protein). The management is described on page 384.
- *Nursing.* Patients require high-dependency/intensive-care nursing. They should be nil by mouth until bleeding has stopped.
- *Sucralfate.* 1 g four times daily is given to reduce oesophageal ulceration following endoscopic therapy.

Management of an acute rebleed

Thirty per cent of patients rebleed within 5 days after a single therapeutic endoscopy. The source of the rebleed should be established by endoscopy. It is sometimes due to an ulcer produced by previous sclerotherapy and this is difficult to manage. Management starts with repeat endoscopic therapy - once only to control rebleeding (further sessions of sclerotherapy or banding are not advisable).

Transjugular intrahepatic portocaval shunt (TIPS)

TIPS is used in cases where the bleeding cannot be stopped after two sessions of endoscopic therapy within 5 days. In this technique, a guidewire is passed from the jugular vein into the liver and an expandable metal shunt is forced over it into the liver substance to form a channel between the systemic and portal venous systems. It reduces the hepatic sinusoidal and portal vein pressure by creating a total shunt, but without the risks of general anaesthesia and major surgery. TIPS is useful in the short term, but recurrent portal hypertension owing to stent stenosis or thrombosis occurs, although this has been reduced by the use of covered stents. Collaterals arising from the splenic or portal veins can be selectively embolized.

Emergency surgery

This is used when other measures fail or if TIPS is not available and, particularly, if the bleeding is from gastric fundal varices. Oesophageal transection and ligation of the feeding vessels to the bleeding varices is the most

common surgical technique. Acute portosystemic shunt surgery (see below) is infrequently performed.

Prevention of recurrent variceal bleeding

Following an episode of variceal bleeding, the risk of recurrence is 60-80% over a 2-year period with an approximate mortality of 20% per episode. These facts justify the use of measures to prevent rebleeding.

Long-term measures

Non-selective beta-blockade. Oral propranolol in a dose sufficient to reduce resting pulse rate by 25% has been shown to decrease portal pressure. Portal inflow is reduced by two mechanisms: by a decrease in cardiac output (P_J), and by the blockade of β_2 vasodilator receptors on the splanchnic arteries, leaving an unopposed vasoconstrictor effect. This has been shown to decrease the frequency of rebleeding, and is as effective as sclerotherapy and ligation as it also prevents bleeding from portal hypertensive gastropathy. It is the treatment of first choice, but a substantial number of patients have either contraindications or are intolerant of treatment. Monitoring target reductions of portal pressure by hepatic venous pressure measurements is being evaluated.

Endoscopic treatment. The use of repeated courses of banding at 2-weekly intervals leads to obliteration of the varices. This markedly reduces rebleeding, most occurring before the varices have been fully obliterated. Between 30% and 40% of varices return per year, so that follow-up endoscopy with ablation should be performed. Banding is superior to sclerotherapy.

Although a reduction in bleeding episodes occurs, the effect on survival is controversial and probably small. Complications include oesophageal ulceration, mediastinitis and rarely strictures.

Transjugular portosystemic stent shunts. These reduce rebleeding rates compared to endoscopic techniques but do not improve survival, and increase encephalopathy. They are used if endoscopic or medical therapy fails. Covered stents are being evaluated.

Surgical procedures

Surgical portosystemic shunting is associated with an extremely low risk of rebleeding, but the diversion of portal blood away from the liver produces significant encephalopathy. Operative mortality is low in patients with Child's grade A (0-5%) but encephalopathy still occurs. Child's grade C has a very poor prognosis. The 'shunts' performed are usually an end-to-side portocaval anastomosis or a selective distal splenorenal shunt (Warren shunt), which maintains hepatic blood flow via the superior mesenteric vein.

Devascularization procedures including oesophageal transection do not produce encephalopathy, and can be used when there is splanchnic venous thrombosis.

Liver transplantation (p. 376) is the best option when there is poor liver function.

Prophylactic measures

Patients with cirrhosis and varices, who have not bled, should be prescribed non-selective beta-blockers (e.g. propranolol). This reduces the chances of upper GI bleeding, may increase survival and is cost-effective. If there are contraindications or intolerance, variceal banding is an option.

Ascites

Ascites is the presence of fluid within the peritoneal cavity and is a common complication of cirrhosis of the liver. The pathogenesis of the development of ascites in liver disease is controversial, but is probably secondary to renal sodium and water retention. Several factors are involved.

- *Sodium and water retention* occur as a result of peripheral arterial vasodilatation and consequent reduction in the effective blood volume. Nitric oxide has been postulated as the putative vasodilator, although other substances (e.g. atrial natriuretic peptide and prostaglandins) may be involved. The reduction in effective blood volume activates various neurohumoral pressor systems such as the sympathetic nervous system and the renin-angiotensin system, thus promoting salt and water retention (Fig. 12.3).
- *Portal hypertension* exerts a local hydrostatic pressure and leads to increased hepatic and splanchnic production of lymph and transudation of fluid into the peritoneal cavity.
- *Low serum albumin* (a consequence of poor synthetic liver function) may further contribute by a reduction in plasma oncotic pressure.

In patients with ascites, urine sodium excretion rarely exceeds 5 mmol in 24 hours. Loss of sodium from extrarenal sites accounts for approximately 30 mmol in 24 hours. The normal daily dietary sodium intake may vary between 120 and 200 mmol, resulting in a positive sodium balance of approximately 90-170 mmol in 24 hours (equivalent to 600-1300 mL of fluid retained).

Clinical features

The abdominal swelling associated with ascites may accumulate over many weeks or as rapidly as a few days. Precipitating factors include a high sodium diet or the development of a hepatocellular carcinoma or splanchnic vein thrombosis. Mild generalized abdominal pain and discomfort are common but, if more severe, should raise the suspicion of spontaneous bacterial peritonitis (see below). Respiratory distress accompanies tense ascites, and also causes difficulty in eating.

The presence of fluid is confirmed by the demonstration of shifting dullness. Many patients will also have peripheral oedema. A pleural effusion (usually on the right side) may infrequently be found and is believed to arise from the passage of ascitic fluid through congenital defects in the diaphragm.

Table 7.14 **Causes of ascites divided according to the type of ascitic fluid**

Straw-coloured	**Chylous**
Malignancy (most common cause) Cirrhosis Infective	Obstruction of main lymphatic duct (e.g. by carcinoma) - chylomicrons are present
Tuberculosis	Cirrhosis
Following infra-abdominal perforation - any bacteria may be found (e.g. *E. coli)*	**Haemorrhagic**
Spontaneous in cirrhotics	Malignancy
Hepatic vein obstruction (Budd-Chiari syndrome) protein level high in fluid	Ruptured ectopic pregnancy
Chronic pancreatitis Congestive cardiac failure Constrictive pericarditis Meigs' syndrome (ovarian tumour)	Abdominal trauma Acute pancreatitis
Hypoproteinaemia, (e.g. nephrotic syndrome)	

Investigations

A diagnostic aspiration of 10-20 mL of fluid should be obtained and the following performed:

- **Cell count.** A neutrophil count above 250 cells/mm^3 is indicative of an underlying (usually spontaneous) bacterial peritonitis.
- Gram **stain and culture** - for bacteria and acid-fast bacilli.
- **Protein.** The ascitic protein level enables a division into transudative and exudative ascites. For this division the serum albumin must be used as a reference point. An ascitic albumin of 11 g/L or more below the serum albumin level suggests a transudate. The level of ascitic protein provides an indirect estimate of opsonization capacity, and thereby the risk of developing spontaneous bacterial peritonitis. Patients at most risk are those with ascitic protein levels below 10 g/L.
- **Cytology** - for malignant cells.
- **Amylase** - to exclude pancreatic ascites.

The differential diagnosis of ascites is listed in Table 7.14.

Management

The aim is to both reduce sodium intake and increase renal excretion of sodium - and by doing so produce a net reabsorption of fluid from the ascites back into the circulating volume. The maximum rate at which ascites can be mobilized is 500-700 mL in 24 hours (see below). The management is as follows:

- Check serum electrolytes and creatinine at the start and every other day; weigh patient and measure urinary output daily.
- Bed rest alone will lead to a diuresis in a small proportion of people by improving renal perfusion, but in practice is not helpful.
- By dietary sodium restriction it is possible to reduce sodium intake to 40 mmol in 24 hours and still maintain an adequate protein and calorie intake with a palatable diet.
- Drugs. Remember, many contain significant amounts of sodium (could be up to 50 mmol daily). Examples include antacids, antibiotics (particularly the penicillins and cephalosporins) and effervescent tablets. Sodium-retaining drugs (non-steroidals, corticosteroids) should be avoided if possible.
- Fluid restriction is probably not necessary unless the serum sodium is under 128 mmol/L (see below).
- The diuretic of first choice is the aldosterone antagonist spironolactone, staring at 100 mg daily. Chronic administration produces gynaecomastia; amiloride, 5-15 mg daily, is then substituted.

The aim of diuretic therapy should be to produce a net loss of fluid approaching 700 mL in 24 hours (0.7 kg weight loss or 1.0 kg if peripheral oedema is present). Although 60% of patients respond with this regimen, diuresis is often poor and the spironolactone can be increased gradually to 500 mg daily providing there is no hyperkalaemia. A loop diuretic, such as furosemide 20^0 mg or bumetanide 1 mg daily, may be added if response is poor. These loop diuretics have several potential disadvantages, including hyponatraemia, hypokalaemia and volume depletion.

Ascitic fluid is mobilized more slowly than interstitial fluid, and diuretics should be given with great care in those without peripheral oedema.

Diuretics should be temporarily discontinued if a rise in serum creatinine level occurs, representing over-diuresis and hypovolaemia. Hyponatraemia occurring during therapy almost always represents haemodilution secondary to a failure to clear free water (usually a marker of reduced renal perfusion) and should be treated by stopping the diuretics if the sodium level falls below approximately 128 mmol/L as well as introducing water restriction. Diuretics should also be stopped if there is hyperkalaemia or the development of precoma.

Paracentesis

This is used to relieve symptomatic tense ascites. It is also used as a means of rapid therapy in patients with ascites and peripheral oedema, thus avoiding prolonged hospital stay. The main danger of this approach is the production of hypovolaemia as the ascites reaccumulates at the expense of the circulating volume. In patients with normal renal function and in the absence of hyponatraemia, this has largely been overcome by the administration of albumin (8 g per litre of ascitic fluid removed). In practice, up to 20 L can be removed over 4—6 hours. This procedure has more complications in end-stage cirrhosis or if the patient has renal failure.

Shunts

A transjugular intrahepatic portosystemic shunt (TIPS) is useful for resistant ascites providing there is inactive cirrhosis and minimal disturbance of renal function; as

renal function improves, diurectic use is reduced and sodium excretion increases, but survival is unchanged. The use of a peritoneo-venous shunt has been abandoned in most centres as there is a high rate of blockage.

Spontaneous bacterial peritonitis (SBP)

This condition represents one of the more serious complications of ascites and occurs in approximately 8% of cirrhotics with ascites. The infecting organisms are believed to gain access to the peritoneum by haematogenous spread. The most frequently incriminated bacteria are *Escherichia coli, Klebsiella* and enterococci. The condition should be suspected in any patient with ascites with evidence of clinical deterioration. Features such as pain and pyrexia are frequently absent. Diagnostic aspiration should always be performed in patients with ascites (see above). A raised neutrophil count in ascites is alone sufficient evidence to start treatment immediately. A third-generation cephalosporin, such as cefotaxime or ceftazidime, is used and is modified on the basis of culture results. Recurrence is common (70% within a year) and an oral quinolone, e.g. norfloxacin, 400 mg twice daily is prescribed to prevent it. This also prolongs the survival.

Today the mortality has decreased to 10-15% depending on the severity of the liver disease. SBP is an indication for referral to a liver transplant centre.

Portosystemic encephalopathy

The term 'portosystemic encephalopathy' (PSE) refers to a chronic neuropsychiatric syndrome secondary to chronic liver disease. This condition occurs with cirrhosis, but a similar acute encephalopathy can occur in acute fulminant hepatic failure (see p. 368). PSE is seen in patients with portal hypertension that is due to spontaneous 'shunting', or in patients following a portosystemic shunt procedure, e.g. TIPS. Encephalopathy is potentially reversible.

Pathogenesis

The mechanism is unknown but several factors are thought to play a part. In cirrhosis, the portal blood bypasses the liver via the collaterals and the 'toxic' metabolites pass directly to the brain to produce the encephalopathy.

Many 'toxic' substances have been suggested as the causative factor, including ammonia, free fatty acids, mercaptans and accumulation of false neurotransmitters (octopamine) or activation of the γ-aminobutyric acid (GABA) inhibitory neurotransmitter system. Increased blood levels of aromatic amino acids (tyrosine and phenylalanine) and reduced branched-chain amino acids (valine, leucine and isoleucine) also occur. Nevertheless, ammonia seems to have a major role, and ammonia-induced alteration of brain neurotransmitter balance - especially at the astrocyte-neurone interface - is the leading concept of the causation. Ammonia is produced by the breakdown of protein by intestinal bacteria, and a high blood ammonia is seen in most patients. The factors that can precipitate PSE are shown in Table 7.15.

Table 7.15 **Factors precipitating portosystemic encephalopathy**

High dietary protein
Gastrointestinal haemorrhage
Constipation
Infection, including spontaneous bacterial peritonitis
Fluid and electrolyte disturbance due to:
diuretic therapy
paracentesis
Drugs (e.g. any CNS depressant)
Portosystemic shunt operations, TIPS Any
surgical procedure Progressive liver damage
Development of hepatocellular carcinoma

TIPS, transjugular intrahepatic portocaval shunt

Clinical features

An acute onset often has a precipitating factor (Table 7.15). The patient becomes increasingly drowsy and comatose.

Chronically, there is a disorder of personality, mood and intellect, with a reversal of normal sleep rhythm. These changes may be fluctuating and a history from a relative must be obtained. The patient is irritable, confused, disorientated and has slow slurred speech. General features include nausea, vomiting and weakness. Coma occurs as the encephalopathy becomes more marked, but there is always hyperreflexia and increased tone. Convulsions are so very rare that other causes must be looked for.

Signs include:

- fetor hepaticus (a sweet smell to the breath)
- a coarse flapping tremor seen when the hands are outstretched and the wrists hyperextended (asterixis)
- constructional apraxia, with the patient being unable to write or draw, for example, a five-pointed star
- decreased mental function, which can be assessed by using the serial-sevens test (see p. 1277). A trail-making test (the ability to join numbers and letters with a pen within a certain time - a standard psychological test for brain dysfunction) is prolonged and is a useful bedside test to assess encephalopathy.

Diagnosis is clinical. Routine liver biochemistry merely confirms the presence of liver disease, not the presence of encephalopathy.

Additional investigations

a Electroencephalography (EEG) shows a decrease in the frequency of the normal cc-waves (8-13 Hz) to δ-waves of 1.5—3 Hz. These changes occur before coma supervenes.

- Visual evoked responses (see p. 1203) also detect subclinical encephalopathy.
- Arterial blood ammonia is occasionally useful in the differential diagnosis of the cause of the coma and to follow the course of the PSE, but is not readily available.

Management

Management consists of evacuation of the bowels and sterilizing the bowel. Restriction of protein intake is reserved for resistant cases.

Immediate management

- Identify and remove the possible precipitating cause, such as drugs with cerebral depressant properties, constipation or electrolyte imbalance due to overdiuresis.
- Give purgation and enemas to empty the bowels of nitrogenous substances. Lactulose (10-30 mL three times daily) is an osmotic purgative that reduces the colonic pH and limits ammonia absorption. Lactilol (β-galactoside sorbitol 30 g daily) is metabolized by colonic bacteria and is comparable in efficacy to lactulose. The value of both agents has been questioned.
- Maintain nutrition with adequate calories, given if necessary via a fine-bore nasogastric tube, and do not restrict protein for more than 48 hours.
- Give antibiotics. Rifaximin is mainly unabsorbed and well tolerated long term. Metronidazole (200 mg four times daily) is also effective in the acute situation. Neomycin should not be used. Stop or reduce diuretic therapy.
- Give intravenous fluids as necessary (beware of too much sodium).
- Treat any infection.
- Increase protein in the diet to the limit of tolerance as the encephalopathy improves.

Course and prognosis

Acute encephalopathy, often seen in FHF, has a very poor prognosis as the disease itself has a high mortality. In cirrhosis, chronic PSE is very variable and the prognosis is that of the underlying liver disease. Very rarely an organic syndrome with cerebellar signs, or choreoathetosis can develop in long-standing cases. Hepatic myelopathy leading to a spastic paraparesis due to demyelination also occurs. Both conditions are associated with chronic portosystemic shunting. Patients should be referred to a live transplant centre.

Renal failure (hepatorenal syndrome)

The hepatorenal syndrome occurs typically in a patient with advanced cirrhosis with jaundice and ascites. The urine output is low with a low urinary sodium concentration, a maintained capacity to concentrate urine (i.e. tubular function is intact) and an almost normal renal histology. The renal failure is described as 'functional'. It is sometimes precipitated by overvigorous diuretic therapy, diarrhoea or paracentesis, but often no precipitating factor is found. Advanced cases may progress beyond the 'functional' stage to produce an acute tubular necrosis.

The mechanism is similar to that producing ascites. The initiating factor is thought to be extreme peripheral vasodilatation possibly due to nitric oxide, leading to an extreme decrease in the effective blood volume and hypotension (p. 665). This activates the homeostatic mechanisms, causing a rise in plasma renin, aldosterone, norepinephrine (noradrenaline) and vasopressin, leading to vasoconstriction of the renal vasculature. There is an increased preglomerular vascular resistance causing the blood flow to be directed away from the renal cortex. This leads to a reduced glomerular filtration rate and plasma renin remains high. Salt and water retention occur with reabsorption of sodium from the renal tubules.

A number of other mediators have been incriminated in the pathogenesis of the hepatorenal syndrome, in particular the eicosanoids. This has been supported by the precipitation of the syndrome by inhibitors of prostaglandin synthetase such as non-steroidal anti-inflammatory agents.

Diuretic therapy should be stopped and intravascular hypovolaemia corrected. Terlipressin has been used as a short-term measure with improvement, but the overall prognosis is poor. Studies of TIPS are in progress. Liver transplantation is the best option.

Hepatopulmonary syndrome

This is defined as a hypoxaemia occurring in patients with advanced liver disease. It is due to intrapulmonary vascular dilatation with no evidence of primary pulmonary disease. The patients have features of cirrhosis with spider naevi and clubbing as well as cyanosis. Most patients have no respiratory symptoms but with more severe disease are breathless on standing. Transthoracic ECHO shows intrapulmonary shunting, and arterial blood gases confirm the arterial oxygen desaturation. These changes are improved with liver transplantation.

This condition must be distinguished from pulmonary hypertension (1-2% in association with cirrhosis) which is often a contraindication for transplantation.

Primary hepatocellular carcinoma

This is discussed on page 394.

TYPES OF CIRRHOSIS

Alcoholic cirrhosis

This is discussed in the section on alcoholic liver disease (p. 389).

Primary biliary cirrhosis

Primary biliary cirrhosis (PBC) is a chronic disorder in which there is a progressive destruction of bile ducts, eventually leading to cirrhosis. Ninety per cent of those affected are women in the age range 40-50 years. PBC was thought to be rare but is now being diagnosed frequently in its milder forms. The prevalence is approximately 7.5 per 100 000, with a 1-6% increase in first-degree relatives. PBC has been called 'chronic non-suppurative destructive cholangitis'; this term is more descriptive of the early lesion and emphasizes that true cirrhosis occurs only in the later stages of the disease.

Aetiology

The aetiology is unknown, but immunological mechanisms play a part. Serum antimitochondrial antibodies are found in almost all patients with PBC, and of the mitochondrial proteins involved, the antigen M2 is specific to PBC.

Five M2-specific antigens have been further defined using immunoblot techniques, of which the E2 component of the pyruvate dehydrogenase complex (PDC) is the major M2 autoantigen. The five antigens are a 72 kDa E2 subunit (PDC.E2), the 52 kDa protein X, the 50 kDa branched-chain 2-oxo-acid dehydrogenase complex (BCOADC.E2), the 48 kDa 2-oxo-glutarate dehydrogenase complex (OGDC.E2), and the 41 kDa El oc-subunit of PDC.

The presence of AMA in high titre is unrelated to the clinical or histological picture and its role in pathogenesis is unclear.

It seems likely that an environmental factor acts on a genetically predisposed host. E. *coli* and other enterobacteria, as well as retroviruses have been proposed as the triggering infective agent.

Although damage to bile ducts is a feature, antibodies to bile ductules are not specific to PBC. Biliary epithelium from patients with PBC expresses aberrant class II HLAs, but it is not known whether this expression is the cause or result of the inflammatory response. Cell-mediated immunity is impaired (demonstrated both in vitro and by skin testing), suggesting that sensitized T lymphocytes might be involved in producing damage. There may be a defect in immunoregulation, or a decrease in T suppressor cells which allows cytotoxic T cells to produce damage to the bile ducts. There is also evidence to suggest that lymphokine secretion and cell activation by T lymphocytes is impaired at the site of tissue destruction. There is an increased synthesis of IgM, thought to be due to a failure of the switch from IgM to IgG antibody synthesis. No specific associated Class 2 MHC loci have been found but DQA1*0102 haplotype has been associated with disease resistance.

Clinical features

Asymptomatic patients are discovered on routine examination or screening to have hepatomegaly, a raised serum alkaline phosphatase or autoantibodies.

Pruritus is often the earliest symptom, preceding jaundice by a few years. Fatigue may accompany pruritus, particularly in progressive cases. When jaundice appears, hepatomegaly is usually found. In the later stages, patients are jaundiced with severe pruritus. Pigmented xanthelasma on eyelids or other deposits of cholesterol in the creases of the hands may be seen.

Associations

Autoimmune disorders (e.g. Sjogren's syndrome, scleroderma, rheumatoid arthritis) occur with increased frequency. Keratoconjunctivitis sicca (dry eyes and mouth) is seen in 70% of cases. Renal tubular acidosis and membranous glomerulonephritis occur.

Investigations

- **Mitochondrial antibodies** - measured routinely by ELISA (in titres > 1 : 160) - are present in over 95% of patients; M2 antibody is specific. Other non-specific antibodies (e.g. antinuclear factor and smooth muscle) may also be present.
- **High serum alkaline phosphatase** is often the only abnormality in the liver biochemistry.
- **Serum cholesterol** is raised.
- **Serum IgM** may be very high.
- **Ultrasound** can show a diffuse alteration in liver architecture.
- **Liver biopsy** shows characteristic histological features of a portal tract infiltrate mainly of lymphocytes and plasma cells; approximately 40% have granulomas. Most of the early changes are in zone 1. Later, there is damage to and loss of small bile ducts with ductular proliferation. Portal tract fibrosis and, eventually, cirrhosis is seen.

Hepatic granulomas are not specific and are also seen in sarcoidosis, tuberculosis, schistosomiasis, drug reactions, brucellosis, parasitic infestation (e.g. strongyloidiasis) and other conditions.

Differential diagnosis

The classical picture presents little difficulty with diagnosis (high serum alkaline phosphatase and the presence of AMA); this can be confirmed by the characteristic features on liver biopsy although this is not necessary except in doubtful cases. There is a group of patients with the histological changes of PBC, but the serology of autoimmune hepatitis (i.e. positive antinuclear and smooth muscle antibodies but negative AMA). This has been given the name of autoimmune cholangitis and responds to steroids and azathioprine.

In the jaundiced patient, extrahepatic biliary obstruction should be excluded by ultrasound and, if there is doubt about the diagnosis, MRCP (or ERCP) should be performed to make sure that the bile ducts are normal.

Treatment

Ursodeoxycholic acid (10-15 mg/kg) improves bilirubin and aminotransferase values. It is not clear if prognosis is altered. Symptoms are not improved. Steroids improve biochemical and histological disease but may lead to increased osteoporosis and other side-effects and should not be used.

Malabsorption of fat-soluble vitamins (A, D and K) occurs and supplementation is required when deficiency is detected and in the jaundiced patient prophylactically. Bisphosphonates are required for osteoporosis. Hyperlipidaemia should be treated (see p. 1139).

Pruritus is difficult to control, but colestyramine, one 4 g sachet three times daily, can be helpful, although it is unpalatable. Rifampicin as well as naloxone hydrochloride and naltrexone (opioid antagonists) have been shown to be of benefit. Intractable pruritus can be relieved by a molecular absorbent re-circulating system (MARS).

The lack of effective medical therapy has made PBC a major indication for orthotopic liver transplantation (p. 376).

Complications

The complications are those of cirrhosis. In addition, osteoporosis, and rarely osteomalacia and a polyneuropathy can also occur.

Course and prognosis

This is very variable. Asymptomatic patients and those presenting with pruritus will survive for more than 20 years. Symptomatic patients with jaundice have a more rapidly progressive course and die of liver failure or bleeding varices in approximately 5 years. Liver transplantation should therefore be offered when the serum bilirubin reaches 100 μ῎ηοI/L. Transplantation has a 5-year survival of at least 80%.

Secondary biliary cirrhosis

Cirrhosis can result from prolonged (for months) large duct biliary obstruction. Causes include bile duct strictures, gallstones and sclerosing cholangitis. An ultrasound examination, followed by ERCP or PTC, is performed to outline the ducts and any remedial cause is dealt with.

Hereditary haemochromatosis

Hereditary haemochromatosis (HH) is an inherited disease characterized by excess iron deposition in various organs leading to eventual fibrosis and functional organ failure. - : .

Prevalence and aetiology

HH is transmitted by an autosomal recessive gene with a prevalence in Caucasians of homozygotes (affected) of 1 in 400 and a heterozygote (carrier) frequency of 1 in 10. It is the most common single gene disorder in Caucasians. It is associated with HLA-A3 (72% versus 28% of the general population); in addition HLA-B14 is increased in France and HLA-B7 in Australia. The most common form of HH has been shown to be due to a mutation in a gene, HFE - on the short arm of chromosome 6, but the clinical phenotype varies greatly between homozygous individuals.

Between 85% and 90% of patients with overt HH are homozygous for the Cys 282 Tyr; C282Y mutation. A second mutation (His 63 Asp; H63D) occurs in about 25% of the population and is in complete linkage disequilibrium with Cys 282 Tyr. A third, different form of haemochromatosis occurs in Southern Europe, and is associated with TfR2, a transferrin receptor isoform.

Dietary intakes of iron and chelating agents (ascorbic acid) may be relevant. Iron overload may be present in alcoholics, but alcohol excess per se does not cause HH although there is a history of excess alcohol intake in 25% of patients.

Mechanism of damage. This is still unclear. The *HFE* gene protein interacts with the transferrin receptor 1, which is a mediator in intestinal iron absorption (see Fig. 8.8). Iron is taken up by the mucosal cells inappropriately, exceeding the binding capacity of transferrin. Hepatic expression of the hepcidin gene is decreased in HFE haemochromatosis, facilitating liver iron overload. Excess iron is then taken up by the liver and other tissues gradually over a long period. It seems likely that it is the iron itself that precipitates fibrosis.

Pathology

In symptomatic patients the total body iron content is 20^10 g, compared with *3-4* g in a normal person. The iron content is particularly increased in the liver and pancreas (50-100 times normal) but is also increased in other organs (e.g. the endocrine glands, heart and skin).

In established cases the liver shows extensive iron deposition and fibrosis. Early in the disease, iron is deposited in the periportal hepatocytes (in pericanalicular lysosomes). Later it is distributed widely throughout all acinar zones, biliary duct epithelium, Kupffer cells and connective tissue. Cirrhosis is a late feature.

Clinical features

The course of the disease depends on a number of factors, including sex, dietary iron intake, presence of associated hepatotoxins (especially alcohol) and genotypes. Overt clinical manifestations occur more frequently in men; the reduced incidence in women is probably explained by physiological blood loss and a smaller dietary intake of iron. Most affected individuals present in the fifth decade. The classic triad of bronze skin pigmentation (due to melanin deposition), hepatomegaly and diabetes mellitus is only present in cases of gross iron overload.

Hypogonadism secondary to pituitary dysfunction is the most common endocrine feature. Deficiency of other pituitary hormones is also found, but symptomatic endocrine deficiencies, such as loss of libido, are very rare. Cardiac manifestations, particularly heart failure and arrhythmias, are common, especially in younger patients.

Calcium pyrophosphate is deposited asymmetrically in both large and small joints (chondrocalcinosis) leading to an arthropathy. The exact relationship of chondrocalcinosis to iron deposition is uncertain.

Complications

Thirty per cent of patients with cirrhosis will develop primary hepatocellular carcinoma (HCC). HCC has only very rarely been described in non-cirrhotic patients in whom the excess iron stores have been removed. Early diagnosis is vital.

Investigations

Homozygotes

- **Serum iron** is elevated (> 30 μηοI/L) in 90% with a reduction in the TIBC and a transferrin saturation of (> 60%) or more.
- **Serum ferritin** is elevated (usually > 500 μg/L or 240 nmol/L).
- **Liver biochemistry** is often normal, even with established cirrhosis.

Heterozygotes

Heterozygotes may have normal biochemical tests or modest increases in serum iron transferrin saturation (> 45%) or serum ferritin (usually > 400 μg/L).

Genetic testing

If abnormal iron studies are found, genetic testing is performed. Liver biopsy is now not usually required.

Liver biopsy

This can define the extent of tissue damage, assess tissue iron, and the hepatic iron concentration can be measured (> 180 μηοΐ/g dry weight of liver indicates haemochromatosis) but it is now not required for diagnosis. Mild degrees of parenchymal iron deposition in patients with alcoholic cirrhosis can often cause confusion with true homozygous HH. It is highly likely that many of this former group are heterozygotes for the haemochromatosis gene.

Magnetic resonance imaging

MRI shows dramatic reduction in the signal intensity of **the** liver and pancreas owing to the paramagnetic affect of ferritin and haemosiderin. A highly T2 weighted gradient recalled echo (GRE) technique detects all clinically relevant liver iron overload (> 60 μΐηοΐ/g of liver). In secondary iron overload (haemosiderosis), which involves the reticuloendothelial cells, the pancreas is spared - enabling distinction between these two conditions.

Treatment and management

Venesection

This prolongs life and may reverse tissue damage; the risk of malignancy still remains if cirrhosis is present. All patients should have excess iron removed as rapidly as possible. This is achieved using venesection of 500 mL performed twice-weekly for up to 2 years; i.e. 160 units with 250 mg of iron per unit, equals 40 g removed. During venesection, serum iron and ferritin and the mean corpuscular volume (MCV) should be monitored. These fall only when available iron is depleted. Three or four venesections per year are required to prevent reaccumulation of iron. Serum ferritin should remain within the normal range. Liver biopsy can show the removal of iron to assess progress but is now seldom used. Manifestations of the disease usually improve or disappear, except for diabetes, testicular atrophy and chondrocalcinosis. The requirements for insulin often diminish in diabetic patients. Testosterone replacement is often helpful.

Chelation therapy

In the rare patient who cannot tolerate venesection (because of severe cardiac disease or anaemia), chelation therapy with desferrioxamine either intermittently or continuously by infusion has been successful in removing iron.

Screening

In all cases of HH, all first-degree family members must be screened to detect early and asymptomatic disease. HFE mutation analysis is performed with measurement of transferrin saturation and serum ferritin.

In the general population, the serum iron and transferrin saturation are the best and cheapest tests available.

Wilson's disease (hepatolenticular degeneration)

Dietary copper is normally absorbed from the stomach and upper small intestine. It is transported to the liver loosely bound to albumin. Here it is incorporated into caeruloplasmin, a glycoprotein synthesized in the liver, and secreted into the blood. Copper is normally excreted in the bile.

Wilson's disease is a very rare inborn error of copper metabolism that results in copper deposition in various organs, including the liver, the basal ganglia of the brain and the cornea. It is potentially treatable and all young patients with liver disease must be screened for this condition.

Aetiology

It is an autosomal recessive disorder with a molecular defect within a copper-transporting ATPase encoded by a gene (designated *ATP7B)* located on chromosome 13. Over 60 mutations have been identified, the most frequent being HislO69 Gly found in approximately 50% of cases in the USA and Europe. It occurs world-wide, particularly in countries where consanguinity is common. There is a failure of both incorporation and biliary excretion of copper. In the liver, *copper* is incorporated into caeruloplasmin and then excreted with bile. There is a low serum caeruloplasmin in over 80% of patients owing to poor synthesis, but the precise mechanism for the failure of copper excretion is not known.

Pathology

The liver histology is not diagnostic and varies from that of chronic hepatitis to macronodular cirrhosis. Stains for copper show a periportal distribution but this can be unreliable (see below). The basal ganglia are damaged and show cavitation, the kidneys show tubular degeneration, and erosions are seen in bones.

Clinical features

Children usually present with hepatic problems, whereas young adults have more neurological problems, such as tremor, dysarthria, involuntary movements and eventually dementia. The liver disease varies from episodes of acute hepatitis, especially in children, which can go on to fulminant hepatic failure to chronic hepatitis or cirrhosis. Typical signs are of chronic liver disease with neurological signs of basal ganglia involvement (p. 1231). A specific sign is the Kayser-Fleischer ring, which is due to copper deposition in Descemet's membrane in the cornea. It appears as a greenish brown pigment at the corneoscleral junction just within the cornea. Identification of this ring frequently requires slit-lamp examination. It may be absent in young children.

Investigations

- **Serum copper and caeruloplasmin** are usually reduced but can be normal.
- **Urinary copper** is usually increased (100-1000 mg in 24 hours; normal levels < 40 mg in 24 hours).
- **Liver biopsy.** The diagnosis depends on measurement of the amount of copper in the liver, although high levels of copper are also found in the liver in chronic cholestasis. Measurement of ^{64}Cu incorporation into the liver may be helpful.
- **Haemolysis and anaemia** may be present.
- **Genetic analysis** is limited as already over 200 mutations have been identified at the ATP7B locus.

Treatment

Lifetime treatment with penicillamine, 1-1.5 g daily, is effective in chelating copper. If treatment is started early, clinical and biochemical improvement can occur. Urine copper levels should be monitored and the drug dose adjusted downwards after 2-3 years. Serious side-effects of the drug occur in 10% and include skin rashes, leucopenia and renal damage. All siblings and children of patients should be screened and treatment given even in the asymptomatic if there is evidence of copper accumulation.

Prognosis

Early diagnosis and effective treatment have improved the outlook. Neurological damage is, however, permanent. Fulminant hepatic failure or decompensated cirrhosis should be treated by liver transplantation.

c^-Antitrypsin deficiency (see also p. 902)

A deficiency of oc$_1$antitrypsin (o^AT) is sometimes associated with liver disease and pulmonary emphysema (particularly in smokers). oCjAT is a glycoprotein, part of a family of serine protease inhibitors, or serpin, superfamily. o^AT-deficiency is inherited as an autosomal dominant and 1 in 10 northern Europeans carries an abnormal gene.

The protein is a 394-amino acid 52kDa acute-phase protein that is synthesized in the liver and constitutes 90% of the serum a,-globulin seen on electrophoresis. Its main role is to inhibit the proteolytic enzyme, neutrophil elastase.

The gene is located on chromosome 14. The genetic variants of o^AT are characterized by their electrophoretic mobilities as medium (M), slow (S) or very slow (Z). The normal genotype is protease inhibitor MM (PiMM), the homozygote for Z is PiZZ, and the heterozygotes are PiMZ and PiSZ. S and Z variants are due to a single amino acid replacement of glutamic acid at positions 264 and 342 of the polypeptide, respectively. This results in decreased synthesis and secretion of the protein by the liver as protein-protein interactions occur between the reactive centre loop of one molecule and the β-pleated sheet of a second (loop sheet polymerization).

How this causes liver disease is uncertain. It is postulated that the failure of secretion of the abnormal protein leads to an accumulation in the liver, causing liver damage.

Clinical features

The majority of patients with clinical disease are homozygotes with a PiZZ phenotype. Some may present in childhood and a few require transplantation. Approximately 10-15% of adult patients will develop cirrhosis, usually over the age of 50 years, and 75% will have respiratory problems. Approximately 5% of patients die of their liver disease. Heterozygotes (e.g. PiSZ or PiMZ) may develop liver disease, but the risk is small.

Investigations

- **Serum oij-antritrypsin** is low, at 10% of the normal level in the PiZZ phenotypes, 60% of normal in the S variant.

On liver biopsy periodic acid-Schiff (PAS)-positive, diastase-resistant globules are seen in periportal hepatocytes. These can be shown to be (XjAT using specific antiserum. Fibrosis and cirrhosis can be present.

Treatment

There is no treatment apart from dealing with the complications of liver disease. Patients with hepatic decompensation should be considered for liver transplantation. Patients should stop smoking (see p. 893).

ALCOHOLIC LIVER DISEASE

This section gives the pathology and clinical features of alcoholic liver disease. The amounts needed to produce liver damage, alcohol metabolism, and other clinical effects of alcohol are described on page263.

Ethanol is metabolized in the liver by two pathways (see p. 262), resulting in an increase in the NADH/NAD ratio. The altered redox potential results in increased hepatic fatty acid synthesis with decreased fatty acid oxidation, both events leading to hepatic accumulation of fatty acid that is then esterified to glycerides.

The changes in oxidation-reduction also impair carbohydrate and protein metabolism and are the cause of the centrilobular necrosis of the hepatic acinus typical of alcohol damage.

Acetaldehyde is formed by the oxidation of ethanol and its effect on hepatic proteins may well be a factor in producing liver cell damage. The exact mechanism of alcoholic hepatitis and cirrhosis is unknown, but since only 10-20% of people who drink heavily will suffer from cirrhosis, a genetic predisposition is suggested. Immunological mechanisms have also been proposed.

Alcohol can enhance the effects of toxic metabolites of drugs (e.g. paracetamol) on the liver, as it induces microsomal metabolism via the microsomal ethanol oxidizing system (MEOS) (p. 262).

Pathology

Alcohol can produce a wide spectrum of liver disease from fatty change to hepatitis and cirrhosis.

Fatty change

The metabolism of alcohol invariably produces fat in the liver, mainly in zone 3. This is minimal with small amounts of alcohol, but with larger amounts the cells become swollen with fat (steatosis) giving, eventually, a Swiss-cheese effect on haematoxylin and eosin stain. Steatosis can also be seen in obesity, diabetes, starvation and occasionally in chronic illness (p. 374) There is no liver cell damage. The fat disappears on stopping alcohol.

In some cases collagen is laid down around the central hepatic veins (perivenular fibrosis) and this can sometimes progress to cirrhosis without a preceding hepatitis. Alcohol directly affects stellate cells, transforming them into collagen-producing myofibroblast cells. Cirrhosis might then develop if there is an imbalance between degradation and production of collagen.

Alcoholic hepatitis

In addition to fatty change there is infiltration by polymorphonuclear leucocytes and hepatocyte necrosis mainly in zone 3. Dense cytoplasmic inclusions called Mallory bodies are sometimes seen in hepatocytes and giant mitochondria are also a feature. Mallory bodies are suggestive of, but not specific for, alcoholic damage as they can be found in other liver disease, such as Wilson's disease and PBC. If alcohol consumption continues, alcoholic hepatitis may progress to cirrhosis.

Alcoholic cirrhosis

This is classically of the micronodular type, but a mixed pattern may also be seen accompanying fatty change, and evidence of pre-existing alcoholic hepatitis may be present.

Clinical features

Fatty liver

There are often no symptoms or signs. Vague abdominal symptoms of nausea, vomiting and diarrhoea are due to the more general effects of alcohol on the gastrointestinal tract. Hepatomegaly, sometimes huge, can occur together with other features of chronic liver disease.

Alcoholic hepatitis

The clinical features vary in degree:

- The patient may be well, with few symptoms, the hepatitis only being apparent on the liver biopsy in addition to fatty change.
- Mild to moderate symptoms of ill-health, occasionally with mild jaundice, may occur. Signs include all the features of chronic liver disease. Liver bio chemistry is deranged and the diagnosis is made on liver histology.
- In the severe case, usually superimposed on patients with alcoholic cirrhosis, the patient is ill, with jaundice and ascites. Abdominal pain is frequently present, with a high fever associated with the liver necrosis. On exam ination there is deep jaundice, hepatomegaly, some-
* times splenomegaly, and ascites with ankle oedema. The signs of chronic liver disease are also present.

Alcoholic cirrhosis

This represents the final stage of liver disease from alcohol abuse. Nevertheless, patients can be very well with few symptoms. On examination, there are usually signs of chronic liver disease. The diagnosis is confirmed by liver biopsy.

Usually the patient presents with one of the complications of cirrhosis. In many cases there are features of alcohol dependency (see p. 1302) as well as evidence of involvement of other systems, such as polyneuropathy.

Investigations

Fatty liver

An elevated MCV often indicates heavy drinking. Liver biochemistry shows mild abnormalities with elevation of both serum aminotransferase enzymes. The γ-GT level is a sensitive test for determining whether the patient is taking alcohol. With severe fatty infiltration, marked changes in all liver biochemical parameters can occur. Ultrasound or CT will demonstrate fatty infiltration, as will liver histology.

Alcoholic hepatitis

Investigations show a leucocytosis with markedly deranged liver biochemistry with elevated:

- serum bilirubin
- serum AST and ALT

serum alkaline phosphatase
- prothrombin time (PT).

A low serum albumin may also be found. Rarely, hyperlipidaemia with haemolysis (Zieve's syndrome) may occurs.

Liver biopsy, if required, is performed by the transjugular route because of prolonged PT.

Alcoholic cirrhosis

Investigations are as for cirrhosis in general.

Management and prognosis

General management

Patients should be advised to stop drinking. Delirium tremens (a withdrawal symptom) may be treated with diazepam. Intravenous thiamine should be given empirically to prevent Wernicke-Korsakoff encephalopathy. Bed rest with a diet high in protein and vitamin supplements is given. Dietary protein may have to be limited because of encephalopathy. Follow-up of patients with alcoholic liver disease shows, however, that - apart from highly motivated groups - most patients continue to drink alcohol.

Fatty liver

In all but the mildest cases the patient is advised to stop drinking alcohol; the fat will disappear and the liver biochemistry usually returns to normal. Small amounts of alcohol can be drunk subsequently as long as patients are aware of the problems and can control their consumption.

Alcoholic hepatitis

In severe cases the patient is confined to bed. Treatment for encephalopathy and ascites is commenced. Patients should be fed preferably via a fine-bore nasogastric tube or sometimes intravenously. Vitamins B and C should be given by injection. Corticosteroids should be given providing infection is absent, or following a course of antibiotics. Antifungal prophylaxis should also be used.

Patients are advised to stop drinking for life, as this is undoubtedly a precirrhotic condition. The prognosis is variable and, despite abstinence, the liver disease is progressive in many patients. Conversely, a few patients continue to drink heavily without developing cirrhosis.

In severe cases the mortality is at least 50%, and with a PT twice the normal, progressive encephalopathy and renal failure, the mortality approaches 90%.

Alcoholic cirrhosis

The management of cirrhosis is described on page 376. Again, all patients are advised to stop drinking for life. Abstinence from alcohol results in an improvement in prognosis, with a 5-year survival of 90%, but with continued drinking this falls to 60%. With advanced disease (i.e. jaundice, ascites and haematemesis) the 5-year survival rate falls to 35%, with most of the deaths occurring in the first year. Liver transplantation is being used widely in some countries with good survival figures.

A trial of abstention to establish if liver disease can improve is mandatory, but transplantation should not be denied if the patient continues to deteriorate.

Hepatocellular carcinoma is a complication particularly in men.

BUDD-CHIARI SYNDROME

In this condition there is obstruction to the venous outflow of the liver owing to occlusion of the hepatic vein. In one-third of patients the cause is unknown, but specific causes include hypercoagulability states, such as polycythaemia vera, taking the contraceptive pill, or leukaemia. Other causes include occlusion of the hepatic vein owing to posterior abdominal wall sarcomas, renal or adrenal tumours, hepatocellular carcinoma, hepatic infections (e.g. hydatid cyst), congenital venous webs, radiotherapy, or trauma to the liver.

The acute form presents with abdominal pain, nausea, vomiting, tender hepatomegaly and ascites (a fulminant form occurs particularly in pregnant women). In the chronic form there is enlargement of the liver (particularly the caudate lobe), mild jaundice, ascites, a negative hepatojugular reflex, and splenomegaly with portal hypertension.

Investigations

Investigations show a high protein content in the ascitic fluid and characteristic liver histology with centrizonal congestion, haemorrhage, fibrosis and cirrhosis. Ultrasound, CT or MRI will demonstrate hepatic vein occlusion with diffuse abnormal parenchyma on contrast-enhancement, which spares the caudate lobe because of its independent blood supply and venous drainage. There may be compression of the inferior vena cava. Pulsed Doppler sonography or a colour Doppler are useful as they show abnormalities in the direction of flow in the hepatic vein. Investigations to identify a cause are also performed, such as blood tests and coagulation studies.

Differential diagnosis

A similar clinical picture can be produced by inferior vena caval obstruction, right-sided cardiac failure or constrictive pericarditis, and appropriate investigations should be performed.

Treatment

In the acute situation, thrombolytic therapy should be given. Ascites should be treated as well as any underlying cause (e.g. polycythaemia). Congenital webs should be treated radiologically or resected surgically. A side-to-side portocaval or splenorenal anastomosis may

decompress the congested liver providing there is no caval obstruction, with considerable improvement in the clinical state of the patient. Transjugular intrahepatic portosystemic shunts (TIPS) instead of portocaval shunts are being increasingly used, as caval compression does not prejudice the efficacy of TIPS. Liver transplantation is the treatment of choice for chronic Budd-Chiari syndrome and for the fulminant form, followed by lifelong anticoagulation.

Prognosis

The prognosis depends on the aetiology, but some patients can survive for several years.

REFERENCE

Menom KVN et al. (2004) The Budd-Chiari syndrome. *New England Journal of Medicine* 350: 578-585.

VENO-OCCLUSIVE DISEA

This is due to injury of the hepatic veins and presents clinically like the Budd-Chiari syndrome. It was originally described in Jamaica, where the ingestion of toxic pyrrolizidine alkaloids in bush tea (made from plants of the genera *Senecio, Heliotropium* and *Crotolaria)* caused damage to the hepatic veins. It can be seen in other parts of the world. It is also seen as a complication of chemotherapy and total body irradiation before allogeneic bone marrow transplantation. The development of veno-occlusive disease after transplantation carries a high mortality. Treatment is supportive with control of ascites and hepatocellular failure. Defibrotide has been tried and TIPS has been used in a few cases.

FIBROPOLYCYSTIC DISEASES

These diseases are usually inherited and lead to the presence of cysts or fibrosis in the liver, kidney and occasionally the pancreas, and other organs.

Polycystic disease of the liver

Multiple cysts can occur in the liver as part of autosomal dominant polycystic disease of the kidney (p. 681). These cysts are usually asymptomatic but occasionally cause abdominal pain and distension. Liver function is normal and complications such as oesophageal varices are very rare. The prognosis is excellent and depends on the kidney disease.

Solitary cysts

These are usually found by chance during imaging and are mainly asymptomatic.

Congenital hepatic fibrosis

In this rare condition the liver architecture is normal but there are broad collagenous fibrous bands extending from the portal tracts. It is often inherited as an autosomal recessive condition but can also occur sporadically. It usually presents in childhood with hepatosplenomegaly, and portal hypertension is common. It may present later in life and can be misdiagnosed as cirrhosis.

A wedge biopsy of the liver may be required to confirm the diagnosis. The outlook is good and the condition should be distinguished from cirrhosis. Patients who bleed do well after endoscopic therapy of varices or a portocaval anastomosis because of their good liver function.

Congenital intrahepatic biliary dilatation (Caroli's disease)

In this rare, non-familial disease there are saccular dilatations of the intrahepatic or extrahepatic ducts. It can present at any age (although usually in childhood) with fever, abdominal pain and recurrent attacks of cholangitis with Gram-negative septicaemia. Jaundice and portal hypertension are absent. Diagnosis is by ultrasound, PTC, ERCP or MRCP.

LIVER ABSCESS

Pyogenic abscess

These abscesses are uncommon, but may be single or multiple. The most common is a portal pyaemia from intra-abdominal sepsis (e.g. appendicitis or perforations), but now in many cases the aetiology is not known. In the elderly, biliary sepsis is a common cause. Other causes include trauma, bacteraemia and direct extension from, for example, a perinephric abscess.

The organism found most commonly is *E. coli. Streptococcus milleri* and anaerobic organisms such as *Bacteroides* are often seen. Other organisms include *Enterococcus faecalis, Proteus vulgaris* and *Staphylococcus aureus.* Often the infection is mixed. Failure to culture an organism may be due to previous antibiotic therapy or inadequate anaerobic culture.

Clinical features

Some patients are not acutely ill and present with malaise lasting several days or even months. Others can present with fever, rigors, anorexia, vomiting, weight loss and abdominal pain. In these patients a Gram-negative septicaemia with shock can occur. On examination there may be little to find. Alternatively, the patient may be toxic, febrile and jaundiced. In such patients, the liver is tender and enlarged and there may be signs of a pleural effusion or a pleural rub in the right lower chest.

Investigations

Patients who are not acutely ill are often investigated as a 'pyrexia of unknown origin' (PUO) and most investigations will be normal. Often the only clue to the diagnosis is a raised serum alkaline phosphatase.

- **Serum bilirubin** is raised in 25% of cases.
- **Normochromic normocytic anaemia** may occur, usually accompanied by a polymorphonuclear leucocytosis.
- **Serum alkaline phosphatase and ESR** are often raised.
- **Serum** B_{12} is very high, as vitamin B_{12} is stored in and subsequently released from the liver.
- **Blood cultures** are positive in only 30% of cases.

Imaging

Ultrasound is useful for detecting abscesses. A CT scan may be of value in complex and multiple lesions. A chest X-ray will show elevation of the right hemidiaphragm with a pleural effusion in the severe case. Depending on age, imaging of the colon may be necessary to find the source of the infection.

Management

Aspiration of the abscess should be attempted under ultrasound control. Antibiotics should initially cover Gram-positive, Gram-negative and anaerobic organisms until the causative organism is identified.

Further drainage via a large-bore needle under ultrasound control or surgically may be necessary if resolution is difficult or slow. Any underlying cause must also be treated.

Prognosis

The overall mortality depends on the nature of the underlying pathology and has been reduced to approximately 16% with needle aspiration and antibiotics. A unilocular abscess in the right lobe has the better prognosis. Scattered multiple abscesses have a very high mortality, with only one in five patients surviving.

Amoebic abscess (see also p. 104)

This condition occurs world-wide and must be considered in patients travelling from endemic areas. *Entamoeba histolytica* (p. 104) can be carried from the bowel to the liver in the portal venous system. Portal inflammation results, with the development of multiple microabscesses and eventually single or multiple large abscesses.

Clinically the onset is usually gradual but may be sudden. There is fever, anorexia, weight loss and malaise. There is often no history of dysentery. On examination the patient looks ill and has tender hepatomegaly and signs of an effusion or consolidation in the base of the right side of the chest. Jaundice is unusual.

Investigations

These are as for pyogenic abscess, plus:

- Serological tests for amoeba (e.g. haemagglutination, amoebic complement-fixation test, ELISA). These are always positive, particularly if there are bowel symptoms, and remain positive after a clinical cure and therefore do not indicate current disease. A repeat negative test, however, is good evidence against an amoebic abscess. Diagnostic aspiration of fluid looking like anchovy

Treatment

Metronidazole 800 mg three times daily is given for 10 days. Aspiration is used in patients failing to respond, in multiple and sometimes large abscesses, and in those with abscesses in the left lobe of the liver or impending rupture.

Complications

Complications include rupture, secondary infection and septicaemia.

OTHER INFECTIONS OF THE LIVER

Schistosomiasis (see also p. 112)

Schistosoma mansoni and S. japonicum affect the liver, but *S. haematobium* rarely does so. During their life cycle the ova reach the liver via the venous system and obstruct the portal branches, producing granulomas, fibrosis and inflammation but not cirrhosis.

Clinically there is hepatosplenomegaly and portal hypertension, which is particularly severe with *S. mansoni.*

Investigations show a raised serum alkaline phosphatase and ova can be found in the stools (centrifuged deposits) and in rectal and liver biopsies. Skin tests and other immunological tests often have false results and may also be positive because of past infection.

Treatment is with praziquantel, but fibrosis still remains with a potential risk of portal hypertension, characteristically pre-sinusoidal due to intense portal fibrosis.

Hydatid disease (see also p. 116)

Cysts caused by *Echinococcus granulosus* are single or multiple. They usually occur in the lower part of the right lower lobe. The cyst has three layers: an outside layer derived from the host, an intermediate laminated layer, and an inner germinal layer that buds off brood capsules to form daughter cysts.

Clinically there may be no symptoms or a dull ache and swelling in the right hypochondrium. Investigations show a peripheral eosinophilia in 30% of cases and usually a positive hydatid complement-fixation test or haemagglutination (85%). Plain abdominal X-ray may show calcification of the outer coat of the cyst. Ultrasound and CT scan demonstrate cysts and may show diagnostic daughter cysts within the parent cyst (Fig. 7.25).

Medical treatment (e.g. with albendazole 10 mg/kg, which penetrates into large cysts) can result in reduction

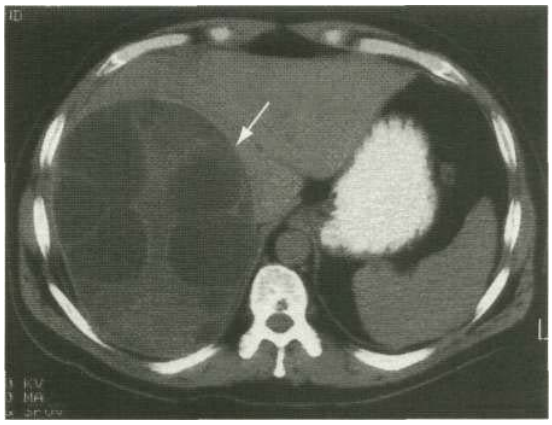

Fig. 7.25 CT scan of liver showing a large hydatid cyst (arrow) with 'daughter' cysts lying within it.

of cyst size. Puncture, aspiration, injection, reaspiration (PAIR) has been used since the 1980s. Fine-needle aspiration is undertaken under ultrasound control with chemotherapeutic cover. Surgery can be performed with removal of the cyst intact if possible after first sterilizing the cyst with alcohol, saline or cetrimide. Chronic calcified cysts can be left. There have been no well-designed clinical trials for any modality.

Complications include rupture into the biliary tree, other organs or intraperitoneally, with spread of infection. The prognosis without any complications is good, although there is always the risk of rupture. Preventative measures include deworming of pet dogs and prevention of pets from eating infected carcasses, as well as veterinary control programmes.

Echinococcus multilocularis causes alveolar echinococcosis and is almost exclusively a hepatic disease, with a high mortality if not treated. Early diagnosis would enable radical surgery and then continued chemosuppression.

Acquired immunodeficiency syndrome

(see also p. 129)

The liver is often involved but rarely causes significant morbidity or mortality. HIV itself is probably not the cause of the liver abnormalities. The following are seen:

- pre-existing/coincidental viral hepatitis — the hepatitis progresses more rapidly (HBV, HCV, HDV)
- neoplasia: Kaposi's sarcoma and non-Hodgkin's lymphoma
- opportunistic infection (e.g. *Mycobacterium tuberculosis, M. avium-intracellulare, Cryptococcus, Candida albicans,* toxoplasmosis)
- drug hepatotoxicity
- sclerosing cholangitis (see p. 404).

Clinical hepatomegaly is common (60% of patients).

LIVER DISEASE IN PREGNANCY

Liver function is not impaired in pregnancy. Any liver disease from whatever cause can occur incidentally and coincide with pregnancy. For example, viral hepatitis accounts for 40% of all cases of jaundice during pregnancy. Pregnancy does not necessarily exacerbate established liver disease, but it is uncommon for women with advanced liver disease to conceive. The following changes take place:

- Plasma and blood volumes increase during pregnancy but the hepatic blood flow remains constant.
- The proportion of cardiac output delivered to the liver therefore falls from 35% to 29% in late pregnancy; drug metabolism can thus be affected.
- The size of the liver remains constant.
- Liver biochemistry remains unchanged apart from a rise in serum alkaline phosphatase from the placenta (up to three to four times) and a decrease in total protein owing to increased plasma volume.
- Triglycerides and cholesterol levels rise, and caeruloplasmin, transferrin, otj-antitrypsin and fibrinogen levels are elevated owing to increased hepatic synthesis.
- Postpartum there is a tendency to hypercoagulability, and acute Budd-Chiari syndrome can occur.

There are a number of liver diseases that complicate pregnancy.

Hyperemesis gravidarum

Pathological vomiting during pregnancy can be associated with liver dysfunction and jaundice. Liver dysfunction resolves when vomiting subsides.

Intrahepatic cholestasis of pregnancy

This condition of unknown aetiology presents usually with pruritus alone in the third trimester. It has a familial tendency and there is a higher prevalence in Scandinavia, Chile and Bolivia.

Liver biochemistry shows a cholestatic picture with high serum ALP (up to four times normal) and raised aminotransferases which occasionally can be very high. The serum bilirubin is slightly raised with jaundice in 60% of cases. Liver biopsy is not indicated but would show centrilobular cholestasis.

Treatment is symptomatic with ursodeoxycholic acid 15 mg/kg. *Prognosis* is usually excellent for the mother but there is increased fetal loss and the condition resolves after delivery. Recurrent cholestasis may occur during subsequent pregnancies or with the ingestion of oestrogen-containing oral contraceptive pills.

Pre-eclampsia and eclampsia

Pre-eclampsia is characterized by hypertension, proteinuria

and oedema occurring in the second or third trimester. Eclampsia is marked by seizures or coma in addition. Hepatic complications include subcapsular haematoma and infarction, and occasionally fulminant hepatic failure. The HELLP syndrome - a combination of haemolysis, elevated liver enzymes and a low platelet count - can occur in association with severe pre-eclampsia. In the HELLP syndrome, there is epigastric pain, nausea and vomiting, with jaundice in 5% of patients. Delivery is the best treatment for eclampsia.

Acute fatty liver of pregnancy (AFLP)

This is a rare, serious condition of unknown aetiology. There is an association between acute fatty liver and long-chain 3-hydroxylacyl-CoA-dihydroxyl (LCHAD) deficiency. The mechanism is unclear, but abnormal fatty acid metabolites produced by the homozygous or heterozygous fetus enter the circulation and overcome maternal hepatic mitochondrial oxidation systems in a heterozygote mother. It presents in the last trimester with symptoms of fulminant hepatitis — jaundice, vomiting, abdominal pain, occasionally haematemesis and coma.

Investigations show hepatocellular damage, hyperuricaemia, thrombocytopenia, and rarely DIC. CT scanning shows a low density of the liver owing to the high fat content. It can sometimes be difficult to differentiate from the HELLP syndrome and as LCHAD deficiency has also been shown in HELLP there is a view that there is a spectrum of HELLP to AFLP. Liver biopsy shows fine droplets of fat (microvesicles) in the liver cells with little necrosis, but is not necessary for diagnosis.

Immediate delivery of the child may save both baby and mother. Early diagnosis and treatment has reduced the mortality to less than 20%. Treatment is as for acute liver failure.

LIVER TUMOURS

The most common liver tumour is a secondary (metastatic) rumour (Fig. 7.26), particularly from the gastrointestinal tract, breast or bronchus. Clinical features are variable but usually include hepatomegaly. Ultrasound is the primary investigation, with CT or MRI used when available; MRI is comparable to CT at detecting metastases. Primary liver tumours may be benign or malignant, but the most common are malignant.

MALIGNANT TUMOURS

Hepatocellular carcinoma (HCC)

Hepatocellular carcinoma (HCC) is one of the 10 most common cancers world-wide.

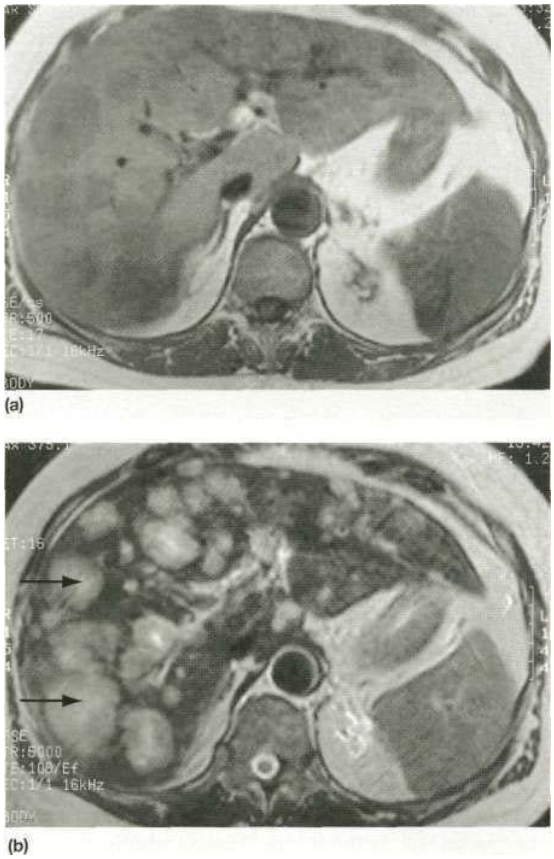

Fig. 7.26 **Liver MRI. (a)** T1 - and **(b)** T2-weighted sequences showing multiple liver metastases. Structures of fluid density have high signal on T2 images. Note the central tumour necrosis in (b) (arrows).

Aetiology

Carriers of HBV and HCV have an extremely high risk of developing HCC. In areas where HBV is prevalent, 90% of patients with this cancer are positive for the hepatitis B virus. Cirrhosis is present in over 80% of these patients. The development of HCC is related to the integration of viral HBV DNA into the genome of the host hepatocyte (see p. 364) and possibly the degree of viral replication. The risk of HCC in HCV is as high as or higher than in HBV despite no viral integration. Primary liver cancer is also associated with other forms of cirrhosis, such as alcoholic cirrhosis and haemochromatosis. Males are affected more than females; this may account for the high incidence seen in haemochromatosis and low incidence in PBC. Other suggested aetiological factors are aflatoxin (a metabolite of a fungus found in groundnuts) and androgenic steroids, and there is a weak association with the contraceptive pill.

Pathology

The tumour is either single or occurs as multiple nodules throughout the liver. Histologically it consists of cells

resembling hepatocytes. It can metastasize via the hepatic or portal veins to the lymph nodes, bones and lungs.

Clinical features

The clinical features include weight loss, anorexia, fever, an ache in the right hypochondrium, and ascites. The rapid development of these features in a cirrhotic patient is suggestive of HCC. On examination, an enlarged, irregular, tender liver may be felt. Increasingly due to surveillance, HCC is found without symptoms in cirrhotics.

Investigations

Serum oc-fetoprotein may be raised, but is normal in at least a third of patients. Ultrasound scans show filling defects in 90% of cases. A liver biopsy, particularly under ultrasonic guidance may be performed for diagnosis, but is increasingly less used as imaging techniques show characteristic appearances and because seeding along the biopsy tract can occur.

Treatment and prognosis

Surgical resection is occasionally possible. Small tumours in patients with cirrhosis do well with liver transplantation. Chemotherapy and radiotherapy are unhelpful, but chemoembolization and probably embolization alone in selected patients prolong survival.

Survival, except in very selected groups, is seldom more than 6 months.

Prevention

Persistent HBV infection, usually acquired after perinatal infection, is a high risk factor for HCC in many parts of the world, such as South East Asia. Widespread vaccination against HBV is being used and this has shown a reduction in the annual incidence of HCC in Taiwan.

Cholangiocarcinoma

Cholangiocarcinomas can be extrahepatic (see p. 405) or intrahepatic. Intrahepatic adenocarcinomas arising from the bile ducts account for approximately 10% of primary tumours. They are not associated with cirrhosis or hepatitis B. In the Far East they may be associated with infestation with *Clonorchis sinensis* or *Opisthorchis viverrini.* The clinical features are similar to primary HCC except that jaundice is frequent with hilar tumours, and cholangitis is more frequent.

Surgical resection is rarely possible and patients usually die within 6 months. Transplantation is contraindicated.

BENIGNTUMOURS

The most common benign tumour is a *haemangioma.* It is usually small and single but can be multiple and large. They are usually found incidentally on ultrasound, CT or MR! and have characteristic appearances. They require no treatment.

Hepatic adenomas are associated with oral contraceptives. They can present with abdominal pain or intraperitoneal bleeding. Resection is only required for symptomatic patients, or in those in whom discontinuation of the oral contraception does not result in shrinkage of the tumour.

Wands JR (2004) Prevention of hepatocellular carcinoma. *New England Journal of Medicine* 351:1567-1570.

MISCELLANEOUS CONDITIONS OF THE LIVER

Hepatic mitochondrial injury syndromes

These syndromes - in which there is mitochondrial damage with inhibition of β-oxidation of fatty acids - can be categorized as follows:

- *Genetic,* with abnormalities which include medium-chain acyl-coenzyme A dehydrogenase deficiency leading to microsteatosis.
- *Toxins* leading to liver failure include aflatoxin and cerulide (produced by *Bacillus cereus)* which causes food poisoning (see p. 69).
- *Drugs* (e.g. i.v. tetracycline, valproic acid and nucleoside reverse-transcriptase inhibitors) can produce a fatal microsteatosis.
- *Idiopathic,* the best known being fatty liver of pregnancy (p. 394) and Reye's syndrome. This condition, due to inhibition of β-oxidation and uncoupling of oxidative phosphorylation in mitochondria, leads in children to an acute encephalopathy and diffuse microvesicular fatty infiltration of the liver. Aspirin ingestion and viral infections have been implicated as precipitating agents. Mortality is about 50%, usually due to cerebral oedema.

Idiopathic adult ductopenia

This unexplained condition is characterized by pruritus and cholestatic jaundice. Histology of the liver shows a decrease in intrahepatic bile ducts in at least 50% of the portal tract, together with the features of cholestasis and marked fibrosis or cirrhosis. In most the disease is progressive and the only treatment is liver transplantation.

Indian childhood cirrhosis

This condition of children is seen in the Indian subcontinent. The cause is unknown. Eventually there is development of a micronodular cirrhosis with excess copper in the liver.

Hepatic porphyrias

These are dealt with on page 1148.

Cystic fibrOSIS (see also p. 909)

This disease affects mainly the lung and pancreas, but patients can develop fatty liver, cholestasis and cirrhosis. The aetiology of the liver involvement is unclear.

DRUGS AND THE LIVER

Drug metabolism

The liver is the major site of drug metabolism. Drugs are converted from fat-soluble to water-soluble substances that can be excreted in the urine or bile. This metabolism of drugs is mediated by a group of mixed-function enzymes (p. 993).

Drug hepatotoxicity

Many drugs impair liver function, and drugs should always be considered as a cause when mildly abnormal liver tests are found. Damage to the liver by drugs is usually classified as being either predictable (or dose-related) or non-predictable (not dose-related) (see p. 996). This classification should not be used rigidly, as there is considerable overlap and at least six mechanisms may be involved in the production of damage: (1) disruption of intracellular calcium homeostasis; (2) disruption of bile canalicular transport mechanisms; (3) formation of non-functioning adducts (enzyme-drug) which may then (4) present on the surface of the hepatocyte as new immunogens (attacked by T cells); (5) induction of apoptosis; (6) inhibition of mitochondrial function, which prevents fatty acid metabolism, and accumulation of both lactate and reactive oxygen species. The predominant mechanism or combination of mechanisms determines the type of liver injury, i.e. hepatitic, cholestatic or immunological (skin rashes, fever and arthralgia (serum-sickness syndrome)). Eosinophilia and circulating immune complexes and antibodies may occasionally be detected.

When a small amount of hepatotoxic drug whose effect is dose-dependent (e.g. paracetamol) is ingested, a large proportion of it undergoes conjugation with glucuronide and sulphate, whilst the remainder is metabolized by microsomal enzymes to produce toxic derivatives that are immediately detoxified by conjugation with glutathione. If larger doses are ingested, the former pathway becomes saturated and the toxic derivative is produced at a faster rate. Once the hepatic glutathione is depleted, large amounts of the toxic metabolite accumulate and produce damage (p. 1017).

The 'predictability' of drugs to produce damage can, however, be affected by metabolic events preceding their ingestion. For example, chronic alcohol abusers may become more susceptible to liver damage because of the enzyme-inducing effects of alcohol, or ill or starving patients may become susceptible because of the depletion of hepatic glutathione produced by starvation. Many other factors such as environmental or genetic effects may be involved in determining the 'susceptibility' of certain patients to certain drugs.

Hepatitic damage

The type of damage produced by various drugs is shown in Table 7.16. The diagnosis of these conditions is usually by exclusion of other causes. Most reactions occur within 3 months of starting the drug. Monitoring liver biochemistry in patients on long-term treatment, such as antituberculosis therapy, is advisable. If a drug is suspected of causing hepatic damage it should be stopped immediately. Liver biopsy is of limited help in confirming the diagnosis, but occasionally hepatic eosinophilia or granulomas may be seen. Diagnostic challenge with subtherapeutic doses of the drug is sometimes required after the liver biochemistry has returned to normal, to confirm the diagnosis.

Individual drugs

Paracetamol

In high doses paracetamol produces liver cell necrosis (see above). The toxic metabolite binds irreversibly to liver cell membranes. Overdosage is discussed on page1017.

Halothane and other volatile liquid anaesthetics

Halothane produces a hepatitis in patients having repeated exposures. The mechanism is thought to be a hypersensitivity reaction. An unexplained fever occurs approximately 10 days after the second or subsequent halothane anaesthetic and is followed by jaundice, typically with a hepatitic picture. Most patients recover spontaneously but there is a high mortality in severe cases. There are no chronic sequelae. Both enflurane and isoflurane also cause hepatotoxicity in those sensitized to halogenated anaesthetics but the risk is smaller than with halothane.

Steroid compounds

Cholestasis is caused by natural and synthetic oestrogens as well as methyltestosterone. These agents interfere with canalicular biliary flow and cause a pure cholestasis. Cholestasis is rare with the contraceptive pill because of the low dosage used. However, the contraceptive pill is associated with an increased incidence of gallstones, hepatic adenomas (rarely HCCs), the Budd-Chiari syndrome and peliosis hepatis. The latter condition, which also occurs with anabolic steroids, consists of dilatation of the hepatic sinusoids to form blood-filled lakes.

Phenothiazines

Phenothiazines (e.g. chlorpromazine) can produce a cholestatic picture owing to a hypersensitivity reaction. It occurs in 1 % of patients, usually within 4 weeks of starting the drug. Typically it is associated with a fever and eosinophilia. Recovery occurs on stopping the drug.

Antituberculous chemotherapy

Isoniazid produces elevated aminotransferases in 10-20% of patients. Hepatic necrosis with jaundice occurs in a

		Hepatic tumours	
		Hepatocellular carcinoma	

NSAID, non-steroidal anti-inflammatory drug

smaller percentage. The hepatotoxicity of isoniazid appears to be related to acetylator status, as the damage is due to the metabolites.

Rifampicin produces a hepatitis, usually within 3 weeks of starting the drug, particularly in patients on high doses.

Pyrazinamide produces abnormal liver biochemical tests and, rarely, liver cell necrosis.

Amiodarone

This leads to a steatohepatitis histologically and liver failure if the drug is not stopped in time.

Drug prescribing for patients with liver disease

The metabolism of drugs is impaired in severe liver disease (with jaundice and ascites) as the removal of many drugs depends on liver blood flow and the integrity of the hepatocyte. In general, therefore, the effect of drugs is prolonged by liver disease and also by cholestasis. This is further accentuated by portosystemic shunting, which diminishes the first-pass extraction of drugs. With hypoproteinaemia there is decreased protein binding of some drugs, and bilirubin competes with many drugs for

the binding sites on serum albumin. In patients with portosystemic encephalopathy, care must be taken in prescribing drugs with a central depressant action.

GALL BLADDER AND BILIARY SYSTEM

The structure, formation and function of bile is discussed on page 349.

GALLSTONES

Prevalence of gallstones

Gallstones may be present at any age but are unusual before the third decade. The prevalence of gallstones is strongly influenced both by age and sex. There is a progressive increase in the presence of gallstones with age but the prevalence is two to three times higher in women than in men, although this difference is less marked in the sixth and seventh decade. At this age the prevalence ranges between 25-30%. There are considerable racial differences, gallstones being more common in Scandinavia, South America and Native North Americans.

Types of gallstones

Two principal types of gallstone disease occur. In the western world 80% of gallstones contain cholesterol. The second less frequent type of gallstone is 'pigment stones', being predominantly composed of calcium bilirubinate or polymer-like complexes with calcium, copper and some cholesterol.

Cholesterol gallstones

The formation of cholesterol stones is the consequence of cholesterol crystallization from gall bladder bile. This is dependent upon three factors:

- cholesterol supersaturation of bile
- crystallization-promoting factors within bile
- motility of the gall bladder.

Cholesterol is derived partly from dietary sources, but in addition is synthesized within the liver. The rate-limiting step in cholesterol synthesis is beta-hydroxy-beta methyl glutaryl Co-A (HMG-CoA) reductase, which catalyses the first step, i.e. the conversion of acetate to mevalonate (see Fig. 7.4). The cholesterol formed is co-secreted with phospholipids into the biliary canaliculus as unilamellar vesicles. Cholesterol will only crystallize into stones when the bile is supersaturated with cholesterol relative to the bile salt and phospholipid content. This can occur as a consequence of excess cholesterol secretion into bile which, in some instances, has been shown to be due to an increase in HMG-CoA reductase activity. Recently, leptin (p. 253) has been shown to increase cholesterol secretion into bile. Elevated levels of leptin during rapid weight loss may account for the increased incidence of cholesterol gallstones. An alternative mechanism of supersaturation is a decreased *bile salt content* which may be genetically predetermined or occur as a consequence of bile salt loss (e.g. terminal ileal Crohn's disease).

The *composition* of the bile salt pool may also influence the ability to maintain cholesterol in solution. There is evidence that an increased proportion of the secondary hydrophobic bile acid (deoxycholic acid) in the bile acid pool may predispose to cholesterol stone formation. This has been linked with slow colonic transit during which the primary bile acid cholic acid may undergo microbial enzyme metabolism yielding deoxycholic acid which is then absorbed back into the bile salt pool (see Fig. 7.4).

Whilst cholesterol supersaturation of bile is essential for cholesterol stone formation, many individuals in whom such supersaturation occurs will never develop stones. It is the balance between cholesterol crystallizing and solubilizing factors that determine whether cholesterol will crystallize out of solution. A number of lipoproteins have been reported as putative crystallizing factors.

Gall bladder motility represents a further factor that may influence the cholesterol crystallization from supersaturated bile. There is evidence from animal models that gall bladder stasis leads to cholesterol crystallization mediated by hypersecretion of mucin.

Abnormalities of gall bladder motility have been suggested as factors in such circumstances as pregnancy, multiparity and diabetes as well as octreotide-related gall bladder stones (p. 1069). Recognized risk factors for gallstones are shown in Table 7.17.

Bile pigment stones

The pathogenesis of pigment stones is entirely independent of cholesterol gallstones. There are two main types of pigment gallstones, black and brown.

Black pigment gallstones are composed of calcium bilirubinate and a network of mucin glycoproteins that interlace with salts such as calcium carbonate and/or

Table 7.17 **Risk factors for cholesterol gallstones**

Increasing age	Drugs (e.g. contraceptive pill)
Sex (F > M)	Ileal disease or resection
Multiparity	Diabetes mellitus
Obesity	Acromegaly treated with octreotide
Rapid weight loss	Liver cirrhosis
Diet (e.g. high in animal fat)	

calcium phosphate. These stones range in colour from deep black to very dark brown and have a glass-like cross-sectional surface on fracturing. Black pigment stones are seen in 40-60% of patients with haemolytic conditions such as sickle cell disease and hereditary spherocytosis in which there is chronic excess bilirubin production. However, the majority of pigment stones occur without haemolysis. These black stones have been shown to contain bacteria, many of which produce glucuronidase and phospholipase, factors that are known to facilitate stone formation. It is speculated that this subclinical bacterial colonization of the bile duct is responsible for the pigment stone formation.

Brown stones are usually of a muddy hue and on cross-section seem to have alternating brown and tan layers. These stones are composed of calcium salts of fatty acids as well as calcium bilirubinate. They are almost always found in the presence of bile stasis and/or biliary infection. Brown stones are a common cause of recurrent bile duct stones following cholecystectomy and may also be found in the intrahepatic ducts in circumstances of duct disease such as Caroli's syndrome and primary sclerosing cholangitis. In the Far East such brown stones are identified within both the intra- and extrahepatic biliary tree and have been linked with chronic parasitic infection.

Clinical presentation of gallstones
(Fig. 7.27)

The majority of gallstones are asymptomatic and remain so during a person's lifetime. Gallstones are increasingly detected as an incidental finding at the time of either abdominal radiography or ultrasound scanning. Over a 10- to 15-year period approximately 20% of these stones will be the cause of symptoms with 10% having severe complications. Once gallstones have become symptomatic there is a strong trend towards recurrent complications, often of increasing severity. Gallstones do not cause dyspepsia, fat intolerance, flatulence or other vague upper abdominal symptoms. The chances of a fair, fat, female of 40 having gallstones is the same as in the general population.

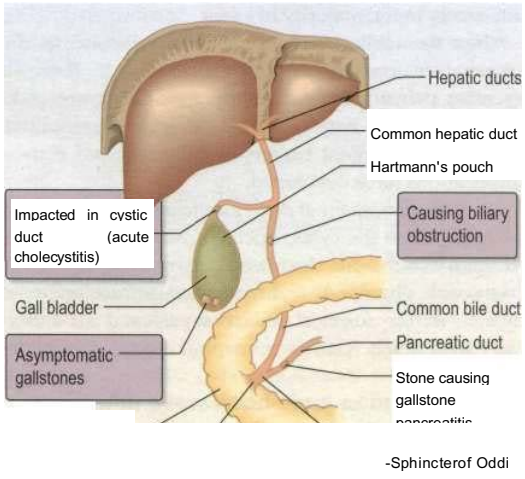

Fig. 7.27 Clinical presentation of gallstones.

Biliary or gallstone colic
Biliary colic is the term used for the pain associated with the temporary obstruction of the cystic or common bile duct by a stone usually migrating from the gall bladder. Despite the term 'colic' the pain of stone-induced ductular obstruction is one of a severe but constant pain, which has a crescendo characteristic. Many sufferers can relate the symptoms to over-indulgence with food, particularly when this has a high fat content. The most common time of day for such an episode is in the mid-evening and lasting until the early hours of the morning. The initial site of pain is usually in the epigastrium but there may be a right upper quadrant component. Radiation may occur over the right shoulder and right subscapular region. Nausea and vomiting frequently accompany the more severe attacks. The cessation of attack may be spontaneous after a number of hours or terminated by the administration of opiate analgesia. More protracted pain, particularly when associated with fevers and rigors, suggests secondary complications such as cholecystitis, cholangitis or gallstone-related pancreatitis (see below).

Acute cholecystitis
The initial event in acute cholecystitis is obstruction to gall bladder emptying. In 95% of cases a gall bladder stone can be identified as the cause. Such obstruction results in an increase of gall bladder glandular secretion leading to progressive distension which in turn may compromise the vascular supply to the gall bladder. There is also an inflammatory response secondary to retained bile within the gall bladder. Infection is a secondary phenomenon following the vascular and inflammatory events described above.

The initial clinical features of an episode of cholecystitis are similar to those of biliary colic described above. However, over a number of hours there is progression with severe localized right upper quadrant abdominal pain corresponding to parietal peritoneal involvement in the inflammatory process. The pain is associated with tenderness and muscle guarding or rigidity. Occasionally the gall bladder can become distended by pus (an empyema) and rarely an acute gangrenous cholecystitis develops which can perforate, with generalized peritonitis.

Investigations
Biliary colic as a consequence of a stone in the neck of the gall bladder or cystic duct is unlikely to be associated with significant abnormality of laboratory tests. Acute cholecystitis is usually associated with a moderate leucocytosis and raised inflammatory markers (e.g. C-reactive protein).

- The **serum bilirubin, alkaline phosphatase and aminotransferase** levels may be marginally elevated

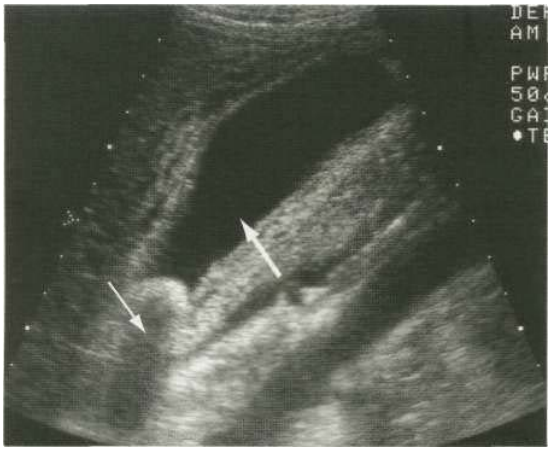

Fig. 7.28 **Ultrasound scan in a patient with acute cholecystitis.** There is a stone (casting an acoustic shadow - thin arrow) impacted in the gall bladder neck, with a distended gall bladder (thick arrow) and thickening and oedema of the gall bladder wall.

in the presence of cholecystitis alone, even in the absence of **bile duct** obstruction. More significant elevation of the bilirubin and alkaline phosphatase is in keeping with bile duct obstruction.

- **A plain abdominal X-ray** may provide evidence of gall bladder disease in the form of radio-opaque stones or calcification of the gall bladder. In severe cases of acute cholecystitis there may be gas within the gall bladder lumen and wall due to either gas-forming organisms or fistulation of a gallstone into the bowel.
- **An abdominal ultrasound scan** is the single most useful investigation for the diagnosis of gallstone-related disease (Fig. 7.28). Look for:
  (a) *gallstones* within the gall bladder, particularly when these are obstructing the gall bladder neck or cystic duct
  (b) *focal tenderness* over the **underlying gall bladder**
  (c) *thickening of the gall bladder wall.* This may also be seen with hypoalbuminaemia, portal hypertension and acute viral **hepatitis.**

  Gallstones are a common finding in an ageing population, and in the absence of specific symptoms great care should be taken as to whether the gallstones are responsible for the symptoms.
- **Biliary scintigraphy using technetium derivatives of iminodiacetate.** These isotopes are taken up by hepatocytes and excreted into bile. They delineate the extrahepatic biliary tree. The absence of cystic duct and gall bladder filling provides evidence towards acute cholecystitis although the findings must be closely correlated with the presenting symptoms.

Differential diagnosis

Typical cases of biliary colic are usually suspected by a careful clinical history. The differential diagnosis includes the irritable bowel syndrome (spasm of the hepatic flexure), carcinoma of the right side of the colon, atypical peptic ulcer disease, renal colic and pancreatitis.

The differential diagnosis of acute cholecystitis includes a number of other conditions marked by severe right upper quadrant pain and fever, e.g. acute episodes of pancreatitis, perforated peptic ulceration or an intrahepatic abscess. Conditions above the right diaphragm such as basal pneumonia as well as myocardial infarction may on occasions mimic the clinical picture.

MANAGEMENT OF GALL BLADDER STONES

Cholecystectomy

Cholecystectomy is the treatment of choice for virtually all patients with *symptomatic* gall bladder stones. Cholecystectomy should not be performed in the absence of typical symptoms just because stones are found on investigation. The laparotomy approach to cholecystectomy has now been largely replaced by the laparoscopic technique. Postoperative pain is minimized with only a short period of ileus and the early ability to mobilize the patient. Laparoscopic cholecystectomy has been carried out on a day-care basis but more commonly requires a 48-hour admission. This has considerable cost benefits over open cholecystectomy, which is now reserved for a small proportion of patients with contraindications such as extensive previous upper abdominal surgery, ongoing bile duct obstruction or portal hypertension.

In approximately 5% of cases a laparoscopic cholecystectomy is converted to an open operation because of technical difficulties, in particular adhesions in the right upper quadrant or difficulty in identifying the biliary anatomy.

Acute cholecystitis. The **initial** management is conservative, consisting of nil by mouth, intravenous fluids, opiate analgesia and intravenous antibiotics (e.g. cefotaxime).

Cholecystectomy is usually delayed for a few days to allow the symptoms to settle but can then be carried out quite safely in the majority of cases.

When the clinical situation fails to respond to this conservative management, particularly if there is increasing pain and fever, an empyema or gangrene of the gall bladder may have occurred. Urgent ultrasound is performed and urgent surgery will be required if these complications have developed.

Specific complications of cholecystectomy include a biliary leak either from the cystic duct or from the gall bladder bed. Injury to the bile duct itself occurs in up to 0.5% of laparoscopic operations and may have serious long-term sequelae in the form of biliary sepsis and secondary biliary liver injury. There is an overall mortality of 0.2%.

Stone dissolution and shock wave lithotripsy

These *non-surgical techniques* for the management of gall bladder stones are infrequently used but are used in a highly selected group of patients who may not be fit for laparoscopic cholecystectomy.

Dissolution Pure or near-pure cholesterol stones can be solubilized by increasing the bile salt content of bile. Chenodeoxycholic acid and ursodeoxycholic acid are used. For dissolution to occur there must be a functioning gall bladder and optimally the stones should be almost pure cholesterol with a diameter of less than 10 mm. Using these criteria, only 20% of patients with gallstones will be eligible and even under such circumstances the time to achieve dissolution is often a matter of several months. There is also a high relapse rate when the drugs are discontinued. These limitations have restricted the application of this approach. Further benefit may be attained by the addition of an HMG-CoA reductase inhibitor (e.g. simvastatin) to a regimen of ursodeoxycholic acid. This will then combine reduced cholesterol content of bile as well an enhanced bile salt concentration but uses are still limited.

Extracorporeal shock wave lithotripsy. A shock wave can be directed either radiologically or by ultrasound on to gall bladder stones. This technique was highly successful but in only a restricted patient population. Fragmentation was limited to a small number of stones only and these had to be greater than 10 mm in diameter. The greater the calcium content of the stone the less likely the success of fragmentation. Gall bladder function has to be intact so the stone fragments can clear via the cystic duct.

The post-cholecystectomy syndrome

This refers to right upper quadrant pain often biliary in type which occurs a few months after the cholecystectomy but it may be delayed for a number of years. The patients often comment that the pain is identical to that for which the original operation was carried out. In many cases this syndrome is related to functional large bowel disease with colonic spasm at the hepatic flexure (hepatic flexure syndrome). In a small proportion of patients the pain is a result of a retained common bile duct stone. In a further minority of patients, hypertension of the sphincter of Oddi is a potential cause. This is most likely in patients with abnormal liver biochemistry and dilatation of the common bile duct (on ultrasound) during episodes of pain (and in the absence of a documented retained stone). The diagnosis is confirmed by pressure measurements of the sphincter of Oddi, and the condition can be successfully managed by endoscopic sphincterotomy (see below).

COMMON BILE DUCT STONES

The classical features of common bile duct (CBD) stones are biliary colic, fever and jaundice (acute cholangitis). This triad is only present in the minority of patients. Abdominal pain is the most common symptom and has the typical features of biliary colic (see above). Jaundice is a variable accompaniment and is almost always preceded by abdominal pain. A patient with bile duct stones may experience sequential episodes of pain, only some of which are accompanied by jaundice. In contrast to malignant bile duct obstruction, the level of jaundice associated with CBD stones characteristically tends to fluctuate.

Fever is only present in a minority of cases but indicates biliary sepsis and sometimes an associated septicaemia. The presence of such biliary sepsis is a significant adverse prognostic factor.

A minority of patients with bile duct stones are discovered incidentally during imaging for gall bladder disease. Fifteen per cent of patients undergoing cholecystectomy will have stones within the bile duct only detected at the time of operative cholangiography.

Physical examination

If the patient is examined between episodes there may be no abnormal physical finding. During a symptomatic episode the patient may be jaundiced with a fever and associated tachycardia. There is tenderness in the right upper quadrant varying from mild to extremely severe.

More widespread abdominal tenderness extending from the epigastrium to the left upper quadrant, associated with distension, may indicate associated stone-related pancreatitis (see below). ■

Investigations

Laboratory tests

- *Full blood count* is usually normal in the presence of uncomplicated bile duct stones.
- *An elevated neutrophil count* as well as raised inflammatory markers (ESR and CRP) are frequent accompaniments of cholangitis.
- *The raised serum bilirubin* tends to be mild and often transient. Very high concentrations of bilirubin (= 200 μmol/L) almost always reflect complete bile duct obstruction.
- *Serum alkaline phosphatase and gamma glutamyl transpeptidase* are similarly elevated in proportion to the degree of hyperbilirubinaemia.
- *Aminotransferase levels* are usually mildly elevated but with complete bile duct obstruction they may rise to 10-15 times the normal value.
- *Serum amylase levels ate* often mildly elevated in the presence of bile duct obstruction but are markedly so if stone-related pancreatitis has occurred.
- *Prothrombin time* may be prolonged if bile duct obstruction has occurred; this reflects decreased absorption of vitamin K.

Trans-abdominal ultrasound

This is the initial imaging technique of choice and in many cases the only imaging technique required.

Bile duct obstruction is characterized by dilatation of intrahepatic biliary radicals, which are usually easily detected by the ultrasound scan. It may, however, not be possible to identify the cause of obstruction. Stones situated in the distal common bile duct are poorly visualized by trans-abdominal ultrasound and up to 50% are missed. The detection of stones within the gall bladder is poorly predictive as to the cause of bile duct obstruction. Asymptomatic gallstones are common (up to 15%) in patients in the cancer age group (65 years and older). Conversely, in 5-10% of patients with bile duct stones no calculi can be seen within the gall bladder.

Other imaging techniques

Magnetic resonance cholangiography (MRC) delineates the fluid column within the biliary tree and is the technique of choice to supplement trans-abdominal ultrasound (Fig. 7.29).

Spiral CT scanning is an alterative way to detect bile duct dilatation. Opaque stones are more readily identifiable within the bile duct than radiolucent cholesterol stones. CT scanning provides a means of excluding other causes of bile duct obstruction such as carcinoma of the head of the pancreas.

Endoscopic ultrasound scanning (Fig. 7.30) has enabled high-resolution imaging of the common bile duct, gall bladder and pancreas, although unlike the preceding imaging techniques it is an invasive procedure. The endoscopic ultrasound probe can be brought into close proximity with the distal common bile duct and hence identify the majority of stones at this level.

This technique may be particularly useful for identifying small calculi (microcalculi).

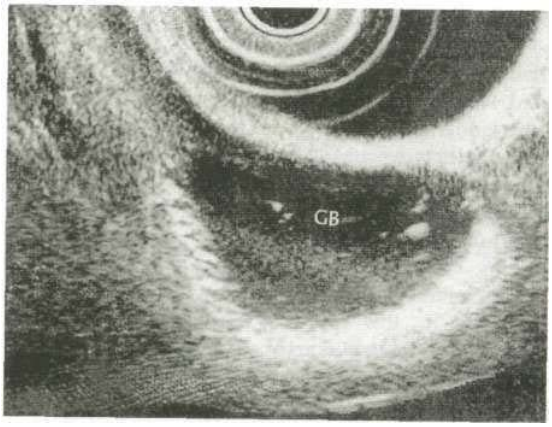

Fig. 7.30 An endoscopic ultrasound scan with the probe within the duodenum (upper margin of the figure) clearly demonstrating the gall bladder (GB) with multiple small stones within.

Endoscopic retrograde cholangiography (ERC)

The endoscopic technique of ERC (p. 356) enables good visualization of the common bile duct. In experienced hands this will be successful in 98% of cases, providing good documentation of bile duct stones (Fig. 7.31). However, microcalculi can still be missed.

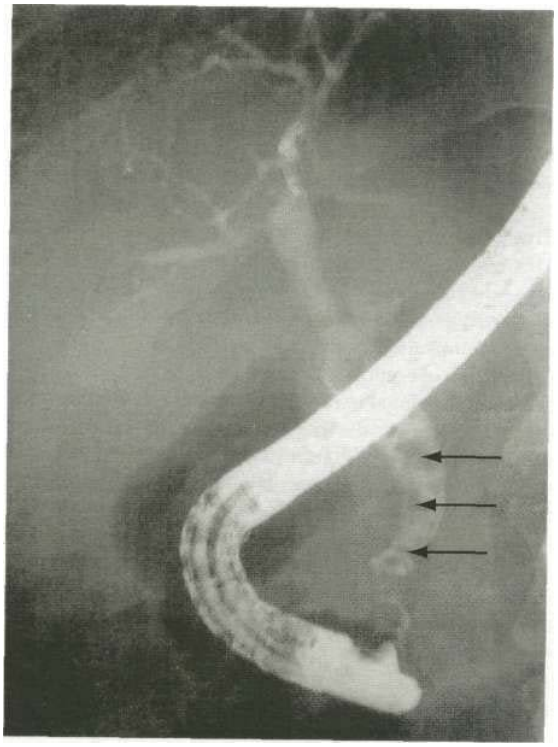

Fig. 7.31 An ERCP in a patient presenting with abdominal pain, jaundice and fever. Several stones can be seen within the dilated common bile duct (arrows).

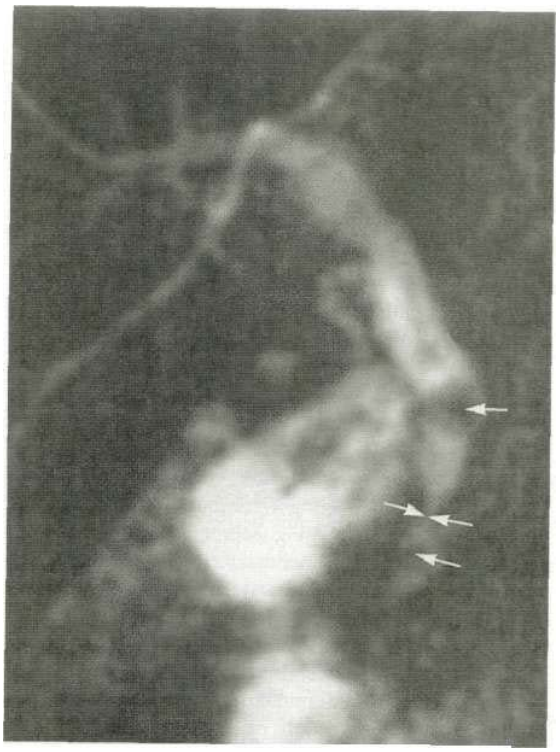

Fig. 7.29 A magnetic resonance cholangiogram in a patient presenting with abdominal pain and jaundice. This shows evidence of a distal common bile duct stricture (arrows) with a large gallstone proximal to this in the mid common bile duct (top arrow).

ERC gives the therapeutic opportunity for sphincterotomy and stone extraction (see below).

Differential diagnosis

Cholangitis may occur independently of gallstones in conditions such as primary sclerosing cholangitis and

Caroli's syndrome. On occasions cholangitis may accompany malignant bile duct obstruction. Jaundice may also be a feature of acute cholecystitis in the absence of bile duct stones when there is pressure on the common bile duct by a gallstone in the cystic duct (Mirizzi's syndrome). Common bile duct stones may produce pain, but in the absence of jaundice, the differential diagnosis is that of biliary colic (see above).

Management

Acute cholangitis has a high morbidity and mortality, particularly in the elderly age group. Successful management depends on intravenous antibiotics (e.g. i.v. cefotaxime), and urgent bile duct drainage by an endoscopic retrograde approach (Fig. 7.31). Access to the bile duct is achieved by sphincterotomy, and thereafter the stones can be removed either by balloon or basket catheters. In the severely ill patient a piece of plastic tubing (termed a stent) can be inserted into the bile duct to maintain bile drainage without the need to remove the stones, hence minimizing the time period to complete the procedure. The residual stones can then be removed endoscopically when the patient has recovered from the episode. In the presence of acute cholangitis surgical drainage has been associated with a high mortality and is now limited to those very few cases which cannot be managed by the endoscopic approach.

Endoscopic bile duct clearance is also the treatment of choice for patients with acute gallstone pancreatitis as well as patients who have retained common bile duct stones after a previous cholecystectomy.

Patients shown to have common bile duct stones as well as gall bladder stones may be treated by two different approaches:

- *Laparoscopic cholecystectomy* which can also include exploration of the CBD via the cystic duct or by direct choledochotomy. By using these techniques the laparoscopist can extract stones from the common bile duct. This, however, prolongs the procedure, particularly in the presence of large stones or biliary sepsis.
- *Endoscopic approach* either immediately before or after the cholecystectomy. Removal of CBD stones by this method is the preferred way in the UK.

COMPLICATIONS OF GALLSTONES

- Acute cholecystitis and acute cholangitis have been discussed (p. 399).
- Gallstone-related pancreatitis is discussed on page 409.
- Gallstones can occasionally erode through the wall of the gall bladder into the intestine giving rise to a biliary enteric fistula. Passage of a gallstone through into the small bowel can give rise to an ileus or true obstruction.
- There is some evidence that gallstones are associated with an increased risk of adenocarcinoma of the gall bladder (p. 405).

MISCELLANEOUS CONDITIONS OF THE BILIARY TRACT

GALL BLADDER

There are a number of non-calculous conditions of the gall bladder, some of which have been associated with symptoms. :

Non-calculous cholecystitis

Almost 10% of gall bladders removed for biliary symptoms are shown to have chronic inflammation within the wall but an absence of gallstones. Such cases are described as non-calculous cholecystitis. In many instances the gall bladder inflammation is minor and of doubtful significance. In a minority of cases non-calculous cholecystitis is characterized by severe inflammation frequently associated with gall bladder perforation. This condition is characteristically found in an elderly and critically ill group of patients.

Chemical inflammation of the gall bladder may also occur from reflux of pancreatic enzymes back into the biliary tree, usually through the common channel at the ampulla of Vater.

Bacterial infection of the gall bladder has occasionally been recognized as a cause of chronic inflammation.

The decision to carry out cholecystectomy in the absence of defined gall bladder stones should be guided by the specific features of the history and whether there is evidence of diseased gall bladder wall on ultrasound scanning.

Cholesterolosis of the gall bladder

In cholesterolosis, cholesterol and other lipids are deposited in macrophages within the lamina propria of the gall bladder. These may be diffusely situated giving a granular appearance to the gall bladder wall or on occasions more discrete, giving a polypoid appearance (see below). Cholesterolosis of the gall bladder may coexist with gallstones but occurs independently. Some degree of cholesterolosis may be found in up to 25% of autopsies in an elderly population. It is doubtful whether this is a cause of symptoms.

Adenomyomatosis of the gall bladder

Adenomyomatosis is a gall bladder abnormality characterized by hyperplasia of the mucosa, thickening of the muscle wall and multiple intramural diverticulae (the so-called Rokitansky-Aschoff sinuses).

The condition is usually detected as an incidental finding during investigation for possible gall bladder disease. It has been suggested that this condition is secondary to increased intraluminal gall bladder pressure but this is not proven. Gallstones may frequently coexist but there is no evidence to support a direct relationship. It is unlikely that adenomyomatosis alone is a cause of biliary symptoms.

Chronic cholecystitis

There are no symptoms or signs that can conclusively be shown to be due to chronic cholecystitis. Symptoms attributed to this condition are vague, such as indigestion, upper abdominal discomfort or distension. There is no doubt that gall bladders studied histologically can show signs of chronic inflammation, and occasionally a small, shrunken gall bladder is found either radiologically or on ultrasound examination. However, these findings can be seen in asymptomatic people and therefore this clinical diagnosis should not be made. Most patients with chronic right hypochondrial pain suffer from functional bowel disease (p. 335).

EXTRAHEPATIC BILIARY TREE

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by fibrosing inflammatory destruction of both the intra- and extrahepatic bile ducts. In 75% of patients PSC is associated with inflammatory bowel disease (usually ulcerative colitis) but it is not unusual for the PSC to predate the onset of the inflammatory bowel disease. The causes are unknown but genetic susceptibility to PSC is associated with the HLA A1-B8-DR3 haplotype. The autoantibody p-ANCA (anti-neutrophil cytoplasmic antibody) is found in serum of 60% of cases. Seventy per cent of patients are men with an average age of onset of approximately 40 years.

With increasing screening of patients with inflammatory bowel disease PSC is detected at an asymptomatic phase with abnormal liver biochemistry, usually a raised serum alkaline phosphatase. Symptomatic presentation is usually with fluctuating pruritus, jaundice and cholangitis. The typical biliary changes associated with PSC may usually be identified by MRC scanning. This technique may not identify minor, but still clinically significant, intrahepatic duct abnormalities and this may require endoscopic retrograde cholangiography (ERC). The cholangiogram characteristically shows irregularity of calibre of both intra- and extrahepatic ducts, although either may be involved alone (see Fig. 7.32).

Confirmation of the diagnosis comes from liver histology, which shows inflammation of the intrahepatic biliary radicals with associated scar tissue classically described as being onion skin in appearance. The histological changes may range from minor inflammatory infiltrates to the level of established cirrhosis. The presence of cirrhosis has prognostic implications.

PSC is a slowly progressive lesion (symptoms and biochemical tests may fluctuate), ultimately leading to liver cirrhosis and associated decompensation. Cholangiocarcinoma occurs in up to 20% of patients.

The only proven treatment is liver transplantation. The bile acid ursodeoxycholic acid has been evaluated extensively in the treatment of PSC, with some transient improvement in liver function but no evidence of proven long-term benefit. In a small minority of patients with PSC the dominant lesion is of the extrahepatic ducts. Such lesions may be amenable to endoscopic biliary intervention with balloon dilatation and temporary stent placement.

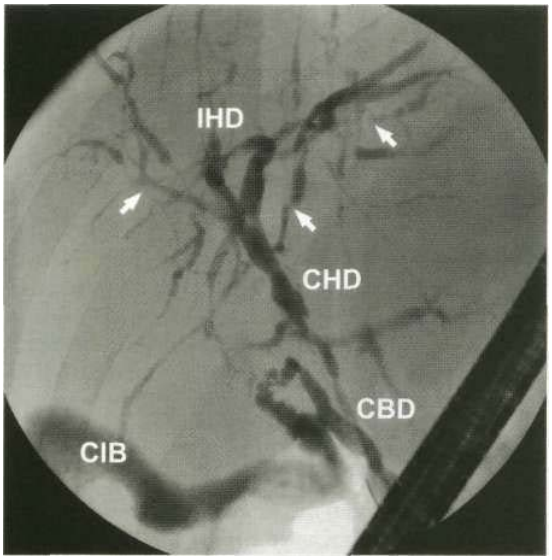

Fig. 7.32 **Primary sclerosing cholangitis.** An endoscopic cholangiogram showing the typical features of primary sclerosing cholangitis. There are calibre irregularities of the intra-hepatic ducts (IHD). There is also minor stricturing of the extra-hepatic ducts at the confluence between the common bile duct (CBD) and the common hepatic duct (CHD).

Choledochal cyst

Congenital cystic disease of the bile ducts may occur at all levels of the biliary tree, although the majority are extrahepatic. The dilatation may be saccular, diverticular or of fusiform configuration. The majority of symptomatic cases present in childhood with features of cholangitis. In adult life choledochal cysts may be a differential diagnosis in patients presenting with symptoms suggestive of bile duct stones. The cyst must be fully resected to avoid the recurrent biliary complications as well as averting the risk (approximately 15%) of subsequent cholangiocarcinoma.

Haemobilia

Haemobilia is the term used to describe bleeding into the biliary tree. This may be as a consequence of liver trauma or as a complication of liver surgery. Biopsy of the liver is also a well-recognized cause. The end result is a fistula between a branch of the hepatic artery and an intrahepatic bile duct.

Haemobilia may be a cause of significant gastrointestinal blood loss and should be suspected when melaena is accompanied by right-sided upper abdominal pain and jaundice. However, the bleeding may occur without any overt biliary symptoms. If the diagnosis is

suspected, bleeding may be managed by occlusion of the feeding artery by thrombosis performed radiologically. Some patients will require surgery to control the bleeding point.

TUMOURS OF THE BILIARY TRACT

Gall bladder polyps

Polyps of the gall bladder are a common finding, being seen in approximately 4% of all patients referred for hepatobiliary ultrasonography. The vast majority of these are small (less than 5 mm), are non-neoplastic and are inflammatory in origin or composed of cholesterol deposits (see above). Adenomas are the most common benign neoplasm of the gall bladder. Only a proportion of these have a cancerous potential. The only reliable means of defining those at risks is by polyp size. Cholecystectomy is recommended for any polyp approximating to 1 cm in diameter or larger.

Primary cancer of the gall bladder

Adenocarcinoma of the gall bladder represents 1% of all cancers. The mean age of occurrence is in the early sixties with a ratio of 3 women to 1 man. Gallstones have been suggested as an aetiological factor but this relationship remains unproven. Diffuse calcification of the gall bladder (porcelain gall bladder), considered to be the end stage of chronic cholecystitis, has also been associated with cancer of the gall bladder and is an indication for early cholecystectomy. Adenomatous polyps of the gall bladder in excess of 1 cm in diameter are also recognized as premalignant lesions (see above).

Carcinoma of the gall bladder is often detected at the time of planned cholecystectomy for gallstones and in such circumstances resection of an early lesion may be curative. Early lymphatic spread to the liver and adjacent biliary tract precludes curative resection in more advanced lesions. There are no proven chemotherapeutic agents for carcinoma of the gall bladder. A small proportion of cases are sensitive to radiotherapy but the overall 5-year survival is less than 5%.

Cholangiocarcinoma (see also p. 395)

Cancer of the biliary tree may be intra- or extrahepatic. These malignancies represent approximately 1% of all cancers. A number of associations have been identified such as that with choledochal cyst (see above), and chronic infection of the biliary tree with, for example, *Clonorchis sinensis*. There are also associations with autoimmune disease processes such as primary sclerosing cholangitis. The bile duct malignancy usually presents with jaundice and may be suspected by imaging, initially ultrasound and thereafter spiral CT and in particular magnetic resonance cholangiopancreatography (MRCP). The disease spread is usually by local lymphatics or by local extension. Cholangiocarcinoma of the common bile duct may be resectable at presentation but local extension precludes such management in the majority of more proximal lesions. Localized disease justifies an aggressive surgical approach including partial hepatic resection.

Secondary malignant involvement of the biliary tree

Carcinoma of the head of the pancreas frequently presents with common bile duct obstruction and jaundice. Metastases to the bile ducts from distant cancers are uncommon. Melanoma is the most frequent neoplasm to do so.

Other carcinomas that have caused bile duct metastases, in order of frequency, are those arising in the lung, breast and colon as well as those from the pancreas (metastatic as compared to direct infiltration). Infiltration of the bile duct is not uncommon in disseminated lymphomatous disease.

Palliation of malignant bile duct obstruction

A small proportion of cholangiocarcinomas are surgically resectable, more commonly those in the distal bile duct as compared to the hilar region. All patients must be fully screened for operability using the imaging techniques described above. However, in the greater proportion of patients the treatment is palliative. The response to chemotherapy and radiation is poor in these tumours. Relief of bile duct obstruction has been shown to improve quality of life considerably and with pain control is the major end point of palliation. In recent years endoscopic techniques have allowed the insertion of stents into the biliary tree to re-established bile flow. The initial use of plastic stents has largely been replaced by self-expanding metal stents which have considerably longer periods of patency (Fig. 7.33). In the small proportion of patients in whom bile duct drainage is not possible endoscopically, the percutaneous route offers an alternative method of stent placement. There is some evidence of benefit from the use of photodynamic therapy in those patients in whom biliary drainage has been achieved. This technique involves the use of a porphyrin derivative to sensitize the malignant cells prior to activation by an endoscopically placed laser probe. The aim is to provide local tumour destruction and maintain bile duct patency.

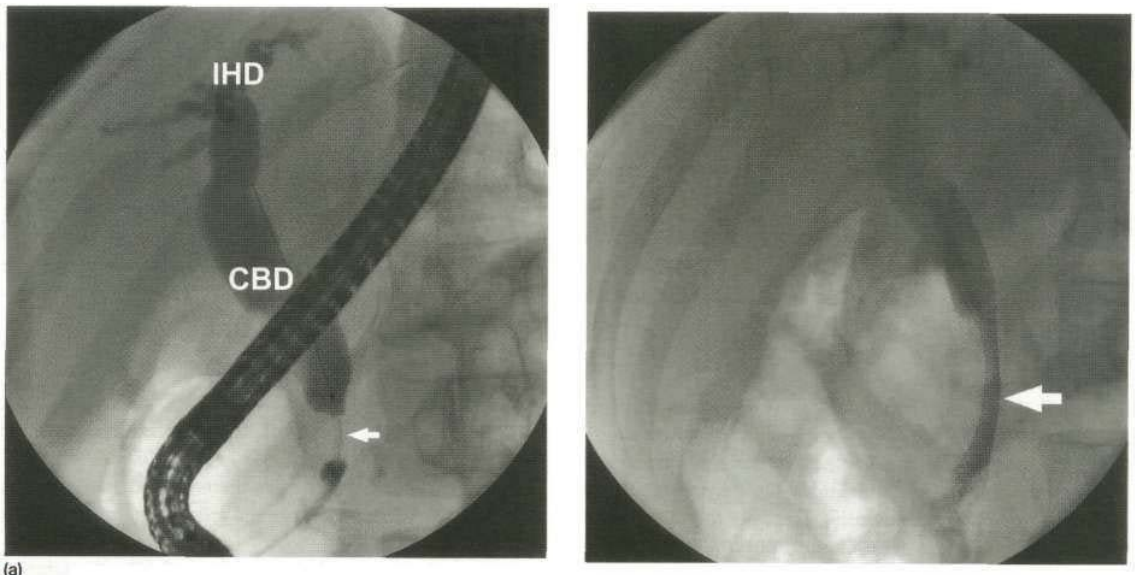

Fig. 7.33 **Stents.**

THE PANCREAS

STRUCTURE AND FUNCTION

Structure

The pancreas extends retroperitoneally across the posterior abdominal wall from the second part of the duodenum to the spleen. The head is encircled by the duodenum; the body, which forms the main bulk of the organ, ends in a tail that lies in contact with the spleen. The pancreas consists of exocrine and endocrine cells making up 98% of the human pancreas.

The pancreatic acinar cells are grouped into lobules forming the ductal system which eventually joins into the main pancreatic duct.

The main pancreatic duct has many tributary ductules and gradually tapers towards the tail of the pancreas. The main pancreatic duct itself usually joins the common bile duct to enter the duodenum as a short single duct at the ampulla of Vater.

Exocrine function

The pancreatic acinar cells are responsible for production of digestive enzymes. These include amylase, lipase, colipase, phospholipase and the proteases (trypsinogen and chymotrypsinogen). These enzymes are stored within the acinar cells in secretory granules and are released by exocytosis (Fig. 7.34).

After ingestion of a meal pancreatic exocrine secretion is regulated by cephalic, gastric, and intestinal stimuli. The cephalic phase is mediated by the central nervous system and is stimulated by behavioural cues related to the sight and smell of food. With ingestion of food, the gastric phase commences and in response to distension of

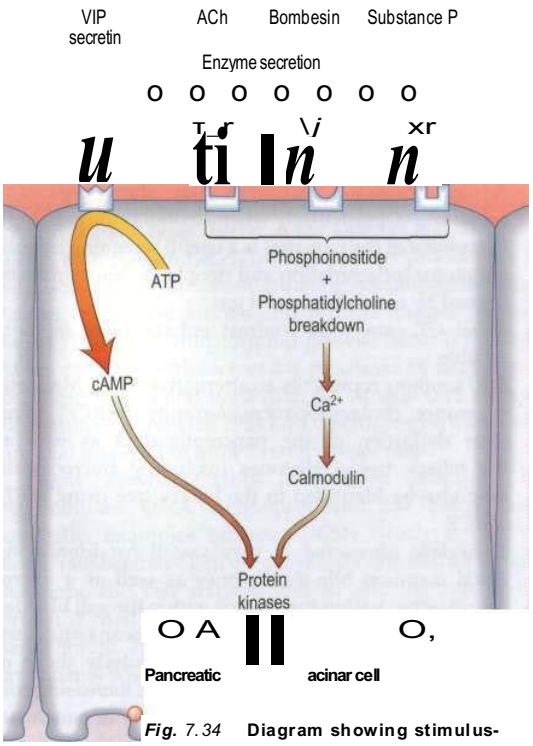

***Fig.** 7.34* **Diagram showing stimulus-secretion coupling of pancreatic cell protein secretion.** There is no CCK receptor in humans; stimulation is probably via neural fibres. VIP, vasoactive intestinal polypeptide; CCK, cholecystokinin; ACh, acetylcholine.

the stomach a neural pathway involving the central nervous system stimulates pancreatic secretion. Both these phases are under vagal control.

Finally, the presence of protein, fat and gastric acid within the small intestine further augments pancreatic secretion by both hormonal and neurotransmitter activity which produces local enteropancreatic control of secretion. Feedback regulatory events eventually terminate pancreatic secretion.

Cholecystokinin (CCK) is produced in specialized gut endocrine cells (I cells) of the mucosa of the small intestine and is secreted in response to intraluminal food. In animals, it exerts its biological activity by binding to specific G-protein-coupled receptors on target cells in the pancreas. Activated G-proteins lead to the activation of phospholipases. This in turn leads to calcium release from intracellular stores, which in turn results in the fusion of the digestive enzyme granules to the apical plasma membrane and enzyme release. There are no CCK receptors in pancreatic cells in humans and CCK acts via receptors on vagal afferent fibres to stimulate pancreatic secretion. Of the enzymes produced by the pancreatic acinar cells, the proteases and colipase are secreted as inactive precursors and require duodenal enterokinase to initiate activity.

Secretin is also released from specialized entero-endocrine cells of the small intestine during a meal and in particular during duodenal acidification. Secretin has a direct effect on the pancreatic acinar cells as well as the ductal cells. There is also a vagal-mediated secretory response. Secretin action is mediated via G-coupled receptors and calcium-mediated enzyme release. Secretin results in a bicarbonate-rich pancreatic secretion.

Completion of the postprandial secretory phase involves both neural and hormonal control.

Central neuronal inhibition of pancreatic secretion acts through dopamine and somatostatin receptors mediated by noradrenergic nerves. The islet cell hormone pancreatic polypeptide is released from the pancreas in response to a meal and has an inhibitory effect upon acinar enzyme secretion both by a local effect and via central receptors.

Somatostatin, present within the pancreas, stomach and central nervous system, is released in response to food. Its effect is mediated both by direct pancreatic acinar inhibition and by a central nervous system effect. Two other mechanisms of inhibition have been described. Proteases within the duodenal lumen have a negative feedback on acinar secretion. Secondly, nutrients within the ileum inhibit pancreatic secretion by means of local hormone release (peptide YY and glucagon-like peptide) acting on the acinar cells themselves as well as centrally.

There is now increasing evidence that the gut-related peptides, leptin and ghrelin, as well as influencing appetite behaviour, are also regulatory factors in the exocrine function of the pancreas. This effect is believed to occur via hypothalamic centres.

The endocrine pancreas

This consists of hormone-producing cells arranged in nests or islets (islets of Langerhans). The hormones produced are secreted directly into the circulation and there is no access to the pancreatic ductular system. There are *five main types of islet cell* corresponding to different secretory components. The beta-cells are the most common and are responsible for insulin production. The alpha-cells produce glucagon. The D cells produce somatostatin, PP-cells produce pancreatic polypeptide and enterochromaffin cells produce serotonin.

A number of other hormones have been identified within the endocrine pancreas including gastrin-releasing peptide, neuropeptide Y and galanin. These are believed to be neurotransmitters active in the neuro-gastrointestinal axis.

INVESTIGATION OF THE PANCREAS

Assessment of exocrine function

Overt fat malabsorption does not occur until approximately 85-90% of the function has been lost. This large reserve of pancreatic function means that any pancreatic function test based upon the measurement of either the

pancreatic enzymes or their breakdown products is insensitive, particularly in mild to moderate disease.

Duodenal sampling and pancreatic function tests

These tests rely upon the analysis of a duodenal aspirate following pancreatic stimulation.

The original test involved the oral administration of a specified meal (Lundh meal). Pancreatic stimulation is now achieved by intravenous secrerin and cholecystokinin. The aspirate is assessed for pancreatic enzymes and bicarbonate production.

The procedure is time-consuming and requires a meticulous technique. There is a good correlation with moderate to severe pancreatic function loss, but not for mild damage. These tests are not widely available.

Non-invasive test of pancreatic function

Serum biochemistry Serum lipase, trypsin-trypsinogen and amylase can all be measured. Serum trypsin is the most useful although diminished levels are only detected after pancreatic insufficiency is clinically detectable by overt malabsorption. Their main use is in acute pancreatitis.

Faecal tests

a *Faecal fat estimation* (see p. 300).

- *Faecal chymotrypsin.* The test is not useful until severe impairment of pancreatic function is present.
- *Faecal elastase.* This pancreatic specific enzyme is not degraded in the intestine and has high concentrations within the faeces. Diminished levels may be detected in moderate as well as severe pancreatic insufficiency, and this is probably more sensitive than other serum and faecal tests.

Oral pancreatic function tests

m *PABA-test.* Oral N-benzoyl-L-tyrosyl-p-aminobenzoic acid is hydrolysed by chymotrypsin to release p-aminobenzoic acid (PABA), which is then absorbed, conjugated and excreted in the urine where it can be measured. The test is time-consuming but is specific for pancreatic insufficiency, with a 65-80% sensitivity.

- *Fluorescein dilaurate test.* Oral fluorescein dilaurate is digested by pancreatic esterase to release the fluorescein which is then absorbed and excreted in the urine. This test is relatively inexpensive and commercially available as the 'Pancreolauryl test'. This is highly sensitive and specific in severe pancreatic insufficiency but has only a 50% sensitivity in mild to moderate disease.

Clinical application of pancreatic function tests

Whilst the invasive duodenal aspiration tests represent the most sensitive and specific means of assessing pancreatic function, these are very rarely used outside specialized centres. The Pancreolauryl and PABA tests are non-invasive and are widely available but are only highly sensitive in the detection of severe pancreatic insufficiency. The faecal elastase test (in a commercially available form) provides similar sensitivity and specificity and is the test of choice as a screening tool for pancreatic insufficiency, but again detection of mild disease is problematic.

Pancreatic imaging (see **p.** 354)

This can detect structural abnormalities even when functional tests are still within normal limits.

- A *plain abdominal radiograph* may show pancreatic calcification, particularly when alcohol is the aetiology.
- *Ultrasound* of the pancreas is a useful screening investigation for inflammation and neoplasia. Views may be limited by overlying bowel gas.
- *Spiral CT scan* with contrast enhancement is more reliable.
- *MRI scanning* represents an alternative to CT. Magnetic resonance cholangiopancreatography (MRCP) gives clear definition of the pancreatic duct as well as the biliary tree. Gallstones (including microcalculi) may also be identified in the biliary tree using MRI/MRCP.
- *Endoscopic ultrasound* is very useful for identifying distal common bile duct stones as well as a microcalculi either within the duct or within the gall bladder. Endoscopic ultrasound is a sensitive means of detecting small pancreatic tumours, particularly those of neuroendocrine origin. There is also an increasing role for this technique to stage the operability of pancreatic adenocarcinoma.
- *Endoscopic retrograde cholangiopancreatography (ERCP)* was considered the gold standard for diagnosing pancreatic disease. However, with MRCP and endoscopic ultrasound, ERCP is restricted to therapeutic intervention.

Summary An initial transabdominal ultrasound supplemented by spiral CT provides sufficient diagnostic information for most inflammatory and neoplastic conditions of the pancreas. MRI and MRCP are now widely available and provide additional information, particularly with respect to pancreatic ductular and biliary anatomy.

Endoscopic ultrasound is available in specialized centres if diagnostic information is still lacking.

PANCREATITIS

Classification

Pancreatitis is divided into acute and chronic. By definition acute pancreatitis is a process that occurs on the background of a previously normal pancreas and can return to normal after resolution of the episode. In chronic pancreatitis there is continuing inflammation with irreversible structural changes.

In practice the differentiation between acute and chronic pancreatitis may be extremely difficult, particularly in the setting of recurrent acute episodes which may represent true acute pancreatitis or may be an acute manifestation of underlying chronic disease.

Table 7.18 Causes of pancreatitis

Acute	Chronic
Gallstones	Alcohol
Alcohol	Tropical (nutritional)
Infections (e.g. mumps, Coxsackie B)	Hereditary
Pancreatic tumours	Trypsinogen and inhibitory protein defects
Drugs (e.g. azathioprine, oestrogens, corticosteroids)	Cystic fibrosis
Iatrogenic (e.g. post-surgical, ERCP)	Idiopathic Trauma
Hyperlipidaemias	Hypercalcaemia
Miscellaneous	
Trauma

Idiopathic	

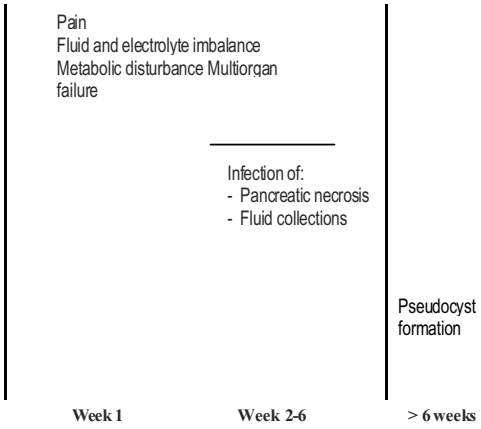

Fig. 7.35 **Complications of acute pancreatitis in relation to time after presentation.**

Acute pancreatitis

The causes of acute pancreatitis are listed in Table 7.18.

In the western world gallstones and alcohol account for the vast majority of episodes. Alcohol also causes chronic pancreatitis (see below). The severity of the pancreatitis may range from mild and self-limiting to extremely severe with extensive pancreatic and peripancreatic necrosis as well as haemorrhage. In its most severe form the mortality rises to between 40-50%.

Pathogenesis

Mechanisms by which pancreatic necrosis occurs remain speculative. Any theory must take into account how a very diverse group of aetiological factors can produce the same end point. There is some suggestion that the final common pathway is a marked elevation of intracellular calcium which in turn leads to activation of intracellular proteases. It is these activated enzymes which are responsible for cellular necrosis.

In the case of gallstone-related pancreatitis it is believed stones occlude the pancreatic drainage at the level of the ampulla leading to pancreatic ductular hypertension. Such ductular hypertension has been shown in animal models to increase cytosolic free ionized calcium. There is also evidence that alcohol interferes with calcium homeostasis in pancreatic acinar cells.

Clinical features

Acute pancreatitis is a differential diagnosis in any patient with upper abdominal pain. The pain usually begins in the epigastrium accompanied by nausea and vomiting. As inflammation spreads throughout the peritoneal cavity the pain becomes more intense. Involvement of the retroperitoneum frequently leads to back pain.

The patient may give a history of previous similar episodes or be known to have gallstones. An attack may follow an alcoholic binge. However, in many cases there are no obvious aetiological factors.

Physical examination at the time of presentation may show little more than a patient in pain with some upper abdominal tenderness but no systemic abnormalities. In more severe disease the patient may have a tachycardia, hypotension and be oliguric. Abdominal examination may show widespread tenderness with guarding as well as reduced or absent bowel sounds. Specific clinical signs that support a diagnosis of severe necrotizing pancreatitis include periumbilical (Cullen's sign) and flank bruising (Grey Turner's sign). In patients with a gallstone aetiology the clinical picture may also include the features of cholangitis. The complications are shown in Figure 7.35.

Diagnosis

Blood tests

- *Serum amylase level* is the standard laboratory test carried out to confirm the diagnosis. If this is measured within 24 hours of the onset of pain an elevation of three times the upper limit of normal is an extremely sensitive test. A number of other conditions may occasionally cause a very elevated amylase (see Table 7.19). Amylase levels gradually fall back towards normal over the next 3-5 days. With a late presentation the serum amylase level may give a false-negative result.
- *Urinary amylase levels* may be diagnostic as these remain elevated over a longer period of time.
- *Serum lipase levels* are also raised in acute pancreatitis and these remain elevated for a longer period of time

Table 7.19 Elevation of serum amylase unrelated to pancreatitis

Leakage of upper gastrointestinal contents into the peritoneum
Upper gastrointestinal perforation
Biliary peritonitis Intestinal infarction

Inherited abnormalities of amylase
Macroamylasaemia

than those of amylase. However, overall, the accuracy of serum lipase is not significantly greater than amylase and it is technically more difficult to measure.

- *Other baseline investigations* include a full blood count and CRP, urea and electrolytes, blood glucose, liver biochemistry, plasma calcium and arterial blood gases. These are documented at presentation and then repeated at 24 and 48 hours and provide a basis for assessing the severity of an attack (see below).

Radiology

a An erect *chest X-ray* is mandatory to exclude gastroduodenal perforation, which also raises the serum amylase (Table 7.19). A supine abdominal film may show gallstones or pancreatic calcification.

- An *abdominal ultrasound scan* is used as a screening test to identify a possible biliary (gallstone) cause of pancreatitis. Gallstones are difficult to detect in the distal common bile duct but dilated intrahepatic ducts may be present in the presence of bile duct obstruction. Stones within the gall bladder are not sufficient to justify a diagnosis of gallstone-related pancreatitis. The ultrasound may also demonstrate pancreatic swelling and necrosis as well as peripancreatic fluid collections if present. In severe pancreatitis the pancreas may be difficult to visualize because of gas-filled loops of bowel.
- *Contrast-enhanced spiral CT scanning* is essential in all but the most mild attacks of pancreatitis (Fig. 7.36). Carried out within 2-3 days of presentation, it allows the extent of pancreatic necrosis to be assessed. This provides very valuable prognostic information. Later in the course of the disease, repeated CT scans may be used to detect other complications including fluid collections, abscess formation and pseudocyst development.
- *MRI (MRCP)* can assess the degree of pancreatic damage and identify gallstones within the biliary tree. MRI is particularly useful to differentiate between fluid and solid inflammatory masses.

Fig. 7.36 **CT scan in patient with acute pancreatitis** showing necrosis of the pancreatic parenchyma (arrow) and a fluid collection extending outside the gland with inflammatory thickening of the colon.

- *ERCP* is used as a treatment measure to remove bile duct stones in the presence of gallstone-related pancreatitis (see below).

Assessment of disease severity

The majority of cases of acute pancreatitis are mild but approximately 25% run a more complicated course which may result in haemodynamic instability and multiple organ failure. The early prediction of such a severe attack allows appropriate monitoring and intensive care to be in place.

Early clinical assessment has been shown to have poor sensitivity for predicting a severe attack. Similarly, individual laboratory tests have very limited value. Elevations of CRP have been associated with severe episodes, although the sensitivity and specificity remains to be defined. To improve the predictive value multiple factors have been used to develop scoring systems (see Table 7.20). The Ranson and Glasgow scoring systems are based on such parameters and have been shown to have an 80% sensitivity for predicting a severe attack, although only after 48 hours following presentation. The acute physiology and chronic health evaluation score (APACHE) currently has been extensively adopted as a means of assessing the severity of a wide spectrum of illness. The APACHE scoring system is based on common physiological and laboratory values and adjusted for age as well as the presence or absence of a number of other chronic health problems (see Table 7.21). This scoring system

Table 7.20 **Factors during the first 48 hours that indicate severe pancreatitis and a poor prognosis (three or more factors present predict a severe episode)**

Age	> 55 years

Score 0-4 (normal-abnormal)
Adjust for age and severe organ insufficiency or for immunocompromised. BMI is an additional parameter

appears to have a high sensitivity as early as 24 hours after onset of symptoms.

There is evidence that obesity predicts the outcome from an episode of pancreatitis as the excessive adipose tissue is a substrate for activated enzyme activity. This will in turn generate an extensive inflammatory reaction.

Even modest obesity (basal metabolic index (BMI) between 25-30) has an adverse affect. This is incorporated as an adverse factor in the APACHE score (p. 410) for acute pancreatitis and other variables have also been added.

Treatment

The initial management of acute pancreatitis is similar, whatever the cause. A multiple factor scoring system (ideally APACHE II with a modification for obesity) should be carried out at the end of the first 24 hours after presentation to allow identification of the 25% of patients with a predicted severe attack. This should be repeated at 48 hours to identify a further subgroup who appear to be moving into the severe category. These patients should then be managed on a high-dependency or intensive care unit. Even patients outside of the severe category may require considerable supportive care.

Early fluid losses in acute pancreatitis may be large, requiring well-maintained intravenous access as well as a central line and urinary catheter to monitor circulating volume and renal function.

- *Nasogastric suction* prevents abdominal distension and vomitus and hence the risk of aspiration pneumonia.
- *Baseline arterial blood gases* determine the need for continuous oxygen administration.
- *Prophylactic antibiotics.* Broad-spectrum antibiotics, e.g. cefuroxime or aztreonam, reduce the risk of infective complications and are given from the outset.
- *Analgesia requirements.* Pethidine and tramadol are the drugs of choice, usually administered by a patient control system. The morphine derivatives should be avoided because they can cause sphincter of Oddi contraction.
- *Feeding.* In patients with a severe episode there is little likelihood of oral nutrition for a number of weeks. Total parenteral nutrition has been associated with a high risk of infection and has been replaced by enteral nutrition. This is administered via a nasojejunal tube, which is well tolerated and can maintain adequate nutritional input. The nasojejunal position of the feeding tube placed endoscopically overcomes the frequent problem of gastric paresis and there is less likelihood of pancreatic stimulation.

In a small proportion of patients, multiorgan failure will develop in the first few days after presentation reflecting the extent of pancreatic necrosis. Such patients will require positive-pressure ventilation and often renal support. The mortality in this group is extremely high (in excess of 80%).

Gallstone-related pancreatitis

In patients with gallstone-related pancreatitis and associated cholangitis, endoscopic intervention with sphincterotomy and stone extraction is of proven benefit and is the treatment of choice. In the absence of cholangitis, sphincterotomy and stone extraction is only of proven benefit when the episode of pancreatitis is predicted as severe. In less severe cases of gallstone-related pancreatitis intervention can be deferred until full recovery is obtained (an approximate 6-week period).

Late complications of acute pancreatitis

Within the first 7 days the morbidity and mortality of acute pancreatitis reflect the systemic inflammatory response which in turn results in multiple organ failure. After this initial period the prognosis thereafter is most closely related to the extent of pancreatic necrosis. This can be most accurately assessed by contrast-enhanced CT, which should be carried out in all patients with severe disease after the first week. Extensive necrosis (greater than 50% of the pancreas) is associated with high risk of further complicated disease frequently requiring surgical intervention.

It is infection of the necrotic pancreas which is of most concern and which may rapidly lead to overwhelming sepsis. Prophylactic antibiotics have been used to prevent this but do not reliably do so. If there is evidence of incipient infection monitored by a rising neutrophil count and CRP level, an aspirate of the necrotic pancreas is taken and cultured. The vast majority of patients with a positive culture should be considered for surgical resection of the necrotic pancreas. In the most severe cases multiple operations are required to fully resect the areas of necrosis.

Peripancreatic fluid collections are common in the early stages of acute pancreatitis, the vast majority of which will resolve spontaneously.

Some fluid collections will be surrounded by granulation tissue producing the so-called *pseudocyst.* These by definition are not found until 6 weeks after the onset of the illness. The smaller pseudocysts (less than 6 cm in diameter) frequently resolve on their own but others may persist in the long term, giving rise to potential complications such as infection and intraperitoneal bleeding. Larger pseudocysts persisting for longer than 6 weeks are usually actively managed by either percutaneous (or endoscopic) drainage or by surgical intervention.

Long-term outcome

The vast majority of patients with a mild to moderate episode of acute pancreatitis will make a full recovery with no long-term sequelae. Recurrent episodes of pancreatitis may occur, particularly if there has been any long-term pancreatic ductular damage. Patients with more severe acute pancreatitis may become pancreatic insufficient both with respect to exocrine (malabsorption) and endocrine function (diabetes).

Chronic pancreatitis

Aetiology

In developed countries by far the most common cause of

chronic pancreatitis is alcohol, accounting for 60-80% of cases (see Table 7.18).

In developing countries malnutrition and associated dietary factors have been implicated. In a small group of patients chronic pancreatitis has been shown to be hereditary, inherited as an autosomal dominant condition with variable penetrance. Almost all patients with cystic fibrosis (p. 413) have established chronic pancreatitis, usually from birth. Cystic fibrosis gene mutations have also been identified in patients with chronic pancreatitis but in whom there were no other manifestations of cystic fibrosis.

Obstruction of the pancreatic duct because of either a benign or malignant process may result in chronic pancreatitis. Congenital abnormalities of the pancreatic duct, in particular pancreas divisum, have been implicated.

Pathogenesis

A possible common pathway for pancreatic damage is the inappropriate activation of enzymes within the pancreas. This has been well demonstrated in the case of hereditary pancreatitis where genetic abnormalities of cationic trypsinogen and its inhibitory proteins have led to unopposed trypsin activity within the pancreas itself. Chronic alcohol intake is also believed to increase the level of trypsinogen relative to its inhibitor. Human trypsinogen has a propensity to autoactivate, and any relative impairment or deficiency of inhibitor proteins will lead to unopposed enzyme activity and possible pancreatic damage.

It is believed that the intrapancreatic enzyme activity leads to the precipitation of proteins within the duct lumen in the form of plugs. These then form a nidus for calcification but are also the cause of ductal obstruction leading to ductal hypertension and further pancreatic damage. Cytokine activation and oxygen stress are thought to play a role in perpetuating this process.

Clinical features

Pain is the most common presentation of chronic pancreatitis and is usually epigastric and often radiating through into the back. The pattern of pain may be episodic with short periods of severe pain or chronic unremitting. Exacerbations of the pain may follow further alcohol excess although this is not a uniform relationship. During periods of abdominal pain anorexia is common and weight loss may be severe. This is particularly so in those patients with chronic unremitting symptoms.

Exocrine and endocrine insufficiency may develop at any time, and occasionally malabsorption or diabetes are the presenting features in the absence of abdominal pain.

Jaundice secondary to common bile duct obstruction during its course through the fibrosed head of pancreas, may also occur and may be a presenting feature in a small proportion of patients.

Investigations

The extent to which investigations are required is dependent upon the clinical setting. In a patient with known alcohol abuse and typical pain few confirmatory tests are required.

Fig. 7.37 Contrast-enhanced CT scan demonstrating multiple calcific densities (arrow) along the line of the main pancreatic duct in a patient with chronic pancreatitis.

- *Serum amylase and lipase* levels are rarely significantly elevated in established chronic pancreatitis.
- *Faecal elastase* level will be abnormal in the majority of patients with moderate to severe pancreatic disease.
- *PABA and Pancreolauryl tests* (see p. 408).
- *Transabdominal ultrasound scan* is used for initial assessment.
- *Contrast-enhanced spiral CT scan* provides a more detailed assessment. In the presence of pancreatic calcification and a dilated pancreatic duct the diagnosis of chronic pancreatitis can be easily established (Fig. 7.37). This may be much more difficult when these features are not present and in particular with an atypical presentation such as with steatorrhoea alone.
- *MRI with MRCP* is increasingly utilized to define more subtle abnormalities of the pancreatic duct which may be seen in non-dilated chronic pancreatitis.
- *Endoscopic ultrasound* is used in a small proportion of patients in whom the diagnosis is not confirmed with the above imaging or specifically for assessing complications of chronic pancreatitis including pseudocyst formation.
- *Diagnostic ERCP* has been replaced by MRCP.

Differential diagnosis

The differential diagnosis is that of pancreatic malignancy. Carcinoma of the pancreas can reproduce many of the symptoms and imaging abnormalities that are commonly seen with chronic pancreatitis. The diagnosis of malignancy should be considered in patients with a short history and in whom there is a localized ductular abnormality. Considerable difficulties may arise when a malignancy develops on the background of established chronic pancreatitis (the latter being a recognized premalignant lesion).

High-quality imaging is able to define malignant features with a localized mass lesion, local invasion and lymph node enlargement. Endoscopic ultrasound may provide the most accurate assessment of a potential mass lesion.

Treatment

In patients with alcohol-related chronic pancreatitis long-term abstinence is likely to be of benefit although this has been difficult to prove.

Abdominal pain. For short-term flare-ups of pain a combination of a non-steroidal anti-inflammatory drug and an opiate (tramadol) is usually sufficient for symptomatic relief. In patients with chronic unremitting pain this may be inadequate and also risk opiate addiction.

Tricyclic antidepressants (e.g. amitriptyline) are used for chronic pain and reduce the need for opiates. Oral pancreatic enzyme supplements reduce pancreatic stimulation (by a negative-feedback mechanism) and hence the intensity of pain. Antioxidant use awaits evidence of benefit. Coeliac axis nerve block may produce good pain relief but is unreliable in its extent and duration of action.

In the majority of patients some spontaneous improvement in pain control occurs with time. After a 6- to 10-year period some 60% of patients will become pain-free. For patients with debilitating pain, surgical intervention is justified. Both duct drainage and limited resection procedures have been carried out with total or partial pain relief in approximately 80% of patients but with a mortality of 5%.

Other endoscopic techniques used to improve pancreatic drainage as well as managing intraductal stones have been tried with reported success.

Steatorrhoea. The steatorrhoea associated with pancreatic insufficiency may be high, with up to 30 mmol of fat lost per 24 hours. This will usually improve with pancreatic enzymes supplements and a low fat diet. Current preparations are presented in the form of microspheres which reduce the problems of acid degradation in the stomach. An acid suppressor (H_2-receptor antagonist or proton pump inhibitor) is also given. Despite this, a proportion of patients continue to malabsorb, usually reflecting the inadequate mixing of the pancreatic supplements with the food as well as the low pH in the duodenum secondary to inadequate pancreatic bicarbonate production.

Diabetes associated with pancreatic endocrine failure may be difficult to control with a rapid progression from oral hypoglycaemic agents to an insulin requirement. Brittle control is a common problem secondary to inadequate glucagon production from the damaged pancreas.

Complications

The most common structural complication of chronic pancreatitis is a pancreatic pseudocyst, a fluid collection surrounded by granulation tissue (see p. 411). These usually occur in relationship to a period of enhanced inflammatory activity within the pancreas giving abdominal pain but may develop silently during what would appear to be a stable phase. Intra- or retroperitoneal rupture, bleeding or cyst infection occur. The larger cysts may occlude nearby structures including the duodenum and the bile duct. In pseudocysts less than 6 cm in diameter, spontaneous resolution can be anticipated. In larger cysts that have been present for a period in excess of 6 weeks, resolution is uncommon and a long-term complication rate of approximately 30% can be anticipated. Many pseudocysts are closely apposed to the posterior wall of the stomach or duodenum and can be successfully drained endoscopically using endoscopic ultrasound to identify the optimum drainage site. A direct fistula is created between the pseudocyst lumen and the gastric or duodenal lumen which is then kept patent by the insertion of plastic stents. This approach will be successful in approximately 75% of cases. Surgical drainage is required for failures of endoscopic therapy or in circumstances in which the pseudocyst anatomy does not allow endoscopic access.

Ascites and occasionally pleural effusions can be a direct consequence of chronic pancreatitis when there has been disruption of the main pancreatic duct. A high ascites or pleural fluid amylase will confirm the aetiology. Such disruptions of the main pancreatic duct require surgical intervention.

Cystic fibrosis (see pp. 909 and 192) This common cause of pancreatic disease in childhood is inherited as an autosomal recessive. A specific gene mutation ΔF_{508} is present in 70% of cases. The gene(s) code for a membrane protein in epithelial cells which regulates chloride transport (the cystic fibrosis trans-membrane regular, CFTR). Defective chloride channel transport secondarily leads to a failure to hydrate pancreatic secretion. The increased viscosity of such secretions then leads to ductular obstruction and secondary pancreatic damage. Ninety per cent of patients with cystic fibrosis will have pancreatic failure, and in the majority of these this will be present from the perinatal period.

It has recently been recognized that a small proportion of patients with chronic pancreatitis of unknown aetiology are homozygous for cystic fibrosis genes but have no other overt manifestation of cystic fibrosis.

Clinical features and diagnosis

Clinical features and diagnostic tests are described on page 910; pancreatic function tests and imaging are described on p. 407.

Treatment

In the vast majority of patients with cystic fibrosis, pulmonary complications dominate the clinical picture. However, the management of pancreatic insufficiency is necessary to optimize the growth and overall nutrition. Pancreatic supplements are closely titrated against the level of steatorrhoea. To obtain optimal enzyme mixing with food, the supplements are taken throughout the meal. These are most commonly administered in an enteric coated form to minimize degradation within the acid milieu of the stomach. A daily lipase intake of up to 10 000 units/kg bodyweight may be required. High-dose enteric-coated preparations are available but have been implicated in right-sided colon stricture formation in

children with cystic fibrosis. The exact mechanism by which this occurred has not been fully defined but these preparations are no longer recommended in children.

Despite appropriate enzyme dosage, up to 20% of patients continue to have significant fat malabsorption. In many cases this is secondary to poor compliance. Other mechanisms include acid degradation of the enzyme preparations, and this can be ameliorated by acid suppression, either with H_2-receptor antagonists or proton pump inhibitors. Coeliac disease (which has an increased prevalence in cystic fibrosis) should be excluded as a possible cause of continued malabsorption.

There is documented evidence of an age-related deterioration in glucose tolerance in patients with cystic fibrosis. Ten per cent of patients will develop clinically significant diabetes mellitus. It is extremely important to detect this at the earliest opportunity to prevent the adverse nutritional effects. In the large proportion of cases, management will be insulin dependent. Restriction of dietary fat helps the steatorrhoea but leads to malnourishment.

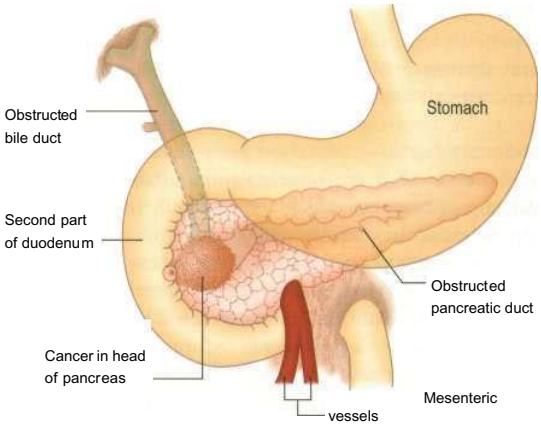

Fig. 7.38 Carcinoma of the head of the pancreas. A diagrammatic representation of the close relationship of a carcinoma of the head of pancreas to the surrounding structures.

CARCINOMA OF THE PANCREAS

The incidence of pancreatic cancer in the West has been estimated at approximately 9 cases per 100 000 with no increase over the last 20 years. Pancreatic cancer is now the fifth most common cause of cancer death in the western world. The incidence increases with age and the majority of cases occur in patients over the age of 60. Approximately 60% of patients with this condition are male. Ninety-six per cent of pancreatic cancers are adenocarcinoma in type and the large majority are of ductal origin. It has proved difficult to identify environmental risk factors but smoking is associated with a twofold increase. Other possible environmental factors include the petroleum product, naphthalamine. Chronic pancreatitis has been documented as a potential precancerous lesion. There is increasing evidence that pancreatic ductal adenocarcinoma is a result of accumulated genetic alterations. Subtle changes in an oncogene and both mutations and deletions of tumour suppressor genes are the most common forms of genetic alteration. The best known among the oncogenes is K-ras, present in 90% of human ductal adenocarcinomas. Other oncogenes include *fi-catenin.* Tumour suppressor genes include *pl6, p53* and *DPC4* (or SMAD4). The latter is a key transcription factor in growth regulation and is inactivated in over 50% of cases.

Clinical picture

Pancreatic adenocarcinoma may be viewed clinically as two diseases - the lesions of the head and lesions of the body and tail.

Symptoms

Carcinoma of the head of pancreas or the ampulla of Vater tends to present earlier with obstruction to the bile duct as this passes through the head of pancreas giving jaundice (Fig. 7.38). These more localized lesions are usually painless, although pain may become a feature with tumour progression.

Carcinoma localized to the body or tail of the pancreas is much more likely to present with abdominal pain as well as non-specific symptoms such as anorexia and weight loss. The pain is often dull in character with radiation through into the back. A characteristic feature is partial relief of pain by sitting forward. Bile duct obstruction and jaundice may infrequently be a late phenomena.

Physical signs

With *carcinoma of the head of pancreas* the patient is jaundiced with the characteristic scratch marks secondary to cholestasis. In a proportion of cases the gall bladder will be palpable (Courvoisier's sign). A central abdominal mass may be palpable as well as hepatomegaly if metastatic disease is present. With *carcinoma of the body and tail,* there are often no physical signs.

Other presenting physical signs include thromboembolic phenomena, polyarthritis and skin nodules. The latter are secondary to localized fat necrosis and associated inflammation. These manifestations, distant to the tumour itself, have not been fully explained but may precede the overt presentation of pancreatic cancer by months to years.

Investigations

a Transabdominal ultrasound is the initial investigation in the majority of patients. In the presence of bile duct obstruction this will confirm dilated intrahepatic bile ducts as well as a mass in the head of the pancreas. Ultrasound is less reliable when the cancer is found in the body and tail of the pancreas because of overlying bowel gas, with a sensitivity of detection of 60%.

- *Contrast-enhanced spiral CT scan* should confirm the presence of a mass lesion (Fig. 7.39). It is also necessary prior to possible surgical resection with contrast

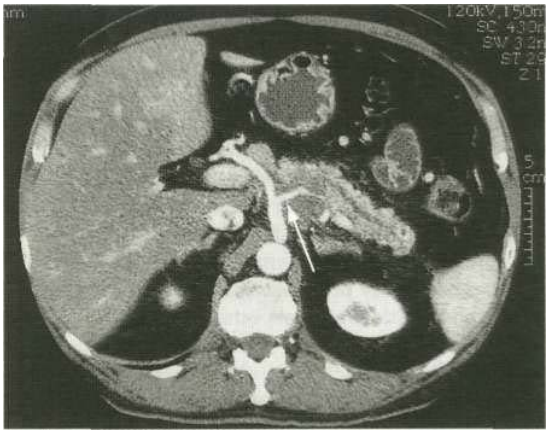

Fig. 7.39 **A contrast-enhanced CT scan showing a cancer of the body of the pancreas.** There is retroperitoneal tumour extension enclosing the branches of the coeliac axis (arrow).

providing vascular definition to exclude tumour invasion as well as local lymph node involvement and distant metastases.

- *Laparoscopy* is also used for preoperative assessment.
- *ERCP* is usually restricted to palliative treatment but may provide a source of cytology to confirm the diagnosis when this is in question.
- *Percutaneous needle biopsy* is discouraged in potentially operable cases as this may be a source of tumour cell spread within the peritoneum. If palliative chemo therapy is considered, a histological diagnosis is essential prior to treatment.
- *MRI scanning and endoscopic ultrasound* are techniques that are useful in a small proportion of patients in whom the tumour has not been adequately defined.
- *Several tumour markers* have been evaluated for the diagnosis and monitoring of pancreatic cancer. The CA19-9 has a high sensitivity (80%) but a high false-positive rate. In individual patients single values of these tumour markers may be of little help but a progressive elevation over time is often diagnostic, and in such circumstances tumour marker levels can be used to monitor response to treatment.

Differential diagnosis

The diagnosis should not be difficult in the presence of painless jaundice or epigastric pain radiating into the back with progressive weight loss.

Unfortunately many patients present with very minor symptoms including pain, change in bowel habit and weight loss. Imaging, particularly abdominal CT should be performed if pancreatic cancer is suspected. Pancreatic cancer may rarely present with recurrent episodes of typical acute pancreatitis.

Management

The 5-year survival rate for carcinoma of the pancreas is approximately 2% with surgical intervention representing the only chance of long-term survival. Approximately 20% of all cases have a localized tumour suitable for resection but in an elderly population many of these have co-morbid factors that preclude such major surgery. To optimize the percentage of patients undergoing possible surgical resection it is necessary to review each case in a multidisciplinary meeting. This approach also allows formulation of treatment strategies for those considered unsuitable for surgery.

In the majority of cases the management is *palliative.* Jaundice is a debilitating complication, often associated with severe pruritus but also the cause of non-specific malaise, lethargy and anorexia. Endoscopic placement of endoprostheses (stents) offers excellent palliation with a low associated procedural morbidity and mortality.

Palliative surgery has a role in duodenal obstruction (a complication seen in 10% of cases) but in advanced disease self-expanding metal stents can be placed across the duodenal obstruction with excellent short-term results.

The results of radiotherapy have been disappointing but there is now increasing evidence of benefit from a number of chemotherapeutic agents. 5-Fluorouracil and gemcitabine have been shown to improve survival in advanced disease and have also demonstrated survival benefit as an adjuvant therapy to pancreatic resection.

With disease progression, abdominal pain is a frequent complicating factor which may prove extremely difficult to treat.

This is best managed by experienced palliative care teams which offer a multidisciplinary approach. Endocrine and exocrine pancreatic failure occur and are managed as described on page 413.

CYSTIC TUMOURS OF THE PANCREAS

Cystic lesions of the pancreas are not uncommon. Seventy-five per cent of these lesions will be pseudocysts (see above) but of the remainder the majority are true cystic neoplasms. These neoplastic lesions can be divided into the serous and mucinous cyst adenomata. Serous cyst adenomata are composed of multiple small cystic cavities lined by cuboidal glycogen-rich, mucin-poor cells. These lesions tend to occur in an elderly age group and are often an asymptomatic finding. Malignant transformation in a serous cystadenoma is extremely rare. Mucinous cyst adenomata are almost exclusively found in women in the 5th and 6th decade and are sited in the pancreatic body and tail. Multiloculor cysts are lined by tall mucin-synthesizing cells. Twenty per cent of these lesions are malignant at the time of presentation and the majority appear to have a malignant potential. As a consequence they are much more likely to produce symptoms.

The importance of cystic lesions of the pancreas is to identify those at high risk of malignancy who should then undergo resection. Pseudocysts can usually be confirmed by the history of pancreatitis and features of the diagnosis upon imaging.

The differentiation between serous and mucinous cyst adenomata may be difficult, even when multiple imaging techniques are applied. Increasingly endoscopic ultrasound scanning and fine-needle aspiration have been applied to confirm the underlying diagnosis. The measurement of cyst fluid CEA and CA19-9 may help to identify malignant change.

NEUROENDOCRINE TUMOURS OF THE PANCREAS

The islets of Langerhans (p. 1101) have the capacity to synthesize more than one hormone. They also synthesize ectopic hormones that are not usually found in the pancreas such as gastrin, adrenocorticotrophin, vasoactive intestinal peptide and growth hormone. Whilst many pancreatic endocrine tumours are multihormonal, one peptide tends to predominate and is responsible for the clinical syndrome. Other tumours, whilst containing peptide hormone, are functionally inactive.

These tumours are rare with an incidence of less than 1 in 100 000 of the population. Insulinomas are the commonest variant and account for approximately 50% of cases, gastrinomas account for 20% and the rarer functioning tumours 5%. The remaining 25% are non-functioning tumours. Approximately 25% of islet cell tumours are associated with a multiple endocrine syndrome (type I) (see p. 1099). The majority of the endocrine pancreatic tumours are malignant in their behaviour.

The presentation of pancreatic neuroendocrine tumours is most commonly related to the actions of ectopic hormone secretion. Chromogranin A is a secretory protein present in 80% of neuroendocrine tumours and has been used as a tumour marker, although the specificity is poor. Identification of the primary and possibly metastatic lesions may be difficult despite multiple-imaging techniques. Endoscopic ultrasound may be the most sensitive means of detecting small tumours. Many of these tumours have somatostatin receptors, and radiolabelled somatostatin analogues (such as octreotide) scanning provide a means of tumour localization.

Treatment options for pancreatic neuroendocrine tumours requires a multidisciplinary approach and is dependent upon the presence or absence of metastatic. (usually hepatic) disease. Surgical resection of the pancreatic lesion is the only potential curative approach. Aggressive surgical intervention including a resection of the primary lesion as well as liver resection for metastasis has been used in selected cases. Somatostatin analogues such as octreotide and lanreotide have been used specifically for the control of symptoms secondary to the hormonal secretion.

There is some evidence that the somatostatin analogues combined with alpha-interferon also control tumour proliferation. The chemotherapeutic agents streptozotocin, 5-fluorouracil and doxorubicin produce partial remission in approximately 40% of cases. In patients with extensive liver metastasis, occlusion of the arterial blood flow by hepatic arterial embolization may control hormone-related symptoms. In most cases the tumours are slowly progressive and may allow a reasonable quality of life for many years.

Clinical syndromes

Insulinoma is described on page 1133.

A *gastrinoma* accounts for approximately 1 :1000 cases of duodenal ulcer disease. This results from hypersecretion of gastric acid secondary to ectopic gastrin secretion within the endocrine pancreas *(Zollinger-Ellisori)*. Recurrent severe duodenal ulceration occurs with only a partial response to acid suppression. The diagnosis is confirmed by an elevated gastrin level. High-dose proton pump inhibitors are used to suppress symptoms.

A *VIPoma* is an endocrine pancreatic tumour producing vasoactive intestinal polypeptide (VIP). This causes a severe secretory diarrhoea secondary to the stimulation of adenyl cyclase within the enterocyte *(Verner-Morrison syndrome)*. The clinical syndrome is one of profuse watery diarrhoea, hypokalaemia and a metabolic acidosis. To produce the syndrome, the tumours are usually in excess of 3 cm in diameter. The clinical syndrome can be controlled by either glucocorticoids, long-acting octreotide or lanreotide.

Glucagonomas are rare alpha-cell tumours which are responsible for the syndrome of migratory necrolytic dermatitis, weight loss, diabetes mellitus, deep vein thrombosis, anaemia and hypoalbuminaemia. The diagnosis is made by measuring pancreatic glucagon in the serum. Metastases are common at presentation but if the tumour is localized, pancreatic resection may be curative.

Somatostatinomas are rare malignant D cell tumours of the pancreas and 30% occur in the duodenum and small bowel. These tumours cause diabetes mellitus, gallstones and diarrhoea/steatorrhoea. They can be diagnosed by high serum somatostatin levels, CT/MR scans or octreotide scintiscans. Treatment is by resection, where possible, and octreotide therapy.

Non-functioning neuroendocrine tumours usually present by the local mass effect with pain, weight loss and the occasional bile duct obstruction. At the time of presentation the tumours are frequently large with distant metastases. Curative resection is possible in only a small proportion. Palliative surgery may be indicated to alleviate mass-related symptoms.

INTRODUCTION AND GENERAL ASPECTS

Blood consists of

- red cells
- white cells
- platelets
- plasma, in which the above elements are suspended.

Plasma is the liquid component of blood, which contains soluble fibrinogen. Serum is what remains after the formation of the fibrin clot.

The formation of blood cells (haemopoiesis)

The haemopoietic system includes the bone marrow, liver, spleen, lymph nodes and thymus. The turnover of cells is enormous; red cells survive 120 days, platelets around 7 days but granulocytes only 7 hours. The production of as many as 10^{13} new myeloid cells (all blood cells except for lymphocytes) per day in the normal healthy state obviously requires to be tightly regulated according to the needs of the body.

Blood islands are formed in the yolk sac in the third week of gestation and produce primitive blood cells which migrate to the liver and spleen. These organs are the chief sites of haemopoiesis from 6 weeks to 7 months, when the bone marrow becomes the main source of blood cells. The bone marrow is the only source of blood cells during normal childhood and adult life.

At birth, haemopoiesis is present in the marrow of nearly every bone. As the child grows the active red marrow is gradually replaced by fat (yellow marrow) so that haemopoiesis in the adult becomes confined to the central skeleton and the proximal ends (trabecular area) of the long bones. Only if the demand for blood cells increases and persists do the areas of red marrow extend. Pathological processes interfering with normal haemopoiesis may result in resumption of haemopoietic activity in the liver and spleen, which is referred to as *extramedullary haemopoiesis.*

All blood cells are derived from pluripotent stem cells. These stem cells are supported by stromal cells (see below) which also influence haemopoiesis. The stem cell has two properties - the first is *self-renewal,* i.e. the production of more stem cells, and the second is its proliferation and differentiation into progenitor cells, committed to one specific cell line.

There are two major ancestral cell lines derived from the pluripotential stem cell: lymphocytic and myeloid (non-lymphocytic) cells (Fig. 8.1). The former gives rise to T and B cells. The myeloid stem cell gives rise to the progenitor CFU-GEMM (colony-forming unit, granulocyte-erythrocyte-monocyte-megakaryocyte). The progenitor cells such as CFU-GEMM cannot be recognized in bone marrow biopsies but are recognized by their ability to form colonies when haemopoietic cells are immobilized in a soft gel matrix. The CFU-GEMM can go on to form CFU-GM, CFU-Eo, and CFU-Meg, each of which can produce a particular cell type (for example, neutrophils, eosinophils and platelets) under appropriate growth conditions. Haemopoiesis is under the control of growth factors and inhibitors, and the microenvironment of the bone marrow also plays a role in its regulation.

Haemopoietic growth factors

Haemopoietic growth factors are glycoproteins which regulate the differentiation and proliferation of haemopoietic progenitor cells and the function of mature blood cells. They act on receptors expressed on haemopoietic cells at various stages of development to maintain the haemopoietic progenitor cells and to stimulate increased production of one or more cell lines in response to stresses such as blood loss and infection (Fig. 8.1).

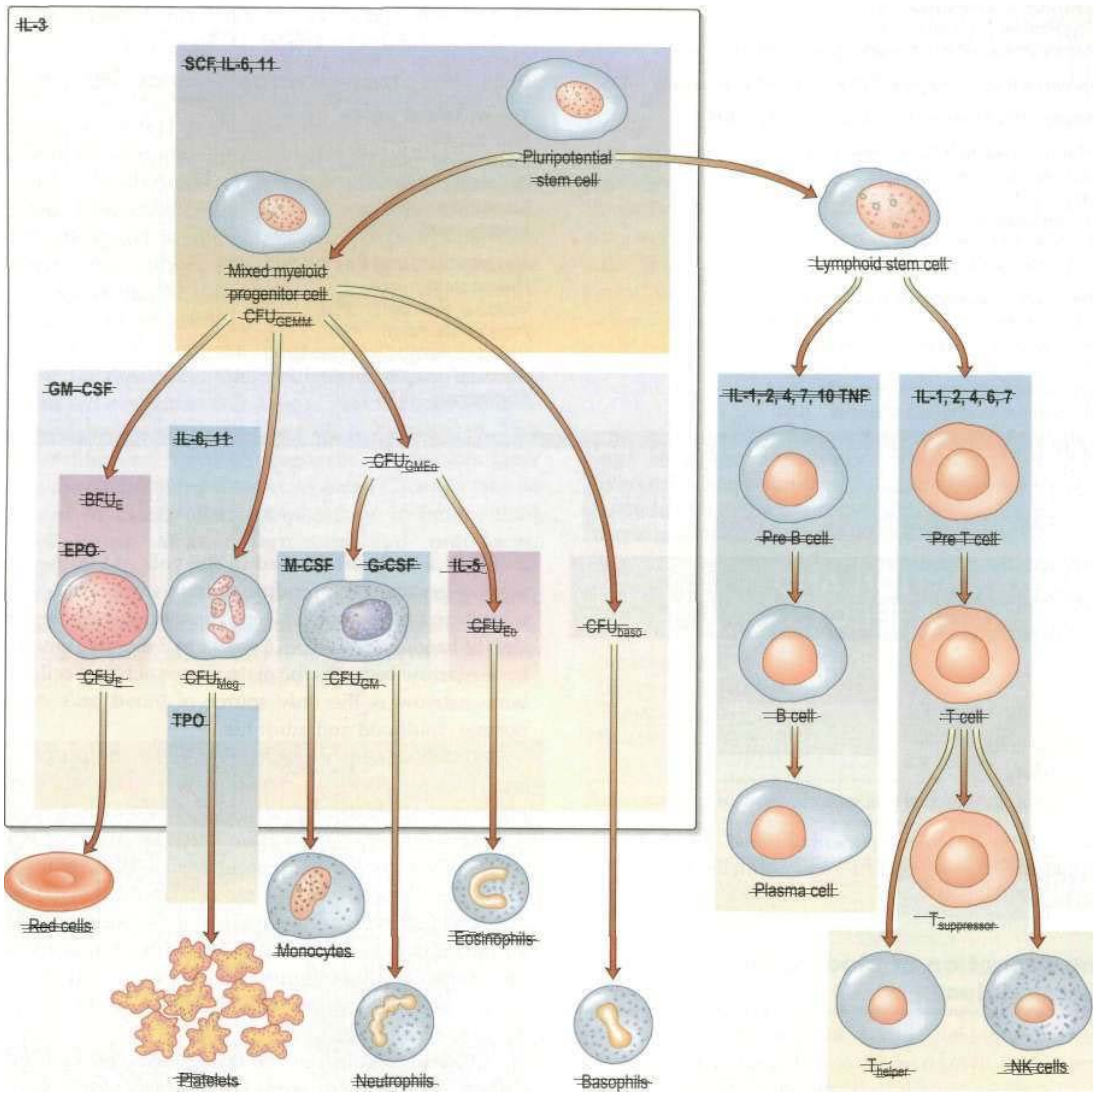

Fig. 8.1 **Role of growth factors in normal haemopoiesis.** Some of the multiple growth factors acting on stem cells and early progenitor cells are shown. BFU, burst-forming unit; CFU, colony-forming unit; CSF, colony-stimulating factor; E, erythroid; Eo, eosinophil; EPO, erythropoietin; G, granulocyte; GEMM, mixed granulocyte, erythroid, monocyte, megakaryocyte; GM, granulocyte, monocyte; IL, interleukin; M, monocyte; Meg, megakaryocyte; SCF, stem cell (Steel) factor or C-kit ligand; TNF, tumour necrosis factor; TPO, thrombopoietin.

The pluripotential stem cells are under the influence of a number of haemopoietic growth factors including interleukin-3 (IL-3), IL-6, -7, -11, fi-catenin and stem cell factor (SCF, Steel factor or C-kit ligand). Colony-stimulating factors (CSFs, the prefix indicating the cell type, see Fig. 8.1), as well as interleukins and erythropoietin (EPO) regulate the lineage committed progenitor cells. Thrombopoietin (TPO, which, like erythropoietin, is produced in the kidneys and the liver) along with IL-6 and IL-11 control platelet production. In addition to these factors stimulating haemopoiesis, other factors inhibit the process and include tumour necrosis factor (TNF) and transforming growth factor-p" (TGF-f3). Many of the growth factors are produced by activated T cells, monocytes and bone marrow stromal cells such as fibroblasts, endothelial cells and macrophages; these cells are also involved in inflammatory responses.

Many growth factors have been produced by recombinant DNA techniques and are being used clinically. Examples include G-CSF, which is used to accelerate haemopoietic recovery after chemotherapy and haemopoietic cell transplantation, and erythropoietin, which is used to treat anaemia in patients with chronic renal failure. Thrombopoietin is undergoing clinical trials in patients with idiopathic thrombocytopenic purpura.

Peripheral blood

Automated cell counters are used to measure the level of haemoglobin (Hb) and the number and size of red cells, white cells and platelets (Table 8.1). Other indices can be derived from these values. The mean corpuscular volume (MCV) of red cells is the most useful of the indices and is used to classify anaemia (see p. 425).

The white cell count (WCC, or WBC, white blood count) gives the total number of circulating leucocytes, and many automated cell counters produce differential counts as well.

Normally, less than 2% of the red cells are reticulocytes (p. 422). The reticulocyte count gives a guide to the erythroid activity in the bone marrow. An increased count is seen with increased marrow maturity, e.g. following haemorrhage or haemolysis, and during the response to treatment with a specific haematinic. A low count in the presence of anaemia indicates an inappropriate response by the bone marrow and may be seen in bone marrow failure (from whatever cause) or where there is a deficiency of a haematinic.

A carefully evaluated blood film is still an essential adjunct to the above, as definitive abnormalities of cells can be seen.

Table 8.1 **Normal values for peripheral blood**

	Male	Female
Hb (g/dL)	13.5-17.5	11.5-16
PCV (haematocrit; L7L)	0.4-0.54	0.37-0.47
RCC(10^{12}/L)	4.5-6.0	3.9-5.0
MCV (fL)		80-96
MCH (pg)		27-32
MCHC (g/dL)		32-36
WBC(10^9/L)		4.0-11.0
Platelets (107L)		150-400
ESR (mm/h)		<20
Reticulocytes	0.5-2.5%	(50-100x107L)

ESR, erythrocyte sedimentation rate; Hb, haemoglobin; MCH, mean corpuscular haemoglobin; MCHC, mean corpuscular haemoglobin concentration; MCV, mean corpuscular volume of red cells; PCV, packed cell volume; RCC, red cell count; WBC, white blood count.

Erythrocyte sedimentation rate (ESR)

This is the rate of fall of red cells in a column of blood and is a measure of the acute-phase response. The pathological process may be immunological, infective, ischaemic, malignant or traumatic. A raised ESR reflects an increase in the plasma concentration of large proteins, such as fibrinogen and immunoglobulins. These proteins cause rouleaux formation, when cells clump together like a stack of coins, and therefore fall more rapidly. The ESR increases with age, and is higher in females than in males. It is low in polycythaemia vera, owing to the high red cell concentration, and increased in patients with severe anaemia.

Plasma viscosity

Plasma viscosity measurement is used instead of the ESR in many laboratories. As with the ESR, the level is dependent on the concentration of large molecules such as fibrinogen and immunoglobulins. There is no difference between levels found in males and females, and viscosity increases only slightly in the elderly. It is not affected by the level of Hb and the result may be obtained within 15 minutes.

C-reactive protein

C-reactive protein is a pentraxin, one of the proteins produced in the acute-phase response (see Table 4.4). It is synthesized exclusively in the liver and rises within 6 hours of an acute event. It rises with fever (possibly triggered by IL-1, IL-6 and TNF-a and other cytokines) and in inflammatory conditions and after trauma. It follows the clinical state of the patient much more rapidly than does the ESR and is unaffected by the level of Hb, but it is less helpful than the ESR or plasma viscosity in monitoring chronic inflammatory diseases. Its measurement is easy and quick to perform using an immunoassay that can be automated. High-sensitivity assays have shown that increased levels predict future cardiovascular disease (p. 802).

THE RED CELL

Erythropoiesis

Red cell precursors pass through several stages in the bone marrow. The earliest morphologically recognizable cells are pronormoblasts. Smaller normoblasts result from

cell divisions, and precursors at each stage progressively contain less RNA and more Hb in the cytoplasm. The nucleus becomes more condensed and is eventually lost from the late normoblast in the bone marrow, when the cell becomes a reticulocyte.

Reticulocytes contain residual ribosomal RNA and are still able to synthesize Hb. They remain in the marrow for about 1-2 days and are released into the circulation, where they lose their RNA and become mature red cells (erythrocytes) after another 1-2 days. Mature red cells are non-nucleated biconcave discs.

Nucleated red cells *(normoblasts)* are not normally present in peripheral blood, but are present if there is extramedullary haemopoiesis and in some marrow disorders (see leucoeryothroblastic anaemia, p. 464).

About 10% of erythroblasts die in the bone marrow even during normal erythropoiesis. Such ineffective erythropoiesis is substantially increased in some anaemias such as thalassaemia major and megaloblastic anaemia.

Erythropoietin is a hormone which controls erythropoiesis. The gene for erythropoietin is on chromosome 7 and codes for a heavily glycosylated polypeptide of 165 amino acids. Erythropoietin has a molecular weight of 30 400 and is produced in the peritubular cells in the kidneys (90%) and in the liver (10%). Its production is regulated mainly by tissue oxygen tension. Production is increased if there is hypoxia from whatever cause - for example, anaemia or cardiac or pulmonary disease. The erythropoietin gene is one of a number of genes that is regulated by the hypoxic sensor pathway. The 3'-flanking region of the erythropoietin gene has a hypoxic response element which is necessary for the induction of transcription of the gene in hypoxic cells. Hypoxia-inducible factor 1 (HIF-1) is a transcription factor which binds to the hypoxia response element and acts as a master regulator of several genes that are responsive to hypoxia. Erythropoietin stimulates an increase in the proportion of bone marrow precursor cells committed to erythropoiesis, and CFU-E are stimulated to proliferate and differentiate. Increased 'inappropriate' production of erythropoietin is also seen in patients with renal disease and neoplasms in other sites which result in polycythaemia (see Table 8.16).

Haemoglobin synthesis

Haemoglobin performs the main functions of red cells - carrying O_2 to the tissues and returning CO_2 from the tissues to the lungs. Each normal adult Hb molecule (Hb A) has a molecular weight of 68 000 and consists of two a and two (3 globin polypeptide chains (0C2P2) which have 141 and 146 amino acids respectively. HbA comprises about 97% of the Hb in adults. Two other types, Hb A_2 ($a_2\delta_2$) and Hb F ($a_2\gamma_2$), are found in adults in small amounts (1.5-3.2% and < 1%, respectively) (p. 440). Haemoglobin synthesis occurs in the mitochondria of the developing red cell (Fig. 8.2). The major rate-limiting step is the conversion of glycine and succinic acid to 8-aminolaevulinic acid (ALA) by ALA synthase (also see Fig. 19.22). Vitamin B_6 is a coenzyme for this reaction, which is inhibited by haem and stimulated by erythropoietin. Two molecules of 8-ALA condense to form a pyrrole ring (porphobilinogen). These rings are then grouped in fours to produce protoporphyrins. Finally, iron is inserted to form haem. Haem is then inserted into the globin chains to form Hb. The structure of Hb is shown in Figure 8.3.

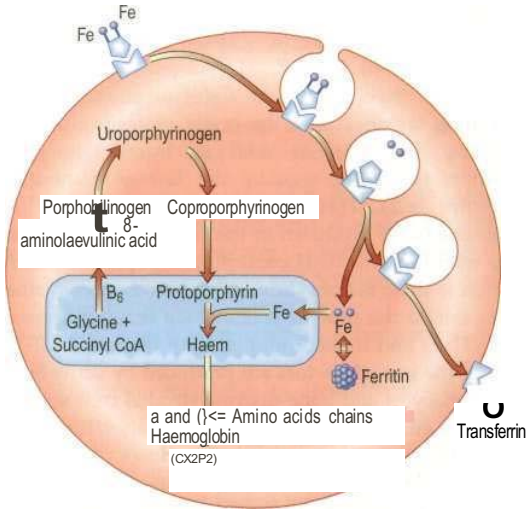

***Fig. 8.2* Haemoglobin synthesis.** Transferrin attaches to a surface receptor on developing red cells. Iron is released and transported to the mitochondria, where it combines with protoporphyrin to form haem. Protoporphyrin itself is manufactured from glycine and succinyl-CoA. Haem combines with a and p chains (formed on ribosomes) to make haemoglobin.

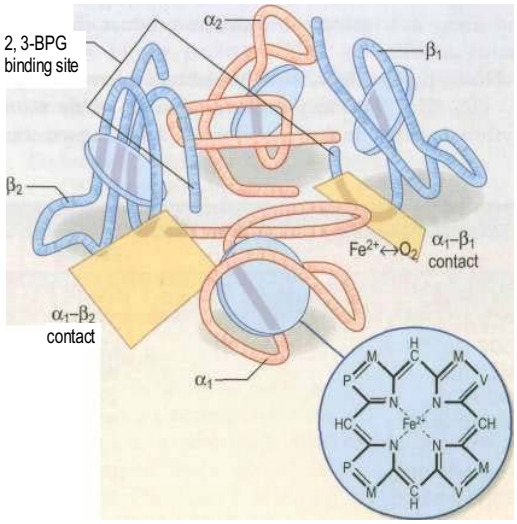

***Fig. 8.3* Model of the haemoglobin molecule showing *a* (pink) and p (blue) chains.** 2,3-BPG (bisphosphoglycerate) binds in the centre of the molecule and stabilizes the deoxygenated form by cross-linking the p chains (also see Fig. 8.4). M, methyl; P, propionic acid; V, vinyl.

Haemoglobin function

The biconcave shape of red cells provides a large surface area for the uptake and release of oxygen and carbon dioxide. Haemoglobin becomes saturated with oxygen in the pulmonary capillaries where the partial pressure of oxygen is high and Hb has a high affinity for oxygen. Oxygen is released in the tissues where the partial pressure of oxygen is low and Hb has a low affinity for oxygen.

In adult haemoglobin (Hb A), a haem group is bound to each of the four globin chains; the haem group has a porphyrin ring with a ferrous atom which can reversibly bind one oxygen molecule. The haemoglobin molecule exists in two conformations, R and T. The T (taut) conformation of deoxyhaemoglobin is characterized by the globin units being held tightly together by electrostatic bonds (Fig. 8.4). These bonds are broken when oxygen binds to haemoglobin, resulting in the R (relaxed) conformation in which the remaining oxygen-binding sites are more exposed and have a much higher affinity for oxygen than in the T conformation. The binding of one oxygen molecule to deoxyhaemoglobin increases the oxygen affinity of the remaining binding sites - this property is known as 'cooperativity' and is the reason for the sigmoid shape of the oxygen dissociation curve. Haemoglobin is, therefore, an example of an allosteric protein. The binding of oxygen can be influenced by secondary effectors - hydrogen ions, carbon dioxide and red-cell 2,3-bisphosphoglycerate (2,3-BPG, formerly called 2,3-diphosphoglycerate (2,3-DPG)). Hydrogen ions and carbon dioxide added to blood cause a reduction in the oxygen-binding affinity of haemoglobin (the Bohr effect) (Fig. 15.5). Oxygenation of haemoglobin reduces its affinity for carbon dioxide (the Haldane effect). These effects help the exchange of carbon dioxide and oxygen in the tissues.

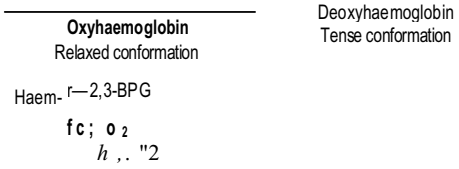

Fig. 8.4 **Oxygenated and deoxygenated haemoglobin molecule.** The O_2 haemoglobin molecule is predominantly stabilized by a-p chain bonds rather than a-a and p-p chain bonds. The structure of the molecule changes during O_2 uptake and release. When O_2 is released, the p chains rotate on the ct|p_2 and o^ contacts, allowing the entry of 2,3-BPG which causes a lower affinity of haemoglobin for O_2 and improved delivery of O_2 to the tissues. From Hoffbrand AV, Pettit JE (1993) *Essential Haematology,* 3rd edn. Oxford: Blackwell Scientific Publications, with permission.

Red cell metabolism produces 2,3-BPG from glycolysis. 2,3-BPG accumulates because it is sequestered by binding to deoxyhaemoglobin. The binding of 2,3-BPG stabilizes the T conformation and reduces its affinity for oxygen. The P_{50} is the partial pressure of oxygen at which the haemoglobin is 50% saturated with oxygen. P_{50} increases with 2,3-BPG concentrations (right-hand shift in Fig. 15.5), which increase when oxygen availability is reduced in conditions such as hypoxia or anaemia. P_{50} also rises with increasing body temperature, which may be beneficial during prolonged exercise. Haemoglobin regulates oxygen transport as shown in the oxyhaemoglobin dissociation curve. When the primary limitation to oxygen transport is in the periphery, e.g. heavy exercise, anaemia, the P_{50} is increased to enhance oxygen unloading. When the primary limitation is in the lungs, e.g. lung disease, high altitude exposure, the P_{50} is reduced to enhance oxygen loading.

A summary of normal red cell production and destruction is given in Figure 8.5.

ANAEMIA

Anaemia is present when there is a decrease in the level of haemoglobin in the blood below the reference level for the age and sex of the individual (Table 8.1). Alterations in the level of Hb may occur as a result of changes in the plasma volume, as shown in Figure 8.6. A reduction in the plasma volume will lead to a spuriously high Hb - this is seen with dehydration and in the clinical condition of apparent polycythaemia (see p. 455). A raised plasma volume produces a spurious anaemia, even when combined with a small increase in red cell volume as occurs in pregnancy. After a major bleed, anaemia may not be apparent for several days until the plasma volume returns to normal.

The various types of anaemia, classified in terms of the red cell indices, particularly the MCV, are shown in Figure 8.7, p. 425. There are three major types:

- hypochromic microcytic with a low MCV
- normochromic normocytic with a normal MCV
- macrocytic with a high MCV.

Clinical features

Patients with anaemia may be asymptomatic. A slowly falling level of Hb allows for haemodynamic compen-

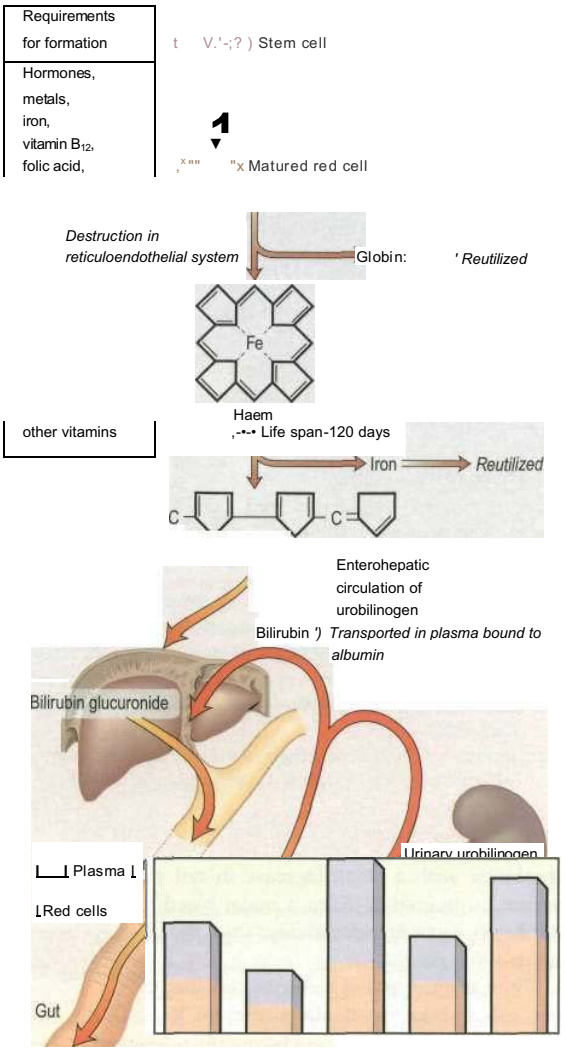

Fig. 8.5 **Red cell production and breakdown** (see p. 350).

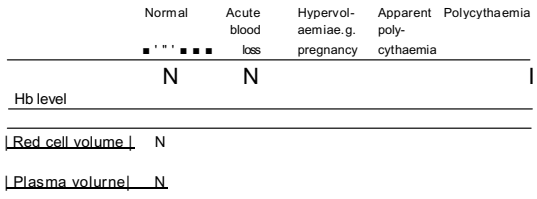

Fig. 8.6 **Alterations of haemoglobin in relation to plasma.**

sation and enhancement of the oxygen-carrying capacity of the blood. A rise in 2,3-BPG causes a shift of the oxygen dissociation curve to the right, so that oxygen is more readily given up to the tissues. Where blood loss is rapid, more severe symptoms will occur, particularly in elderly people.

Symptoms (all non-specific)

- Fatigue
- Headaches
- Faintness

(The above three symptoms are all very common in the general population.)

- Breathlessness
- Angina
- Intermittent claudication
- Palpitations.

Signs

Pallor
Tachycardia
Systolic flow murmur
Cardiac failure
Rarely papilloedema and retinal haemorrhages after an acute bleed (can be accompanied by blindness).

Specific signs of the different types of anaemia will be discussed in the appropriate sections. Examples include:

- koilonychia - spoon-shaped nails seen in iron deficiency anaemia
- jaundice - found in haemolytic anaemia
- bone deformities - found in thalassaemia major
- leg ulcers - occur in association with sickle cell disease.

It must be emphasized that anaemia is not a diagnosis, and a cause must be found.

Investigations

Peripheral blood

A low haemoglobin should always be considered in relation to:

- the white blood cell (WBC) count
- the platelet count
- the reticulocyte count (as this indicates marrow activity)
- the blood film, as abnormal red cell morphology (see Fig. 8.8) may indicate the diagnosis.

Where two populations of red cells are seen, the blood film is said to be dimorphic. This may, for example, be seen in patients with 'double deficiencies' (e.g. combined iron and folate deficiency in coeliac disease, or following treatment of anaemic patients with the appropriate haematinic).

Bone marrow

Examination of the bone marrow is performed to further investigate abnormalities found in the peripheral blood

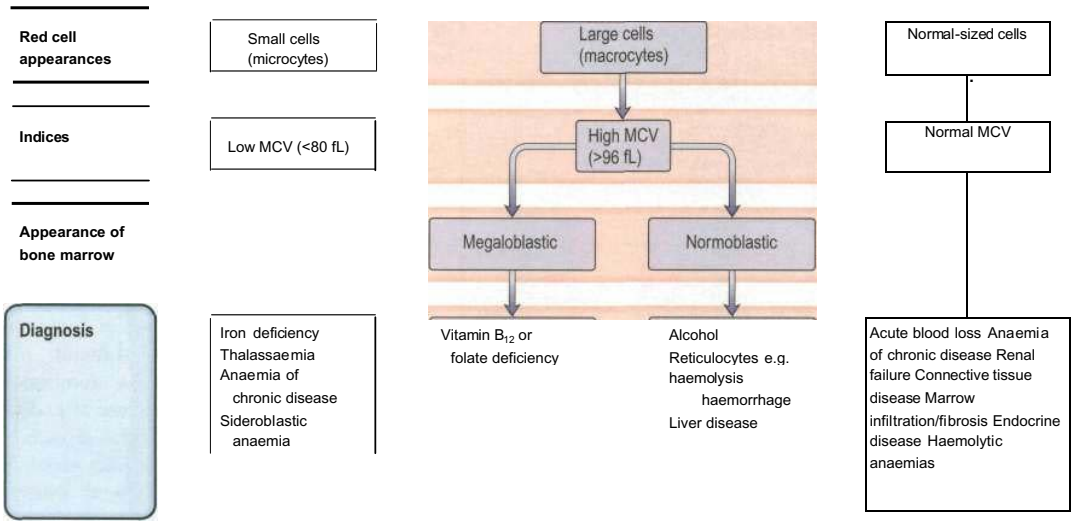

Fig. 8.7 **Classification of anaemia.** MCV, mean corpuscular volume.

(Practical box 8.1). Aspiration provides a film which can be examined by microscopy for the morphology of the developing haemopoietic cells. The trephine provides a core of bone which is processed as a histological specimen and allows an overall view of the bone marrow architecture, cellularity and presence/absence of abnormal infiltrates.

The following are assessed:

- cellularity of the marrow
- type of erythropoiesis (e.g. normoblastic or megaloblastic)
- cellularity of the various cell lines
- infiltration of the marrow
- iron stores.

Special tests may be performed: cytogenetic, immunological, cytochemical markers, biochemical analyses (e.g. deoxyuridine suppression test), microbiological culture.

Practical Box 8.1
Techniques for obtaining bone marrow

The technique should be explained to the patient and consent obtained

Aspiration

Site - usually iliac crest
Give local anaesthetic injection
Use special bone marrow needle (e.g. Salah)
Aspirate marrow
Make smear with glass slide
Stain with:
- Romanowsky technique
- Perls' reaction (acid ferrocyanide) for iron.

Trephine

Indications include:
- 'Dry tap' obtained with aspiration Better assessment of cellularity, e.g. aplastic anaemia Better assessment of presence of infiltration or fibrosis.

Technique

Site - usually posterior iliac crest
Give local anaesthetic injection
Use special needle (e.g. Jamshidi - longer and wider than for aspiration)
Obtain core of bone
Fix in formalin; decalcify - this takes a few days
Stain with:
- Haematoxylin and eosin
- Reticulin stain.

MICROCYTIC ANAEMIA

Iron deficiency is the most common cause of anaemia in the world, affecting 30% of the world's population equivalent to 500 million people. This is because of the body's limited ability to absorb iron and the frequent loss of iron owing to haemorrhage. Although iron is abundant, most is in the insoluble ferric (Fe^{3+}) form, which has poor bioavailability. Ferrous (Fe^{2+}) is more readily absorbed. Free iron is toxic, and it is bound to various proteins for transport and storage.

The other causes of a microcytic hypochromic anaemia are anaemia of chronic disease, sideroblastic anaemia, and thalassaemia. In thalassaemia (p. 440) there is a defect in globin synthesis, in contrast to the other three causes of microcytic anaemia where the defect is in the synthesis of haem.

Iron

Dietary intake

The average daily diet in the UK contains 15-20 mg of

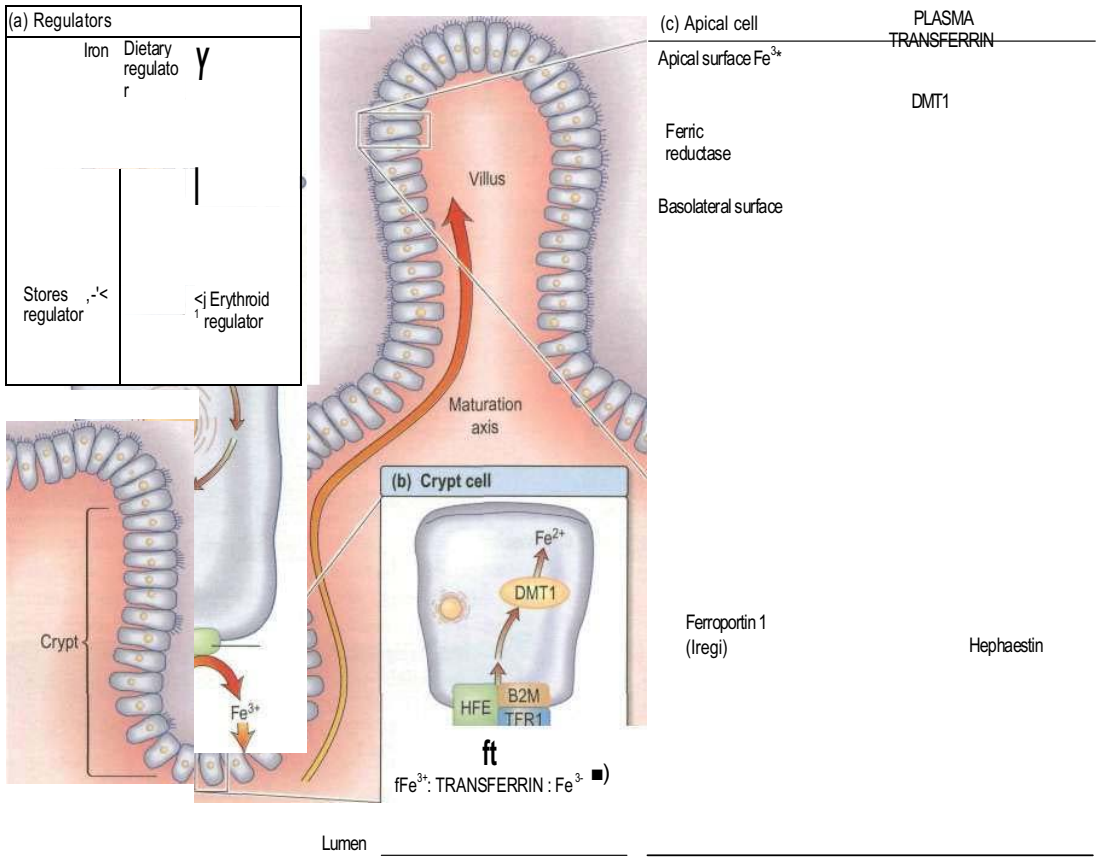

Fig. 8.8 **(a) Regulation of the absorption of intestinal iron.** The iron-absorbing cells of the duodenal epithelium originate in the intestinal crypts and migrate toward the tip of the villus as they differentiate (maturation axis). Absorption of intestinal iron is regulated by at least three independent mechanisms. First, iron absorption is influenced by recent dietary iron intake (dietary regulator). After a large dietary bolus, absorptive cells are resistant to iron uptake for several days. Second, iron absorption can be modulated considerably in response to body iron stores (stores regulator). Third, a signal communicates the state of bone marrow erythropoiesis to the intestine (erythroid regulator), **(b) Duodenal crypt** cells sense body iron status through the binding of transferrin to the HFE/B2 microglobulinATFRI complex. Cytosolic enzymes change the oxidative state of iron from ferric (Fe^{3+}) to ferrous (Fe^{2+}). A decrease in crypt cell iron concentration upregulates the divalent metal transporter (DMT1). This increases as crypt cells migrate up the villus and become mature absorptive cells, **(c) Apical cell.** Dietary iron is reduced from the ferrous to the ferric state by the brush border ferrireductase. DMT1 facilitates iron absorption from the intestinal lumen. The export proteins , e.g. ferroportin 1 (Iregi) and hephaestin, transfer iron from the enterocyte into the circulation. HFE, hereditary haemochromatosis gene; B2M, p_2-microglobulin.

iron, although normally only 10% of this is absorbed. Absorption may be increased to 20-30% in iron deficiency and pregnancy.

Non-haem iron is mainly derived from cereals, which are commonly fortified with iron; it forms the main part of dietary iron. Haem iron is derived from haemoglobin and myoglobin in red or organ meats. Haem iron is better absorbed than non-haem iron, whose availability is more affected by other dietary constituents.

Absorption (Fig. 8.8(a),(b))

Factors influencing iron absorption are shown in Table 8.2. Haem iron is partly broken down to non-haem iron, but some haem iron is absorbed intact into mucosal cells. Iron absorption occurs primarily in the duodenum. Non-haem iron is dissolved in the low pH of the stomach and reduced from the ferric to the ferrous form by a brush border ferrireductase. Cells in duodenal crypts are able to sense the body's iron requirements and retain this information as they mature into cells capable of absorbing iron at the tips of the villi. A protein, divalent metal transporter 1 (DMT1), (formerly called divalent cation transporter [DCT1] or natural resistance-associated macrophage protein [NRAMP2]) transports iron (and other metals) across the apical (luminal) surface of the mucosal cells in the small intestine. Haem iron is absorbed in a separate less-well-characterized process.

Once inside the mucosal cell, iron may be transferred across the cell to reach the plasma, or be stored as ferritin; the body's iron status at the time the absorptive cell developed from the crypt cell is probably the crucial deciding factor. Iron stored as ferritin will be lost into the gut lumen when the mucosal cells are shed; this regulates iron balance. The mechanism of transport of iron across

Table 8.2 Factors influencing iron absorption

Haem iron is absorbed better than non-haem iron
Ferrous iron is absorbed better than ferric iron
Gastric acidity helps to keep iron in the ferrous state and soluble in the upper gut Formation of insoluble complexes with phytate or phosphate decreases iron absorption Iron absorption is increased with low iron stores and increased erythropoietic activity, e.g. bleeding, haemolysis, high altitude There is a decreased absorption in iron overload, except in hereditary haemochromatosis, where it is increased

the basolateral surface of mucosal cells involves a transporter protein, ferroportin 1 (Iregl). This transporter protein requires an accessory, multicopper protein, hephaestin (see Fig. 8.9c).

The iron content of the body is kept within narrow limits and its loss and intake are normally finely balanced. Its absorption is closely related to the total iron stores of the body; in iron deficiency, absorption of iron may increase to 3-4 mg daily. The body is unable to excrete iron once it has been absorbed so the regulation of iron absorption is critical. Iron absorption is regulated in several ways (see Fig. 8.9) by dietary, stores and erythroid regulators. The liver peptide hepcidin may be the store and/ or erythroid regulator. The hereditary haemochromatosis gene *(HFE)* plays a role in iron absorption, although the mechanism is not fully understood. It is not the prime regulator since iron absorption also responds to the stores of iron and erythroid regulators when HFE is either mutated or absent.

Anaemias with increased rates of erythropoiesis do not cause equal increases in iron absorption; for example, conditions with 'ineffective erythropoiesis' such as thalassaemia stimulate greater iron absorption than haemolytic anaemias such as hereditary spherocytosis and autoimmune haemolytic anaemia where red cell destruction occurs in the periphery.

Transport in the blood

The normal serum iron level is about 13-32 umol/L; there is a diurnal rhythm with higher levels in the morning. Iron is transported in the plasma bound to transferrin, a P-globulin that is synthesized in the liver. Each transferrin molecule binds two atoms of ferric iron and is normally one-third saturated. Most of the iron bound to transferrin comes from macrophages in the reticuloendothelial system and not from iron absorbed by the intestine. Transferrin-bound iron becomes attached by specific receptors to erythroblasts and reticulocytes in the marrow and the iron is removed (see Fig. 8.2).

In an average adult male, 20 mg of iron, chiefly obtained from red cell breakdown in the macrophages of the reticuloendothelial system, is incorporated into Hb every day.

Iron stores

About two-thirds of the total body iron is in the circulation as haemoglobin (2.5-3 g in a normal adult man). Iron is stored in reticuloendothelial cells, hepatocytes and skeletal muscle cells (500-1500 mg). About two-thirds of this is stored as ferritin and one-third as haemosiderin in normal individuals. Small amounts of iron are also found in plasma (about 4 mg bound to transferrin), with some in myoglobin and enzymes.

Ferritin is a water-soluble complex of iron and protein. It is more easily mobilized than haemosiderin for Hb formation. It is present in small amounts in plasma.

Haemosiderin is an insoluble iron-protein complex found in macrophages in the bone marrow, liver and spleen. Unlike ferritin, it is visible by light microscopy in tissue sections and bone marrow films after staining by Perls' reaction.

Requirements

Each day 0.5-1.0 mg of iron is lost in the faeces, urine and sweat. Menstruating women lose 30-40 mL of blood per month, an average of about 0.5-0.7 mg of iron per day. Blood loss through menstruation in excess of 100 mL will usually result in iron deficiency as increased iron absorption from the gut cannot compensate for such losses of iron. The demand for iron also increases during growth (about 0.6 mg per day) and pregnancy (1-2 mg per day). In the normal adult the iron content of the body remains relatively fixed. Increases in the body iron content (haemochromatosis) are classified into:

- hereditary haemochromatosis (p. 386), where a mutation in the HFE gene causes upregulation of DMT1 and increased iron absorption
- secondary haemochromatosis (transfusion siderosis; see p. 441). This is due to iron overload in conditions where repeated transfusion is the only therapy.

Iron deficiency

Iron deficiency anaemia develops when there is inadequate iron for haemoglobin synthesis. A normal level of Hb is maintained for as long as possible after the iron stores are depleted; latent iron deficiency is said to be present during this period.

Causes

- Blood loss
- Increased demands such as growth and pregnancy
- Decreased absorption (e.g. postgastrectomy)
- Poor intake.

Most iron deficiency is due to blood loss, usually from the uterus or gastrointestinal tract. Premenopausal women are in a state of precarious iron balance owing to menstruation. Iron deficiency affects more than a quarter of the world's population, but isolated nutritional iron deficiency is rare in developed countries. The most common cause of iron deficiency world-wide is blood loss from the gastrointestinal tract resulting from hookworm infestation. The poor quality of the diet, predominantly containing vegetables, also contributes to the high prevalence of iron deficiency in developing countries. Even in developed countries, iron deficiency is not uncommon in infancy

where iron intake is insufficient for the demands of growth. It is more prevalent in infants born prematurely or where the introduction of mixed feeding is delayed.

Clinical features

The symptoms of anaemia are described on page 424. Other clinical features occur as a result of tissue iron deficiency. These are mainly epithelial changes induced by the effect of inadequate iron in the cells:

- brittle nails
- spoon-shaped nails (koilonychia)
- atrophy of the papillae of the tongue
- angular stomatitis
- brittle hair
- a syndrome of dysphagia and glossitis (Plummer-Vinson or Paterson-Brown-Kelly syndrome; see p. 279).

The diagnosis of iron deficiency anaemia relies on a good clinical history with questions about dietary intake, regular self-medication with non-steroidal anti-inflammatory drugs (which may give rise to gastrointestinal bleeding), and the presence of blood in the faeces (which may be a sign of haemorrhoids or carcinoma of the lower bowel). In women, a careful enquiry about the duration of periods, the occurrence of clots and the number of sanitary towels or tampons (normal 3-5/day) used should be made.

Investigations

Blood count and film

A characteristic blood film is shown in Figure 8.9. The red cells are microcytic (MCV < 80 fL) and hypochromic (MCH < 27 pg). There is poikilocytosis (variation in shape) and anisocytosis (variation in size). Target cells are seen.

Serum iron and iron-binding capacity

The serum iron falls and the total iron-binding capacity (TIBC) rises in iron deficiency compared with normal. Iron deficiency is regularly present when the transferrin saturation (i.e. serum iron divided by TIBC) falls below 19% (Table 8.3).

Fig. 8.9 **Hypochromic microcytic cells (arrow) on a blood film.** Poikilocytosis and anisocytosis are seen.

Serum ferritin

The level of serum ferritin reflects the amount of stored iron. The normal values for serum ferritin are 30-300 u.g/L (11.6-144 nmol/L) in males and 15-200 ng/L (5.8-96 nmol/L) in females. In simple iron deficiency, a low serum ferritin confirms the diagnosis. However, ferritin is an acute-phase reactant, and levels increase in the presence of inflammatory or malignant diseases. In these cases, measurement of serum iron/TIBC, serum ferritin and soluble transferrin receptors is used.

Serum soluble transferrin receptors

The number of transferrin receptors increases in iron deficiency. The results of this immunoassay compares well with results from bone marrow aspiration at estimating iron stores.

This assay can help to distinguish between iron deficiency and anaemia of chronic disease (see Table 8.3), and may avoid the need for bone marrow examination even in complex cases.

Bone marrow

Erythroid hyperplasia with ragged normoblasts is seen in the marrow in iron deficiency. Staining using Perls' reaction (acid ferrocyanide) does not show the characteristic Prussian-blue granules of stainable iron in the bone marrow fragments or in the erythroblasts.

Examination of the bone marrow is not essential for the diagnosis of iron deficiency but it may be helpful in

Table 8.3 **Microcytic anaemia: the differential diagnosis**

	Iron deficiency	Anaemia of chronic disease	Thalassaemia trait (a or p)	Sideroblastic anaemia
MCV	Reduced	Low normal or normal	Very low for degree of anaemia	Low in inherited type but often raised in acquired type

Iron in marrow	Absent	Present	Present	Present
Iron in erythroblasts	Absent	Absent or reduced	Present	Ring forms

TIBC, total iron binding capacity

the investigation of complicated cases of anaemia, e.g. to determine if iron deficiency is present in a patient with anaemia of chronic disease.

Other investigations

These will be indicated by the clinical history and examination. Investigations of the gastrointestinal tract are often required to determine the cause of the iron deficiency (see p. 293).

Differential diagnosis

The presence of anaemia with microcytosis and hypochromia does not necessarily indicate iron deficiency. The most common other causes are thalassaemia, sideroblastic anaemia and anaemia of chronic disease, and in these disorders the iron stores are normal or increased. The differential diagnosis of microcytic anaemia is shown in Table 8.3.

Treatment

Iron deficiency is not a diagnosis per se. The correct management of iron deficiency is to find and treat the underlying cause, and to give iron to correct the anaemia and replace iron stores. The response to iron therapy can be monitored using the reticulocyte count and Hb level, with an expected rise in haemoglobin of 1 g/dL per week.

Oral iron is all that is required in most cases. The best preparation is ferrous sulphate (200 mg three times daily, a total of 180 mg ferrous iron) which is absorbed best when the patient is fasting. If the patient has side-effects such as nausea, diarrhoea or constipation, taking the tablets with food or reducing the dose using a preparation with less iron such as ferrous gluconate (300 mg twice daily, only 70 mg ferrous iron) is all that is usually required to reduce the symptoms. The use of expensive iron compounds, particularly the slow-release ones which release iron beyond its main sites of absorption, is unnecessary.

In developing countries, distribution of iron tablets is the main approach for the alleviation of iron deficiency. However, iron supplementation programmes have been ineffective, probably mainly because of poor compliance.

Oral iron should be given for long enough to correct the Hb level and to replenish the iron stores. This can take 6 months. The commonest causes of failure of response to oral iron are:

- lack of compliance
- continuing haemorrhage
- incorrect diagnosis, e.g. thalassaemia trait.

These possibilities should be considered before parenteral iron is used. However, parenteral iron is required by occasional patients, including those who have general intolerance of oral preparations even at low dose, those with severe malabsorption, and those who have chronic gastrointestinal diseases such as ulcerative colitis or Crohn's disease. Iron stores are replaced much faster with parenteral iron than with oral iron, but the haematological response is no quicker. Parenteral iron can be given as repeated deep intramuscular injections of iron-sorbitol (1.5 mg of iron per kg body weight) or by slow intravenous infusion of iron-sucrose.

Anaemia of chronic disease

One of the most common types of anaemia, particularly in hospital patients, is the anaemia of chronic disease, occurring in patients with chronic infections such as infective endocarditis or tuberculosis and osteomyelitis in developing countries. Other causes include chronic inflammatory diseases such as Crohn's disease, rheumatoid arthritis, systemic lupus erythematosus (SLE), polymyalgia rheumatica, and malignant disease. There is decreased release of iron from the bone marrow to developing erythroblasts, an inadequate erythropoietin response to the anaemia, and decreased red cell survival. The exact mechanisms responsible for these effects are not clear, but they seem to be mediated by inflammatory cytokines such as IL-1, tumour necrosis factor and interferons.

The serum iron and the TIBC are low, and the serum ferritin is normal or raised because of the inflammatory process. The serum soluble transferrin receptor level is normal (Table 8.3). Stainable iron is present in the bone marrow, but iron is not seen in the developing erythroblasts. Patients do not respond to iron therapy, and treatment is, in general, that of the underlying disorder. Recombinant erythropoietin therapy is used in the anaemia of renal disease (p. 673), inflammatory disease (rheumatoid arthritis, inflammatory bowel disease) and is being trialled in, for example, myelodyplasia).

Sideroblastic anaemia

Sideroblastic anaemias are inherited or acquired disorders characterized by a refractory anaemia, a variable number of hypochromic cells in the peripheral blood, and excess iron and ring sideroblasts in the bone marrow. The presence of ring sideroblasts is the diagnostic feature of sideroblastic anaemia. There is accumulation of iron in the mitochondria of erythroblasts owing to disordered haem synthesis forming a ring of iron granules around the nucleus that can be seen with Perls' reaction. The blood film is often dimorphic; ineffective haem synthesis is responsible for the microcytic hypochromic cells. Sideroblastic anaemias are classified as shown in Table 8.4. A structural defect in 8-aminolaevulinic acid (ALA) synthase, the pyridoxine-dependent enzyme responsible for the first step in haem synthesis (see Fig. 8.2), has been identified in one form of inherited sideroblastic anaemia. Primary acquired sideroblastic anaemia is one of the myelodysplastic syndromes (see p. 455). Lead toxicity is described on p. 1014.

Treatment

Some patients respond when drugs or alcohol are withdrawn, if these are the causative agents. In occasional cases, there is a response to pyridoxine. Treatment with folic acid may be required to treat accompanying folate deficiency.

NORMOCYTIC ANAEMIA

Normocytic, normochromic anaemia is seen in anaemia of chronic disease, in some endocrine disorders (e.g. hypopituitarism, hypothyroidism and hypoadrenalism) and in some haematological disorders (e.g. aplastic anaemia and some haemolytic anaemias) (see Fig. 8.7). In addition, this type of anaemia is seen acutely following blood loss. ■

MACROCYTIC ANAEMIAS

These can be divided into megaloblastic and non-megaloblastic types, depending on bone marrow findings.

MEGALOBLASTIC ANAEMIA

Megaloblastic anaemia is characterized by the presence in the bone marrow of erythroblasts with delayed nuclear maturation because of defective DNA synthesis (megaloblasts). Megaloblasts are large and have large immature nuclei. The nuclear chromatin is more finely dispersed than normal and has an open stippled appearance (Fig. 8.10). A characteristic abnormality of white cells, giant metamyelocytes, is frequently seen in megaloblastic anaemia. These cells are about twice the size of normal cells and often have twisted nuclei. Megaloblastic changes occur in:

- vitamin B_{12} deficiency or abnormal vitamin B_{12} metabolism
- folic acid deficiency or abnormal folate metabolism

Fig. 8.10 **Megaloblasts (arrowed) in the bone marrow.**

- other defects of DNA synthesis, such as congenital enzyme deficiencies in DNA synthesis (e.g. orotic aciduria), or resulting from therapy with drugs interfering with DNA synthesis (e.g. hydroxycarbamide (hydroxyurea), azathioprine, zidovudine - AZT)
- myelodysplasia due to dyserythropoiesis.

Haematological values

Anaemia may be present. The MCV is characteristically > 96 fL unless there is a coexisting cause of microcytosis when there may be a dimorphic picture with a normal/low average MCV. The peripheral blood film shows macrocytes with hypersegmented polymorphs with six or more lobes in the nucleus (see Fig. 8.11). If severe, there may be leucopenia and thrombocytopenia.

Biochemical basis of megaloblastic anaemia

The key biochemical problem common to both vitamin B_{12} and folate deficiency is a block in DNA synthesis owing to an inability to methylate deoxyuridine monophosphate to deoxythymidine monophosphate, which is then used to build DNA (Fig. 8.12). The methyl group is supplied by the folate coenzyme, methylene tetrahydrofolate.

Deficiency of folate reduces the supply of this coenzyme; deficiency of vitamin B_{12} also reduces its supply by slowing the demethylation of methyltetrahydrofolate (methyl THF) and preventing cells receiving tetrahydrofolate for synthesis of methylene tetrahydrofolate polyglutamate.

Other congenital and acquired forms of megaloblastic anaemia are due to interference with purine or pyrimidine synthesis causing an inhibition in DNA synthesis.

Deoxyuridine suppression test

This is a useful method for rapidly determining the nature and severity of the vitamin B_{12} or folate deficiency in severe or complex cases of megaloblastic anaemia.

Fig. 8.11 **Macrocytes and a hypersegmented neutrophil (arrowed) on a peripheral blood film.**

Vitamin B_{12} deficiency

There are a number of causes of B_{12} deficiency and abnormal B_{12} metabolism (Table 8.5). The most common cause of vitamin B_{12} deficiency in adults is pernicious anaemia. Malabsorption of vitamin B_{12} because of pancreatitis, coeliac disease or treatment with metformin is mild and does not usually result in significant vitamin B_{12} deficiency.

Pernicious anaemia

Pernicious anaemia (PA) is an autoimmune disorder in which there is atrophic gastritis with loss of parietal cells in the gastric mucosa with consequent failure of intrinsic factor production and vitamin B_{12} malabsorption.

Pathogenesis of pernicious anaemia

This disease is common in the elderly, with 1 in 8000 of the population aged over 60 years being affected in the UK. It can be seen in all races, but occurs more frequently in fair-haired and blue-eyed individuals, and those who have the blood group A. It is more common in females than males.

There is an association with other autoimmune diseases, particularly thyroid disease, Addison's disease and vitiligo. Approximately one-half of all patients with PA have thyroid antibodies. There is a higher incidence of gastric carcinoma with PA than in the general population; the incidence in PA is 1-3%.

Parietal cell antibodies are present in the serum in 90% of patients with PA- and also in many older patients with gastric atrophy. Conversely, intrinsic factor antibodies, although found in only 50% of patients with PA, are specific for this diagnosis. Two types of intrinsic factor antibodies are found: a blocking antibody, which inhibits binding of intrinsic factor to B_{12}, and a precipitating antibody, which inhibits the binding of the B_{12}-intrinsic factor complex to its receptor site in the ileum.

B_{12} deficiency may rarely occur in children from a congenital deficiency or abnormality of intrinsic factor, or as a result of early onset of the adult autoimmune type.

Pathology

Autoimmune gastritis (see p. 287) affecting the fundus is present with plasma cell and lymphoid infiltration. The parietal and chief cells are replaced by mucin-secreting cells. There is achlorhydria and absent secretion of intrinsic factor. The histological abnormality can be improved by corticosteroid therapy, which supports an autoimmune basis for the disease.

Clinical features

The onset of PA is insidious, with progressively increasing symptoms of anaemia. Patients are sometimes said to have a lemon-yellow colour owing to a combination of pallor and mild jaundice caused by excess breakdown of haemoglobin. A red sore tongue (glossitis) and angular stomatitis are sometimes present.

The neurological changes, if left untreated for a long time, can be irreversible. These neurological abnormalities occur only with very low levels of serum B_{12} (less than 60 ng/L) and occasionally occur in patients who are not clinically anaemic. The classical neurological features are those of a polyneuropathy progressively involving the peripheral nerves and the posterior and eventually the lateral columns of the spinal cord (subacute combined degeneration; p. 1263). Patients present with symmetrical paraesthesiae in the fingers and toes, early loss of vibration sense and proprioception, and progressive weakness and ataxia. Paraplegia may result. Dementia, psychiatric problems, e.g. depression, hallucinations, delusions, and optic atrophy also occur from vitamin B_{12} deficiency.

Investigations

- **Haematological findings** show the features of a megaloblastic anaemia as described on page 430.
- **Bone marrow** shows the typical features of mega loblastic erythropoiesis (Fig. 8.10), although it is frequently not performed in cases of straightforward macrocytic anaemia and a low serum vitamin B_{12}.
- **Serum bilirubin** may be raised as a result of ineffective erythropoiesis. Normally a minor fraction of serum bilirubin results from premature breakdown of newly formed red cells in the bone marrow. In many megaloblastic anaemias, where the destruction of developing red cells is much increased, the serum bilirubin can be increased.
- **Serum vitamin B_{12}** is usually well below 160 ng/L, which is the lower end of the normal range. Serum vitamin B_{12} can be assayed using radioisotope dilution or immunological assays.
- **Serum folate level** is normal or high, and the red cell folate is normal or reduced owing to inhibition of normal folate synthesis.

Absorption tests

Vitamin B_{12} absorption tests are performed only occasionally when the underlying cause of the B_{12} deficiency is not

obvious. They cannot be performed in the UK as radioactive B_{12} is not available. However, the principle of the absorption test is useful.

Schilling test. Radioactive B_{12} is given orally followed by an i.m. injection of non-radioactive B_{12} to saturate B_{12} binding proteins and to flush out ^{58}Co-B_{12}. The urine is collected for 24 hours and > 10% of the oral dose would be excreted in a normal person. If this is abnormal, the test is repeated with the addition of oral intrinsic factor capsules. If the excretion is now normal, the diagnosis is pernicious anaemia or gastrectomy. If the excretion is still abnormal, the lesion must be in the terminal ileum or there may be bacterial overgrowth. The latter could be confirmed by repeating the test after a course of antibiotics.

Gastrointestinal investigations

In PA there is achlorhydria. Intubation studies can be performed to confirm this but are rarely carried out in routine practice. Endoscopy or barium meal examination of the stomach is performed only if gastric symptoms are present.

Differential diagnosis

Vitamin B_{12} deficiency must be differentiated from other causes of megaloblastic anaemia, principally folate deficiency, but usually this is quite clear from the blood level of these two vitamins.

Pernicious anaemia should be distinguished from other causes of vitamin B_{12} deficiency (see Table 8.5). Any disease involving the terminal ileum or bacterial overgrowth in the small bowel can produce vitamin B_{12} deficiency (see p. 304). Gastrectomy can lead, in the long term, to vitamin B_{12} deficiency. Vegans are strict vegetarians and eat no meat or animal products. A careful dietary history should be obtained.

Treatment

See page 434.

Folic acid

Folic acid monoglutamate is not itself present in nature but occurs as polyglutamates (extra glutamic acid residues).

Folates are present in food as polyglutamates in the reduced dihydrofolate or tetrahydrofolate (THF) forms (Fig. 8.14), with methyl (CH_3), formyl (CHO) or methylene (CH_2) groups attached to the pteridine part of the molecule. Polyglutamates are broken down to monoglutamates in the upper gastrointestinal tract, and during the absorptive process these are converted to methyl THF monoglutamate, which is the main form in the serum. The methylation of homocysteine to methionine requires both methylcobalamin and methyl THF as coenzymes. This reaction is the first step in which methyl THF entering cells from the plasma is converted into folate polyglutamates. Intracellular polyglutamates are the active forms of folate and act as coenzymes in the transfer

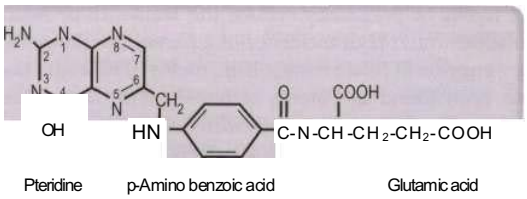

Fig. 8.14 **Folic acid structure.** This is formed from three building blocks as shown. Tetrahydrofolate has additional hydrogen atoms at positions 5, 6, 7 and 8.

of single carbon units in amino acid metabolism and DNA synthesis (see Fig. 8.12).

Dietary intake

Folate is found in green vegetables such as spinach and broccoli, and offal, such as liver and kidney. Cooking causes a loss of 60-90% of the folate. The minimal daily requirement is about 100 \ig.

Folate deficiency

The causes of folate deficiency are shown in Table 8.6. The main cause is poor intake, which may occur alone or in combination with excessive utilization or malabsorption. The body's reserves of folate, unlike vitamin B_{12}, are low (about 10 mg). On a deficient diet, folate deficiency develops over the course of about 4 months, but folate deficiency may develop rapidly in patients who have both a poor intake and excess utilization of folate (e.g. patients in intensive care units).

There is no simple relationship between maternal folate status and fetal abnormalities but folic acid supplements at the time of conception and in the first

Table 8.6 **Causes of folate deficiency**

Nutritional (major cause)
Poor intake
Old age
Poor social conditions
Starvation
Alcohol excess (also causes impaired utilization)

Poor intake due to anorexia
Gastrointestinal disease, e.g. partial gastrectomy, coeliac disease, Crohn's disease
Cancer

Antifolate drugs
Anticonvulsants:
phenytoin
primidone
Methotrexate
Pyrimethamine
Trimethoprim

Excess utilization
Physiological
Pregnancy
Lactation
Prematurity

Pathological
Haematological disease with excess red cell production, e.g. haemolysis
Malignant disease with increased cell turnover
Inflammatory disease
Metabolic disease, e.g. homocystinuria
Haemodialysis or peritoneal dialysis

Malabsorption
Occurs in small bowel disease, but the effect is minor compared with that of anorexia

12 weeks of pregnancy reduce the incidence of neural tube defects. A high incidence of a partial deficiency in a key enzyme in folate metabolism, methyl THF reductase, has been found in parents of fetuses with neural tube defects. The 5% of individuals with this abnormality have increased levels of homocysteine (Fig. 8.12), which may be the mechanism underlying the increased incidence of neural tube defects. Autoantibodies to the folate receptor have also been found in some women with a pregnancy complicated by a neural tube defect.

Clinical features

Patients with folate deficiency may be asymptomatic or present with symptoms of anaemia or of the underlying cause. Glossitis can occur. Unlike with B_{12} deficiency, neuropathy does not occur.

Investigations

The haematological findings are those of a megaloblastic anaemia as discussed on page 430.

Blood measurements

Serum and red cell folate are assayed by radioisotope dilution or immunological methods. Normal levels of serum folate are 4-18 ug/L (5-63 nmol/L). The amount of folate in the red cells is a better measure of tissue folate; the normal range is 160-640 |ig/mL.

Further investigations

In many cases of folate deficiency the cause is not obvious from the clinical picture or dietary history. Occult gastrointestinal disease should then be suspected and appropriate investigations, such as small bowel biopsy, should be performed (p. 300).

Treatment and prevention of megaloblastic anaemia

Treatment depends on the type of deficiency. **Blood** transfusion is not indicated in chronic anaemia; indeed, it is dangerous to transfuse elderly patients, as heart failure may be precipitated. Folic acid may produce a haematological response in vitamin B_{12} deficiency but may aggravate the neuropathy. Large doses of folic acid alone should not be used to treat megaloblastic anaemia unless the serum vitamin B_{12} level is known to be normal. In severely ill patients, it may be necessary to treat with both folic acid and vitamin B_{12} while awaiting serum levels.

Treatment of vitamin B_{12} deficiency

Hydroxocobalamin 1000 (ig can be given intramuscularly to a total of 5-6 mg over the course of 3 weeks; 1000 ug is then necessary every 3 months for the rest of the patient's life. Alternatively, it is now recommended that oral B_{12} 2 mg per day is given, as 1-2% of an oral dose is absorbed by diffusion and therefore does not require intrinsic factor. Compliance with an oral daily regimen may be a problem, particularly in elderly patients. The use of sublingual nuggets of B_{12} (2 x 1000 ug daily) has been suggested to be an effective and more convenient option.

Clinical improvement may occur within 48 hours and a reticulocytosis can be seen some 2-3 days after starting therapy, peaking at 5-7 days. Improvement of the polyneuropathy may occur over 6-12 months, but long-standing spinal cord damage is irreversible. Hypokalaemia can occur and, if severe, supplements should be given. Iron deficiency often develops in the first few weeks of therapy. Hyperuricaemia also occurs but clinical gout is uncommon. In patients who have had a total gastrectomy or an ileal resection, vitamin B_{12} should be monitored; if low levels occur, prophylactic vitamin B_{12} should be given.

Treatment of folate deficiency

Folate deficiency can be corrected by giving 5 mg of folic acid daily; the same haematological response occurs as seen after treatment of vitamin B_{12} deficiency. Treatment should be given for about 4 months to replace body stores. Any underlying cause, e.g. coeliac disease, should be treated.

Prophylactic folic acid (400 ug daily) is recommended for all women planning a pregnancy. Many authorities also recommend prophylactic administration of folate throughout pregnancy. Whether this can be achieved by increased consumption of foods with a high folate content or whether women should take folate supplements is under debate. The US Food and Drugs Administration has introduced a requirement for the fortification with folic acid of grain products such as bread, flour and rice (p. 247).

Women who have had a child with a neural tube defect should take 5 mg folic acid daily before and during a subsequent pregnancy.

Prophylactic folic acid is also given in chronic haematological disorders where there is rapid cell turnover. A dose of 5 mg each week is probably sufficient.

MACROCYTOSIS WITHOUT MEGALOBLASTIC CHANGES

A raised MCV with macrocytosis on the peripheral blood film can occur with a normoblastic rather than a megaloblastic bone marrow.

A common *physiological* cause of macrocytosis is pregnancy. Macrocytosis may also occur in the newborn.

Common *pathological* causes are:

- alcohol excess
- liver disease
- reticulocytosis
- hypothyroidism
- some haematological disorders (e.g. aplastic anaemia, sideroblastic anaemia, pure red cell aplasia)
- drugs (e.g. cytotoxics - azathioprine)
- spurious (agglutinated red cells measured on red cell counters)
- cold agglutinins due to autoagglutination of red cells (see p. 449) (the MCV decreases to normal with warming of the sample to 37°C).

In all these conditions, normal serum levels of vitamin B_{12} and folate will be found. The exact mechanisms in each case are uncertain, but in some there is increased lipid deposition in the red cell membrane.

An increased number of reticulocytes leads to a raised MCV because they are large cells.

Alcohol is a frequent cause of a raised MCV in an otherwise normal individual. A megaloblastic anaemia can also occur in people who abuse alcohol; this is due to a toxic effect of alcohol on erythropoiesis or to dietary folate deficiency.

ANAEMIA DUE TO MARROW FAILURE (APLASTIC ANAEMIA!

Aplastic anaemia is defined as pancytopenia with hypocellularity (aplasia) of the bone marrow; there are no leukaemic, cancerous or other abnormal cells in the peripheral blood or bone marrow. It is an uncommon but serious condition that may be inherited but is more commonly acquired.

Aplastic anaemia is due to a reduction in the number of pluripotential stem cells (see Fig. 8.1) together with a fault in those remaining or an immune reaction against them so that they are unable to repopulate the bone marrow. Failure of only one cell line may also occur, resulting in isolated deficiencies such as the absence of red cell precursors in pure red cell aplasia. Evolution to myelodysplasia, paroxysmal nocturnal haemoglobinuria (PNH) or acute myeloblastic leukaemia occurs in some cases, probably owing to the emergence of an abnormal clone of haemopoietic cells.

Causes

A list of causes of aplasia is given in Table 8.7. Immune mechanisms are probably responsible for most cases of idiopathic acquired aplastic anaemia and play a part in at least the persistence of many secondary cases. Activated cytotoxic T cells in blood and bone marrow are responsible for the bone marrow failure.

Many drugs may cause marrow aplasia, including cytotoxic drugs such as busulfan and doxorubicin, which are expected to cause transient aplasia as a consequence of their therapeutic use. However, some individuals develop aplasia due to sensitivity to non-cytotoxic drugs such as chloramphenicol, gold, carbimazole, chlorpromazine, phenytoin, tolbutamide, non-steroidal anti-inflammatory agents, and many others which have been reported to cause occasional cases of aplasia.

Table 8.7 **Causes of aplastic anaemia**

Primary
Congenital, e.g. Fanconi's anaemia
Idiopathic acquired (67% of cases)
Secondary
Chemicals, e.g. benzene
Drugs:
chemotherapeutic
idiosyncratic reactions
Insecticides Ionizing
radiation Infections:
viral, e.g. hepatitis, EBV, HIV, parvovirus
other, e.g. tuberculosis Paroxysmal
nocturnal haemoglobinuria
Miscellaneous, e.g. pregnancy

Congenital aplastic anaemias are rare. Gene mutations are being identified, e.g. the telomeraze RNA component, and have also been seen in one third of aplastic anaemias. Fanconi's anaemia is inherited as an autosomal recessive and is associated with skeletal, renal and central nervous system abnormalities. It usually presents between the ages of 5 and 10 years.

Clinical features

The clinical manifestations of marrow failure from any cause are anaemia, bleeding and infection. Bleeding is often the predominant initial presentation of aplastic anaemia with bruising with minimal trauma or blood blisters in the mouth. Physical findings include ecchymoses, bleeding gums and epistaxis. Mouth infections are common. Lymphadenopathy and hepatosplenomegaly are rare in aplastic anaemia.

Investigations

- pancytopenia
- the virtual absence of reticulocytes
- a hypocellular or aplastic bone marrow with increased fat spaces (Fig. 8.15). ■

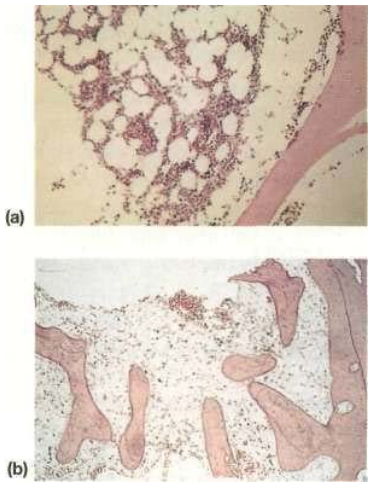
Differential diagnosis

This is from other causes of pancytopenia (Table 8.8). A bone marrow trephine is essential for assessment of the bone marrow cellularity.

Treatment and prognosis

The treatment of aplastic anaemia depends on providing supportive care while awaiting bone marrow recovery and specific treatment to accelerate marrow recovery.

The main danger is infection and stringent measures should be undertaken to avoid this (see also p. 495). Any suspicion of infection in a severely neutropenic patient



Fig, 8.15 **Bone marrow trephine biopsies in low-power view, (a)** Normal cellularity. (b) Hypocellularity in aplastic anaemia.

nocturnal haemoglobinuria Overwhelming
sepsis

should lead to immediate institution of broad-spectrum parenteral antibiotics. Supportive care including transfusions of red cells and platelets should be given as necessary. The cause of the aplastic anaemia must be eliminated if possible.

The course of aplastic anaemia can be variable, ranging from a rapid spontaneous remission to a persistent increasingly severe pancytopenia, which may lead to death through haemorrhage or infection. The most reliable determinants for the prognosis are the number of neutrophils, reticulocytes, platelets, and the cellularity of the bone marrow.

A bad prognosis (i.e. severe aplastic anaemia) is associated with the presence of two of the following three features:

- neutrophil count of $< 0.5 \times 10^9$/L
- platelet count of $< 20 \times 10^9$/L
- reticulocyte count of $< 40 \times 10^9$/L.

In severe aplastic anaemia, there is a very poor outcome without treatment. Bone marrow transplantation is the treatment of choice for patients under 40 years of age who have an HLA-identical sibling donor, which gives a 75-90% chance of long-term survival and restoring the blood count to normal. Patients over the age of 40 are not eligible for bone marrow transplantation whether an HLA-identical donor is available or not, because of the high risk of graft-versus-host disease as a complication of bone marrow transplantation. Immunosuppressive therapy is used for patients without HLA-matched siblings and those over the age of 40 years; antilymphocyte globulin (ALG) and ciclosporin in combination give a response rate of 60-80%.

For the patients under the age of 40 who fail to respond to immunosuppression, bone marrow transplantation using unrelated donors is an option, but the results are poor (5-year survival of only 30%) owing to a high incidence of graft rejection, graft-versus-host disease and viral infections.

Levels of haemopoietic growth factors (Fig. 8.1) are normal or increased in most patients with aplastic anaemia, and are ineffective as primary treatment.

Androgens (e.g. oxymethalone) are sometimes useful in patients not responding to immunosuppression and in patients with moderately severe aplastic anaemia.

Steroids have little activity in severe aplastic anaemia but are used for serum sickness due to ALG. They are also used to treat children with congenital pure red cell aplasia (Diamond-Blackfan syndrome). Adult pure red cell aplasia is associated with a thymoma in 30% of cases and thymectomy may induce a remission. It may also be associated with autoimmune disease or may be idiopathic. Steroids and ciclosporin are effective treatment in some cases.

HAEMOLYTIC ANAEMIAS: AN INTRODUCTION

Haemolytic anaemias are caused by increased destruction of red cells. The red cell normally survives about 120 days, but in haemolytic anaemias the red cell survival times are considerably shortened.

Breakdown of normal red cells occurs in the macrophages of the bone marrow, liver and spleen (see Fig. 8.5).

Consequences of haemolysis

Shortening of red cell survival does not always cause anaemia as there is a compensatory increase in red cell

production by the bone marrow. If the red cell loss can be contained within the marrow's capacity for increased output, then a haemolytic state can exist without anaemia *(compensated haemolytic disease).* The bone marrow can increase its output by six to eight times by increasing the proportion of cells committed to erythropoiesis *(erythroid hyperplasia)* and by expanding the volume of active marrow. In addition, immature red cells *(reticulocytes)* are released prematurely. These cells are larger than mature cells and stain light blue on a peripheral blood film (the description of this appearance on the blood film is *polychromasia).* Reticulocytes may be counted accurately as a percentage of all red cells on a blood film using a supra-vital stain for residual RNA (e.g. new methylene blue).

Sites of haemolysis

Extravascular haemolysis

In most haemolytic conditions red cell destruction is extravascular. The red cells are removed from the circulation by macrophages in the reticuloendothelial system, particularly the spleen.

Intravascular haemolysis

When red cells are rapidly destroyed within the circulation, haemoglobin is liberated (Fig. 8.16). This is initially bound to plasma haptoglobins but these soon become saturated.

Excess free plasma Hb is filtered by the renal glomerulus and enters the urine, although small amounts are reabsorbed by the renal tubules. In the renal tubular cell, Hb is broken down and becomes deposited in the cells as *haemosiderin.* This can be detected in the spun sediment of urine using Perls' reaction. Some of the free plasma Hb is oxidized to *methaemoglobin,* which dissociates into *ferrihaem* and globin. *Plasma haemopexin* binds ferrihaem; but if its binding capacity is exceeded, ferrihaem becomes attached to albumin, forming *methaemalbumin.* On spectrophotometry of the plasma, methaemalbumin forms a characteristic band; this is the basis of *Schumm's test.*

The *liver* removes Hb bound to haptoglobin and *haemopexin* and any remaining free Hb.

Evidence for haemolysis

Increased red cell breakdown leads to:

- elevated serum bilirubin (unconjugated)
- excess urinary urobilinogen (resulting from bilirubin breakdown in the intestine, Fig. 8.5)
- reduced plasma haptoglobin
- raised serum lactic dehydrogenase (LDH).

Increased red cell production leads to:

- reticulocytosis
- erythroid hyperplasia of the bone marrow.

There may be evidence of abnormal red cells in some haemolytic anaemias:

- spherocytes (see Fig. 8.18)
- sickle cells (see Fig. 8.23)
- red cell fragments.

Demonstration of shortened red cell lifespan

Red cell survival can be estimated from ^{51}Cr-labelled red cells given intravenously but is rarely performed.

Intravascular haemolysis

This is suggested by raised levels of plasma Hb, haemosiderinuria, very low or absent haptoglobins, and the presence of methaemalbumin (positive Schumm's test). Various laboratory studies will be necessary to determine the exact type of haemolytic anaemia present. The causes of haemolytic anaemias are shown in Table 8.9.

INHERITED HAEMOLYTIC ANAEMIA

RED CELL MEMBRANE DEFECTS

The normal red cell membrane consists of a lipid bilayer crossed by integral proteins with an underlying lattice of proteins (or cytoskeleton), including spectrin, actin, ankyrin and protein 4.1, attached to the integral proteins (Fig. *8.17).*

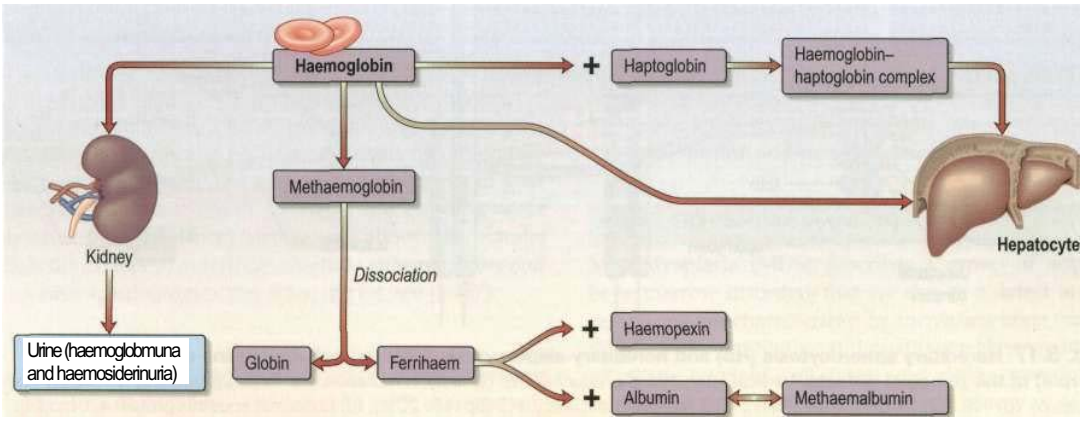

Fig. 8.16 The fate of haemoglobin in the plasma following haemolysis.

Hereditary spherocytosis (HS)

HS is the most common inherited haemolytic anaemia in northern Europeans, affecting 1 in 5000. It is inherited in an autosomal dominant manner, but in 25% of patients neither parent is affected and it is presumed that HS has occurred by spontaneous mutation. HS is due to defects in the red cell membrane, resulting in the cells losing part of the cell membrane as they pass through the spleen, possibly because the lipid bilayer is inadequately supported by the membrane skeleton. The best-characterized defect is a deficiency in the structural protein spectrin, but quantitative defects in other membrane proteins have been identified (Fig. 8.17), with ankyrin defects being the most common. The abnormal red cell membrane in HS is associated functionally with an increased permeability to sodium, and this requires an increased rate of active transport of sodium out of the cells which is dependent on ATP produced by glycolysis. The surface-to-volume ratio decreases, and the cells become spherocytic. Spherocytes are more rigid and less deformable than normal red cells. They are unable to pass through the splenic microcirculation and they die.

Clinical features

The condition may present with jaundice at birth. However, the onset of jaundice can be delayed for many years and some patients may go through life with no symptoms and are detected only during family studies. The patient may eventually develop anaemia, splenomegaly and ulcers on the leg. As in many haemolytic anaemias, the course of the disease may be interrupted by aplastic, haemolytic and megaloblastic crises. Aplastic anaemia usually occurs after infections, particularly with parvovirus, whereas megaloblastic anaemia is the result of folate depletion owing to the hyperactivity of the bone marrow. Chronic haemolysis leads to the formation of pigment gallstones (see p. 398).

Investigations

- **Anaemia.** This is usually mild, but occasionally can be severe.
- **Blood film.** This shows spherocytes (Fig. 8.18) and reticulocytes.
- **Haemolysis** is evident (e.g. the serum bilirubin and urinary urobilinogen will be raised).

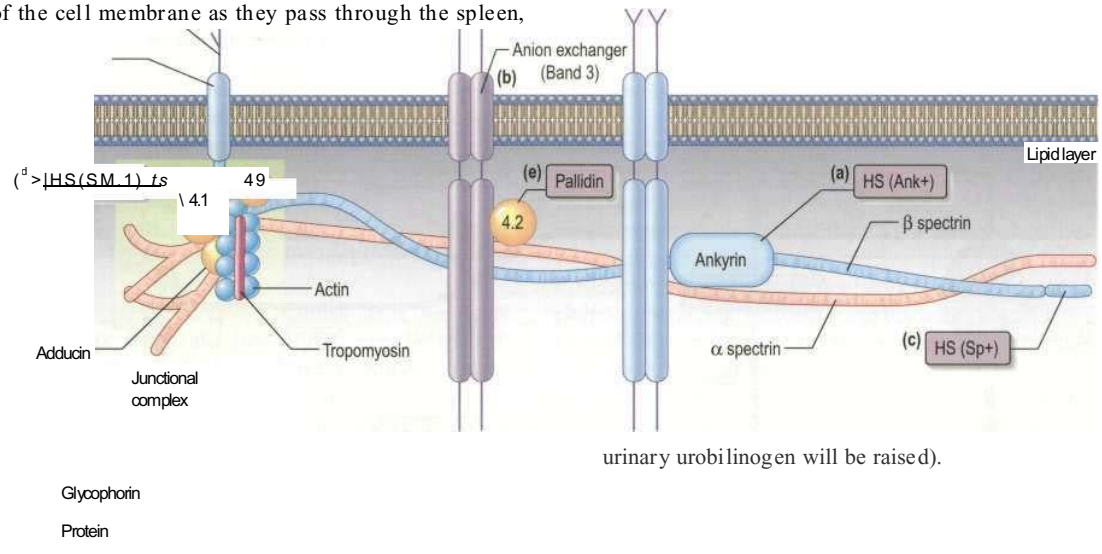

Fig. 8.17 **Hereditary spherocytosis (HS) and hereditary elliptocytosis (HE): red cell membrane showing the sites (purple) of the principal defects.** *Vertical interactions producing HS:* (a) ankyrin mutation, HS (Ank+) producing deficiency (45% of cases); (b) HS band 3 deficiency (20%); (c) p spectrin deficiency, HS (Sp+) (< 20%); (d) abnormal spectrin/protein 4.1 binding, HS (Sp-4.1); (e) protein 4.2 (pallidin) deficiency (Japanese). These produce various autosomal dominant and recessive forms of the disease. *Horizontal interactions producing HE: a* spectrin (80%), protein 4.1 (15%), p spectrin (5%).

Fig. 8.18 **Spherocytes (arrowed). This blood film also shows reticulocytes, polychromasias and a nucleated erythroblast.**

- **Osmotic fragility.** When red cells are placed in solutions of increasing hypotonicity, they take in water, swell, and eventually lyse. Spherocytes tolerate hypotonic solutions less well than do normal biconcave red cells. Osmotic fragility tests are infrequently carried out in routine practice, but may be useful to confirm a suspicion of spherocytosis on a blood film.
- **Direct antiglobulin (Coombs') test** is negative in spherocytosis, virtually ruling out autoimmune haemolytic anaemia where spherocytes are also commonly present.

Treatment

The spleen, which is the site of cell destruction, should be removed in all but the mildest cases. The decision about splenectomy in symptomless patients is difficult, but a raised bilirubin and especially the presence of gallstones should encourage splenectomy.

It is best to postpone splenectomy until after childhood, as sudden overwhelming fatal infections, usually due to encapsulated organisms such as pneumococci, may occur (see p. 457). Splenectomy should be preceded by appropriate immunization and followed by lifelong penicillin prophylaxis (see Box 2.9).

Following splenectomy, the spherocytes persist but the Hb level usually returns to normal as the red cells are no longer destroyed.

Folate deficiency often occurs in chronic haemolysis with rapid cell turnover. Folate levels should be monitored, or folic acid can be given prophylactically.

Hereditary elliptocytosis

This disorder of the red cell membrane is inherited in an autosomal dominant manner and has a prevalence of 1 in 2500 in Caucasians. The red cells are **elliptical** due to deficiencies of protein 4.1 or the spectrin/actin/4.1 complex which leads to weakness of the horizontal protein interaction and to the membrane defect (Fig. 8.17). Clinically it is a similar condition to HS but milder. Only a minority of patients have anaemia and only occasional patients require splenectomy.

Rarely, hereditary spherocytosis or elliptocytosis may be inherited in a homozygous fashion giving rise to a severe haemolytic anaemia sometimes necessitating splenectomy in early childhood.

Hereditary stomatocytosis

Stomatocytes are red cells in which the pale central area appears slit-like. Their presence in large numbers may occur in a hereditary haemolytic anaemia associated with a membrane defect, but excess alcohol intake is also a common cause.

HAEMOGLOBIN ABNORMALITIES

In early embryonic life, haemoglobins Gower 1, Gower 2 and Portland predominate (Fig. 8.19). Later, fetal haemoglobin (Hb F), which has two **a** and two *y* chains, is produced. There is increasing synthesis of (3 chains from 13 weeks of gestation and at term there is 80% Hb F and 20% Hb A. The switch from Hb F to Hb A occurs after birth when the genes for *y* chain production are further suppressed and there is rapid increase in the synthesis of P chains. The exact mechanism responsible for the switch remains unknown. There is little Hb F produced (normally less than 1%) from 6 months after birth. The 5 chain is synthesized just before birth and Hb A_2 (oc_28_2) remains at a level of about 2% throughout adult life (Table 8.10).

Globin chains are synthesized in the same way as any protein (see Ch. 3). Four globin chain genes are required to control oc-chain production (Fig. 8.19). Two are present on each haploid genome (genes derived from one parent). These are situated close together on chromosome 16. The genes controlling the production of e, *y,* 8 and fS chains are close together on chromosome 11. The globin genes are arranged on chromosomes 16 and 11 in the order in which they are expressed and combine to give different haemo globins. Normal haemoglobin synthesis is discussed on page 422.

Abnormal haemoglobins

Abnormalities occur in:

- globin chain production (e.g. thalassaemia)
- structure of the globin chain (e.g. sickle cell disease)
- combined defects of globin chain production and structure, e.g. sickle cell P-thalassaemia.

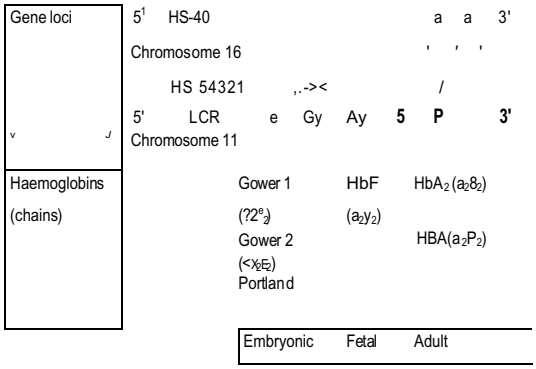

Fig. 8.19 **Loci of genes on chromosomes 16 and 11 and the combination of various chains to produce different haemoglobins.** HS-40 (for a genes) and locus control region (LCR) HS1-5 (for p genes) are regulatory control elements.

Table 8.10 **Some types of haemoglobin**

	Haemoglobin	Structure	Comment
Normal	A	02ft.	Comprises 97% of adult haemoglobin
	A_2		Comprises 2% of adult haemoglobin
			Elevated in p-thalassaemia
		OI2Y2	Normal haemoglobin in fetus from 3rd to 9th month
			Increased in p-thalassaemia
Abnormal chain production			Comprises < 1 % of haemoglobin in adult
H			Found in a-thalassaemia
			Biologically useless
	Bails	Y4	Comprises 100% of haemoglobin in homozygous a-thalassaemia Biologically useless Substitution of valine for glutamine acid in position 6 of
Abnormal chain structure	S		p chain Substitution of lysine for glutamic acid in position 6 of
		a,B,[c]	**p** chain

Genetic defects in haemoglobin are the most common of all genetic disorders.

THE THALASSAEMIAS

The thalassaemias (Greek *thalassa* = sea) affect people throughout the world (Fig. 8.20). Normally there is balanced (1:1) production of a and p chains. The defective synthesis of globin genes in thalassaemia leads to 'unbalanced' globin chain production, leading to precipitation of globin chains within the red cell precursors and resulting in ineffective erythropoiesis. Precipitation of globin chains in mature red cells leads to haemolysis.

p-Thalassaemia

In *homozygous* P-thalassaemia, either no normal P chains are produced ((3°), or (3-chain production is very reduced (P^+). There is an excess of a chains, which precipitate in erythroblasts and red cells causing ineffective erythropoiesis and haemolysis. The excess *a* chains combine with whatever (5, 5 and *y* chains are produced, resulting in increased quantities of Hb A_2 and Hb F and, at best, small amounts of Hb A. In *heterozygous* p-thalassaemia there is usually symptomless microcytosis with or without mild anaemia. Table 8.11 shows the findings in the homozygote and heterozygote for the common types of (3-thalassaemia.

Molecular genetics

The molecular errors accounting for over 200 genetic defects leading to P-thalassaemia have been characterized. Unlike in a-thalassaemia, the defects are mainly point mutations rather than gene deletions. The mutations result in defects in transcription, RNA splicing and modification, translation via frame shifts and nonsense codons producing highly unstable P-globin which cannot be utilized.

Clinical syndromes

Clinically, p-thalassaemia can be divided into the following:

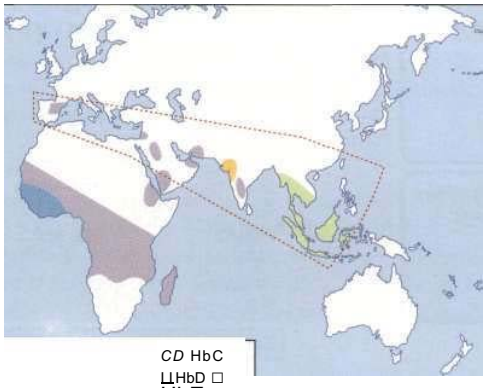

Fig. 8.20 **Major haemoglobin abnormalities: geographical distribution.**

Table 8.11 **(i-Thalassaemia: common findings**

Type of thalassaemia	Findings in homozygote	Findings in heterozygote
P^+	Thalassaemia major	Thalassaemia minor
	Hb A + F + A_2	Hb A_2 raised
P°	Thalassaemia major Hb F + A_2	Thalassaemia minor Hb A_2 raised
5p	Thalassaemia intermedia	Thalassaemia minor HbF5-15%
	Hb F only	Hb A_2 normal
5p⁺ (Lepore)	Thalassaemia major	Thalassaemia minor
	or intermedia	Hb Lepore 5-15%
	Hb F and Lepore	Hb A_2 normal

Hb Lepore is a cross fusion product of 8 and p globin genes Adapted with permission from Weatherall DJ (2003) Disorders of the synthesis of function of haemoglobin. In: Weatherall DJ, Warrell DA, Cox TM, Firth JD (eds) *Oxford Textbook of Medicine,* 4th edn. Oxford: Oxford University Press.

- thalassaemia minor (or trait), the symptomless heterozygous carrier state
- thalassaemia intermedia, with moderate anaemia, rarely requiring transfusions
- thalassaemia major, with severe anaemia requiring regular transfusions.

Thalassaemia minor (trait)

This common carrier state (heterozygous (3-thalassaemia) is asymptomatic. Anaemia is mild or absent. The red cells are hypochromic and microcytic with a low MCV and MCH, and it may be confused with iron deficiency. However, the two are easily distinguished, as in thalassaemia trait the serum ferritin and the iron stores are normal (see Table 8.3). Hb electrophoresis usually shows a raised Hb A_2 and often a raised Hb F (Fig. 8.21). Iron should not be given to these patients unless they develop coincidental iron deficiency.

Thalassaemia intermedia

Thalassaemia intermedia includes patients who are symptomatic with moderate anaemia (Hb 7-10 g/dL) and who do not require regular transfusions. That is, it is more severe than in fS-thalassaemia trait but milder than in transfusion-dependent thalassaemia major.

Thalassaemia intermedia may be due to a combination of homozygous mild p^+- and oc-thalassaemia, where there is reduced cc-chain precipitation and less ineffective erythropoiesis and haemolysis. The inheritance of hereditary persistence of Hb F with homozygous P-thalassaemia also results in a milder clinical picture than unmodified P-thalassaemia major because the excess a chains are partially removed by the increased production of *y* chains.

Patients may have splenomegaly and bone deformities. Recurrent leg ulcers, gallstones and infections are also seen.

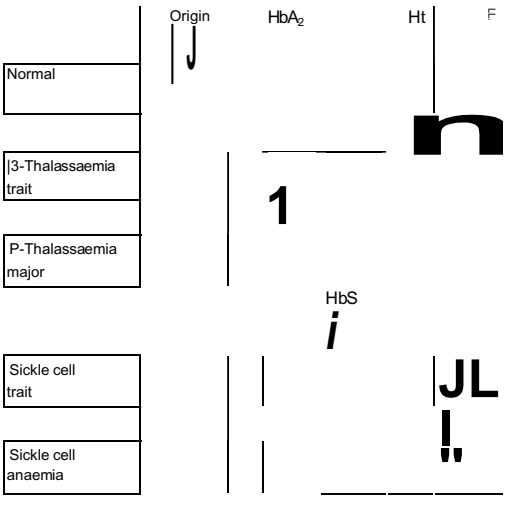

Fig. 8.21 Patterns of haemoglobin electrophoresis.

Thalassaemia major (Cooley's anaemia)

Most children affected by homozygous P-thalassaemia present during the first year of life with:

- failure to thrive and recurrent bacterial infections
- severe anaemia from 3-6 months when the switch from y- to (3-chain production should normally occur
- extramedullary haemopoiesis that soon leads to hepatosplenomegaly and bone expansion, giving rise to the classical thalassaemic facies (Fig. 8.22a).

Skull X-rays in these children show the characteristic 'hair on end' appearance of bony trabeculation as a result of expansion of the bone marrow into cortical bone (Fig. 8.22b). The expansion of the bone marrow is also shown in an X-ray of the hand (Fig. 8.22c).

The classic features of untreated thalassaemia major are only observed in patients from countries without good blood transfusion support.

Management

The aims of treatment are to suppress ineffective erythropoiesis, prevent bony deformities and allow normal activity and development. Long-term folic acid supplements are required, and regular transfusions should be given to keep the Hb above 10 g/dL. Blood transfusions may be required every 4-6 weeks.

If transfusion requirements increase, splenectomy should be considered, although this is usually delayed until after the age of 6 years because of the risk of infection. Prophylaxis against infection is required for patients undergoing splenectomy (see p. 457).

Iron overload caused by repeated transfusions (transfusion haemosiderosis) may lead to damage to the endocrine glands, liver, pancreas and the myocardium by the time patients reach adolescence. The iron-chelating agent of choice remains desferrioxamine, although it has to be administered parenterally. The oral iron-chelating agent ICL670 appears to be safe and effective but long-term studies are awaited. Desferrioxamine is given as an overnight subcutaneous infusion on 5-7 nights each week. Ascorbic acid 200 mg daily is given, along with desferrioxamine, as it increases the urinary excretion of iron in response to desferrioxamine.

With current therapy, normal growth and sexual development occur but compliance may be a problem, especially in teenagers. Intensive treatment with desferrioxamine has been reported to reverse damage to the heart in patients with severe iron overload, but excessive doses of desferrioxamine may cause cataracts, retinal damage and nerve deafness. Infection with *Yersinia enterocolitica* occurs in iron-loaded patients treated with desferrioxamine. Iron overload should be periodically assessed by measuring the serum ferritin and by measurement of hepatic iron stores.

Bone marrow transplantation has been used in young patients with HLA-matched siblings. It has been successful in cases in good clinical condition with a 3-year mortality of less than 5%, but there is a high mortality (> 50%) in patients in poor condition with iron overload and liver dysfunction.

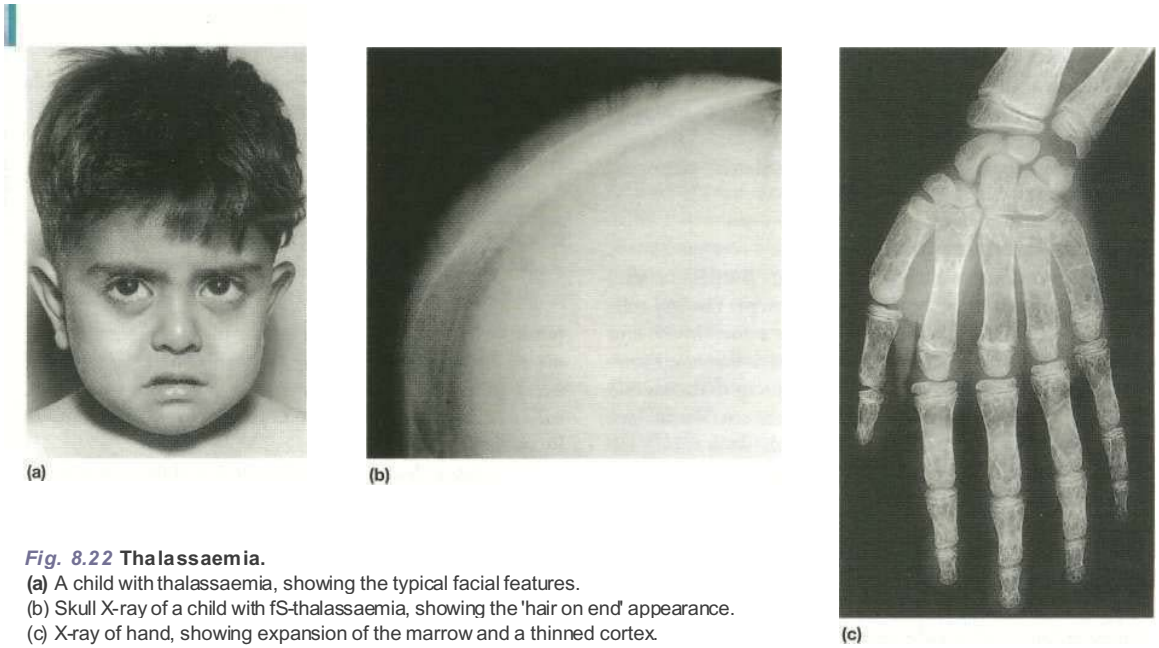

Fig. 8.22 **Thalassaemia.**
(a) A child with thalassaemia, showing the typical facial features.
(b) Skull X-ray of a child with fS-thalassaemia, showing the 'hair on end' appearance.
(c) X-ray of hand, showing expansion of the marrow and a thinned cortex.

Prenatal diagnosis and gene therapy are discussed on page 191.

a-Thalassaemia

Molecular genetics

In contrast to p-thalassaemia, oc-thalassaemia is often caused by gene deletions, although mutations also occur. The gene for a chains is duplicated on both chromosomes 16, i.e. there are four genes. Deletion of one a-chain gene (oe^+) or both a-chain genes (a^0) on each chromosome 16 may occur (Table 8.12). The former is the most common of these abnormalities.

- Four-gene deletion (deletion of both genes on both chromosomes); there is no a-chain synthesis and only Hb Barts (y_4) is present. Hb Barts cannot carry oxygen and is incompatible with life (Tables 8.10 and 8.12). Infants are either stillborn at 28^10 weeks or die very shortly after birth. They are pale, oedematous and have enormous livers and spleens - a condition called hydrops fetalis.
- Three-gene deletion; there is moderate anaemia (Hb 7-10 g/dL) and splenomegaly (Hb H disease). The patients are not usually transfusion-dependent. Hb A, Hb Barts and Hb H (fS_4) are present. Hb A_2 is normal or reduced.
- Two-gene deletion (a-thalassaemia trait); there is microcytosis with or without mild anaemia. Hb H bodies may be seen on staining a blood film with brilliant cresyl blue.
- One-gene deletion; the blood picture is usually normal.

Globin chain synthesis studies for the detection of a reduced ratio of a to P chains may be necessary for the definitive diagnosis of a-thalassaemia trait.

Less commonly, a-thalassaemia may result from genetic defects other than deletions, for example mutations in the stop codon producing an a chain with many extra amino acids (Hb Constant Spring). (See p. 177.)

Table 8.12 **The a-thalassaemias**

Gene deletion	Haemoglobin	Clinical picture type
4 genes a^0	--/-- Hb Barts (y4)	Hydrops fetalis
3 genes a^0	- -/- a Hb H **(04)**	Moderate anaemia Splenomegaly
2 genes a^0	- -7a a Some Hb H or *-oJ-a*	Mild anaemia bodies Hb A a-Thalassaemia trait
1 gene a^+	- a/a a 'Normal'	a-Thalassaemia trait

SICKLE SYNDROMES

Sickle cell haemoglobin (Hb S) results from a single-base mutation of adenine to thymine which produces a substitution of valine for glutamine at the sixth codon of the P-globin chain ($a_2p2^{6glu\wedge val}$). In the homozygous state *(sickle cell anaemia)* both genes are abnormal (Hb SS), whereas in the heterozygous state *(sickle cell trait,* Hb AS) only one chromosome carries the gene. As the synthesis of Hb F is normal, the disease usually does not manifest itself until the Hb F decreases to adult levels at about 6 months of age.

The disease occurs mainly in Africans (25% carry the gene) but is also found in India, the Middle East and southern Europe (see Fig. 8.20).

Pathogenesis

Deoxygenated Hb S molecules are insoluble and polymerize. The flexibility of the cells is decreased and they become rigid and take up their characteristic sickle appearance. This process is initially reversible but, with repeated sickling, the cells eventually lose their membrane flexibility and become irreversibly sickled. This is due to dehydration, partly caused by potassium leaving the red cells via calcium activated potassium channels called the Gados channel. These irreversibly sickled cells are dehydrated and dense and will not return to normal when oxygenated. Sickling can produce:

- a shortened red cell survival
- impaired passage of cells through the microcirculation, leading to obstruction of small vessels and tissue infarction.

Sickling is precipitated by infection, dehydration, cold, acidosis or hypoxia. In many cases the cause is unknown, but adhesion proteins on activated endothelial cells (VCAM-1) may play a causal role, particularly in vaso-occlusion when rigid cells are trapped, facilitating polymerization. Hb S releases its oxygen to the tissues more easily than does normal Hb (see Fig. 15.5), and patients therefore feel well despite being anaemic (except of course during crises or complications).

Depending on the type of haemoglobin chain combinations, three clinical syndromes occur:

- homozygous Hb SS have the most severe disease
- combined heterozygocity (Hb SC) for Hb S and C (see below) who suffer intermediate symptoms.
- heterozygous Hb AS (sickle cell trait) usually have no symptoms (see p. 445).

Sickle cell anaemia

Clinical features

Vaso-occlusive crises

The earliest presentation in the first few years of life is acute pain in the hands and feet (dactylitis) owing to vaso-occlusion of the small vessels. Severe pain in other bones, e.g. femur, humerus, vertebrae, ribs, pelvis, occurs in older children/adults. These attacks vary in frequency from daily to perhaps only once a year. Fever often accompanies the pain.

Anaemia

Chronic haemolysis produces a stable haemoglobin level, usually in the 6-8 g/dL range but an acute fall in the haemoglobin level can occur owing to:

- splenic sequestration
- bone marrow aplasia
- further haemolysis.

Splenic sequestration

Vaso-occlusion produces an acute painful enlargement of the spleen. There is splenic pooling of red cells and hypovolaemia, leading in some to circulatory collapse and death. The condition occurs in childhood before multiple infarctions have occured. The latter eventually leads to a fibrotic non-functioning spleen. Liver sequestration can also occur.

Bone marrow aplasia

This most commonly occurs following infection with parvovirus B_{19}, which invades proliferating erythroid progenitors. There is a rapid fall in haemoglobin with no reticulocytes in the peripheral blood, because of the failure of erythropoiesis in the marrow.

Haemolysis due to drugs, acute infection or associated G6PD deficiency also occurs. Anaemia can also result from folate deficiency.

Long-term problems

In adults, nearly every organ is involved eventually, as patients survive longer with better treatment.

Growth and development. Young children are short but regain their height by adulthood. However, they remain below the normal weight. There is often delayed sexual maturation which may require hormone therapy. (Splenectomy can also reverse this.)

Bones are a common site for vaso-occlusive episodes, leading to chronic infarcts. Avascular necrosis of hips, shoulders, compression of vertebrae and shortening of bones in the hands and feet occur. Pain is a major problem. Osteomyelitis is commoner in sickle cell disease and is caused by *Salmonella, Staphylococcus aureus* and *Staph. pneumoniae.* Antibiotic treatment is necessary (p. 573). Joint replacements therapy may be required.

Infections are common in tissues susceptible to vaso-occlusion, e.g. bones, lungs, kidneys.

Respiratory. The acute sickle chest syndrome occurs in up to 30%, and pulmonary hypertension and chronic lung disease are the commonest cause of death of adults with sickle cell disease. The acute chest syndrome is caused by infection, fat embolism from necrotic bone marrow or pulmonary infarction due to sequestration of sickle cells. It comprises shortness of breath, chest pain, hypoxia, and new chest X-ray changes due to consolidation. The presentation may be gradual or very rapid, leading to death in a few hours. Initial management is with pain relief, inspired oxygen, antibiotics and exchange transfusion to reduce the amount of Hb S to < 20%; occasionally ventilation may be necessary. Infections can be due to chlamydia and mycoplasma, as well as *Streptococcus pneumoniae.*

Leg ulcers occur spontaneously (vaso-occlusive episodes) or following trauma and are usually over the medial or lateral malleoli. They often become infected and are quite resistant to treatment.

Cardiac problems occur, with cardiomegaly, arrhythmias and iron overload cardiomyopathy. Myocardial infarctions occur due to thrombotic episodes which are not secondary to atheroma.

Neurological complications occur in 25% of patients, with transient ischaemic attacks, fits, cerebral infarction, cerebral haemorrhage and coma. Ischaemic strokes occur in children and it has been suggested that regular transcranial Doppler ultrasonography is performed annually and patients are transfused in order to avoid brain damage.

Cholelithiasis. Pigment stones occur as a result of chronic haemolysis.

Liver. Chronic hepatomegaly and liver dysfunction are caused by trapping of sickle cells.

Renal. Chronic tubulo-intestitial nephritis occurs (see p.643).

Priapism. An unwanted painful erection occurs from vaso-occlusion and can be recurrent. This may result in impotence. Treatment is with an a-adrenergic blocking drug, analgesia and hydration.

Eye. Background retinopathy, proliferative retinopathy, vitreous haemorrhages and retinal detachments all occur. Regular yearly eye checks are required.

Pregnancy. Impaired placental blood flow causes spontaneous abortion, intrauterine growth retardation, pre-eclampsia and fetal death. Painful episodes, infections and severe anaemia occur in the mother. Prophylactic transfusion does not improve fetal outcome. Oral contraceptives with low-dose oestrogens are safe.

Investigations

- **Blood count.** The level of Hb is in the range 6-8 g/dL with a high reticulocyte count (10-20%).
- **Blood films** can show features of hyposplenism (see Fig. 8.28).
- **Sickling** of red cells on a blood film can be induced in the presence of sodium metabisulphite (see Fig. 8.23).
- **Sickle solubility test.** A mixture of Hb S in a reducing solution such as sodium dithionite gives a turbid appearance because of precipitation of Hb S, whereas normal Hb gives a clear solution. A number of commercial kits such as Sickledex are available for rapid screening for the presence of Hb S, for example before surgery in appropriate ethnic groups and in the A&E department.
- **Hb electrophoresis** (see Fig. 8.21) is always needed to confirm the diagnosis. There is no Hb A, 80-95% **Hb** SS, and 2-20%Hb F.
- **The parents** of the affected child will show features of sickle cell trait.

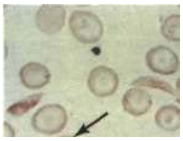

Fig. 8.23 **Sickle cells (arrowed) and target cells.**

Management

Precipitating factors (see above) should be avoided or treated quickly. The complications requiring inpatient management are shown in Table 8.13.

Acute painful attacks require supportive therapy with intravenous fluids, oxygen, antibiotics and adequate analgesia. Crises can be extremely painful and require strong, usually narcotic, analgesia. Morphine is the drug of choice. Milder pain can sometimes be relieved by codeine, paracetamol and NSAIDs.

Prophylaxis is with penicillin 500 mg daily and vaccination with polyvalent pneumococcal and *Haemophilus influenzae* type B vaccine (see p. 42). Folic acid is given to all patients with haemolysis.

Anaemia

Transfusions should only be given for clear indications. Patient with steady state anaemia, those having minor surgery or having painful episodes without complications should not be transfused. Transfusions should be given for heart failure, TIAs, strokes, acute chest syndrome, acute splenic sequestration and aplastic crises. Before elective operations and during pregnancy, repeated transfusions may be used to reduce the proportion of circulating Hb S to less than 20% to prevent sickling. Exchange transfusions may be necessary in patients with severe or recurrent crises, or before emergency surgery. Transfusion and splenectomy may be life-saving for young children with splenic sequestration. A full compatibility screen should always be performed.

Hydroxycarbamide (hydroxyurea) is the first drug which has been widely used as therapy for sickle cell anaemia. It acts by increasing Hb F concentrations but the reduction in neutrophils may also help. Hydroxycarbamide has been shown in trials to reduce the episodes of pain, the acute chest syndrome, and the need for blood transfusions.

Table 8.13 **Complications requiring inpatient management**

Pain uncontrolled by non-opiate analgesia
Swollen painful joints
Central nervous system deficit
Acute sickle chest syndrome or pneumonia
Mesenteric sickling and bowel ischaemia
Splenic or hepatic sequestration
Cholecystitis
Renal papillary necrosis resulting in colic or severe haematuria Hyphema and retinal detachment

From Davies SC, Oni L (1997) Management of patients with sickle cell disease. *British Medical Journal* 315: 656-660.

Inhaled nitric oxide inhibits platelet function, reduces vascular adhesion of red cells and is also a vasodilator. It has been shown to reduce opiate requirements in acute painful episodes.

Bone marrow transplantation has been used to treat sickle cell anaemia although in fewer numbers than for thalassaemia. Children and adolescents younger than 16 years of age who have severe complications (strokes, recurrent chest syndrome, or refractory pain) and have an HLA-matched donor are the best candidates for transplantation.

Counselling

A multidisciplinary team should be involved, with regular clinic appointments to build up relationships. Adolescents require careful counselling over psychosocial issues, drug and birth control.

Prognosis

Some patients with Hb SS die in the first few years of life from either infection or episodes of sequestration. However, there is marked individual variation in the severity of the disease and some patients have a relatively normal lifespan with few complications.

Sickle cell trait

These individuals have no symptoms unless extreme circumstances cause anoxia, such as flying in non-pressurized aircraft or problems with anaesthesia. Sickle cell trait protects against *Plasmodium falciparum* malaria (see p. 97), and consequently the sickle gene has been seen as an example of a balanced polymorphism (where the advantage of the malaria protection in the heterozygote is balanced by the mortality of the homozygous condition). Typically there is 60% Hb A and 40% Hb S. The blood count and film are normal. The diagnosis is made by a positive sickle test or by Hb electrophoresis (see Fig. 8.21).

Other structural globin chain defects

There are many Hb variants (e.g. Hb C, D), many of which are not associated with clinical manifestations.

Hb C ($a_2f5_2^{6Glu\to lys}$) disease may be associated with Hb S (Hb SC disease). The clinical course is similar to that with Hb SS, but there is an increased likelihood of thrombosis, which may lead to life-threatening episodes of thrombosis in pregnancy, and retinopathy.

Combined defects of globin chain production and structure

Abnormalities of Hb structure (e.g. Hb S, C) can occur in combination with thalassaemia. The combination of P-thalassaemia trait and sickle cell trait (sickle cell P-thalassaemia) resembles sickle cell anaemia (Hb SS) clinically.

Hb E ($a_2p_2^{26Glu\to lys}$) is the most common Hb variant in South East Asia, and the second most prevalent haemoglobin variant world-wide. Hb E heterozygotes are asymptomatic; the haemoglobin level is normal, but red cells are microcytic. Homozygous Hb E causes a mild microcytic anaemia, but the combination of heterozygosity for Hb E and (3-thalassaemia produces a variable anaemia which can be as severe as P-thalassaemia major.

Prenatal screening and diagnosis of severe haemoglobin abnormalities

Of the offspring of parents who both have either P-thalassaemia or sickle cell trait, 25% will have P-thalassaemia major or sickle cell anaemia, respectively. Recognition of these heterozygous states in parents and family counselling provide a basis for antenatal screening and diagnosis.

Prognosis

Pregnant women with either sickle cell trait or thalassaemia trait must be identified at antenatal booking either by selective screening of high-risk groups on the basis of ethnic origin or by universal screening of all pregnant women. p-Thalassaemia trait can always be detected by a low MCV and MCH and confirmed by haemoglobin electrophoresis. However, sickle cell trait is undetectable from a blood count and the laboratory need a specific request to screen for sickle cell trait.

If a pregnant woman is found to have a haemoglobin defect, her partner should be tested. Antenatal diagnosis is offered if both are affected as there is a risk of a severe fetal Hb defect, particularly P-thalassaemia major. Fetal DNA analysis can be carried out using amniotic fluid, chorionic villus or fetal blood samples. Abortion is offered if the fetus is found to be affected. Chorionic villus biopsy has the advantage that it can be carried out in the first trimester, thus avoiding the need for second trimester abortions.

Gene therapy would be the ultimate corrective therapy for severe Hb abnormalities. Normal Hb genes could be inserted into the patient's haemopoietic cells in vitro and these cells could be transplanted back into the patient after ablative bone marrow treatment.

METABOLIC DISORDERS OF THE RED CELL

Red cell metabolism

The mature red cell has no nucleus, mitochondria or ribosomes and is therefore unable to synthesize proteins. Red cells have only limited enzyme systems but they maintain the viability and function of the cells. In particular, energy is required in the form of ATP for the maintenance of the flexibility of the membrane and the biconcave shape of the cells to allow passage through small vessels, and for regulation of the sodium and potassium pumps to ensure osmotic equilibrium. In addition, it is essential that Hb be maintained in the reduced state.

The enzyme systems responsible for producing energy and reducing power are (Fig. 8.24):

- the glycolytic (Embden-Meyerhof) pathway, in which glucose is metabolized to pyruvate and lactic acid with production of ATP

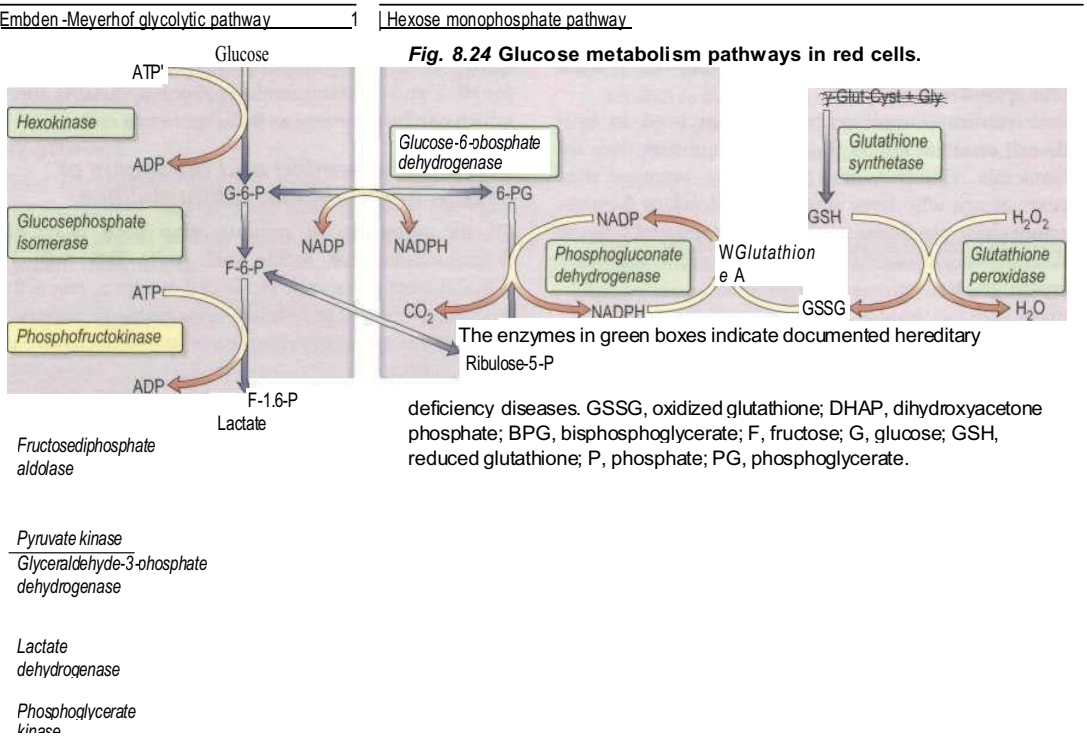

Fig. 8.24 **Glucose metabolism pathways in red cells.**

deficiency diseases. GSSG, oxidized glutathione; DHAP, dihydroxyacetone phosphate; BPG, bisphosphoglycerate; F, fructose; G, glucose; GSH, reduced glutathione; P, phosphate; PG, phosphoglycerate.

- the hexose monophosphate (pentosephosphate) path way, which provides reducing power for the red cell in the form of NADPH.

About 90% of glucose is metabolized by the former and 10% by the latter. The hexose monophosphate shunt maintains glutathione (GSH) in a reduced state. Glutathione is necessary to combat oxidative stress to the red cell, and failure of this mechanism may result in:

- rigidity due to cross-linking of spectrin, which decreases membrane flexibility (see Fig. 8.17) and causes 'leakiness' of the red cell membrane
- oxidation of the Hb molecule, producing methaemoglobin and precipitation of globin chains as Heinz bodies localized on the inside of the membrane; these bodies are removed from circulating red cells by the spleen.

2,3-BPG is formed from a side-arm of the glycolytic pathway (see Fig. 8.24). It binds to the central part of the Hb tetramer, fixing it in the low-affinity state (see Fig. 8.4). A decreased affinity with a shift in the oxygen dissociation curve to the right enables more oxygen to be delivered to the tissues (see Fig. 15.5).

In addition to the G6PD and pyruvate kinase deficiencies described below, there are a number of rare enzyme deficiencies that need specialist investigation.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency

The enzyme G6PD holds a vital position in the hexose monophosphate shunt (Fig. 8.24), oxidizing glucose-6-phosphate to 6-phosphoglycerate with the reduction of NADP to NADPH. The reaction is necessary in red cells

where it is the only source of NADPH, which is used via glutathione to protect the red cell from oxidative damage. G6PD deficiency is a common condition that presents with a haemolytic anaemia and affects millions of people throughout the world, particularly in Africa, around the Mediterranean, the Middle East (around 20%) and South East Asia (up to 40% in some regions).

The gene for G6PD is localized to chromosome Xq28 near the factor VIII gene. The deficiency is more common in males than in females. However, female heterozygotes can also have clinical problems due to lyonization, whereby because of random X-chromosome inactivation female heterozygotes have two populations of red cells - a normal one and a G6PD-deficient one.

There are over 400 structural types of G6PD, and mutations are mostly single amino acid substitutions. The most common types with normal activity are called type B^+, which is present in almost all Caucasians and about 70% of black Africans, and type A^+, which is present in about 20% of black Africans. There are many variants with reduced activity but only two are common. In the African, or A~ type, the degree of deficiency is mild and more marked in older cells. Haemolysis is self-limiting as the young red cells newly produced by the bone marrow have nearly normal enzyme activity. However, in the Mediterranean type, both young and old red cells have very low enzyme activity. After an oxidant shock the Hb level may fall precipitously; death may follow unless the condition is recognized and the patient is transfused urgently.

Clinical syndromes

- Acute drug-induced haemolysis (Table 8.14) - usually dose related
- Favism (ingestion of fava beans)
- Chronic haemolytic anaemia
- Neonatal jaundice
- Infections and acute illnesses will also precipitate haemolysis in patients with G6PD deficiency.

Mothballs containing naphthalene can also cause haemolysis.

Table 8.14 **Drugs causing haemolysis in glucose-6-phosphate deficiency**

Analgesics, such as:
Aspirin
Phenacetin (withdrawn in the UK)

Antimalarials, such as:
Primaquine
Pyrimethamine
Quinine
Chloroquine
Pamaquin

Antibacterials, such as:
Most sulphonamides
Dapsone
Nitrofurantoin
Chloramphenicol
Quinolones

Miscellaneous drugs, such as:
Vitamin K
Probenecid
Nalidixic acid
Quinidine
Dimercaprol
Phenylhydrazine

Fig. 8.25 **'Blister' cells (arrowed) in G6PD deficiency.**

The clinical features are due to rapid intravascular haemolysis with symptoms of anaemia, jaundice and haemoglobinuria.

Investigations

- **Blood count** is normal between attacks.
- **During an attack** the blood film may show irregularly contracted cells, bite cells (cells with an indentation of the membrane), blister cells (cells in which the Hb appears to have become partially detached from the cell membrane; see Fig. 8.25), Heinz bodies (best seen on films stained with methyl violet) and reticulocytosis.
- **Haemolysis** is evident (see p. 437).
- **G6PD deficiency** can be detected using several screening tests, such as demonstration of the decreased ability of G6PD-deficient cells to reduce dyes. The level of the enzyme may also be directly assayed. There are two diagnostic problems. Immediately after an attack the screening tests may be normal (because the oldest red cells with least 6GPD activity are destroyed selectively). Secondly, the diagnosis of heterozygous females may be difficult because the enzyme level may range from very low to normal depending on lyonization. However, the risk of clinically significant haemolysis is minimal in patients with borderline G6PD activity.
- DNA analysis may also be performed.

Treatment

- Any offending drugs should be stopped.
- Underlying infection should be treated.
- Blood transfusion may be life-saving.
- Splenectomy is not usually helpful.

Pyruvate kinase deficiency

This is the most common defect of red cell metabolism after G6PD deficiency, affecting thousands rather than millions of people. The site of the defect is shown in Figure 8.24. There is reduced production of ATP, causing rigid red cells. Homozygotes have haemolytic anaemia and splenomegaly. It is inherited as an autosomal recessive.

Investigations

- **Anaemia** of variable severity is present (Hb 5-10 g/dL). The oxygen dissociation curve is shifted to the right as a result of the rise in intracellular 2,3-BPG (Fig. 15.5), and this reduces the severity of symptoms due to anaemia.

- **Blood film** shows distorted ('prickle') cells and a reticulocytosis.
- **Pyruvate kinase activity** is low (affected homozygotes have levels of 5-20%).

Treatment

Blood transfusions may be necessary during infections and pregnancy. Splenectomy may improve the clinical condition and is usually advised for patients requiring frequent transfusions.

ACQUIRED HAEMOLYTIC ANAEMIA

These anaemias may be divided into those due to immune, non-immune, or other causes (see Table 8.9).

Causes of immune destruction of red cells

- Autoantibodies
- Drug-induced antibodies
- Alloantibodies.

Causes of non-immune destruction of red cells

- Acquired membrane defects (e.g. paroxysmal nocturnal haemoglobinuria; see p. 452).
- Mechanical factors (e.g. prosthetic heart valves, or microangiopathic haemolytic anaemia; see p. 453).
- Secondary to systemic disease (e.g. renal and liver disease).

Miscellaneous causes

- Various toxic substances can disrupt the red cell membrane and cause haemolysis (e.g. arsenic, and products of *Clostridium welchii).*
- Malaria frequently causes anaemia owing to a combination of a reduction in red cell survival and reduced production of red cells.
- Hypersplenism (p. 457) results in a reduced red cell survival, which may also contribute to the anaemia seen in malaria.
- Extensive burns result in denaturation of red cell membrane proteins and reduced red cell survival.
- Some drugs (e.g. dapsone, sulfasalazine) cause oxidative haemolysis with Heinz bodies.
- Some ingested chemicals (e.g. weedkillers such as sodium chlorate) cause severe oxidative haemolysis leading to acute renal failure.

AUTOIMMUNE HAEMOLYTIC: ANAEMIAS

Autoimmune haemolytic anaemias (AIHA) are acquired disorders resulting from increased red cell destruction due to red cell autoantibodies. These anaemias are characterized by the presence of a positive direct antiglobulin (Coombs') test, which detects the autoantibody on the surface of the patient's red cells (Fig. 8.26).

AIHA is divided into 'warm' and 'cold' types, depending on whether the antibody attaches better to the red cells at body temperature (37°C) or at lower temperatures. The major features and the causes of these two forms of AIHA are shown in Table 8.15. In warm AIHA, IgG antibodies predominate and the direct antiglobulin test is positive with IgG alone, IgG and complement, or complement only. In cold AIHA, the antibodies are usually IgM. They easily elute off red cells, leaving complement which is detected as C3d.

immune destruction of red cells

IgM or IgG red cell antibodies which fully activate the complement cascade cause lysis of red cells in the circulation (intravascular haemolysis).

IgG antibodies frequently do not activate complement and the coated red cells undergo extravascular haemolysis (Fig. 8.27). They are either completely phagocytosed in the spleen through an interaction with Fc receptors on macrophages, or they lose part of the cell membrane through partial phagocytosis and circulate as spherocytes until they too become sequestered in the spleen. Some IgG antibodies partially activate complement, leading to deposition of C3b on the red cell surface, and this may enhance phagocytosis as macrophages also have receptors for C3b.

Non-complement-binding IgM antibodies are rare and have little or no effect on red cell survival. IgM antibodies which partially rather than fully activate complement cause adherence of red cells to C3b receptors on macrophages, particularly in the liver, although this is an ineffective mechanism of haemolysis. Most of the red cells are released from the macrophages when C3b is cleaved to C3d and then circulate with C3d on their surface.

'Warm' autoimmune haemolytic anaemias

Clinical features

These anaemias may occur at all ages and in both sexes, although they are most frequent in middle-aged females. They can present as a short episode of anaemia and

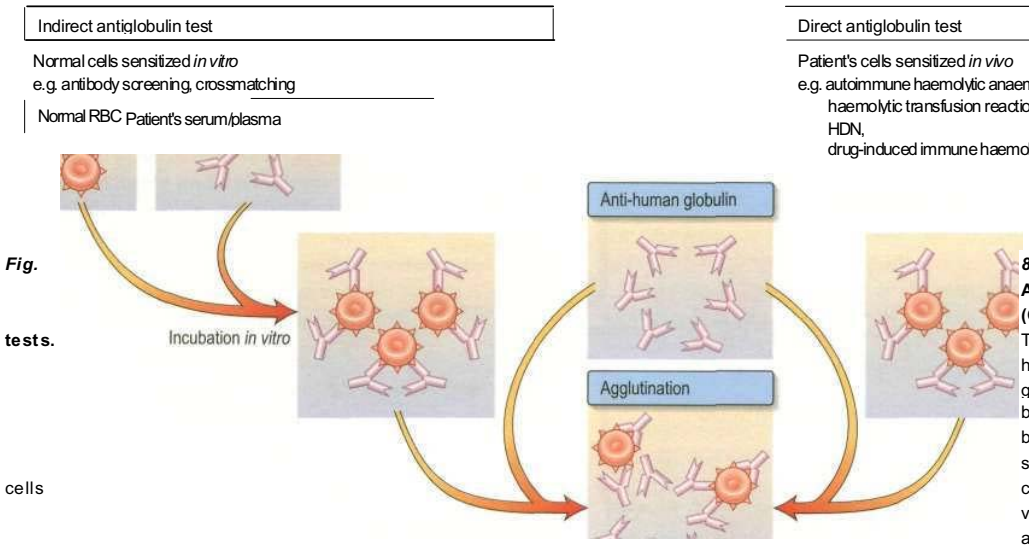

Fig. 8.26 **Antiglobulin (Coombs') tests.** The anti-human globulin forms bridges between the sensitized cells causing visible agglutination.

The direct test detects patients' cells sensitized in vivo. The indirect test detects normal cells sensitized in vitro. HDN, haemolytic disease of newborn.

Table 8.15 **Causes and major features of autoimmune haemolytic anaemias**

	Warm	Cold
Temperature at which antibody attaches best to red cells Type of antibody Direct Coombs' test Causes of primary conditions Causes of secondary condition	37°C IgG Strongly positive Idiopathic Autoimmune disorders, e.g. systemic lupus erythematosus Chronic lymphocytic leukaemia Lymphomas Hodgkin's lymphoma Carcinomas Drugs, e.g. methyldopa	Lower than 37°C IgM Positive Idiopathic Infections, e.g. infectious mononucleosis, *Mycoplasma* pneumoniae, other viral infections (rare) Lymphomas Paroxysmal cold haemoglobinuria (IgG)

jaundice but they often remit and relapse and may progress to an intermittent chronic pattern. The spleen is often palpable. Infections or folate deficiency may provoke a profound fall in the haemoglobin level.

In more than 30% of cases, the cause remains unknown. These anaemias may be associated with lymphoid malignancies or diseases such as rheumatoid arthritis and SLE or drugs (Table 8.15).

Investigations

m **Haemolytic anaemia** is evident (see p. 437).

- **Spherocytosis** is present as a result of red cell damage.
- **Direct antiglobulin test** is positive, with either IgG alone (67%), IgG and complement (20%), or comple ment alone (13%) being found on the surface of the red cells.
- **Autoantibodies** may have specificity for the Rh blood group system (e.g. for the e antigen).
- **Autoimmune thrombocytopenia** and/or neutropenia may also be present (Evans' syndrome).

Treatment and prognosis

Corticosteroids (e.g. prednisolone in doses of 1 mg/kg daily) are effective in inducing a remission in about 80% of patients. Steroids reduce both production of the red cell autoantibody and destruction of antibody-coated cells. Splenectomy may be necessary if there is no response to steroids or if the remission is not maintained when the dose of prednisolone is reduced. Other immunosuppressive drugs, such as azathioprine and cyclophosphamide, may be effective in patients who fail to respond to steroids and splenectomy.

'Cold' autoimmune haemolytic anaemias

Normally, low titres of IgM cold agglutinins reacting at

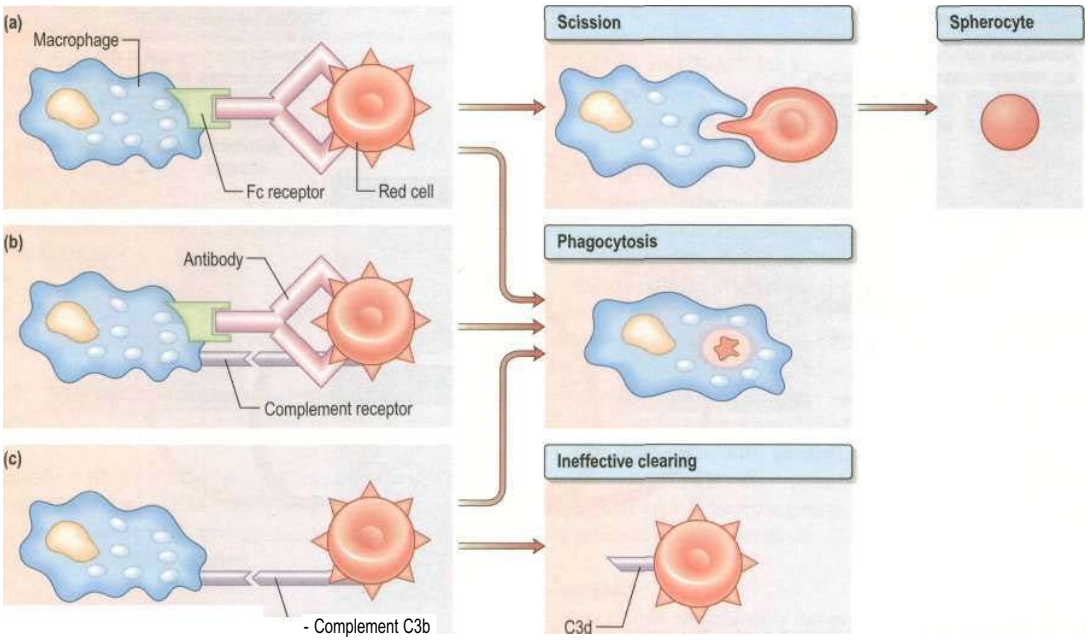

Fig. 8.27 **Extravascular haemolysis is due to interaction of antibody-coated cells with cells in the reticuloendothelial system, predominantly in the spleen, (a)** Spherocytosis results from partial phagocytosis, (b) Complete phagocytosis may occur and this is enhanced if there is complement as well as antibody on the cell surface, (c) Cells coated with complement only are ineffectively removed and circulate with C3d or C3b on their surface.

4°C are present in plasma and are harmless. At low temperatures these antibodies can attach to red cells and cause their agglutination in the cold peripheries of the body. In addition, activation of complement may cause intravascular haemolysis when the cells return to the higher temperatures in the core of the body.

After certain infections (such as *Mycoplasma,* cytomegalovirus, Epstein-Barr virus (EBV)) there is increased synthesis of polyclonal cold agglutinins producing a mild to moderate transient haemolysis.

Chronic cold haemagglutinin disease (CHAD)

This usually occurs in the elderly with a gradual onset of haemolytic anaemia owing to the production of monoclonal IgM cold agglutinins. After exposure to cold, the patient develops an acrocyanosis similar to Raynaud's (see p. 869) as a result of red cell autoagglutination.

Investigations

- **Red cells** agglutinate in the cold or at room temperature. Agglutination is sometimes seen in the sample tube after cooling but is more easily seen on the peripheral blood film made at room temperature. The agglutination is reversible after warming the sample. The agglutination may cause a spurious increase in the MCV (see p. 1425).
- **Direct antiglobulin test** is positive with complement alone.
- **Monoclonal IgM antibodies** with specificity for the Ii blood group system, usually for the I antigen but occasionally for the i antigen.

Treatment

The underlying cause should be treated, if possible. Patients should avoid exposure to cold. Treatment with steroids, alkylating agents and splenectomy is usually ineffective. Treatment with anti-CD20 (rituximab) has been successful in some cases.

Paroxysmal cold haemoglobinuria (PCH)

This is a rare condition associated with common childhood infections, such as measles, mumps and chickenpox. Intravascular haemolysis is associated with polyclonal IgG complement-fixing antibodies. These antibodies are biphasic, reacting with red cells in the cold in the peripheral circulation, with lysis occurring due to complement activation when the cells return to the central circulation. The antibodies have specificity for the P red cell antigen. The lytic reaction is demonstrated in vitro by incubating the patient's red cells and serum at 4°C and then warming the mixture to 37°C (Donath-Landsteiner test). Haemolysis is self-limiting but supportive transfusions of warmed blood may be necessary.

DRUG-INDUCED IMMUNE HAEMOLYTIC ANAEMIA

The interaction between a drug and red cell membrane produces a composite antigenic structure (or neoantigen), provoking two types of antibodies:

- *Drug-dependent antibodies,* which bind to both the drug and the cell membrane but not to either separately.

Clinically there is usually severe complement-mediated intravascular haemolysis, which resolves quickly after withdrawal of the drug. ■ *Drug-independent antibodies,* which are induced by a subtle alteration of the red cell membrane. Such antibodies react with red cells in vitro in the absence of the drug and are indistinguishable from 'true' autoantibodies. There is extravascular haemolysis and the clinical course tends to be more protracted.

This concept for drug-induced immune haemolytic anaemia probably also applies to drug-induced thrombocytopenia and neutropenia.

ALLOIMMUNE HAEMOLYTIC ANAEMIA

Antibodies produced in one individual react with the red cells of another. This situation occurs in haemolytic disease of the newborn, haemolytic transfusion reactions (see p. 461) and after allogeneic bone marrow, renal, liver or cardiac transplantation when donor lymphocytes transferred in the allograft ('passenger lymphocytes') may produce red cell antibodies against the recipient and cause haemolytic anaemia.

Haemolytic disease of the newborn (HDN)

HDN is due to fetomaternal incompatibility for **red** cell antigens. Maternal alloantibodies against fetal red cell antigens pass from the maternal circulation via the placenta into the fetus, where they destroy the fetal red cells. Only IgG antibodies are capable of transplacental passage from mother to fetus.

The most common type of HDN is that due to ABO incompatibility, where the mother is usually group O and the fetus group A.

HDN due to ABO incompatibility is usually mild and exchange transfusion is rarely needed. HDN due to RhD incompatibility has become much less common in developed countries following the introduction of anti-D prophylaxis (see below). HDN may be caused by antibodies against antigens in many blood group systems (e.g. other Rh antigens such as c and E, and Kell, Duffy and Kidd; see p. 458).

Sensitization occurs as a result of passage of fetal red cells into the maternal circulation (which most readily occurs at the time of delivery), so that first pregnancies are rarely affected. However, sensitization may occur at other times, for example after a miscarriage, ectopic pregnancy or blood transfusion, or due to episodes during pregnancy which cause transplacental bleeding such as amniocentesis, chorionic villus sampling and threatened miscarriage.

Clinical features

These vary from a mild haemolytic anaemia of the newborn to intrauterine death from 18 weeks' gestation with the characteristic appearance of hydrops fetalis (hepatosplenomegaly, oedema and cardiac failure).

Kernicterus occurs owing to severe jaundice in the neonatal period, where the unconjugated (lipid-soluble) bilirubin exceeds 250(imol/L and bile pigment deposition occurs in the basal ganglia. This can result in permanent brain damage, choreoathetosis, and spasticity. In mild cases it may present as deafness.

Investigations

Routine antenatal serology

All mothers should have their ABO and RhD groups determined and their serum tested for atypical antibodies after attending the antenatal booking clinic. Tests for red cell antibodies should be repeated at 28 weeks' gestation. If an antibody is detected, its blood group specificity should be determined and the mother should be retested at least monthly. A rising antibody titre of IgG antibodies or a history of HDN in a previous pregnancy is an indication for referral to a specialist unit to determine the need for amniocentesis (to assess the level of bilirubin in the amniotic fluid) or fetal blood sampling to determine the severity of HDN and to guide further management.

Ultrasound

This shows changes in the fetal blood flow and cardiac function caused by compensated anaemia and can be demonstrated in utero before hydrops develops. Fetal DNA may be obtained by amniocentesis, chorionic villous sampling, or fetal blood sampling. Soluble fetal DNA in maternal plasma can also be used for this purpose, avoiding an invasive procedure.

At the birth of an affected infant

A sample of cord blood is obtained. This shows: - . . . - '

- anaemia with a high reticulocyte count
- a positive direct antiglobulin test
- a raised serum bilirubin.

Treatment

Management of the baby

In mild cases, phototherapy may be used to convert bilirubin to water-soluble biliverdin. Biliverdin can be excreted by the kidneys and this therefore reduces the chance of kernicterus.

In more severely affected cases, exchange transfusion may be necessary to replace the infant's red cells and to remove bilirubin. Indications for exchange transfusion include:

- a cord Hb of < 12 g/dL (normal cord Hb is 13.6-19.6 g/dL)
- a cord bilirubin of > 60 |imol/L
- a later serum bilirubin of > 300 |imol/L
- a rapidly rising serum bilirubin level.

Further exchange transfusions may be necessary to remove the unconjugated bilirubin.

The blood used for exchange transfusions should be ABO-compatible with the mother and infant, lack the antigen against which the maternal antibody is directed, be fresh (no more than 5 days from the day of collection), and be CMV-seronegative to prevent transmission of cytomegalovirus.

A severely affected fetus may need intrauterine blood transfusions carried out in a special unit.

An advance in the antenatal management of RhD alloimmunized women is the development of molecular methods for fetal RhD blood grouping in women with partners heterozygous for RhD. RhD-negative fetuses, who will be unaffected, can be distinguished from RhD-positive fetuses, who may be severely affected and require intensive monitoring.

Prevention of RhD immunization in the mother

Anti-D should be given after delivery when all of the following are present:

- the mother is RhD negative
- the fetus is RhD positive
- there is no maternal anti-D detectable in the mother's serum; i.e. the mother is not already immunized.

The dose is 500 i.u. of IgG anti-D intramuscularly within 48 hours of delivery. *The Kleihauer test* is used to assess the number of fetal cells in the maternal circulation. A blood film prepared from maternal blood is treated with acid, which elutes Hb A. Hb F is resistant to this treatment and can be seen when the film is stained with eosin. If large numbers of fetal red cells are present in the maternal circulation, a higher or additional dose of anti-D will be necessary.

It may be necessary to give prophylaxis to RhD-negative women at other times when sensitization may occur, for example after an ectopic pregnancy, threatened miscarriage or amniocentesis. The dose of anti-D is 250 i.u. before 20 weeks' gestation and 500 i.u. after 20 weeks.

Of previously non-immunized RhD-negative women carrying RhD-positive fetuses, 1-2% are immunized by the time of delivery. *Antenatal prophylaxis* with administration of 500 i.u. anti-D to RhD-negative women at both 28 and 34 weeks' gestation has been shown to reduce the incidence of immunization, and its routine use is being implemented in the UK. Monoclonal anti-D could in principle replace polyclonal anti-D, which is collected from RhD-negative women immunized in pregnancy and deliberately immunized RhD-negative males, but it is likely to be some years before trials have been completed and it is available in sufficient quantity.

NON-IMMUNE HAEMOLYTIC ANAEMIA

Paroxysmal nocturnal haemoglobinuria (PNH)

This is a rare acquired red cell defect in which a clone of red cells is particularly sensitive to destruction by activated complement. These cells are continually haemolysed intravascularly. Platelets and granulocytes are also affected and there may be thrombocytopenia and neutropenia.

The underlying defect is an inability of PNH cells to make glycosylphosphatidylinositol (GPI), which anchors surface proteins such as decay accelerating factor (DAF; CD55) and membrane inhibitor of reactive lysis (MIRL; CD59) to cell membranes. CD55 and CD59 and other proteins are involved in complement degradation (at the C3 and C5 levels), and in their absence the haemolytic action of complement continues. The molecular basis of PNH has been found to be mutations in the *pig-A* (phosphatidylinositol glycan protein A) gene responsible for synthesis of the GPI anchor.

Clinical features

The major clinical signs are intravascular haemolysis, venous thrombosis and haemoglobinuria. Haemolysis may be precipitated by infection, iron therapy or surgery. Characteristically only the urine voided at night and in the morning on waking is dark in colour, although the reason for this phenomenon is not clear. In severe cases all urine samples are dark. Urinary iron loss may be sufficient to cause iron deficiency.

Some patients present insidiously with signs of anaemia and recurrent abdominal pains.

Venous thrombotic episodes are very common in unusual places and severe thromboses may occur, for example in hepatic (Budd-Chiari syndrome), mesenteric or cerebral veins. The cause of the increased predisposition to thrombosis is not known, but may be due to complement-mediated activation of platelets deficient in CD55 and CD59.

Investigations

- **Intravascular haemolysis** is evident (see p. 437).
- **Flow** cytometric analysis of red cells with anti-CD55 and anti-CD59 has replaced the Ham's test.
- **Bone marrow** is sometimes hypoplastic (or even aplastic) despite haemolysis.

Treatment and prognosis

PNH is a chronic disorder requiring supportive measures such as blood transfusions, which are necessary for patients with severe anaemia. Leucocyte-depleted blood should be used in order to prevent transfusion reactions resulting in complement activation and acceleration of the haemolysis. Recently a recombinant humanized monoclonal antibody (eculizumab) that prevents the cleavage of C5 (and therefore the formation of the membrane attack complex) has been shown to reduce intravascular haemolysis, haemoglobinuria and the need for transfusion in PNH.
