Tube wells are successful as a source of drinking water in many parts of India. They yield water which is bacteriologically safe, and are also cheap in comparison to other sources of supply. Shallow tube wells or "driven wells" have become the largest individual source of water supply to the rural community. The tube well consists of a pipe (usually galvanized iron) sunk into the water-bearing stratum and fitted with a *strainer* at the bottom, and a hand-pump at the top. A water-tight concrete platform with a drain all round should be provided. The area within 15 m of the tube well should be kept free from pollution with liquid and solid wastes. The hand-pump should be kept in good repair. The life of the tube well is not the same everywhere. It varies from place to place depending upon the type of strainer, quality of underground water and the nature of soil. An average well may last for a period of 5 to 10 years; in some cases, tube wells have given satisfactory service even after 30 years *(8)*. When the tube well is derelict, it is withdrawn and then resunk with a new strainer using as much of the withdrawn pipes as can be recovered. *Deep tube* wells or bored wells are sunk by drilling through successive substrata of gravel or rock until a suitable supply of ground water is located. They may be several hundred feet deep and require complicated mechanical drilling equipment and skilled engineering direction. This type of wells, although costly to construct and to operate, are in many ways the ideal supply. The yield is normally very high and does not depend upon direct rainfall in the immediate vicinity. Chandigarh, the capital of Punjab, derives its entire water supply from tube wells.

SPRINGS

When ground water comes to the surface and flows freely under natural pressure, it is called a "spring". Springs may be of two types–shallow springs and deep springs. Shallow springs dry up quickly during summer months, whereas deep springs do not show seasonal fluctuations in the flow of water. In some geographic areas, springs constitute an important source of water. Springs are simpler to exploit, as no pumping is needed to bring the water to the surface. Springs are exposed to contamination. Well built protective structures are necessary to safeguard water quality.

WATER POLLUTION

Pure uncontaminated water does not occur in nature. It contains impurities of various kinds – natural and man-made. The natural impurities are not essentially dangerous. These comprise dissolved gases (e.g. nitrogen, carbon dioxide, hydrogen sulphide, etc. which may be picked up during rainfall), and dissolved minerals (e.g., salts of calcium, magnesium, sodium, etc.) which are natural constituents of water following its contact with soil; and suspended impurities (e.g., clay, silt, sand and mud), and microscopic organisms. These impurities are derived from the atmosphere, catchment area and the soil.

A more serious aspect of water pollution is that caused by human activity – urbanization and industrialization. The sources of pollution resulting from these are : (a) *sewage*, which contains decomposable organic matter and pathogenic agents (b) *industrial and trade wastes*, which contain toxic agents ranging from metal salts to complex synthetic organic chemicals (c) *agricultural pollutants*, which comprise fertilizers and pesticides, and (d) *physical pollutants*, viz heat (thermal pollution) and radioactive substances *(9)*.

The indicators of pollution include the amount of total suspended solids, biochemical oxygen demand (BOD) at 20 deg. C, concentration of chlorides, nitrogen and phosphorus and absence of dissolved oxygen.

Even if the source of water supply and its treatment are of a high standard, water pollution may still occur as often happens, due to corrosion of pipe lines, leaky joints and cross connections between water supply pipes and sewage drainage pipes. Surveillance has to be exercised at every point in the distribution system to ensure supply of safe water to the consumer.

Water-related diseases

Man's health may be affected by the ingestion of contaminated water either directly or through food; and by the use of contaminated water for purpose of personal hygiene and recreation. The term water-related diseases includes the classical water-borne diseases. Developing countries carry a heavy burden of water-related diseases, the heaviest being the diarrhoeal diseases. Water-related diseases may be classified as follows :

A. Biological (Water-borne diseases)

1. Those caused by the presence of an infective agent :

(a) Viral	: Viral hepatitis A, hepatitis E, poliomyelitis, rotavirus diarrhoea in infants
(b) Bacterial	: typhoid and paratyphoid fever, bacillary dysentery, *Esch. coli* diarrhoea, cholera
(c) Protozoal	: amoebiasis, giardiasis
(d) Helminthic	: roundworm, threadworm, hydatid disease.
(e) Leptospiral	: weil's disease

2. Those due to the presence of an aquatic host :

(a) Snail	: schistosomiasis
(b) Cyclops	: guineaworm , fish tape worm.

B. Chemical

Chemical pollutants of diverse nature derived from industrial and agricultural wastes are increasingly finding their way into public water supplies. These pollutants include detergent solvents, cyanides, heavy metals, minerals and organic acids, nitrogenous substances, bleaching agents, dyes, pigments, sulphides, ammonia, toxic and biocidal organic compounds of great variety. Chemical pollutants may affect man's health not only directly, but also indirectly by accumulating in aquatic life (e.g. fish) used as human food. The present concern about chemical pollutants

in water relates not so much as to their acute toxic effects on human health as to the possible long-term effects of low level exposure, which are often non-specific and difficult to detect. Further, some of the new pollutants are not easily removed by conventional water treatment or purification processes. In many developed countries where water-borne communicable diseases have virtually disappeared, more attention is now being paid to chemical pollution.

In addition to the above, water is associated with the following :

(a) *Dental health* : The presence of fluoride at about 1 mg/litre in drinking water is known to protect against dental caries, but high levels of fluoride cause mottling of the dental enamel;

(b) *Cyanosis in infant* : High nitrate content of water is associated with methaemoglobinaemia. This is a rare occurrence but may occur when surface water from farmland, treated with a fertilizer, gain access to the water supply.

(c) *Cardiovascular diseases* : Hardness of water appears to have a beneficial effect against cardiovascular diseases;

(d) Some diseases are transmitted because of inadequate use of water like shigellosis, trachoma and conjunctivitis, ascariasis, scabies *(10)*.

(e) Some diseases are related to the disease carrying insects breeding in or near water, like : malaria, filaria, arboviruses, onchocerciasis, African trypanosomiasis *(10)*.

While pollution seems to be an inevitable consequence of modern industrial technology, the problem, now, is to determine the level of pollution that permits economic and social development without presenting hazards to health. The evaluation of the health effects of environmental pollutants is currently being carried out as part of the WHO Environmental Health Criteria Programme.

WATER POLLUTION LAW

In India, water pollution is becoming a serious problem. To protect water from being contaminated, the Indian Parliament in 1974 passed the Water (Prevention and Control of Pollution) Act. The Act seeks to provide legal deterrent against the spread of water pollution. The Act is a comprehensive piece of legislation. It provides for the constitution of Central and State Water Boards and Joint Water Boards endowed with wide powers for controlling pollution.

PURIFICATION OF WATER

Purification of water is of great importance in community medicine. It may be considered under two headings :

1. Purification of water on a large scale.
2. Purification of water on a small scale.

1. PURIFICATION OF WATER ON A LARGE SCALE

The purpose of water treatment is to produce water that is safe and wholesome. The method of treatment to be employed depends upon the nature of raw water, and the desired standards of water quality. For example, ground water (e.g., wells and springs) may need no treatment, other than disinfection. Surface water (e.g., river water) which tends to be turbid and polluted, requires extensive treatment. The components of a typical water purification system comprise one or more of the following measures :

I. Storage
II. Filtration
III. Disinfection

(I) Storage

Water is drawn out from the source and impounded in natural or artificial reservoirs. Storage provides a reserve of water from which further pollution is excluded. As a result of storage, a very considerable amount of purification takes place. This is natural purification, and we may look at it from three points of view : (a) *Physical* : By mere storage, the quality of water improves. About 90 per cent of the suspended impurities settle down in 24 hours by gravity. The water becomes clearer. This allows penetration of light, and reduces the work of the filters, (b) *Chemical* : Certain chemical changes also take place during storage. The aerobic bacteria oxidize the organic matter present in the water with the aid of dissolved oxygen. As a result, the content of free ammonia is reduced and a rise in nitrates occurs. (c) *Biological* : A tremendous drop takes place in bacterial count during storage. The pathogenic organisms gradually die out. It is found that when river water is stored the total bacterial count drops by as much as 90 per cent in the first 5–7 days. This is one of the greatest benefits of storage. The optimum period of storage of river water is considered to be about 10–14 days. If the water is stored for long periods, there is likelihood of development of vegetable growths such as algae which impart a bad smell and colour to water.

(II) Filtration

Filtration is the second stage in the purification of water, and quite an important stage because 98–99 per cent of the bacteria are removed by filtration, apart from other impurities. Two types of filters are in use, the "biological" or "slow sand" filters and the "rapid sand" or "mechanical" filters. A brief description of these filters is given below :

SLOW SAND OR BIOLOGICAL FILTERS *(11)*

Slow sand filters were first used for water treatment in 1804 in Scotland and subsequently in London. During the 19th century their use spread throughout the world. Even today, they are generally accepted as the standard method of water purification.

Elements of a slow sand filter

Fig. 4 shows in diagrammatic form, the various elements of a slow sand filter. Essentially these consists of :

(1) supernatant (raw) water
(2) a bed of graded sand
(3) an under-drainage system; and
(4) a system of filter control valves.

(1) Supernatant water

The supernatant water above the sand bed, whose depth varies from 1 to 1.5 metre, serves two important purposes : it provides a constant head of water so as to overcome the resistance of the filter bed and thereby promote the downward flow of water through the sand bed; and secondly, it provides waiting period of some hours (3 to 12 hours, depending upon the filtration velocity) for the raw water to undergo partial purification by sedimentation,

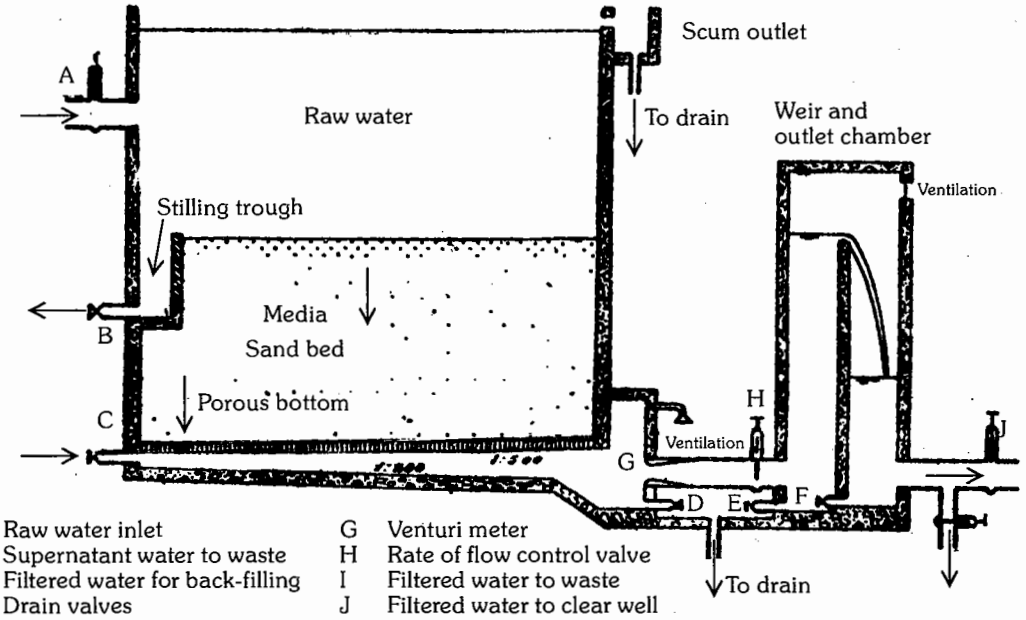

FIG. 4
Slow sand filter

oxidation and particle agglomeration. The level of supernatant water is always kept constant.

(2) Sand bed

The most important part of the filter is the sand bed. The thickness of the sand bed is about 1 metre. The sand grains are carefully chosen so that they are preferably rounded and have an "effective diameter" between 0.2 and 0.3 mm. The sand should be clean and free from clay and organic matter. The sand bed is supported by a layer of graded gravel (Fig. 5), 30–40 cm deep which also prevents the fine grains being carried into the drainage pipes.

The sand bed presents a vast surface area; one cubic metre of filter sand presents some 15,000 sq. metres of surface area. Water percolates through the sand bed very slowly (a process taking two hours or more), and as it does so, it is subjected to a number of purification processes – mechanical straining, sedimentation, adsorption, oxidation and bacterial action, all playing their part. The designed rate of filtration of water normally lies between 0.1 and 0.4 m^3/hour/per square metre of sand bed surface.

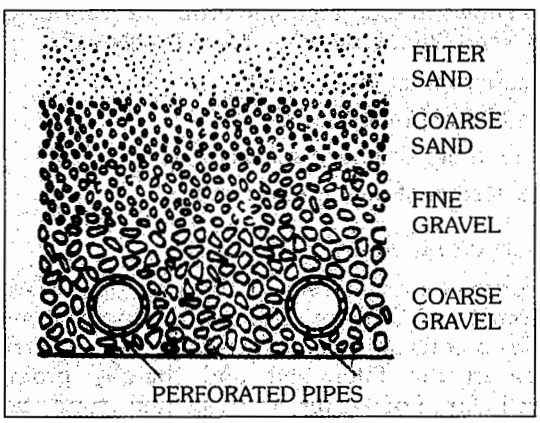

FIG. 5
Section of filter bed

Vital layer : When the filter is newly laid, it acts merely as a mechanical strainer, and cannot truly be considered as "biological". But very soon, the surface of the sand bed gets covered with a slimy growth known as "Schmutzdecke", vital layer, zoogleal layer or biological layer. This layer is slimy and gelatinous and consists of threadlike algae and numerous forms of life including plankton, diatoms and bacteria. The formation of vital layer is known as "ripening" of the filter. It may take several days for the vital layer to form fully, and when fully formed it extends for 2 to 3 cm into the top portion of the sand bed. The vital layer is the "heart" of the slow sand filter. It removes organic matter, holds back bacteria and oxidizes ammoniacal nitrogen into nitrates and helps in yielding a bacteria-free water. Until the vital layer is fully formed, the first few days filtrate is usually run to waste.

(3) Under-drainage system

At the bottom of the filter bed is the under-drainage system. It consists of porous or perforated pipes which serve the dual purpose of providing an outlet for filtered water, and supporting the filter medium above. Once the filter bed has been laid, the under-drainage system cannot be seen.

Filter box : The first 3 elements (e.g. supernatant water, sand bed and under-drainage system) are contained in the filter box. The filter box is an open box, usually rectangular in shape, from 2.5 to 4 metres deep and is built wholly or partly below ground. The walls may be made of stone, brick or cement. The filter box consists from top to bottom :

Supernatant water	.....	1 to 1.5 metre
Sand bed	.....	1.2 metre
Gravel support	.....	0.30 metre
Filter bottom	.....	0.16 metre

(4) Filter control

The filter is equipped with certain valves and devices which are incorporated in the outlet-pipe system. The purpose of these devices is to maintain a constant rate of filtration. An important component of the regulation system is the "Venturi meter" (Fig. 4) which measures the bed

resistance or "loss of head". When the resistance builds up, the operator opens the regulating valve so as to maintain a steady rate of filtration. When the "loss of head" exceeds 1.3 metre it is uneconomical to run the filter.

Filter cleaning : Normally the filter may run for weeks or even months without cleaning. When the bed resistance increases to such an extent that the regulating valve has to be kept fully open, it is time to clean the filter bed, since any further increase in resistance is bound to reduce the filtration rate. At this stage, the supernatant water is drained off, and the sand bed is cleaned by "scraping" off the top portion of the sand layer to a depth of 1 or 2 cm. This operation may be carried out by unskilled labourers using hand tools or by mechanical equipment. After several years of operation, and say 20 or 30 scrapings, the thickness of the sand bed will have reduced to about 0.5 to 0.8 metre. Then the plant is closed down and a new bed is constructed.

The advantages of a slow sand filter are : (1) simple to construct and operate (2) the cost of construction is cheaper than that of rapid sand filters (3) the physical, chemical and bacteriological quality of filtered water is very high. When working ideally, slow sand filters have been shown to reduce total bacterial counts by 99.9 to 99.99 per cent and *E. coli* by 99 to 99.9 per cent.

In recent years, a mistaken idea has grown that biological or slow sand filtration is an old fashioned, outdated method of water treatment which has been completely superseded by rapid sand filtration. This is definitely not the case. Slow sand filtration is still the chosen method of water purification in a number of highly industrialized cities as well as urban areas. In a number of cities in U.S. and Europe, slow sand filters have recently been constructed.

RAPID SAND OR MECHANICAL FILTERS

In 1885, the first rapid sand filters were installed in the USA. Since that time, they have gained considerable popularity especially in highly industrialized countries .

Rapid sand filters are of two types, the gravity type (e.g. Paterson's filter) and the pressure type (e.g. Candy's filter). Both the types are in use. The following steps are involved in the purification of water by rapid sand filters : (Fig. 6).

(1) *Coagulation :* The raw water is first treated with a chemical coagulant such as alum, the dose of which varies from 5 to 40 mg or more per litre, depending upon the turbidity and colour, temperature and the pH value of the water. (2) *Rapid mixing :* The treated water is then subjected to violent agitation in a "mixing chamber" for a few minutes. This allows a quick and thorough dissemination of alum throughout the bulk of the water, which is very necessary. (3) *Flocculation :* The next phase involves a slow and gentle stirring of the treated water in a "flocculation chamber" for about 30 minutes. The mechanical type of flocculator is the most widely used. It consists of a number of paddles which rotate at 2 to 4 rpm. The paddles rotate with the help of motors. This slow and gentle stirring results in the formation of a thick, copious, white flocculant precipitate of aluminium hydroxide. The thicker the precipitate or flock diameter, the greater the settling velocity. (4) *Sedimentation :* The coagulated water is now led into sedimentation tanks where it is detained for periods varying from 2–6 hours when the flocculent precipitate together with impurities and bacteria settle down in the tank. At least 95 per cent of the flocculant precipitate needs to be removed before the water is admitted into the rapid sand filters. The precipitate or sludge which settles at the bottom is removed from time to time without disturbing the operation of the tank. For proper maintenance, the tanks should be cleaned regularly from time to time, otherwise they may become a breeding ground for molluscs and sponges. (5) *Filtration :* The partly clarified water is now subjected to rapid sand filtration.

Filter beds

Each unit of Filter bed has a surface of about 80 to 90 m^2 (about 900 sq. feet). Sand is the filtering medium. The "effective size" of the sand particles is between 0.4–0.7 mm. The depth of the sand bed is usually about 1 metre (2 $^1/_2$ to 3 feet). Below the sand bed is a layer of graded gravel, 30 to 40 cm. (1–1$^1/_2$ feet) deep. The gravel supports the sand bed and permits the filtered water to move freely towards the under-drains. The depth of the water on the top of the sand bed is 1.0 to 1.5 m (5–6 feet). The under-drains at the bottom of the filter beds collect the filtered water. The rate of filtration is 5–15 m^3/m^2/hour. A view of the rapid sand filter is given in Fig. 7.

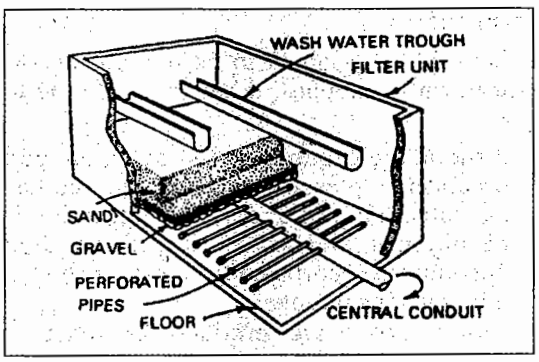

FIG. 7
A view of a rapid sand filter

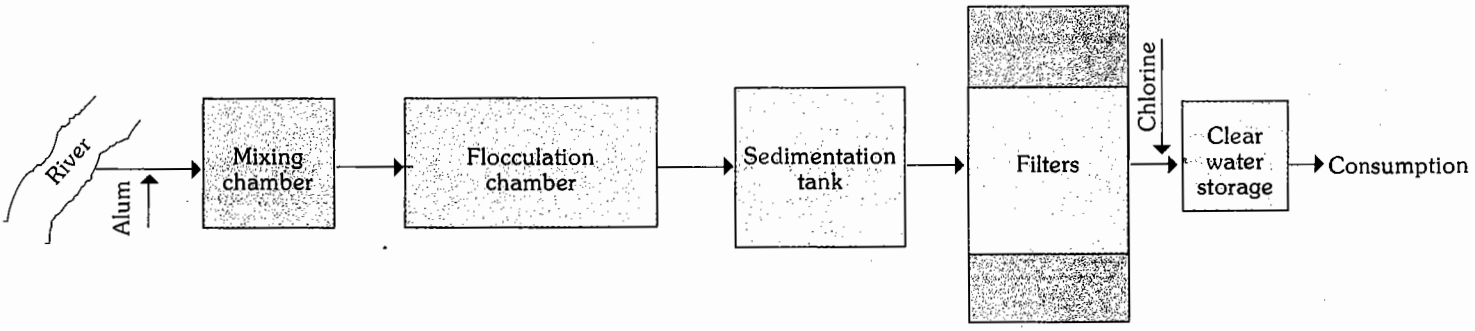

FIG. 6
Flow diagram of a rapid sand filtration plant

Filtration

As filtration proceeds, the "alum-floc" not removed by sedimentation is held back on the sand bed. It forms a slimy layer comparable to the zoogleal layer in the slow sand filters. It adsorbs bacteria from the water and effects purification. Oxidation of ammonia also takes place during the passage of water through the filters. As filtration proceeds, the suspended impurities and bacteria clog the filters. The filters soon become dirty and begin to lose their efficiency. When the "loss of head" approaches 7–8 feet, filtration is stopped and the filters are subjected to a washing process known as "backwashing".

Backwashing

Rapid sand filters need frequent washing daily or weekly, depending upon the loss of head. Washing is accomplished by reversing the flow of water through the sand bed, which is called "backwashing". Backwashing dislodges the impurities and cleans up the sand bed. The washing is stopped when clear sand is visible and the wash water is sufficiently clear. The whole process of washing takes about 15 minutes. In some rapid sand filters, compressed air is used as part of the backwashing processes.

Advantages

The advantages of a rapid sand filter over the slow sand filter are : (1) rapid sand filter can deal with raw water directly. No preliminary storage is needed (2) the filter beds occupy less space (3) filtration is rapid, 40–50 times that of a slow sand filter (4) the washing of the filter is easy (5) there is more flexibility in operation.

Comparison of rapid and slow sand filters

The main features of rapid and slow sand filters are as given in Table 3.

(III) Disinfection

For a chemical or an agent to be potentially useful as a disinfectant in water supplies, it has to satisfy the following criteria :

(a) it should be capable of destroying the pathogenic organisms present, within the contact time available and not unduly influenced by the range of physical and chemical properties of water encountered particularly temperature, pH and mineral constituents;

(b) should not leave products of reaction which render the water toxic or impart colour or otherwise make it unpotable;

(c) have ready and dependable availability at reasonable cost permitting convenient, safe and accurate application to water;

(d) possess the property of leaving residual concentration to deal with small possible recontamination; and

(e) be amenable to detection by practical, rapid and simple analytical techniques in the small concentration ranges to permit the control of the efficiency of the disinfection process.

In water works practice, the term disinfection is synonymous with chlorination.

CHLORINATION

Chlorination is one of the greatest advances in water purification. It is supplement, not a substitute to sand filtration. Chlorine kills pathogenic bacteria, but is has no effect on spores and certain viruses (e.g., polio, viral hepatitis) except in high doses. Apart from its germicidal effect, chlorine has several important secondary properties of value in water treatment : it oxidizes iron, manganese and hydrogen sulphide; it destroys some taste and odour-producing constituents; it controls algae and slime organisms; and aids coagulation.

Action of chlorine : When chlorine is added to water, there is formation of hydrochloric and hypochlorous acids. The hydrochloric acid is neutralized by the alkalinity of the water. The hypochlorous acid ionizes to form hydrogen ions and hypochlorite ions, as follows :–

$$H_2O + Cl_2 \rightarrow HCl + HOCl$$
$$HOCl \rightarrow H + OCl$$

The disinfecting action of chlorine is mainly due to the hypochlorous acid, and to a small extent due to the hypochlorite ions. The hypochlorous acid is the most effective form of chlorine for water disinfection. It is more effective (70–80 times) than the hypochlorite ion. Chlorine acts best as a disinfectant when the pH of water is around 7 because of the predominance of hypochlorous acid. When the pH value exceeds 8.5 it is unreliable as a disinfectant because about 90 per cent of the hypochlorous acid gets ionized to hypochlorite ions. It is fortunate that most waters have a pH value between 6–7.5.

Principles of chlorination : The mere addition of chlorine to water is not chlorination. There are certain rules which should be obeyed in order to ensure proper chlorination : (1) First of all, the water to be chlorinated should be clear and free from turbidity. Turbidity impedes efficient chlorination (2) Secondly, the "chlorine demand" of the

TABLE 3
Comparison of rapid and slow sand filters

		Rapid sand filter	Slow sand filter
1.	Space	Occupies very little space	Occupies large area
2.	Rate of filtration	200 m.g.a.d	2–3 m.g.a.d.
3.	Effective size of sand	0.4–0.7 mm	0.2–0.3 mm
4.	Preliminary treatment	Chemical coagulation and sedimentation	Plain sedimentation
5.	Washing	By back-washing	By scraping the sand bed
6.	Operation	Highly skilled	Less skilled
7.	Loss of head allowed	6–8 feet (2–2.5 m)	4 feet (1.5 m)
8.	Removal of turbidity	Good	Good
9.	Removal of colour	Good	Fair
10.	Removal of bacteria	98–99 per cent	99.9–99.99 per cent

water should be estimated. "The chlorine demand of water is the difference between the amount of chlorine added to the water, and the amount of residual chlorine remaining at the end of a specific period of contact (usually 60 minutes), at a given temperature and pH of the water". In other words, it is the amount of chlorine that is needed to destroy bacteria, and to oxidize all the organic matter and ammoniacal substances present in the water. The point at which the chlorine demand of the water is met is called the "break-point". If further chlorine is added beyond the break point, free *chlorine* (HOCl and OCl) begins to appear in the water (3) Thirdly the contact period. The presence of free residual chlorine for a contact period of at least one hour is essential to kill bacteria and viruses *(20)*. It should be noted however, that chlorine has no effect on spores, protozoal cysts and helminthic ova, except in higher doses. (4) The minimum recommended concentration of free chlorine is 0.5 mg/L for one hour *(12)*. The free residual chlorine provides a margin of safety against subsequent microbial contamination such as may occur during storage and distribution. (5) The sum of the chlorine demand of the specific water plus the free residual chlorine of 0.5 mg/L constitutes the correct dose of chlorine to be applied.

METHOD OF CHLORINATION

For disinfecting large bodies of water, chlorine is applied either as (1) chlorine gas (2) chloramine or (3) perchloron. Chlorine gas is the first choice, because it is cheap, quick in action, efficient and easy to apply. Since chlorine gas is an irritant to the eyes and poisonous, a special equipment known as "chlorinating equipment" is required to apply chlorine gas to water supplies. Paterson's chloronome is one such device for measuring, regulating and administering gaseous chlorine to water supplies. In some water treatment plants, they use *chloramine* instead of chlorine gas. Chloramines are loose compounds of chlorine and ammonia. They have a less tendency to produce chlorinous tastes and give a more persistent type of residual chlorine. The greatest drawback of chloramines is that they have a slower action than chlorine and therefore they are not being used to any great extent in water treatment. Perchloron or high test hypochlorite (H.T.H.) is a calcium compound which carries 60–70 per cent of available chlorine. Solutions prepared from H.T.H. are also used for water disinfection. As mentioned already, chlorine gas has replaced all the other chlorine derivatives in the disinfection of urban water supplies.

BREAK POINT CHLORINATION

The addition of chlorine to ammonia in water produces chloramines which do not have the same efficiency as free chlorine. If the chlorine dose in the water is increased, a reduction in the residual chlorine occurs, due to the destruction of chloramine by the added chlorine. The end products do not represent any residual chlorine. This fall in residual chlorine will continue with further increase in chlorine dose and after a stage, the residual chlorine begins to increase in proportion to the added dose of chlorine. This point at which the residual chlorine appears and when all combined chlorines have been completely destroyed is the breakpoint and corresponding dosage is the breakpoint dosage. Breakpoint chlorination achieves the same results as superchlorination in a rational manner and can therefore be construed as controlled superchlorination *(4)*.

SUPERCHLORINATION

Superchlorination followed by dechlorination comprises the addition of large doses of chlorine to the water, and removal of excess of chlorine after disinfection, this method is applicable to heavily polluted waters whose quality fluctuates greatly.

ORTHOTOLIDINE (OT) TEST

Orthotolidine test enables both free and combined chlorine in water to be determined with speed and accuracy. The test was developed in 1918. The reagent consists of analytical grade Orthotolidine, dissolved in 10 per cent solution of hydrochloric acid. When this reagent is added to water containing chlorine, it turns yellow and the intensity of the colour varies with the concentration of the gas. The yellow colour is produced by both free and combined chlorine residuals. OT reacts with *free chlorine* instantaneously but reacts more slowly with *combined* chlorine *(12)*.

The test is carried out by adding 0.1 ml of the reagent to 1 ml of water. The yellow colour produced is matched against suitable standards or colour discs. Commercial equipment is available for this purpose. It is essential to take the reading within 10 seconds after the addition of the reagent to estimate *free chlorine* in water *(14)*. The colour that is produced after a lapse, say 15–20 minutes, is due to the action of both free and combined chlorine.

ORTHOTOLIDINE-ARSENITE (OTA) TEST

This is a modification of the OT test to determine the free and combined chlorine residuals separately *(13, 14, 15)*. Further, the errors caused by the presence of interfering substances such as nitrites, iron and manganese all of which produce a yellow colour with Orthotolidine, are overcome by the OTA test *(12)*.

Other agents

While chlorine continues to be the most commonly used sterilizing agent because of its germicidal properties and the comparatively low cost and ease of application, its pre-eminence in water disinfection is being seriously challenged because of the discovery that chlorination of water can lead to the formation of many "halogenated compounds" some of which are either known or suspected carcinogens. As a result, many chlorine alternatives are receiving renewed interest. These include bromine, bromine-chloride, iodine and chlorine dioxide – but these do not seem to present a viable alternative to chlorine at the present time. Ozone is showing the greatest promise, and ultra-violet irradiation's limited usefulness as complimentary agents for chlorine in water disinfection.

Ozonation *(19)*

Ozone is a powerful oxidant and has many uses in water treatment, including oxidation of organic chemicals. Ozone can be used as a primary disinfectant. Ozone gas (O_3) is formed by passing dry air or oxygen through a high-voltage electric field. The resultant ozone-enriched air is dosed directly into the water by means of porous diffusers at the base of baffled contactor tanks. The contactor tanks, typically about 5 metre deep, provide 10–20 minutes of contact time. Dissolution of atleast 80% of the applied ozone should be possible, with the remainder contained in the off-gas, which is passed through an ozone destructor and vented to the atmosphere.

The performance of ozonation relies on achieving the desired concentration after a given contact period. For

oxidation of organic chemicals, such as some oxidizable pesticides, a residual of about 0.5 mg/l after a contact time of upto 20 minutes is typically used. The doses required to achieve this vary with the type of water, but are typically in the range 2–5 mg/l. Higher doses are needed for untreated waters, because of the ozone demand of the natural background organics.

Ozone reacts with natural organics to increase their biodegradability, measured as assimilable organic carbon. To avoid undesirable bacterial growth in distribution, ozonation is normally used with subsequent treatment, such as biological filtration or granular activated carbon (GAC), to remove biodegradable organics, followed by a chlorine residual, as ozone does not provide a disinfectant residual. Ozone is effective for the degradation of a wide range of pesticides and other organic chemicals.

Membrane processes *(19)*

The membrane processes of most significance in water treatment are reverse osmosis, ultrafiltration, microfiltration and nanofiltration. These processes have traditionally been applied to the production of water for industrial or pharmaceutical applications, but are now being applied to the treatment of drinking-water.

High-pressure processes

If two solutions are separated by a semipermeable membrane (i.e. a membrane that allows the passage of the solvent but not of the solute), the solvent will naturally pass from the lower-concentration solution to the higher-concentration solution. This process is known as osmosis. It is possible however, to force the flow of solvent in the opposite direction, from the higher to the lower concentration, by increasing the pressure on the higher-concentration solution. The required pressure differential is known as the osmotic pressure, and the process is known as reverse osmosis.

Reverse osmosis results in the production of a treated water stream and a relatively concentrated waste stream. Typical operating pressures are in the range 15–50 bar, depending on the application. Reverse osmosis rejects monovalent ions and organics of molecular weight greater than about 50 daltons (membrane pore sizes are less than 0.002 μm). The most common application of reverse osmosis is desalination of brackish water and seawater.

Nanofiltration uses a membrane with properties between those of reverse osmosis and ultrafiltration membranes; pore sizes are typically 0.001–0.01 μm. Nanofiltration membranes allow monovalent ions such as sodium or potassium to pass but reject a high proportion of divalent ions such as calcium and magnesium and some higher molecular weight organics. Operating pressures are typically about 5 bar. Nanofiltration may be effective for the removal of colour-forming organic compounds also.

Lower-pressure processes

Ultrafiltration is similar in principle to reverse osmosis, but the membranes have much larger pore sizes (typically 0.002–0.03 μm) and operate at lower pressures. Ultrafiltration membranes reject organic molecules of molecular weight above about 800 daltons and usually operate at pressure less than 5 bar.

Microfiltration is a direct extension of conventional filtration into the sub-micrometre range. Microfiltration membranes have pore sizes typically in the range 0.01–12 μm and do not separate molecules but reject colloidal and suspended material at operating pressures of 1–2 bar. Microfiltration is capable of sieving out particles greater than 0.05 μm. It has been used for water treatment in combination with coagulation or PAC to remove particulates and some dissolved organic carbon prior to reverse osmosis membranes and to improve permeate flux.

2. PURIFICATION OF WATER ON A SMALL SCALE

(1) Household purification of water

Three methods are generally available for purifying water on an individual or domestic scale. These methods can be used singly or in combination.

(a) BOILING

Boiling is a satisfactory method of purifying water for household purposes. To be effective, the water must be brought to a "rolling boil" for 10 to 20 minutes. It kills all bacteria, spores, cysts and ova and yields sterilized water. Boiling also removes temporary hardness by driving off carbon dioxide and precipitating the calcium carbonate. The taste of water is altered, but this is harmless. While boiling is an excellent method of purifying water, it offers no "residual protection" against subsequent microbial contamination. Water should be boiled preferably in the same container in which it is to be stored to avoid contamination during storage.

(b) CHEMICAL DISINFECTION

(1) *Bleaching powder :* Bleaching powder or chlorinated lime ($CaOCl_2$) is a white amorphous powder with a pungent smell of chlorine. When freshly made, it contains about 33 per cent of "available chlorine". It is, however, an unstable compound. On exposure to air, light and moisture, it rapidly loses its chlorine content. But when mixed with excess of lime, it retains its strength; this is called "stabilized bleach." Bleaching powder should be stored in a dark, cool, dry place in a closed container that is resistant to corrosion. The chlorine content of bleaching powder stocks should be frequently checked.

Appendix III gives in a tabular form the amount of bleaching powder required to disinfect certain quantities of water. The principle in chlorination is to ensure a "free" residual chlorine of 0.5 mg/litre at the end of one hour contact. Highly polluted and turbid waters are not suited for direct chlorination.

(2) *Chlorine solution :* Chlorine solution may be prepared from bleaching powder. If 4 kg of bleaching powder with 25 per cent available chlorine is mixed with 20 litres of water, it will give a 5 per cent solution of chlorine *(13)*. Ready-made chlorine solutions in different strengths are also available in the market. Like bleaching powder, the chlorine solution is subject to losses on exposure to light or on prolonged storage. The solution should be kept in a dark, cool and dry place in a closed container.

(3) *High test hypochlorite :* High test hypochlorite (HTH) or perchloron is a calcium compound which contains 60 to 70 per cent available chlorine. It is more stable than bleaching powder and deteriorates much less on storage. Solutions prepared from HTH are also used for water disinfection. Appendix III (page 730) shows the amount of HTH needed to disinfect certain quantities of water.

(4) *Chlorine tablets :* Under various trade names (viz., halazone tablets) are available in the market. They are quite good for disinfecting small quantities of water, but they are costly. The National Environmental Engineering Research Institute, Nagpur formulated a new type of chlorine tablet which is 15 times better than ordinary halogen tablets. These tablets are manufactured in various strengths and are now available in plenty, in the Indian market at a cheap rate. A single tablet of 0.5 g is sufficient to disinfect 20 litres of water.

(5) *Iodine :* Iodine may be used for emergency disinfection of water. Two drops of 2 per cent ethanol solution of iodine will suffice for one litre of clear water. A contact time of 20 to 30 minutes is needed for effective disinfection. Iodine does not react with ammonia or organic compounds to any great extent; hence it remains in its active molecular form, over a wide range of pH values and water conditions and persists longer than either chlorine or bromine. Iodine is unlikely to become a municipal water supply disinfectant in a broad sense. High costs and the fact that the element is physiologically active (thyroid activity) are its major disadvantages *(17)*.

(6) *Potassium permanganate :* Once widely used it is no longer recommended for water disinfection. Although a powerful oxidizing agent, it is not a satisfactory agent for disinfecting water. It may kill cholera vibrios, but is of little use against other disease organisms*(15)*. It has other drawbacks, too, such as altering the colour, smell and taste of water.

(c) FILTRATION

Water can be purified on a small scale by filtering through ceramic filters such as Pasteur Chamberland filter, Berkefeld filter and "Katadyn" filter. The essential part of a filter is the "candle" which is made of porcelain in the Chamberland type, and of kieselgurh or infusorial earth in the Berkefeld filter (Fig. 8). In the Katadyn filter, the surface of the filter is coated with a silver catalyst so that bacteria coming in contact with the surface are killed by the "oligodynamic" action of the silver ions, which are liberated into the water. Filter candles of the fine type usually remove bacteriae found in drinking water, but not the filter–passing viruses. Filter candles are liable to be logged with impurities and bacteriae. They should be cleaned by scrubbing with a hard brush under running water and boiled at least once a week. Only clean water should be used with ceramic filters. Although ceramic filters are effective in purifying water, they are not quite suitable for widespread use under Indian conditions.

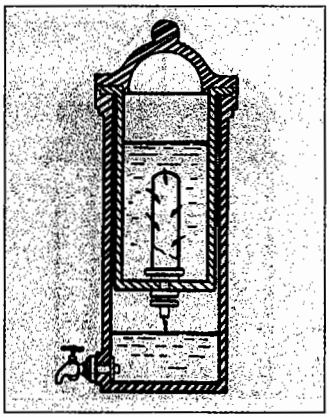

FIG. 8
Berkefeld filter

(d) ULTRAVIOLET IRRADIATION

Germicidal property of UV rays have been recognized for many years. UV irradiation is effective against most microorganisms known to contaminate water supplies like bacteria, yeast, viruses, fungi, algae, protozoa etc.

This method of disinfection involves the exposure of a film of water, upto about 120 mm thick, to one or several quartz mercury vapour arc lamps emitting ultraviolet radiation at a wavelength of 254 (Nano-metre). Applications are limited to individual or institutional systems. The water should be free from turbidity and suspended or colloidal constituents for efficient disinfection.

The advantages are that the exposure is for short period, no foreign matter introduced and no taste and odour produced. Overexposure does not result in any harmful effects. The disadvantages are that no residual effect is available and there is a lack of a rapid field test for assessing the treatment efficiency; moreover, the apparatus needed is expensive.

(e) MULTI-STAGE REVERSE OSMOSIS PURIFICATION OF WATER

Multistage reverse osmosis purification process is used to make water both chemically and microbiologically potable by reducing the total dissolved solids, hardness, heavy metals and disease causing bacteria, virus, protozoa and cysts.

The Fig. 9 shows the diagrammatic form and the various elements of a typical multistage reverse osmosis process.

The clarity cartridge removes the suspended particles such as dust, mud and sand from the water. The Reverse osmosis cartridge reduces the total dissolved solids, hardness, heavy metals (like arsenic, lead, mercury) and eliminates micro-organisms.

(2) Disinfection of wells

Wells are the main source of water supply in the rural areas. The need often arises to disinfect them, sometimes on a mass scale, during epidemics of cholera and gastroenteritis. The most effective and cheapest method of disinfecting wells is by bleaching powder. *Potassium permanganate* should not be used, as it is not a satisfactory disinfecting agent.

STEPS IN WELL DISINFECTION

(1) Find the volume of water in a well

(a) Measure the depth of water column ... (h) metre

(b) Measure the diameter of well ... (d) metre

Take the average of several readings of the above measurements.

(c) Substitute h and d in :

$$\text{Volume (litres)} = \frac{3.14 \times d^2 \times h}{4} \times 1000$$

(d) One cubic metre = 1,000 litres of water

(2) Find the amount of bleaching powder required for disinfection

Estimate the chlorine demand of the well water by *"Horrock's Apparatus* (vide Annex I) and calculate the amount of bleaching powder required to disinfect the well. Annex–III gives the amount of chemicals needed to disinfect water for drinking. Roughly, 2.5 grams of good quality

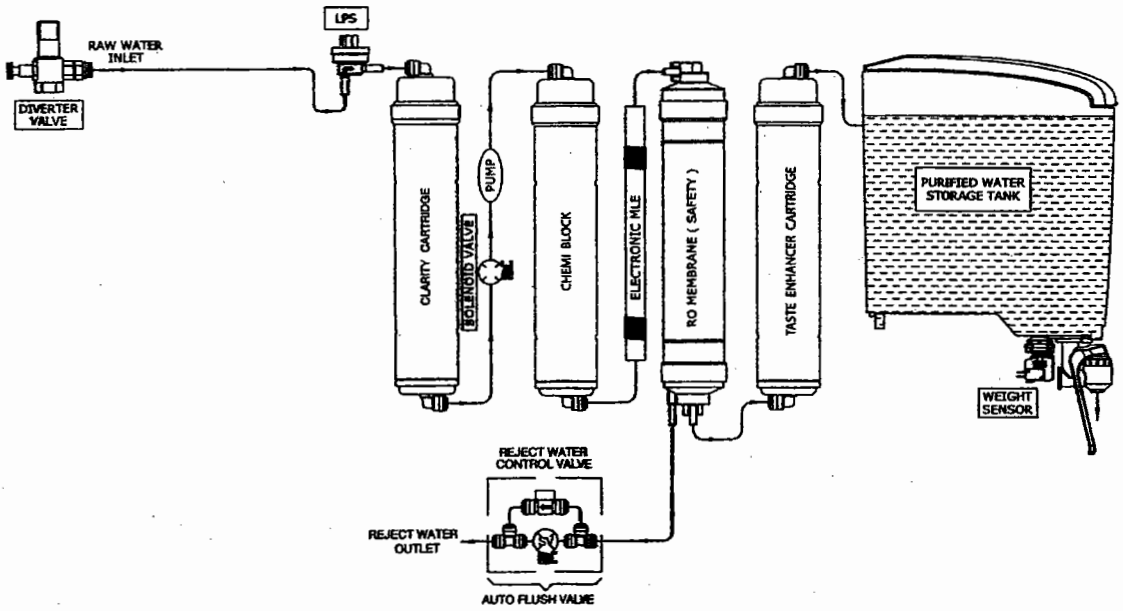

FIG. 9
Multistage reverse osmosis purification of water

bleaching powder would be required to disinfect 1,000 litres of water. This will give an approximate dose of 0.7 mg of applied chlorine per litre of water.

(3) Dissolve bleaching powder in water

The bleaching powder required for disinfecting the well is placed in a bucket (not more than 100 g in one bucket of water) and made into a thin paste. More water is added till the bucket is nearly three-fourths full. The contents are stirred well, and allowed to sediment for 5 to 10 minutes when lime settles down. The supernatant solution which is chlorine solution, is transferred to another bucket, and the chalk or lime is discarded. (Note : the lime sediment should not be poured into the well, as it increases the hardness of well water).

(4) Delivery of chlorine solution into the well

The bucket containing the chlorine solution is lowered some distance below the water surface, and the well water is agitated by moving the bucket violently both vertically and laterally. This should be done several times so that the chlorine solution mixes intimately with the water inside the well.

(5) Contact period

A contact period of one hour is allowed before the water is drawn for use.

(6) Orthotolidine arsenite test

It is good practice to test for residual chlorine at the end of one hour contact. If the "free" residual chlorine level is less than 0.5 mg/litre, the chlorination procedure should be repeated before any water is drawn. Wells are best disinfected at night after the day's draw off. During epidemics of cholera, wells should be disinfected every day.

THE DOUBLE POT METHOD *(13, 18)*

During an emergency, it is desirable to ensure a constant dosage of chlorine to well water. Several simple and effective methods have been devised for this purpose, of which the pot method of chlorination is one which has been used with success in various countries. The double pot method is an improvement devised by the National Environmental Engineering Research Institute, Nagpur, India. This method uses two cylindrical pots, one placed inside the other. The inside height and diameter are 30 cm and 25 cm respectively, for the outer pot. A hole 1 cm in diameter is made in each pot; in the inner pot the hole is in the upper portion, near the rim and in the outer pot it is 4 cm above the bottom.

A mixture of 1 kg of bleaching powder and 2 kg of coarse sand (approx. 2 mm in diameter) is prepared and slightly moistened with water. The inner pot is filled with this mixture up to 3 cm below the level of the hole. The inner pot is introduced into the outer one, and the mouth of the latter closed with polyethylene foil. The use of two pots makes it possible to have larger holes without the risk of over chlorination.

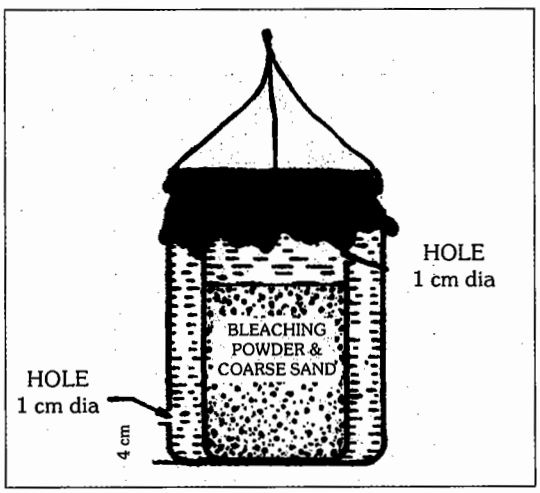

FIG. 10
Double pot

The double pot is lowered into the well by means of a rope attached to the well kerb. The pot should be immersed at least 1 m below the water level to prevent damage by the buckets used for drawing water. It has been found that this device works satisfactorily for 2–3 weeks in small household wells containing about 4,500 litres of water and having a draw-off rate of 360–450 litres per day.

WATER QUALITY – CRITERIA AND STANDARDS

The quest for pure water dates back to antiquity. In modern times, it has led to the formulation of specific standards to provide a basis for judging the quality of water. These standards are exposure limits for bacteriological, viral, chemical and physical agents that have been adopted by governments or appropriate authorities and therefore have legal force. The purpose of standards is to minimise all the known health hazards, since it is obviously impossible to prevent all pollution.

The WHO has published in 1993 vol.1 and in 1996 vol. 2 of second edition, and more recently vol. I and II in 2011 of *guidelines for drinking water quality* intended for use by countries as a basis for the development of standards, which, if properly implemented, will ensure the safety of drinking water supplies. In order to define standards, it is necessary to consider these recommendations in the context of prevailing environmental, social, economic and cultural conditions. These guidelines are intended to supersede the guidelines for drinking water published in 1984 *(19)*.

The guidelines for drinking water quality recommended by WHO (2011) relate to following variables :

I Acceptability aspects
II Microbiological aspects
III Chemical aspects
IV Radiological aspects.

I. ACCEPTABILITY ASPECTS

A. Physical parameters

The ordinary consumer judges the water quality by its physical characteristics. The provision of drinking water that is not only safe but also pleasing in appearance, taste and odour is a matter of high priority. The supply of water that is unsatisfactory in this respect will undermine the confidence of consumers, leading to use of water from less safe source. The acceptability of drinking water can be influenced by many different constituents. These are :

1. *Turbidity :* On aesthetic grounds, drinking water should be free from turbidity. Turbidity in drinking water is caused by particulate matter that may be present as a consequence of inadequate treatment or from resuspension of sediment in the distribution system. It may also be due to the presence of inorganic particulate matter in some ground water. Turbidity interferes with disinfection and microbiological determination. Water with turbidity of more than 4 nephelometric turbidity units (NTU) is usually noticeable to the naked eye.

2. *Colour :* Drinking water should be free from colour which may be due to the presence of coloured organic matter (primarily humic substances), metals such as iron and manganese, or highly coloured industrial wastes. Consumers may turn to alternative, perhaps unsafe, sources when their water is coloured to an aesthetically displeasing degree. The guideline value is upto 15 true colour units (TCU) although levels of colour above 15 TCU can be detected in a glass of water.

3. *Taste and odour :* Taste and odour originate from natural and biological sources or processes, from contamination by chemicals, or as a by-product of water treatment (e.g., chlorination). Taste and odour may develop during storage and distribution. It is indicative of some form of pollution or malfunction during water treatment or distribution. The cause should be investigated, particularly if there is substantial change. An unusual taste or odour might be an indication of the presence of potentially harmful substances. No health based guideline value is proposed for taste and odour.

4. *Temperature :* Cool water is generally more palatable. Low water temperature tends to decrease the efficiency of treatment process, including disinfection, and may thus have a deleterious effect on drinking water quality. However, high water temperature enhances the growth of microorganisms and taste, odour, colour and corrosion problem may increase. No guideline value is recommended since its control is usually impracticable.

To sum up, we cannot judge the quality of drinking water by physical characteristics alone. A detailed chemical and microbiological examination is also needed for complete assessment.

B. Inorganic constituents

1. *Chlorides :* All waters including rain water contain chlorides. In the neighbourhood of the sea, the salinity of water tends to be high. Since the chloride content of water varies from place to place, it is necessary, first of all, to determine the normal range of chlorides of the unpolluted surface and ground water in the given locality. Any excess over the normal range should arouse suspicion of water contamination. The standard prescribed for chloride is 200 mg/litre. The maximum permissible level is 600 mg/litre.

2. *Hardness :* Public acceptability of the degree of hardness may vary considerably from one community to another, depending on local conditions. The taste threshold for the calcium ion is in the range of 100–300 mg/litre, depending on the associated anion, and the taste threshold of magnesium is probably less than that for calcium. In some instances water hardness in excess of 500 mg/litre is tolerated by consumers.

Depending on the interaction of other factors, such as pH and alkalinity, water with a hardness of approximately 200 mg/litre may cause scale deposition in the distribution system and will result in excessive soap consumption and subsequent scum formation. On heating, hard water forms deposits of calcium carbonate scale. Soft water, with a hardness of less than 100 mg/litre, may, on the other hand, have a low buffer capacity and so be more corrosive for water pipes *(19)*.

3. *Ammonia :* The term ammonia includes the non-ionized (NH_3) and ionized (NH_4+). Ammonia in the environment originates from metabolic, agricultural and industrial processes and from disinfection with chloramine. Natural levels in ground and surface waters are usually below 0.2 mg/litre. Anaerobic ground waters may contain upto 3mg/litre. Intensive rearing of farm animals can give rise to much higher levels in surface water. Ammonia contamination can also arise from cement mortar pipe linings. Ammonia in water is an indicator of possible bacterial, sewage and animal waste pollution. Ammonia can

compromise disinfection efficiency, result in nitrite formation in distribution systems, can cause the failure of filters for the removal of manganese, and cause taste and odour problems.

4. *pH :* One of the main objectives in controlling the pH is to minimize corrosion and incrustation in the distribution system. pH levels of less than 7 may cause severe corrosion of metals in the distribution pipes and elevated levels of certain chemical substances, such as lead, may result. At pH levels above 8, there is a progressive decrease in the efficiency of the chlorine disinfection process. An acceptable pH drinking water is between 6.5 and 8.5. In the absence of a distribution system, the acceptable range of pH may be broader.

5. *Hydrogen sulphide :* The taste and odour threshold of hydrogen sulphide in water are estimated to be between 0.05 and 0.1 mg/litre. The "rotten eggs" odour of hydrogen sulphide is particularly noticeable in some ground waters and in stagnant drinking water in the distribution system, as a result of oxygen depletion and the subsequent reduction of sulphate by bacterial activity. Sulphide is oxidized rapidly to sulphate in well-aerated water, and hydrogen sulphide level in oxygenated water supplies are normally very low. The presence of hydrogen sulphide in drinking water can be easily detected by the consumer and requires immediate corrective action.

6. *Iron :* Anaerobic ground water may contain ferrous iron at concentrations of upto several mg/litre without discoloration or turbidity in water when directly pumped from the well. On exposure to the atmosphere, however, the ferrous iron oxidizes to ferric iron, giving an objectionable reddish – brown colour to the water. Iron also promotes the growth of "iron bacteria", which derive their energy from the oxidation of ferrous iron to ferric iron, and in the process deposit a slimy coating on the pipe. At level above 0.3 mg/litre, iron stains laundry and plumbing fixtures.

7. *Sodium :* The taste threshold concentration of sodium in water depends on the associated anion and the temperature of the solution. At room temperature, the average taste threshold for sodium is about 200 mg/litre.

8. *Sulphate :* The presence of sulphate in drinking water can cause noticeable taste. Taste impairment varies with the nature of the associated cation. It is generally considered that taste impairment is minimal at levels below 250 mg/litre. It has been found that addition of calcium and magnesium sulphate (but not sodium sulphate) to distilled water improves the taste; optimal taste was recorded at 270 and 90 mg/litre for the two compounds respectively.

9. *Total dissolved solids :* Total dissolved solids (TDS) can have an important effect on the taste of drinking water. The palatability of water with a TDS level of less than 600 mg/litre is generally considered to be good. Drinking water becomes increasingly unpalatable at TDS levels greater than 1,200 mg/litre. Water with extremely low concentrations of TDS may be unacceptable because of its flat, insipid taste. The presence of high level of TDS may also be objectionable to consumers owing to excessive scaling in water pipes, heaters, boilers and household appliances. Water with concentrations of TDS below 1000 mg/litre is usually acceptable to the consumers.

10. *Zinc :* Zinc imparts an undesirable astringent taste to water. Tests indicate a taste threshold concentration of 4 mg/litre (as zinc sulphate). Water containing zinc at concentrations in excess of 5 mg/litre may appear opalescent and develop a greasy film on boiling, although these effects may also be noticeable at concentrations as low as 3 mg/litre. Drinking water seldom contains zinc at concentrations above 0.1 mg/litre, levels in tapwater can be considerably higher because of the zinc used in plumbing material.

11. *Manganese :* Manganese concentrations below 0.1 mg/litre are usually acceptable to consumers, this may vary with local circumstances. At levels above 0.1 mg/litre, manganese in water supplies stains sanitary ware and laundry, and causes an undesirable taste in beverages. It may lead to accumulation of deposits in the distribution system. Even at concentration of 0.2 mg/litre, manganese will often form a coating on pipes, which may slough off as a black precipitate.

12. *Dissolved oxygen :* The dissolved oxygen content of water is influenced by the raw water temperature, composition, treatment and any chemical or biological processes taking place in the distribution system. Depletion of dissolved oxygen in water supplies can encourage microbial reduction of nitrate to nitrite and sulphate to sulphide, giving rise to odour problem. It can also cause an increase in the concentration of ferrous iron in solution. No health–based guideline value has been recommended.

13. *Copper :* The presence of copper in a water supply may interfere with the intended domestic uses of water. It increases the corrosion of galvanized iron and steel fittings. Staining of laundry and sanitary ware occurs at copper concentrations above 1 mg/litre.

14. *Aluminium :* The presence of aluminium at concentrations in excess of 0.2 mg/litre often leads to deposition of aluminium hydroxide floc in distribution system and the exacerbation of discoloration of water by iron.

Substances and parameters in drinking water and the reasons for consumer complaints are listed in Table 4.

II. MICROBIOLOGICAL ASPECTS

(a) **Bacteriological indicators :** Natural and treated waters vary in microbiological quality. Ideally, drinking water should not contain any microorganisms known to be pathogenic. It should also be free from bacteria indicative of pollution with excreta. Failure to provide adequate protection, effective treatment and disinfection of drinking water will expose the community to the risk of outbreaks of intestinal and other infectious diseases. Those at greatest risk of water-borne diseases are infants and young children, people who are debilitated or living under insanitary conditions, the sick and the elderly. For them the infective dose is significantly lower than for the healthy population. The potential consequences of microbial contamination are such that its control must always be of paramount importance and must never be compromised.

The primary bacterial indicator recommended for this purpose is the coliform group of organisms as a whole. Supplementary indicator organisms, such as faecal streptococci and sulphite-reducing clostridia, may sometimes be useful in determining the origin of faecal pollution as well as in assessing the efficiency of water treatment processes.

(1) *Coliform organisms :* The "coliform" organisms include all aerobic and facultative anaerobic, gram-negative, non–sporing, motile and non–motile rods capable of fermenting lactose at 35 to 37 deg. C in less than 48 hours. The coliform group includes both faecal and non-faecal organisms. Typical example of the faecal group is *E. coli* and

TABLE 4
Substances and parameters in drinking-water that may give rise to complaints from consumers

Constituents or characteristics	Levels likely to give rise to consumer complaints	Reasons for consumer complaints
Physical parameters		
Colour	15 TCU	appearance
Taste and odour	–	should be acceptable
Temperature	–	should be acceptable
Turbidity	1 NTU	appearance; for effective terminal disinfection, median turbidity ≤1 NTU,
Inorganic constituents		
Aluminium	0.2 mg/L	depositions, discolouration
Ammonia	1.5 mg/L	odour and taste
Chloride	250 mg/L	taste, corrosion
Copper	1 mg/L	staining of laundry and sanitary ware (health based provisional guideline value 2 mg/L)
Hardness	–	high hardness : scale deposition, scum formation; low hardness; possible corrosion
Hydrogen sulfide	0.05 mg/L	odour and taste
Iron	0.3 mg/L	staining of laundry and sanitary ware
Manganese	0.1 mg/L	staining of laundry and sanitary ware (health-based provisional guideline value 0.4 mg/L)
Dissolved oxygen	–	indirect effects
pH	–	low pH : corrosion; high pH : taste, soapy feel preferably < 8.0 for effective disinfection with chlorine
Sodium	200 mg/L	taste
Sulphate	250 mg/L	taste, corrosion
Total dissolved solids	1000 mg/L	taste
Zinc	4 mg/L	appearance, taste

Source : *(19)*

of the non-faecal group, *Klebsiella aerogens.* From a practical point of view it is assumed that all coliforms are of faecal origin unless a non–faecal origin can be proved.

There are several reasons why coliform organisms are chosen as indicators of faecal pollution rather than the water–borne pathogens directly : (1) the coliform organisms are constantly present in great abundance in the human intestine. It is estimated that an average person excretes 200–400 billion of these organisms per day. These organisms are foreign to potable waters, and hence their presence in water is looked upon as evidence of faecal contamination, (2) they are easily detected by culture methods – as small as one bacteria in 100 ml of water, whereas the methods for detecting the pathogenic organisms are complicated and time-consuming, (3) they survive longer than the pathogens, which tend to die out more rapidly than coliform bacilli, (4) the colifiorm bacilli have greater resistance to the forces of natural purification than the water borne pathogens. If the coliform organisms are present in a water sample, the assumption is the probable presence of intestinal pathogens.

(2) *Faecal streptococci :* Faecal streptococci regularly occur in faeces, but in much smaller numbers than *E.coli;* in doubtful cases, the finding of faecal streptococci in water is regarded as important confirmatory evidence of recent faecal pollution of water. Streptococci are highly resistant to drying and may be valuable for routine control testing after laying new mains or repairs in distribution systems or for detecting pollution by surface run-off to ground or surface waters.

(3) *Cl. perfringens :* They also occur regularly in faeces, though generally in much smaller numbers than *E.coli.* The spores are capable of surviving in water for a longer time than organisms of the coliform group, and usually resist chlorination at the doses normally used in waterworks practice. The presence of spores of *Cl. perfringens* in a natural water suggests that faecal contamination has occurred, and their presence, in the absence of the coliform group, suggests that faecal contamination occurred at some remote time. Its presence in filtered supplies may indicate deficiency in filtration practice.

The guideline values for bacteriological quality are given in Table 5. It is only a guidance required to ensure bacteriologically safe supplies of drinking water whether piped, unpiped or bottled.

(b) **Virological aspects :** It is recommended that, to be acceptable, drinking–water should be free from any viruses infections for man. Disinfection with 0.5 mg/L of free chlorine residual after contact period of at least 30 minutes at a pH of 8.0 is sufficient to inactivate virus. This free chlorine residual is to be insisted in all disinfected supplies in areas suspected of endemicity of hepatitis A to take care of the safety of the supply from the virus point of view, which incidently takes care of safety from the bacteriologic point of view as well. For other areas 0.2 mg/L of free residual chlorine for half an hour should be insisted. The turbidity condition of 1 NTU or less, must be fulfilled prior to disinfection of water if adequate treatment is to be achieved. Ozone has been shown to be effective viral disinfectant, preferably for clean water, if residuals of 0.2–0.4 mg/L are maintained for 4 minutes, but it is not possible to maintain an ozone residual in distribution system.

(c) **Biological aspects :** (i) *Protozoa* – Species of protozoa known to have been transmitted by the ingestion of contaminated drinking-water include *Entamoeba histolytica, Giardia spp.* and *rarely, Balantidium coli.* These organisms can be introduced into water supply through human or, in some instances, animal faecal contamination. Drinking-water should not contain any pathogenic intestinal

TABLE 5

Bacteriological quality of drinking-water[a]

Organisms	Guideline value
All water intended for drinking	
E.coli or thermotolerant coliform bacteria[b,c]	Must not be detectable in any 100 ml sample
Treated water entering the distribution system	
E.coli or thermotolerant coliform bacteria[b]	Must not be detectable in any 100 ml sample
Total coliform bacteria	Must not be detectable in any 100 ml sample
Treated water in the distribution system	
E.coli or thermotolerant coliform bacteria[b]	Must not be detectable in any 100 ml sample
Total coliform bacteria	Must not be detectable in any 100 ml sample. In the case of large supplies, where sufficient samples are examined, must not be present in 95% of samples taken throughout any 12 month period.

a. Immediate investigative action must be taken if either *E.coli* or total coliform bacteria are detected. The minimum action in the case of total coliform bacteria is repeat sampling; if these bacteria are detected in the repeat sample, the cause must be determined by immediate further investigation.

b. Although *E.coli* is the more precise indicator of faecal pollution, the count of thermotolerant coliform bacteria is an acceptable alternative. If necessary, proper confirmatory tests must be carried out. Total coliform bacteria are not acceptable indicators of the sanitary quality of rural water supplies, particularly in tropical areas where many bacteria of no sanitary significance occur in almost all untreated supplies.

c. It is recognized that, in the great majority of rural water supplies in developing countries, faecal contamination is widespread. Under these conditions, the national surveillance agency should set medium-term targets for progressive improvement of water supplies.

protozoa. Rapid or slow sand filtration have been shown to be effective in removing a high proportion of pathogenic protozoa. Standard methods are not currently available for the detection of pathogenic protozoa in water supplies in the context of a routine monitoring programme; (ii) *Helminths* : The infective stages of many parasitic roundworms and flatworms can be transmitted to man through drinking-water. A single mature larva or fertilized egg can cause infection and such infective stages should be absent from drinking-water. However, the water route is relatively unimportant except in the case of *Dracunculus medinensis* (guinea worm) and the human schistosomes, which are primarily hazards of unpiped water supplies. Source protection is the best approach to prevention. The methods for detection of these parasites are unsuited for routine monitoring; (iii) *Free-living organisms* : Free living organisms that may occur in water supplies include fungi, algae etc. The most common problem with these are their interference in the operation of water-treatment process, colour, turbidity, taste and odour of finished water.

III. CHEMICAL ASPECTS

The health risk due to toxic chemicals in drinking water differs from that caused by micro-biological contaminants. There are few chemical constituents of water that can lead to acute health problems except through massive accidental contamination of a supply. Moreover, experience shows that, in such incidents the water usually becomes undrinkable owing to unacceptable taste, odour and appearance.

The chemicals selected for the development of guideline value include those considered potentially hazardous to human health, those detected relatively frequently in drinking water and those detected in relatively high concentrations. The problem associated with chemical constituents of drinking water arise primarily from their ability to cause adverse health effects after prolonged periods of exposure; of particular concern are contaminants that have cumulative toxic properties, such as heavy metals and substances that are carcinogenic.

Health-related chemical constituents

The presence of certain chemicals in excess of prescribed limits may constitute ground for rejection of the water as a source of public water supply. These substances may be inorganic or organic *(9)*.

a. Inorganic constituents : These substances include arsenic, cadmium, chromium, cyanide, fluoride, lead, mercury, nickel, nitrate, selenium etc. The guide line value of these constituents are as shown in Table 6.

1. *Arsenic :* Arsenic is introduced into water through the dissolution of minerals and ores, from industrial effluents, and from atmospheric deposition; concentrations in ground water in some areas are sometimes elevated as a result of erosion from natural sources. The average daily intake of inorganic arsenic in water is estimated to be similar to that from food. Intake from air is negligible. A provisional guideline value for arsenic in drinking water of 0.01 mg/litre is established.

TABLE 6

Inorganic chemicals of health significance in drinking water

Constituents	Recommended maximum limit of concentration (mg/litre)	(µg/litre)
Antimony	0.02 (P)	20
Arsenic	0.01 (P)	10
Barium	0.7	700
Boron	2.4	2,400
Cadmium	0.003	0.3
Chromium	0.05 (P)	50
Copper	2	2,000
Fluoride	1.5	1,500
Lead	0.01	10
Manganese	0.4 (P)	400
Mercury (total)	0.006	6
Molybdenum	0.07	70
Nickel	0.07	70
Nitrate (as NO_3)	50	50,000
Nitrite (as NO_2)	3 (P)	3,000
Selenium	0.04	40

Source : *(19)* P – Provisional guideline value

2. *Cadmium :* Cadmium metal is used in the steel industry and in plastics. Cadmium compounds are widely used in batteries. It is released to the environment in waste-water and diffuse pollution is caused by contamination from fertilizers and local air pollution. Contamination in drinking water may also be caused by impurities in the zinc of galvanized pipes and some metal fittings, although levels in drinking water are usually less than 1µg/litre. Absorption of cadmium compound is dependent on the solubility of the compound. Cadmium accumulates primarily in the kidneys and has a long biological half-life in humans of 10–35 years. A guideline value for cadmium is established at 0.3 µg/litre *(19)*.

3. *Chromium :* Chromium is widely distributed in the earth's crust. In general, food appears to be the major source of intake. The absorption of chromium after oral exposure is relatively low and depends on the oxidation state. The guideline value for chromium is 0.05 mg/litre, which is considered to be unlikely to give rise to significant health risks.

4. *Cyanide :* The acute toxicity of cyanide is high. Cyanides can be found in some foods, particularly in some developing countries, and they are usually found in drinking water, primarily as a consequence of industrial contamination. Effects on thyroid and particularly the nervous system were observed in some populations as a consequence of the long-term consumption of inadequately processed cassava containing high levels of cyanide.

5. *Fluoride :* Fluoride accounts for about 0.3 g/kg of the earth's crust. Inorganic fluorine compounds are used in the production of aluminium, and fluoride is released during the manufacture and use of phosphate fertilizers which contain upto 4 per cent fluorine. Levels of daily exposure of fluoride depends on the geographical area. If diets contain fish and tea, exposure *via* food may be particularly high. In specific areas, other foods and indoor air pollution may contribute considerably to total exposure. Additional intake may result from the use of fluoride toothpastes.

Exposure to fluoride from drinking water depends greatly on natural circumstances. Levels in raw water are normally below 1.5 mg/litre, but ground water may contain about 10 mg/litre in areas rich in fluoride – containing minerals. High fluoride levels, above 5 mg/litre, have been found in several countries (e.g., China, India and Thailand). Such high levels have at times led to dental or skeletal fluorosis. Fluoride is sometimes added to drinking water to prevent dental caries. Soluble fluorides are readily absorbed in the gastrointestinal tract after intake in drinking water. The guideline value suggested is 1.5 mg/litre. In setting national standards for fluoride, it is particularly important to consider climatic conditions, volume of water intake and intake of fluoride from other sources (e.g., food and air).

6. *Lead :* Lead is present in tapwater to some extent as a result of its dissolution from natural sources, but primarily from household plumbing systems containing lead in pipes, solder, fittings or the service connections to homes. The amount of lead dissolved from the plumbing system depends on several factors, including pH, temperature, water hardness and standing time of the water, with soft, acidic water being the most plumbosolvent.

Placental transfer of lead occurs in humans as early as twelfth week of gestation and continues throughout development. Young children absorb 4–5 times as much lead as adults, and the biological half-life may be considerably longer in children than in adults. Lead is a general toxicant that accumulates in the skeleton. Infants, children upto six years of age, and pregnant women are most susceptible to its adverse health effects. Lead also interferes with calcium metabolism, both directly and by interfering with vitamin D metabolism. Lead is toxic to both central and peripheral nervous system, inducing sub-encephalopathic neurological and behavioural effects. Renal tumours have been induced in experimental animals exposed to high concentrations of lead compounds in the diet and it is grouped in Group B (possible human carcinogen). The health-based guideline value of lead is 0.01 mg/litre.

Lead is exceptional in that most lead in drinking water arises from plumbing in buildings and the remedy consists principally of removing plumbing and fittings containing lead. This requires much time and money, and it is recognized that not all water will meet the guideline immediately. Measures to control corrosion should also be implemented.

7. *Mercury :* Mercury is present in inorganic form in surface and ground water at concentrations usually less than 0.5 µg/litre. The kidney is the main target organ for inorganic mercury, whereas methyl mercury affects mainly the central nervous system. The guideline value for total mercury is 0.006 mg/litre.

8. *Nitrate and nitrite :* Nitrate and nitrite are naturally occurring ions that are part of the nitrogen cycle. Naturally occurring nitrate level in surface and ground water are generally a few milligrams per litre. In many ground waters, an increase of nitrate level has been observed owing to the intensification of farming practice. In some countries, upto 10 per cent of the population may be exposed to nitrate levels in drinking water of above 50 mg/litre.

In general, vegetables are the main source of nitrate intake when levels in drinking water is below 10 mg/litre. When nitrate level in drinking water exceeds 50 mg/litre, drinking water will become the main source of total nitrate intake. The guideline value for nitrate in drinking water is solely to prevent methaemoglobinaemia, which depends upon the conversion of nitrate into nitrite. Bottle-fed infants of less than 3 months of age are most susceptible.

The guideline value should not be expressed on the basis of nitrate-nitrogen but on the basis of nitrate itself, which is the chemical entity of concern to health and the guideline value for nitrate is 50 mg/litre.

As a result of recent evidence of the presence of nitrite in some water supplies, it was concluded that a guideline value of 3 mg/litre for nitrite should be proposed. Because of the possibility of simultaneous occurrence of nitrite and nitrate in drinking water, the sum of the ratios of the concentration of each to its guideline value should not exceed 1, i.e.

$$\frac{\text{Concentration of nitrate}}{\text{Guideline value of nitrate}} + \frac{\text{Concentration of nitrite}}{\text{Guideline value of nitrite}} = \leq 1$$

9. *Selenium :* Selenium levels in drinking water vary greatly in different geographical areas, and are usually much less than the guideline value of 0.01 mg/litre. Food stuffs are the principal source, and the level depends according to geographical area of production. Selenium is an essential element for humans and forms an integral part of the enzyme glutathione peroxidase. Most selenium compounds are water soluble. In humans, the toxicity of long-term exposure are manifested in nails, hair and liver.

b. Organic constituents : The guideline values of some of the organic chemical constituents in water are as shown in Table 7.

TABLE 7

Guideline values for health related organic constituents

Organic constituents	Upper limit of concentration (µg/litre)
Chlorinated alkanes	
Carbon tetrachloride	2
Dichloromethane	20
Chlorinated ethenes	
Vinyl chloride	55
1.1 – dichloroethene	30
1.2 – dichloroethene	50
Aromatic hydrocarbons	
Benzene	10
Toluene	700
Xylenes	500
Ethylbenzene	300
Styrene	20
Benzolalpyrene	0.7

Source : *(19)*

Polynuclear aromatic hydrocarbons : A large number of polynuclear aromatic hydrocarbons (PAHs) from a variety of combustion and pyrolysis sources have been identified in the environment. The main source of human exposure to PAHs is food, with drinking water contributing only minor amounts.

Little information is available on the oral toxicity of PAHs, especially after long-term exposure. Benzo (a) pyrene, which constitutes a minor fraction of total PAHs have been found to be carcinogenic in mice by the oral route of administration. Some PAH compounds have been found to be carcinogenic by non-oral routes, Benzo (a) pyrene has been found to be mutagenic in a number of in *vitro* and in *vivo* assays.

The following recommendations are made for the PAH group :

- Because of the close association of PAH with suspended solids, the application of treatment, when necessary to achieve the recommended level of turbidity will ensure that PAH levels are reduced to a minimum.
- Contamination of water with PAH should not occur during water treatment or distribution. Therefore, the use of coal-tar-based and similar materials for pipe lining and coatings on storage tanks should be discontinued.
- In situation where contamination of drinking water by PAH has occurred, the specific compounds present and the source of the contamination should be identified, as the carcinogenic potential of PAH compounds varies.

Pesticides : The pesticides that are of importance in connection with water quality include chlorinated hydro–carbons and their derivatives, persistent herbicides, soil insecticides, pesticides that are easily leached out from the soil, and pesticides that are systematically added to water supplies for disease vector control. The recommended guideline value (Table 8) are set at a level to protect human health.

TABLE 8

Guideline values of certain pesticides

Pesticides	Upper limit of concentrations (µg/litre)
Aldrin/dieldrin	0.03
Chlordane	0.2
DDT	2
2,4-D	30
Heptachlor and heptachlor epoxide	0.03
Hexachlorobenzene	1
Lindane	2
Methoxychlor	20
Pentachlorophenol	9 (P)

Source : *(19)* P – Provisional value

Drinking water consumption and body weight : The average *daily per capita* consumption of drinking water is usually found to be around 2 litres, but there are considerable variations between individuals as water intake is likely to vary with climate, physical activity and culture, e.g., at temperature above 25°C, there is a sharp rise in fluid intake, largely to meet the demands of an increased sweat rate. In developing the guideline values for potentially hazardous chemicals, a daily *per capita* consumption of 2 litres by a person weighing 60 kg was generally assumed. However, such an assumption may underestimate the consumption of water per unit weight, and this exposure, for those living in hot climates as well as for infants and children, who consume more fluid per unit weight than adults. Where it was judged that this segment of the population was at a particularly high risk from exposure to certain chemicals, the guideline value was derived on the basis of a 10 kg child consuming 1 litre water per day or a 5 kg infant consuming 0.75 litre water per day.

Health-risk assessment : For most kinds of toxicity, it is generally believed that there is a dose below which no adverse effects will occur. For chemicals that give rise to such toxic effects, a tolerable daily intake (TDI) can be derived.

Tolerable daily intake (TDI) *:* The TDI is an estimate of the amount of a substance in food or drinking water, expressed on a body weight basis (mg/kg or µg/kg of body weight), that can be ingested daily over a lifetime without appreciable health risk *(19)*.

Acceptable daily intake (ADI) are established for food additives and pesticide residues that occur in food for necessary technological purposes or plant protection reasons. For chemical contaminants, which usually have no intended function in drinking water the term TDI is seen as more appropriate than ADI, as it signifies permissibility rather than acceptability.

No–observed–adverse–effect level (NOAEL) : The NOAEL is defined as the highest dose or concentration of a chemical in a single study, found by experiment or observation, that causes no detectable adverse health effect *(19)*. Whenever possible, the NOAEL is based on long–term studies, preferably of ingestion in drinking water.

Lowest–observed–adverse–effect level (LOAEL) : LOAEL

is the lowest observed dose or concentration of a substance at which there is a detectable adverse health effect *(19)*. When LOAEL is used instead of NOAEL, an additional uncertainty factor (UF) is normally used.

Uncertainty factors (UF) : The application of uncertainty factors has been widely used in the derivation of ADI for food additives, pesticides and environmental contaminants. The derivation of these factors requires expert judgement and a careful sifting of the available scientific evidence.

In the derivation of the WHO drinking water quality guideline values, uncertainty factors were applied to the lowest NOAEL or LOAEL for the response considered to be most biologically significant and were determined by consensus among a group of experts using the approach outlined below :

Source of uncertainty	Factor
Interspecies variation (animal to humans)	1 – 10
Intraspecies variation (individual variation)	1 – 10
Adequacy of studies or database	1 – 10
Nature and severity of effect	1 – 10

The total uncertainty factor should not exceed 10,000. If the risk assessment would lead to a higher uncertainty factor, then the resulting TDI would be so imprecise as to lack meaning. For substances for which uncertainty factors were greater than 1000, guideline values are designated as provisional in order to emphasize the high level of uncertainty inherent in these values *(19)*.

Derivation of guideline value using a TDI approach : TDI can be calculated by following formula.

$$TDI = \frac{NOAEL\ OR\ LOAEL}{UF}$$

The guideline value (GV) is then derived from the TDI as follows :

$$GV = \frac{TDI \times bw \times P}{C}$$

Where bw = body weight (60 kg for adult, 10 kg for children, 5 kg for infants)

P = fraction of the TDI allocated to drinking water

C = daily drinking water consumption (2 litres for adults, 1 litre for children and 0.75 litre for infants)

IV. RADIOLOGICAL ASPECTS

The effects of radiation exposure are called "somatic" if they become manifest in the exposed individual, and "hereditary" if they affect the descendants. Malignant disease is the most important delayed somatic effect *(30)*. For some somatic effects such as carcinogenesis, the probability of an effect occurring, rather than its severity, is regarded as a function of dose without a threshold (stochastic effect). Whereas for other somatic effects the severity of the effect varies with the dose (non-stochastic effects); a threshold may therefore exist for such effects. The aim of radiation protection is to prevent harmful non-stochastic effects and to reduce the probability of stochastic effects to a level deemed acceptable.

Radioactivity in drinking water should not only be kept within safe limits; it should also, within those limits, be kept as low as is reasonably possible. The guideline values recommended take account of both naturally occurring radioactivity and any radioactivity that may reach the water source as a result of man's activities. From a radiological point of view, they represent a value below which water can be considered potable without any further radiological examination.

The activity of a radio-active material is the number of nuclear disintegration per unit of time. The unit of activity is a becquerel (Bq); 1 Bq = 1 disintegration per second. Formerly, the unit of activity was curie (Ci).

The proposed guideline values are :

gross alpha activity 0.5 Bq / L
gross beta activity 1.0 Bq / L

SURVEILLANCE OF DRINKING WATER QUALITY *(20)*

The activities that ideally should be included in the surveillance function are :

a. approval of new sources (including private-owned supplies);
b. watershed protection;
c. approval of the construction and operating procedures of waterworks, including :
   (i) disinfection of the plant and of the distribution system after repair or interruption of supply,
   (ii) periodic flushing programmes and cleaning of water storage facilities,
   (iii) certification of operators,
   (iv) regulation of chemical substances used in water treatment,
   (v) cross-connection control, back-flow prevention and leak detection control ;
d. sanitary surveys;
e. monitoring programmes, including provision for central and regional analytical laboratory services;
f. development of codes of practice for well construction, pump installation and plumbing;
g. inspection quality control in bottled-water and ice manufacturing operations.

Surveillance of drinking water is essentially a health measure. It is intended to protect the public from water-borne diseases. The elements of a surveillance programme are :

1. Sanitary survey

Sanitary survey is an on-the-spot inspection and evaluation by a qualified person of the entire water supply system. The purpose of the survey is detection and correction of faults and deficiencies. A sanitary survey is essential for adequate interpretation of laboratory results.

2. Sampling

Sampling of water should be done with the thoroughness of a surgical operation, with the observation of similar aseptic precautions, for upon it depends the results of analysis. It should be carried out by competent and trained personnel in strict accordance with the methods and frequency of sampling prescribed in the WHO guidelines for drinking-water quality or the ICMR 'Manual of Standards of

Quality for Drinking Water Supplies' *(21)*. The methods of sampling are set out briefly in Appendix II.

3. Bacteriological surveillance

The tests usually employed in water bacteriology are presumptive coliform test, tests for the detection of faecal streptococci and *Cl. perfringens* and colony count. A complete bacteriological examination consists of all these tests.

(1) PRESUMPTIVE COLIFORM TEST

(i) *Multiple tube method :* This test is based on estimating the most probable number (MPN) of coliform organisms in 100 ml of water. The test is carried out by inoculating measured quantities of the sample water (0.1, 1.0, 10, 50 ml) into tubes of McConkey's Lactose Bile Salt Broth with bromcresol purple as an indicator. The tubes are incubated for 48 hours. From the number of tubes showing acid and gas, an estimate of the MPN of coliform organisms in 100 ml of the sample water can be obtained from statistical tables. This result is known as "presumptive coliform count", the presumption being each tube showing fermentation, contains coliform organisms. The reaction may occasionally be due to the presence of some other organisms or combination of organisms.

Confirmatory tests : The next step is to confirm the presence of coliform organisms in each tube showing a presumptive positive reaction. Such confirmation is not generally required in case of unchlorinated water, but is required in case of chlorinated water. Confirmation is done by subculturing each presumptive positive tube in 2 tubes of brilliant green bile broth, one of which is incubated at 37 deg C for up to 48 hours for confirmation of the presence of coliform organisms, and the other incubated at 44°C and inspected after 6 and 24 hours to decide whether or not *E. coli* is present. *E. coli* is almost the only coliform organism which is capable of producing gas from lactose at 44 deg C. Further confirmation of the presence of *E. coli,* if desired, can be obtained by testing for indol production at 44°C.

(ii) *Membrane filtration technique :* In some countries membrane filter technique is used as a standard procedure to test for the presence of coliform organisms. A measured volume of the sample is filtered through a membrane specially made of cellulose ester. All the bacteria present in water are retained on the surface of the membrane and by inoculating the membrane face upwards on suitable media and at appropriate temperature, it is possible to count the colonies and obtain results within 20 hours as compared to 72–96 hours required for the usual multiple tube technique.

(2) THE DETECTION OF FAECAL STREPTOCOCCI AND *Cl. PERFRINGENS*

The presence of faecal streptococci and *Cl. perfringens* provides useful confirmatory evidence of the faecal pollution of water in doubtful cases.

(3) COLONY COUNT

Colony counts on nutrient agar at 37 deg C and 22 deg C are frequently used in the bacteriological examination of water. Colony counts provide an estimate of the general bacterial purity of water. A single count is of little value, but counts from the same source at frequent intervals may be of considerable value. A sudden increase in the colony count may give the earliest indication of contamination. The recommended plate counts are:

Water at the point of consumption	*Plate count after 2 days at 37 deg C*	*Plate count after 3 days at 22 deg C.*
(i) Disinfected	0	20
(ii) Not-disinfected	10	100

Recent studies indicate that a bacterial plate count on yeast extract agar after incubation at 22 deg C for 7 days might serve as the best general purpose indicator of microbiological quality because in the absence of chlorine residual, the number of bacteria growing at 22 deg C after 7 days incubation can increase enormously *(22)*.

4. Biological examination

Water may contain microscopic organisms such as algae, fungi, yeast, protozoa, rotifers, crustaceans, minute worms, etc. These organisms are collectively called 'plankton'. The plankton organisms produce objectionable tastes and odours in water. They are an index of pollution. The degree of pollution is assessed qualitatively and quantitatively by noting the type and number of organisms prevailing in water.

5. Chemical surveillance

Chemical surveillance of drinking water is assuming greater importance in view of industrial and agricultural pollutants finding their way into raw water sources. Tests for pH, colour, turbidity, chlorides, ammonia, chlorine demand and residual chlorine are the basic tests. Regular measurement of chlorine residuals in supply may in part replace bacteriological surveillance. Tests for iron and manganese are required when these substances are present in the raw water in sufficient amount to influence water treatment. Complete chemical analysis would also include analysis for toxic metals, pesticides, persistent organic chemicals and radioactivity.

HARDNESS OF WATER

Hardness may be defined as the soap destroying power of water. The consumer considers water hard if large amounts of soap are required to produce lather. The hardness in water is caused mainly by four dissolved compounds. These are (1) Calcium bicarbonate (2) Magnesium bicarbonate (3) Calcium sulphate, and (4) Magnesium sulphate. The presence of any one of these compounds produces hardness. There are others which are of less importance. Chlorides and nitrates of calcium and magnesium can also cause hardness but they occur generally in small amounts. Iron, manganese and aluminium compounds also cause hardness, but as they generally are present in such small amounts, it is customary not to consider them in connection with hardness.

Hardness is classified as carbonate and non-carbonate. The carbonate hardness which was formerly designated as "temporary" hardness is due to the presence of calcium and magnesium bicarbonates. The non-carbonate hardness, formerly designated as "permanent" hardness, is due to calcium and magnesium sulphates, chlorides and nitrates.

Hardness in water is expressed in terms of "milli–equivalents per litre (mEq/L)". One mEq/L of hardness–producing ion is equal to 50 mg $CaCO_3$ (50ppm) in one litre of water *(23)*. The terms soft and hard water are used when the levels of hardness are as given in Table 9.

TABLE 9
Classification of hardness in water

Classification	Level of hardness (mEq./litre)
(a) Soft water	Less than 1 (<50 mg/L)
(b) Moderately hard	1–3 (50–150 mg/L)
(c) Hard water	3–6 (150–300 mg/L)
(d) Very hard water	over 6 (> 300 mg/L)

Drinking water should be moderately hard. Softening of water is recommended when the hardness exceeds 3 mEq/l (150 mg per litre).

DISADVANTAGES OF HARDNESS

Hardness in water presents several disadvantages both to the domestic and industrial consumer. These may be stated as follows: (1) hardness in water consumes more soap and detergents (2) when hard water is heated, the carbonates are precipitated and bring about furring or scaling of boilers. This leads to great fuel consumption, loss of efficiency and may sometimes cause boiler explosions (3) hard water adversely affects cooking; food cooked in soft water retains its natural colour and appearance (4) fabrics washed with soap in hard water do not have a long life (5) there are many industrial processes in which hard water is unsuited and gives rise to economic losses (6) hardness shortens the life of pipes and fixtures.

SPECIAL TREATMENT

(a) Removal of hardness

The methods of removal of hardness are briefly stated as below:

Temporary hardness

(a) Boiling
(b) Addition of lime
(c) Addition of sodium carbonate
(d) Permutit process.

Permanent hardness

(a) Addition of sodium carbonate
(b) Base exchange process.

1. BOILING

Boiling removes the temporary hardness by expelling carbon dioxide, and precipitating the insoluble calcium carbonate. It is an expensive method to soften water on a large scale.

$$Ca(HCO_3)_2 \longrightarrow CaCO_3 + H_2O + CO_2$$

2. ADDITION OF LIME

Lime softening not only reduces total hardness but also accomplishes magnesium reduction. Lime absorbs the carbon dioxide, and precipitates the insoluble calcium carbonate. In the Clark's method of softening water, one ounce of quick lime is added to every 700 gallons of water for each degree (14.25 ppm.) of hardness.

$$Ca(OH)_2 + Ca(HCO_3)_2 \longrightarrow 2CaCO_3 + 2H_2O$$

3. ADDITION OF SODIUM CARBONATE

Sodium carbonate (soda ash) removes both temporary and permanent hardness, as shown below :

(i) $Na_2CO_3 + Ca(HCO_3)_2 \longrightarrow 2NaHCO_3 + CaCO_3$
(ii) $CaSO_4 + Na_2CO_3 \longrightarrow CaCO_3 + Na_2SO_4$

4. BASE EXCHANGE PROCESS

In the treatment of large water supplies, the permutit process is used. Sodium permutit is a complex compound of sodium, aluminium and silica ($Na_2Al_2Si_2OH_2O$). It has the property of exchanging the sodium cation for the calcium and magnesium ions in the water. When hard water is passed through the permutit the calcium and magnesium ions are entirely removed by base exchange and the sodium permutit is finally converted into calcium and magnesium permutit. By this process, water can be softened to zero hardness. Since water of zero hardness is corrosive, a part of the raw water is mixed with the softened water to secure the desired hardness. After permutit has been used for sometime, it loses its effectiveness but it may be regenerated by treating with concentrated solution of sodium chloride or brine and washing away the soluble calcium and magnesium chloride formed. Permutit process removes both temporary and permanent hardness.

Water hardness and cardiovascular diseases

Reports from several countries have shown an inverse statistical association between the hardness of drinking water and the death rate from cardiovascular diseases. Areas supplied with soft drinking water showed a significantly higher prevalence of either arteriosclerotic heart disease, or degenerative heart disease, hypertension, sudden deaths of cardiovascular origin, or a combination of these. The evidence is based solely on circumstantial evidence and statistical association. Further studies are in progress to establish a possible connection between certain water characteristics and the development of cardiovascular diseases *(24)*.

(b) Fluoridation of water

Fluorine is one of the constituents naturally present in water supplies. In fact, the main source of fluorine is drinking water. Deficiency of fluorine in drinking water is associated with dental caries, and excess with dental and skeletal fluorosis. Leading workers in India regard fluorine in concentration of 0.5 to 0.8 ppm in drinking water as optimum (a concentration of 1 ppm is regarded as optimum in temperate climates because the consumption of water is low). The term "fluoridation" has been given to the process of supplementing the natural fluoride content of potable waters to the point of optimum concentration. The WHO in 1969 recommended fluoridation of community water supplies in areas where the total intake of fluorides by the population is below the optimal levels for protection against dental caries. Fluoridation is now an accepted public health procedure in many developed countries *(25)*.

(c) Defluoridation

In some geographic areas, water may contain a high level of fluorides. In such communities, water is defluoridated by phosphate to reduce fluorides to optimum levels.

SELECTION OF SOURCE OF WATER

In selecting a source, attention must be given to possible future developments that may influence the continued suitability of the source. Other considerations include (a) *Quantity (source capacity)* : The quantity of water should be sufficient to meet continuing water demands, taking into account daily and seasonal variations and projected growth in the size of the community being served. (b) *Quality* : The quality of raw water should be such that, with appropriate

treatment, it meets the drinking water standards. (c) *Protection :* The watershed must be protected from pollution with human excreta, industrial discharge and agricultural run-off. (d) *Feasibility :* The source should be available at reasonable cost. (e) *Treatability :* The raw water should be treated adequately under locally prevailing conditions.

Potential new sources should be examined in the field by qualified and experienced sanitary surveyors and physical, bacteriological and chemical analysis should be carried out for a period covering seasonal variations prior to final selection of the source. Such information is essential in order to define appropriate water treatment requirements and necessary pollution control measures to protect raw water resources. It is preferable to choose the source that requires the least treatment. The source should be protected from contaminants emanating from septic tanks, sewers, cesspools, sullage water and flooding and from contamination by users. Maintaining adequate residual chlorine levels in the distribution system is the most reliable indicator of protection against contamination resulting from cross-connection, back siphonage, leaks etc.

DISTRIBUTION OF WATER

There are two main systems of water distribution, the intermittent supply and the continuous supply. In the intermittent system, water is delivered only during fixed hours. The disadvantages of the intermittent system are : (1) the pipes may be empty during times of emergency (2) people need to store water in containers which may not be clean always. The safe water is likely to be rendered unsafe through improper storage (3) when the pipes are empty, there is negative pressure and by what is known as back-siphoning, bacteria and foul gases may be sucked in through leaky joints. A number of recorded outbreaks of typhoid and of relapsing fever, among other diseases, have been traced back to the contamination of water in the intermittent piped water supplies. Flowing water available 24 hours is therefore desirable, although it may entail some wastage of water through misuse. The supply of water in most cities in India is intermittent. A WHO Expert Committee (1965) strongly recommended that intermittent and low pressure service should be avoided *(26)*. DUAL WATER SUPPLY: In Kolkata, there was a dual water supply system, i.e., one set of pipes supplying filtered water for personal use and the other set supplying unfiltered water for flushing toilets, washing roads and other civic purposes. The greatest drawback of the dual system is that people may mistake one for the other through ignorance. The WHO Expert Committee (1965) strongly disapproved of the practice of supplying two kinds of water *(26)*. The possibility of cross-connection constitutes a serious health hazard.

SWIMMING POOL SANITATION

Swimming pool water is exposed to (1) faecal contamination and (2) organisms from skin and nasopharynx. The health hazards associated with swimming pools are:

(1) fungal and viral infections of the skin. This includes **Epidermophyton** and **Trichophyton** species which produce "athlete's foot." The papilloma virus is the inciting agent of "plantar warts"

(2) infections of the eye, ear, nose and throat

(3) infections of the upper respiratory tract,

(4) intestinal infections, and

(5) accidents.

SANITATION MEASURES

(1) *Recommended area:* The recommended area is 2.2 sq.m. (24 sq.ft.) per swimmer *(27)*. (2) *Surveillance:* Rules and regulations governing the use of the pool should be posted in a conspicuous place for the information of the users. These are: (a) Persons suffering from skin diseases, sore eyes, cold, nasal or ear discharge or any other communicable disease should not be allowed into the swimming pool. (b) All bathers are strictly instructed to empty the bladder, and if necessary use the toilet. (c) A cleansing shower bath in the nude with soap and water is required before entering the pool. (d) spitting, spouting of water, blowing the nose, etc. are prohibited. (e) The environment of the swimming pool including the shower rooms, walk ways and pool decks should receive proper disinfection to destroy bacterial, viral and fungal agents. (2) *Filtration of water :* Swimming pools are equipped with rapid sand filters. The filtering is continuous such that all the water is refiltered in less than 6 hours. Part of the water, up to 15 per cent, should be replaced by fresh water every day. The function of water replacement is to remove solutes consisting of ammonia, albuminoid, organic and nitrate nitrogen derived from the bathers. These solutes have the capacity to reduce the bactericidal activity of chlorine. (3) *Chlorination :* Chlorination is the most widely used method of pool disinfection. Various workers have stated that a continuous maintenance of 1.0 mg/litre (1 ppm) of free chlorine residual provides adequate protection against bacterial and viral agents *(28)*. The pH of water is kept between 7.4–7.8. (4) *Bacteriological quality :* The bacteriological quality of water should reach, as nearly as possible, the standards prescribed for drinking water.

National Water Supply and Sanitation Programme

The National Water Supply and Sanitation Programme was launched in 1954 by the Govt. of India as part of the Health Plan to assist the States to provide adequate water supply and sanitation facilities in the entire country. Provision has been made in the successive 5–year Plans to improve the water supply *(29)*.

For further details see chapter 7 page 476.

Health education

The provision of merely good water supply does not in itself secure freedom from water-borne diseases. People must recognize safe water as a "felt" health need and give up their old, unhygienic habits of polluting water supplies. In these circumstances, health education emerges as an important weapon in creating among people a desire for higher standards of life.

APPENDIX I

HORROCK'S APPARATUS

Horrock's water testing apparatus is designed to find out the dose of bleaching powder required for disinfection of water.

CONTENTS

1. 6 white cups (200 ml capacity each)
2. One black cup with a circular mark on the inside
3. 2 metal spoons (each holds 2g of bleaching powder when filled level with the brim)
4. 7 glass stirring rods
5. One special pipette
6. Two droppers
7. Starch–iodide indicator solution
8. Instruction folder.

PROCEDURE

1. Take one level spoonful (2 g) of bleaching powder in the black cup and make it into a thin paste with a little water. Add more water to the paste and make up the volume upto the circular mark with vigorous stirring. Allow to settle. This is the stock solution.

2. Fill the 6 white cups with water to be tested, upto about a cm below the brim.

3. With the special pipette provided add one drop of the stock solution to the 1st cup, 2 drops to the 2nd cup, 3 drops to the 3rd cup, and so on.

4. Stir the water in each cup using a separate rod.

5. Wait for half an hour for the action of chlorine.

6. Add 3 drops of starch-iodide indicator to each of the white cups and stir again. Development of blue colour indicates the presence of free residual chlorine.

7. Note the first cup which shows distinct blue colour. Supposing the 3rd cup shows blue colour, then 3 level spoonfuls or 6 grams of bleaching powder would be required to disinfect 455 litres of water.

APPENDIX II

SAMPLING

1. Samples for physical and chemical examination

Samples for physical and chemical examination should be collected in clean glass stoppered bottles made of neutral glass, of capacity not less than 2 litres. Stoppered glass bottles technically known as "Winchester Quart bottles" are suitable. Before collecting the sample rinse the bottle well three times with the water, filling it each time about 1/3 full. Then fill it with the water, tie the stopper tightly down, with a piece of cloth over it and seal the string.

2. Samples for bacteriological examination

Samples for bacteriological examination should be collected in clean sterilized bottles made of neutral glass, of capacity 200–250 ml and provided with a ground glass stopper having an overlapping rim. The stopper must be relaxed by an intervening strip of paper to prevent breakage of the bottle during sterilization or jamming of the stopper. The stopper and the neck of the bottle should be protected by a paper or parchment cover. If the water to be sampled contains, or is likely to contain chlorine, a small quantity of sodium thiosulphate (0.1 ml of 3.0 per cent solution or a small crystal of the salt) should be added to the bottle before sterilization. Sterile sampling bottles should be obtained from the laboratory which is to carry out the analysis. The sampling bottle should not be opened until the moment at which it is required for filling.

(1) COLLECTION OF THE SAMPLE FROM A TAP

When the sample is to be taken from a tap in regular use, the tap should be opened fully, and the water run to waste at least for 2 minutes in order to flush the interior of the nozzle and to discharge the stagnant water in the service pipe. In the case of samples to be collected from taps which are not in regular use, the tap should be sterilized by heating it either with a blow lamp or with an ignited piece of cotton soaked in methylated spirit, until it is unbearably hot to the touch. Then the tap should be cooled by allowing the water to run to waste before the sample is collected.

The bottle should be held near the base with one hand and the stopper and paper cover over it removed together and held in the fingers. The sample bottle should be filled from a gentle stream of water from the tap, avoiding splashing. The collection of samples from taps which are leaky, should be avoided because the water might run down the outside of the tap and enter the bottle causing contamination. If this cannot be avoided, special precautions should be taken to clean the outside of the tap and to flame it sufficiently to ensure sterility.

(2) COLLECTION OF SAMPLES FROM RIVERS, LAKES, RESERVOIRS, WELLS, ETC

Samples from rivers and streams should not be taken too near the bank or too far away from the point of draw off. For collecting samples directly from rivers, lakes, tanks, wells etc., a bottle with a string attached to the neck which is fully wrapped in paper and sterilized should be used. Before taking the sample, the paper cover should be removed, taking care not to allow the sides of the bottle to come in contact with anything. Another long clean string should be tied to the end of the sterilized string, and the bottle lowered into the water and allowed to fill up. The bottle should be then raised and the stopper with cover replaced.

Another method of collecting samples from rivers or reservoirs is to hold the bottle by the bottom and plunge its neck down-wards below the surface of the water. The bottle is then turned until the neck points slightly up-wards, the mouth being directed towards the current. If no current exists, as in a reservoir, a current should be artificially created by pushing the bottle horizontally forward in a direction away from the hand. When full, the bottle is raised rapidly above the surface and the stopper replaced.

If a sample is to be taken from a well fitted with a pump, the water should be pumped to waste for about 2 minutes and the sample collected from the pump delivery or from a tap on the discharge.

(3) TRANSPORT AND STORAGE OF SAMPLES

The bacteriological examination of the sample should be commenced as soon as possible after collection. Where this is not feasible, the sample should be kept in ice until it is taken for analysis. All such iced samples should be taken for analysis within 48 hours after collection. Samples not preserved in this manner should not be accepted for bacteriological examination. Certain particulars regarding the date and time of collection and despatch, source of water, particulars of recent rainfall and findings of the sanitary survey should also be supplied with the sample.

APPENDIX III

*QUANTITY OF CHEMICALS NEEDED TO DISINFECT WATER FOR DRINKING**

Water (m^3)	Bleaching powder (25–35%) (g)	High strength calcium hypochlorite (70%) (g)	Liquid bleach (5% sodium hypochlorite) (ml)
1	2.3	1	14
1.2	3	1.2	17
1.5	3.5	1.5	21
2	5	2	28
2.5	6	2.5	35
3	7	3	42
4	9	4	56
5	12	5	70
6	14	6	84
7	16	7	98
8	19	8	110
10	23	10	140
12	28	12	170
15	35	15	210
20	50	20	280
30	70	30	420
40	90	40	560
50	120	50	700
60	140	60	840
70	160	70	980
80	190	80	1,100
100	230	100	1,400
120	280	120	1,700

APPENDIX IV

WATER CONSERVATION

Declining trend of rainfall and rapid urbanization with industrialization has created increasing demand for water. Growing water shortage is already causing problems in several areas and available resources like rivers, ponds, lakes are shrinking, causing more & more prrssure on sub-soil water resources. Already, the rate of water extraction is exceeding the replenishment that takes place by natural processes – mainly recharge due to rainfall. This is causing alarming fall in sub-soil water levels which is going down in and around several cities. Development of agriculture dependent on tube wells has further worsened the situation. The underground water resources, therefore, urgently need conservation. The term conservation implies both, protection of water resources, and further building up the precious water reserves.

Conservation of water resources requires :

(a) PREVENTION OF WASTAGE : Wide-spread awareness needs to be developed among people about economical use of water. It has to be propagated that people should make an effort not to waste water, and help in reducing consumption of the invaluable water reserves. Efficient water management can substantially reduce total water requirement of communities. Domestic consumption of water can be reduced by individuals, by cultivating better habits in kitchen and bathroom use, to avoid free running of water.

(b) WATER HARVESTING : Simple innovative ideas like water harvesting are extremely important to preserve and buildup underground water reserves in urban and semi-urban areas, where considerable water is drawn out by tube wells for domestic consumption. Vast quantity of rainwater is normally discharged in to drains. This rainwater can be easily added to the underground reserves by diversion of rainwater from rooftops and courtyards into soaking pits or trenches, instead of drains. It is also viable to clean and filter this water and divert it into existing tube wells or wells. Various economic designs are suggested by agencies like Central Ground Water Board (CGWB), UNICEF etc. Suitably large pit is filled in layers with big stones, followed by gravel and sand. Collected rainwater from rooftops is brought into the pit by PVC pipes. The rainwater filtered through these layers, then travels by a PVC pipe connecting bottom of the pit into the nearby well or tube well.

AIR

The immediate environment of man comprises of air on which depends all forms of life. Apart from supplying the life-giving oxygen, air and atmospheric conditions serve several functions. The human body is cooled by the air contact; the special senses of hearing and smell function through air-transmitted stimuli ; disease agents may be conveyed by air. Pollution of air by dust, smoke, toxic gases and chemical vapours has resulted in sickness and death. Man's adventure into outer space has broadened our concept of air environment. Human beings need a continuous supply of air to exist. The requirement for air is relatively constant (about 10–20m^3 per day)

Composition

Air is a mechanical mixture of gases. The normal composition of external air by volume is approximately as follows: Nitrogen – 78.1 per cent; Oxygen – 20.93 per cent; Carbon dioxide – 0.03 per cent. The balance is made up of other gases which occur in traces, e.g., argon, neon, krypton, xenon and helium. In addition to these gases, air also contains water vapour, traces of ammonia and suspended matter such as dust, bacteria, spores and vegetable debris.

Air is rendered impure by (1) Respiration of men and animals (2) Combustion of coal, gas, oil, etc. (3) Decomposition of organic matter and (4) Trade, traffic and manufacturing processes which give off dust, fumes, vapours and gases. Under ordinary conditions, the composition of outdoor air is remarkably constant. This is brought about by certain self–cleansing mechanisms which operate in nature (1) *Wind :* Wind dilutes and sweeps away the impurities by its movement. Because of wind movement, impurities do-not accumulate in any one place; (2) *Sunlight :* The atmospheric temperature and sunlight play their own part by oxidizing impurities, and killing bacteria; (3) *Rain :* It cleanses the atmosphere by removing the suspended and gaseous impurities; (4) *Plant life :* The green plants utilize the carbon dioxide and generate oxygen; this process is reversed during the night time. When the rate of pollution becomes too high or when the cleansing process becomes ineffective, it constitutes a health hazard.

The air of occupied room

Human occupancy and activity vitiate air in occupied rooms and give a sense of discomfort to the occupants. The changes in air that take place in confined places are both chemical and physical. (a) *CHEMICAL CHANGES :* The air becomes progressively contaminated by carbon dioxide and the oxygen content decreases due to metabolic processes. An average person at rest gives off 0.7 c.ft. of carbon dioxide per hour; this may increase up to 2 c.ft. during physical activity. In a mixed gathering comprising all age groups, the per capita output of carbon dioxide is taken as 0.6 c.ft. per hour, (b) *PHYSICAL CHANGES :* The most important changes that occur due to human occupancy are the physical changes. These are (i) *Rise in temperature :* The indoor temperature tends to rise as a result of the emanation of body heat. A man at rest gives off approximately 400 Btu per hour. One Btu (British Thermal Unit) is the quantity of heat required to raise the temperature of one pound of water by 1 deg. F. Under conditions of physical exertion, the heat output may go up to 4,000 Btu. (ii) *Increase of humidity :* There is an increase in the relative humidity due to moisture evaporated from the skin and lungs. The expired air contains about 6 per cent of water vapour. An adult person at rest releases an average 700 gms. of water vapour per 24 hours in the form of perspiration. It has been calculated that a human being releases 18.4 gms of water vapour per hour when sleeping and upto 175 gms of water vapour when engaged in really vigorous exercise *(1).* (iii) *Decrease in air movement :* In crowded places, the natural movement of air is impeded. (iv) *Body odours :* Unpleasant odours arise from foul breath, perspiration, bad oral hygiene, dirty clothes and other sources. The production of body odours depends upon the social status, age and personal hygiene of the people. (v) *Bacterial pollution :* The exhaled air contains microorganisms in suspension. These are principally saprophytic bacteria and may include pathogenic bacteria. These organisms are discharged into the air during conversation, coughing, sneezing and loud talking.

Unless the vitiated air is replaced by fresh air, it may adversely affect the comfort, health and efficiency of the occupants. It is known that a feeling of suffocation or discomfort is experienced by the occupants in insufficiently ventilated rooms and also complaints of headache, drowsiness and inability to concentrate. There is also the risk of droplet infection and lowered resistance to disease (on prolonged exposure).

Discomfort

Discomfort is a subjective sensation which people experience in ill-ventilated and crowded rooms. For a long time it was believed to be due to increased carbon dioxide and decreased oxygen, resulting from respiration. This theory has since been refuted. Studies have shown that the oxygen content may be reduced to 18 per cent and the carbon dioxide content may be raised to over 5 per cent, without adverse effects, provided the temperature and humidity are kept satisfactory. In the 'Black Hole of Kolkata', 146 prisoners were imprisoned in a room, $18 \times 14 \times 10$ out of whom only 23 survived. There were two small windows which were adequate to supply all the oxygen needs – even then only 23 survived. It was concluded that the deaths were due to changes in the physical condition of the air, leading to 'heat retention'. It is now established that the causes of discomfort are not due to chemical changes but physical changes. These are temperature, humidity, air

movement and heat radiation. These factors determine the "cooling power" of the air with respect to the human body. It has been so well said by Professor Lee that "The problems of ventilation are physical, not chemical; cutaneous not respiratory".

Indices of thermal comfort

Thermal comfort is a complex entity. Much work was done in the past to determine what constitutes "thermal comfort". Several indices have been put forward from time to time to express thermal comfort and heat stress. These are as follows : (1) AIR TEMPERATURE : For a long time, air temperature was used as an index of thermal comfort, but it was realised that air temperature alone was not an adequate index of thermal comfort. (2) AIR TEMPERATURE AND HUMIDITY : Later, air temperature and humidity were considered together to express thermal comfort: even this was found to be unsatisfactory. (3) COOLING POWER : Still later, air temperature, humidity and air movement were considered together and expressed as "cooling power" of the air. An instrument was devised by Hill called the Kata Thermometer to measure the cooling power. A dry Kata reading of 6 and above, and a wet Kata reading of 20 and above, were regarded as indices of thermal comfort. Further researches have shown that the Kata cooling powers are also not reliable indices of comfort conditions. (4) EFFECTIVE TEMPERATURE : Effective temperature is an arbitrary index which combines into a single value the effect of temperature, humidity and movement of the internal air on the sensation of warmth or cold felt by the human body. The numerical value of effective temperature is that of the temperature of still, saturated air which would induce the same sensation of warmth or cold as that experienced in the given conditions. For example, if the environment has an ET value of 30 deg.C (86 deg.F), it implies that the subjective sensation of it will be same as in a saturated atmosphere of 30 deg.C (86 deg.F) with no air movement. This scale was evolved in 1923 after a long series of experiments carried out in the Pittsburgh Laboratory of the American Society of Heating and Ventilation Engineers by Houghton and Yaglou. Two scales are available one of which refers to men who are stripped to the waist and the other to men who are fully clad in indoor clothing. Effective temperature may be obtained from special charts by reference to the three variables (Fig. 1). A criticism of the effective temperature scale is that

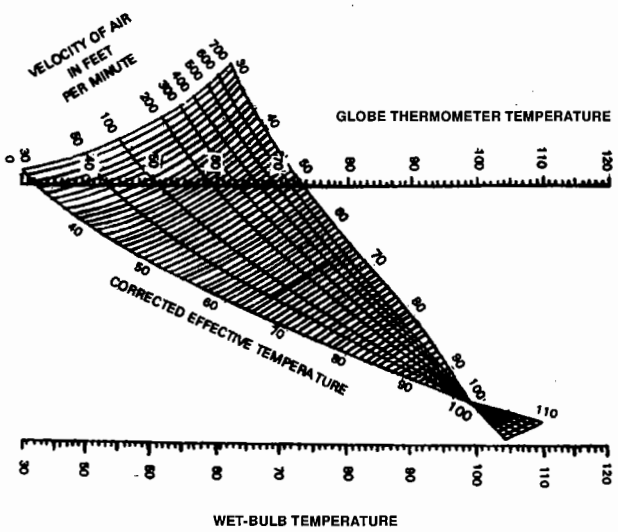

FIG. 1
Effective temperature chart

it ignores the effects of a radiation from the surrounding structures. (5) CORRECTED EFFECTIVE TEMPERATURE : This Index is an improvement over the Effective Temperature Index. Instead of the dry bulb temperature, the reading of the Globe Thermometer is used to allow for radiant heat. That is, the C.E.T. scales deal with all the four factors namely, air temperature, velocity, humidity and mean radiant heat. Whenever a source of radiation is present, it is preferable to take C.E.T. The C.E.T. may be readily obtained from prepared nomograms by reference to the globe thermometer temperature, the wet bulb temperature and air speed. At present, effective temperature and C.E.T. scales are widely used as indices of thermal comfort *(1)*. McARDLE'S MAXIMUM ALLOWABLE SWEAT RATE : McArdle and associates took 4.5 litres of sweat excreted in four hours as the maximum allowable sweat rate compatible with physiological normal reaction of acclimatized, healthy young men for repeated exposures to heat. They prepared a chart from which the "predicted four-hour sweat rate" (P_4SR) can be obtained from any combination of dry and wet bulb temperature of the air, mean radiant air temperature and air velocity, under different work intensity. McArdle has put P_4SR value of 3 as upper limit of comfort zone *(3)*.

Comfort zones

Comfort zones may be defined as the range of ETs over which the majority of adults feel comfortable. There is no unanimous decision on a single zone of comfort for all people because comfort is quite a complex subjective experience which depends not only on physical, physiological factors, but also on psychological factors which are difficult to determine. Considering only the environmental factors, 'comfortable thermal conditions are those under which a person can maintain normal balance between production and loss of heat, at normal body temperature and without sweating'. Comfort zones evaluated in India are as below :

		Corrected effective temperature deg C
1. Pleasant and cool	.....	20
2. Comfortable and cool	.....	20–25
3. Comfortable	.....	25–27
4. Hot and uncomfortable	.....	27–28
5. Extremely hot	.....	28 +
6. Intolerably hot	.....	30 +
		Predicted four–hour sweat rate (P_4SR)
1. Comfort zone	.....	1–3 litres
2. Just tolerable	.....	3–4.5 litres
3. Intolerable	.....	4.5 + litres

AIR POLLUTION

The phenomenon called "pollution" is an inescapable consequence of the presence of man and his activities. The term "air pollution" signifies the presence in the ambient (surrounding) atmosphere of substances (e.g., gases, mixtures of gases and particulated matter) generated by the activities of man in concentrations that interfere with human health, safety or comfort, or injurious to vegetation and animals and other environmental media resulting in chemicals entering the food chain or being present in drinking-water and thereby constituting additional source of

human exposure. The direct effect of air pollutants on plants, animals and soil can influence the structure and function of ecosystems, including self regulation ability, thereby affecting the qualify of life *(2)*. In the past, air pollution meant smoke pollution. Today, air pollution has become more subtle and recognizes no geographical or political boundaries. Air pollution is one of the present-day health problems throughout the world.

Basic definitions *(4)*

Before discussing in detail the sources of air pollutants it is necessary to establish a few basic principles that will place the information on sources in context. Air pollutants may be either emitted into the atmosphere or formed within the atmosphere itself.

Primary air pollutants : Primary air pollutants are those that are emitted into the atmosphere from a source such as a factory chimmey or exhaust pipe, or through suspension of contaminated dusts by the wind. In principle, therefore, it is possible to measure the amounts emitted at the source itself.

Secondary air pollutants : Secondary air pollutants are those formed within the atmosphere itself. They arise from chemical reactions of primary pollutants, possibly involving the natural components of the atmosphere, especially oxygen and water. The most familiar example is ozone, which arises almost entirely from chemical reactions that differ with altitude within the atmosphere. Because of this mode of formation, secondary pollutants cannot readily be included in emissions inventories, although it is possible to estimate formation rates per unit volume of atmosphere per unit time.

Another important distinction must be made in relation to the physical state of a pollutant.

Gaseous air pollutants : Gaseous air pollutants are those present as gases or vapours, i.e. as individual small molecules capable of passing through filters, provided they do not adsorb to or chemically react with the filter medium. Gaseous air pollutants are readily taken into the human respiratory system, although if water-soluble, they may very quickly be deposited in the upper respiratory tract and not penetrate to the deep lung.

Particulate air pollutants : Particulate air pollutants comprise material in solid or liquid phase suspended in the atmosphere. Such particles can be either primary or secondary and cover a wide range of sizes. Newly formed secondary particles can be as small as 1–2 μm in diameter, while coarse dust and sea salt particles can be as large as 100 μm in diameter. (Please note – 1 μm is one millionth of a metre = 1 micron = 0.001 mm)

Local scale : Some pollutants, by virtue of their source or of having a very short atmospheric lifetime, are only encountered in appreciable concentrations close to where they are emitted. For example in less developed countries, poorly controlled household and neighbourhood sources, often involving the burning of biomass fuels, cause serious local pollution.

Urban scale : Pollutants from urban sources, such as nitrogen oxides and carbon monoxide generated by road traffic, tend to be present at high concentrations throughout the city and at significantly reduced concentrations in adjacent rural areas. Their atmospheric lifetimes are not long (typically hours) and therefore concentrations in the remote background atmosphere tend to be very low (except in the case of carbon monoxide, which is more persistent).

Regional scale : Pollutants in the form of fine particles (<2.5 μm diameter, but not ultrafine particles) and some gas-phase pollutants such as ozone have atmospheric lifetimes of days or even weeks, which permit them to be transported on a regional scale. Pollutants such as sulphate particles and ozone readily travel thousands of kilometres in a process known as long-range transport, crossing national boundaries in doing so.

Hemispheric and global scales : Some pollutants, and especially those associated with greenhouse warming effects (carbon dioxide, nitrous oxide and methane) have atmospheric lifetimes of years and are therefore capable of distribution throughout a hemisphere and ultimately globally.

Sources of air pollution

The main sources of air pollution are : (a) AUTOMOBILES : Motor vehicles are a major source of air pollution throughout the urban areas. They emit hydrocarbons, carbon monoxide, lead, nitrogen oxides and particulate matter. In strong sunlight, certain of these hydrocarbons and oxides of nitrogen may be converted in the atmosphere into "photochemical" pollutants of oxidizing nature. In addition, diesel engines, when misused or badly adjusted are capable of emitting black smoke and malodorous fumes. (b) INDUSTRIES : Industries emit large amounts of pollutants into the atmosphere. Combustion of fuel to generate heat and power produces smoke, sulphur dioxide, nitrogen oxides and fly ash. Petrochemical industries generate hydrogen fluoride, hydrochloric acid and organic halides. Many industries discharge carbon monoxide, carbon dioxide, ozone, hydrogen sulphide and sulphur dioxide. Industries discharge their wastes from high chimneys at high temperature and high speed. (c) DOMESTIC SOURCES : Domestic combustion of coal, wood or oil is a major source of smoke, dust, sulphur dioxide and nitrogen oxides. The London disaster of air pollution in 1952 in which thousands had died was due to domestic coal burning. (d) The most direct and important source of air pollution affecting the health of many people is tobacco smoke. Even those who do not smoke may inhale the smoke produced by others ("passive smoking"). (e) MISCELLANEOUS : These comprise burning refuse, incinerators, pesticide spraying, natural sources (e.g., wind borne dust, fungi, molds, bacteria) and nuclear energy programmes. All these contribute to air pollution.

Meteorological factors

Although the Earth's atmosphere extends to several layers above the surface, it is only the first 30 km that hold the major portion of the atmospheric gases. Man is most directly concerned with only the 8–10 km of the atmosphere *(3)*.

The level of atmospheric pollution at any one time depends upon meteorological factors, e.g., topography, air movement and climate. Winds help in the dispersal and dilution of pollutants. If the topography is dominated by mountains (or tall buildings) the winds become weak and calm, and pollutants tend to concentrate in the breathing zone.

The vertical diffusion of pollutants depends upon the temperature gradient. When there is a rapid cooling of lower layers of air (temperature inversion), there is little vertical motion and the pollutants and water vapours remain trapped at the lower levels and the result is "smog". The "temperature inversion" which is more frequent in the winter months than in spring or summer, is a threat to human health.

Air pollutants

More than 100 substances which pollute air have been identified. The important ones are carbon monoxide, carbon dioxide, hydrogen sulphide, sulphur dioxide, sulphur trioxide, nitrogen oxides, fluorine compounds, organic compounds (e.g., hydrocarbons, aldehydes, ketones, organic acids), metallic contaminants (e.g., arsenic, zinc, iron resulting from smelting operation), radio-active compounds, photochemical oxidants (e.g., ozone). Others include asbestos, beryllium, mercury, benzene, fluorides, vinyl chloride, lead and radiation. Contaminants differ greatly from place to place depending upon the specific complex of contaminant source. Pollutants may be in the form of solids, liquids (vapours) or gases. The combination of smoke and fog is called "smog".

(1) **Carbon monoxide :** Carbon monoxide is one of the most common and widely distributed air pollutants. It is a product of incomplete combustion of carbon containing materials, such as in automobiles, industrial process, heating facilities and incinerators. Estimates of man-made carbon monoxide emission vary from 350 to 600 million tonnes per annum *(2)*. Some widespread natural non-biological and biological sources have also been identified. Concentrations in urban areas depend on weather and traffic density. It varies with the density of petrol-powered vehicles and most cities have carbon monoxide peak levels that coincide with the morning and evening rush-hours. Variations in these levels are also influenced by topography. The fluctuation in ambient concentrations is only slowly reflected in the carboxyhaemoglobin levels in humans, as it takes 4–12 hours for approximate equilibrium between air levels and blood levels to occur. Thus environmental concentrations tend to be expressed in terms of 8 hour average concentrations.

(2) **Sulphur dioxide :** It is one of the several forms in which sulphur exists in air. The others include H_2S, H_2SO_4 and sulphate salts. Sulphur dioxide (SO_2) is a colourless gas with a sharp odour, results from the combustion of sulphur containing fossil fuel, the smelting of sulphur–containing ores, and other industrial processes. Domestic fires, power generation and motor vehicles can also produce emissions containing sulphur dioxide.

SO_2 can affect the respiratory system and the function of lungs, and causes irritation of eyes. Inflammation of the respiratory tract causes coughing, mucus secretion, aggravation of asthma and chronic bronchitis, and makes people more prone to infections of the respiratory tract. Hospital admissions for cardiac disease and mortality increase on days with higher SO_2 levels. When SO_2 combines with water, it forms sulphuric acid; this is the main component of acid rain which is a cause of deforestation. A SO_2 concentration of 500 $\mu g/m^3$ should not be exceeded over average periods of 10 minutes duration. Studies indicate that a proportion of people with asthma experience changes in pulmonary function and respiratory symptoms after periods of exposure to SO_2 as short as 10 minutes. The revision of 24–hour guideline for SO_2 from 125 to 20 $\mu g/m^3$ is based on the health effects known to be associated with much lower levels of SO_2 than previously believed *(5)*.

(3) **Lead :** The combustion of alkyl lead additives in motor fuels accounts for the major part of all lead emissions into the atmosphere. An estimated 80–90 per cent of lead in ambient air derives from the combustion of leaded petrol. The degree of pollution from this source differs from country to country, depending on motor vehicle density and the efficiency of effort to reduce the lead content of petrol. The mining and smeltering of lead ores create pollution problems in some areas. Children upto 6 years of age are a population at increased risk for lead exposure, as well as for adverse health effects, as children have behaviour characteristics (outdoor activity) which increase the risk of lead exposure; the blood–brain barrier is not yet fully developed in young children; and haematological and neurological effects of lead occur at lower threshold in children than in adults.

Since the placenta is no effective biological barrier, pregnant women represent a second group at increased risk because of exposure of the foetus to lead.

(4) **Carbon dioxide :** This is not commonly regarded as an air pollutant, although man generates enormous amount of it in combustion process using coal, oil and gas. Carbon dioxide is a natural constituent of the air. It does not take part in any significant chemical reactions with other substances in the air. However, its global concentration is rising above the natural level by an amount that could increase global temperature enough to affect climate markedly *(6)*.

(5) **Hydrocarbons :** Man-made sources of hydrocarbons include incineration, combustion of coal, wood, processing and use of petroleum. Hydrocarbons exert their pollutant action by taking part in the chemical reactions that cause photochemical smog.

(6) **Cadmium :** The steel industry, waste incineration, volcanic action and zinc production seem to account for the largest emissions. Incineration is increasingly chosen as a method of refuse disposal in European countries. This source of atmospheric cadmium pollution is of growing concern. Tobacco contains cadmium, and smoking may contribute significantly to the uptake of cadmium. Cigarettes may contain from 0.5 to 3 µg cadmium per gram of tobacco, depending on the country of origin.

(7) **Hydrogen sulphide :** Human activities can release naturally occurring hydrogen sulphide into ambient air. In Industry, hydrogen sulphide can be formed whenever elemental sulphur or sulphur containing compounds come in contact with organic material at high temperatures. Hydrogen sulphide is formed during coke production, in viscose rayon production, waste-water treatment plants, wood pulp production using the sulphate method, sulphur extraction process, oil refining and in tanning industry. Hydrogen sulphide is the main toxic substance involved in livestock rearing systems with liquid manure storage *(7)*. The first noticeable effect of hydrogen sulphide at low concentration is its unpleasant odour. Conjunctival irritation is the next subjective symptom. Workers exposed to hydrogen sulphide concentrations of less than 30 $\mu g/m^3$ are reported to have rather diffuse neurological and mental symptoms *(2)*.

(8) **Ozone :** Ozone at ground level – not to be confused with the ozone layer in the upper atmosphere – is one of the major constituents of photochemical smog. It is formed by the photochemical reaction of sunlight with pollutants such as nitrogen oxides from vehicle, industry emissions and volatile organic compounds (VOCs) emitted by vehicles, solvents and industry. The highest levels of ozone pollution occurs during periods of sunny weather. Excessive ozone in the air can have a marked effect on human health. It can cause breathing problems, trigger asthma, reduce lung function and cause lung diseases. In Europe it is currently

one of the air pollutants of most concern. Several European studies have reported that the daily mortality rises by 0.3% and that for heart diseases by 0.4%, per 10 μg/m³ increase in ozone exposure. The previously recommended limit, which was fixed at 120 μg/m³ of 8-hour mean, has been reduced to 100 μg/m³ based on recent conclusive associations between daily mortality and ozone levels occurring at ozone concentrations below 120 μg/m³ *(5)*.

(9) **Oxides of nitrogen :** Emission of oxides of nitrogen occur predominantly in the form of nitric oxide, which comprises around 95 per cent of nitrogen oxides from a combustion source. Coal is the most important fuel in this context, other sources are road traffic and electricity generation. The pollutant of far greater concern in relation to human health is nitrogen dioxide. Epidemiological studies have shown that symptoms of bronchitis in asthmatic children increase in association with long-term exposure to nitrogen dioxide. Reduced lung function growth is also linked to nitrogen dioxide at concentrations currently measured (or observed) in the cities of Europe and North America. The current WHO guideline value of 40 μg/m³ (annual mean) set to protect the public from the health effects of gaseous nitrogen dioxide remains unchanged from the level recommended in the previous AQGs.

(10) **Polycyclic aromatic hydrocarbons (PAH) :** Polycyclic aromatic hydrocarbons (PAHs) (also known as polynuclear aromatic hydrocarbons) are a group of approximately 10,000 compounds. The examples are Benzo (a) pyrene (BaP), Benzanthracene, Benzo (b) fluoranthene, fluoranthene, Nephthalene etc. BaP is commonly used as an indicator species for PAH contamination and most available data refer to this compound. Most PAHs in the environment are produced by incomplete burning of carbon containing material like wood, garbage, coal and oil. Automobile exhaust, industrial emission and smoke from burning wood, charcoal and tobacco contain high levels of PAHs. In general, more PAHs form when materials burn at low temperatures, such as in wood fires and cigarettes. The fine PAH particles can bind with ash particles and can move long distances. PAHs can also be toxic when ingested or when they come in contact with skin (they are used in some skin creams and anti-dandruff shampoos). When inhaled some PAHs are carcinogenic, mutagen and reproductive toxin (BaP is one of the most potent carcinogens among the known PAHs). A person who smokes one pack of unfiltered cigarettes per day is exposed daily to 2 to 5 μg of carcinogenic PAHs. Occupational exposure can occur through inhalation and dermal contact. People with highest exposure are smokers, people who live with or work with smokers, roofers, road builders and people who live near major highways or industrial sources.

Based on epidemiological data from studies on coke-oven workers, a unit risk for lung cancer for PAH mixture is estimated to be 8.7×10^{-5} ng/m³ BaP. This is the guideline for PAH in indoor air. The corresponding concentration of lifetime exposure to BaP producing excess lifetime cancer risk of 1/10,000, 1/100,000 and 1/1,000,000 are approximately 1.2, 0.12 and 0.012 ng/m³ respectively *(8)*.

(11) **Particulate matter :** Airborne particulate matter represents a complex mixture of organic and inorganic substance. Particles are generally classified by their size measured in μm (micro metre, i.e. one millionth of a metre). Initially guidelines were directed at very general measure of PM concentration including total suspended particulate (TSP) matter in US, and black smoke (BS) in Europe. In 1987, USEPA promulgated a standard for PM – less than 10 μm in aerodynamic diameter (PM_{10}). In 1997, a standard for PM less than 2.5 μm in aerodynamic diameter ($PM_{2.5}$) was added. By definition PM_{10} includes $PM_{2.5}$ and thoracic coarse mass PM (the difference between PM_{10} and $PM_{2.5}$ is referred to as coarse mass PM). PM_{10} includes those inhalable particles that are sufficiently small to penetrate to the thoracic region; the fine fraction of PM_{10} is cut-off from coarse fraction at 2.5 μm, a size fraction with a high probability of deposition in the smaller conducting airways and alveoli.

The major components of PM are sulfate, nitrates, ammonia, sodium chloride, black carbon, mineral dust and water. It consists of a complex mixture of solid and liquid particles of organic and inorganic substances.

The large particles usually contain earth's crustal material and fugitive dust from roads and industries. Particulate matter of respirable size may be emitted from a number of sources, some of them natural (e.g. dust storms) and many others that are more widespread and more important (e.g., power plants and industrial processes, vehicular traffic, domestic coal burning, industrial incinerators). The particulate matter of diameter smaller than 2.5 μm are more dangerous since, when inhaled, they may reach the peripheral regions of the bronchioles, and interfere with gas exchange inside the lungs. The effects of PM on health occur at levels of exposure currently being experienced by most urban and rural populations in both developed and developing countries. Chronic exposure to particles contributes to the risk of developing cardiovascular and respiratory diseases, as well as of lung cancer. In developing countries, exposure to pollutants from indoor combustion of solid fuels on open fires or traditional stoves increases the risk of acute lower respiratory infections and associated mortatlity among young children; indoor air pollution from solid fuel use is also a major risk factor for chronic obstructive pulmonary disease and lung cancer among adults. The mortality in cities with high levels of pollution exceeds that observed in relatively cleaner cities by 15–20 per cent. The 2005 AQG set for the first time a guideline value for particular matter (PM) as 10 μg/m³ annual mean and 25 μg/m³ 24-hour mean for $PM_{2.5}$, and 20 μg/m³ annual mean and 50 μg/m³ 24-hour mean for PM_{10} *(5)*. The aim is to achieve the lowest concentrations possible. As no threshold for PM has been identified below which no damage to health is observed, the recommended value should represent an acceptable and achievable objective to minimize health effects in the context of local constraints, capabilities and public health priorities.

Indoor air pollution *(4)*

The indoor environment represents an important microenvironment in which people spend a large part of their time each day. As a result, indoor air pollution, originating from both outdoor and indoor sources, is likely to contribute more to population exposure than the outdoor environment. The extent and magnitude of consequent health risks, however, remain poorly understood. The large number of indoor air pollutants, including chemical and biological contaminants, and the influence of a variety of factors such as the nature and location of sources, air exchange between indoor and outdoor environments, and individual behaviour make accurate estimations of health effects very difficult.

The major sources of indoor air pollution worldwide

include combustion of solid fuels indoors, tobacco smoking, outdoor air pollutants, emissions from construction materials and furnishings, and improper maintenance of ventilation and air conditioning systems (Table 1). There are, however, marked variations in the importance of these different sources in different areas of the world, closely related to the level of socio-economic development.

Although relatively clean sources of household energy predominate in developed countries, improvements in energy efficiency have led to homes being relatively airtight, reducing ventilation and raising indoor pollutant levels.

4.3 million people die every year prematurely from illness attributable to the household air pollution caused by inefficient use of solid fuels. Among these deaths 12 per cent are due to pneumonia, 34 per cent from stroke, 26 per cent from ischaemic heart disease, 22 per cent from COPD and 6 per cent from lung cancer.

Exposure to household air pollution almost doubles the risk for childhood pneumonia. Over half of deaths among children less than 5 years old from acute lower respiratory infections (ALRI) are due to particulate matter inhaled from indoor air pollution from household solid fuels.

Nearly one quarter of all premature deaths due to stroke (i.e. about 1.4 million deaths of which half are in women) can be attributed to the chronic exposure to household air pollution caused by cooking with solid fuels. Approximately 15% of all deaths due to ischaemic heart disease, accounting for over a million premature deaths annually, can be attributed to exposure to household air pollution. Over one-third of premature deaths from chronic obstructive pulmonary disease (COPD) in adults in low and middle-income countries are due to exposure to household air pollution. Women exposed to high levels of indoor smoke are 2.3 times as likely to suffer from COPD than women who use cleaner fuels. Among men (who already have a heightened risk of COPD due to their higher rates of smoking), exposure to indoor smoke nearly doubles that risk. Approximately 17% of annual premature lung cancer deaths in adults are attributable to exposure to carcinogens from household air pollution caused by cooking with solid fuels like wood, charcoal or coal. The risk for women is higher, due to their role in food preparation. More generally, small particulate matter and other pollutants in indoor smoke inflame the airways and lungs, impairing immune response and reducing the oxygen-carrying capacity of the blood. There is also evidence of links between household air pollution and low birth weight, tuberculosis, cataract, nasopharyngeal and laryingeal cancers *(4A)*.

TABLE 1
Major health-damaging pollutants generated from indoor sources

Pollutant	Major indoor sources
Fine particles	Fuel/tobacco combustion, cleaning operations, cooking
Carbon monoxide	Fuel/tobacco combustion
Polycyclic aromatic hydrocarbons	Fuel/tobacco combustion, cooking
Nitrogen oxides	Fuel combustion
Sulphur oxides	Coal combustion
Arsenic and fluorine	Coal combustion
Volatile and semi-volatile organic compounds	Fuel/tobacco combustion, consumer products, furnishings, construction materials, cooking
Aldehydes	Furnishings, construction materials, cooking
Pesticides	Consumer products, dust from outside
Asbestos	Remodelling/demolition of construction materials
Lead	Remodelling/demolition of painted surfaces
Biological pollutants	Damp materials/furnishings, components of climate control systems, occupants, outdoor air, pets
Radon	Soil under buildings, construction materials
Free radicals and other short-lived, highly reactive compounds	Indoor chemistry

Source : *(4)*

Monitoring of air pollution

The best indicators of air pollution are sulphur dioxide, smoke and suspended particles. These are monitored on a daily basis over several sites. The results are then collected by a central agency. (a) *Sulphur dioxide :* This gas is a major contaminant in many urban and industrial areas. Its concentration is estimated in all air pollution surveys. (b) *Smoke or soiling index :* A known volume of air is filtered through a white filter paper under specified conditions and the stain is measured by photoelectric meter. Smoke concentration is estimated and expressed as micrograms/cubic metre of air as an average level over a period of time. (c) *Grit and dust measurement :* Deposit gauges collect grit, dust and other solids. These are analyzed monthly. (d) *Coefficient of haze :* A factor used, particularly in the USA in assessing the amount of smoke or other aerosol in air. (e) *Air pollution index :* It is an arbitrary index which takes into account one or more pollutants as a measure of the severity of pollution. For example, the following index has been used in USA : 10 times the sulphur dioxide concentration plus twice the carbon monoxide concentration (both in ppm by volume) plus twice the coefficient of haze. It was considered to be a cause for alarm when the value of this index rose from its value of about 12–50 or more.

The WHO (1987) in its publication "Air quality guidelines for Europe" and more recently 2005 ed. has described approved methods of determining the concentration of common air pollutants and their health hazards. The emphasis in the guideline is placed on exposure, since this is the element that can be controlled to lessen the dose and hence lessen response. The starting point for the derivation of guideline value was to define the lowest concentration at which adverse effects are observed. On the basis of the body of scientific evidence and judgements of protection (safety) factors, the guideline values were established. The regulatory approach to controlling air pollution differs from country to country as several sources of air pollutants having unique national components are best subject to national control procedures. The approach taken in the preparation of the air quality guidelines was to evaluate data on health effects of individual compounds. As part of this approach, each chemical is considered in isolation. Inevitably, there is little emphasis on such factors as interaction between pollutants that might lead to synergistic effects and on the environmental fate of the pollutants. For some of the substances, a direct relationship between concentrations in air and possible toxic effects is very difficult to establish. This is especially true of those metals for which a greater body-burden results from ingestion than from inhalation. For example, available data show that the food chain is, for most

people, the critical route of non-occupational exposure to lead and cadmium.

On the basis of the evidence concerning adverse effects, judgements about the protection factors needed to minimize health risks were made. Averaging times were included, since the time of exposure is critical in determining the toxicity.

Table 2 shows the maximum upper limit with averaging time.

TABLE 2

Guideline values for individual substances based on effects other than cancer or odour/annoyance

Substance	Time-weighted average	Averaging time
Cadmium	1–5 ng/m³	1 year (rural areas)
	10–20 ng/m³	1 year (urban areas)
Carbon disulphide	100 µg/m³	24 hours
Carbon monoxide	100 mg/m³	15 minutes
	60 mg/m³	30 minutes
	30 mg/m³	1 hour
	10 mg/m³	8 hours
1.2–Dichloroethane	0.7 mg/m³	24 hours
Dichloromethane (Methylene chloride)	3 mg/m³	24 hours
Formaldehyde	100 µg/m³	30 minutes
Hydrogen sulphide	150 µg/m³	24 hours
Lead	0.5–1.0 µg/m³	1 year
Manganese	1 µg/m³	1 year
Mercury	1 µg/m³ (indoor air)	1 year
Nitrogen dioxide	400 µg/m³	1 hour
	150 µg/m³	24 hours
Ozone	150–200 µg/m³	1 hour
	100–120 µg/m³	8 hours
Styrene	800 µg/m³	24 hours
Sulphur dioxide	500 µg/m³	10 minutes
	350 µg/m³	1 hour
Tetrachloroethylene	5 mg/m³	24 hours
Toluene	8 mg/m³	24 hours
Trichloroethylene	1 mg/m³	24 hours
Vanadium	1 µg/m³	24 hours

Air pollution monitoring in India

The National Air Quality Monitoring Programme, sponsored by the Central Pollution Control Board (CPCB) since 1990, has generated database over last 14 years in 10 major Indian cities, viz. Ahemedabad, Mumbai, Kolkata, Delhi, Hyderabad, Jaipur, Kanpur, Kochi, Chennai and Nagpur. The programme facilitates evaluation of long-term air quality trends for health-related criteria pollutants such as inhalable dust, sulphur dioxide, nitrogen dioxide, lead, hydrogen sulphide, ammonia and PAH. The trend analysis showed that Suspended Particulate Matter (SPM) exceeds the CPCB standards in all cities most of the time throughout the year. The concentration ratio of < P10 fraction (human respirable particles) to the total SPM varies between 30 to 60 per cent, with coastal cities showing higher percentages. The concentration of respirable suspended particulate matter is invariably higher at the industrial sites. The PAH in suspended particles at various cities did not show specific trend. The BaP concentration was higher than the CPCB standard at Ahmedabad, Mumbai, Kolkata, Delhi and Nagpur in winter months. Chromium, copper, nickel, arsenic, lead, iron, zinc, sulphate, nitrate, chloride, fluoride, ammonia, sodium and potassium are secondary pollutants analyzed for the assessment of dry deposition of air pollutants. Wet deposition of air pollution has also been evaluated by analyzing rain water samples at all monitoring stations. The successive three years data indicates that the first rain event has the maximum concentration of pollutants with low pH values and higher sulphate and nitrate contents. The acid rain phenomenon thus prevails, albeit for a limited period, in the urban atmosphere of Indian cities *(9)*.

Effects of air pollution

About 1.3 billion urban residents worldwide are exposed to air pollution level above recommended limits. Air quality in the developed countries has generally improved in the past two decades, but in many developing countries air quality has deteriorated because of rising industrial activity, increasing power generation and the congestion of streets with poorly maintained motor vehicles that use leaded fuel. Air pollution can affect by two ways :

(a) **Health aspects :** The health effects of air pollution are both immediate and delayed. The immediate effects are borne by the respiratory system, the resulting state is acute bronchitis. If the air pollution is intense, it may result even in immediate death by suffocation. This has taken place in the air pollution epidemic which occurred in London in 1952. The delayed effects most commonly linked with air pollution are chronic bronchitis, lung cancer, bronchial asthma, emphysema, and respiratory allergies.

Lead poisons many systems in the body and is particularly dangerous to children developing brain and nervous system. Elevated lead levels in children have been associated with impaired neuropsychologic development as measured by loss of IQ, poor school performance and behavioural difficulties *(10)*. Table 3 shows the major air pollutants, their source and adverse effects on health.

TABLE 3

Major air pollutants, their sources and adverse effects

Noxious agent	Sources	Adverse effects
Oxides of nitrogen	Automobile exhaust, gas stoves and heaters, wood–burning stoves, kerosene space heaters	Respiratory tract irritation, bronchial hyperactivity, impaired lung defences, bronchiolitis obliterans
Hydrocarbons	Automobile exhaust, cigarette smoke	Lung cancer
Ozone	Automobile exhaust, high altitude aircraft cabins	Cough, substernal discomfort, bronchoconstriction, decreased exercise performance, respiratory tract irritation
Sulphur dioxide	Power plants, Smelters, oil refineries, kerosene space heaters	Exacerbation of asthma and COPD, respiratory tract irritation, hospitalization may be necessary, and death may occur in severe exposure
Lead	Automobile exhaust using leaded gasoline	Impaired neuropsychological development in children

COPD – Chronic obstructive pulmonary disease

Source : *(11, 12)*

Precise estimates of the risk of air pollution to health are difficult to quantify because of problems in estimating the degree of exposure of individuals and the influence of possible confounding variables such as smoking, nutrition, occupation and climate. Air pollution damages the human respiratory and cardio respiratory system in various ways. The elderly, children, smokers and those with chronic respiratory difficulties are most vulnerable. Under the assumption that achievable reduction in urban air pollution can prevent 5 per cent of all infections and chronic respiratory diseases, these reductions could avert 0.6 per cent of the global burden of disease. Epidemiological studies have shown that a sudden increase in the air pollution has often been associated with immediate increase in morbidity and mortality.

(b) **Social and economic aspects :** These comprise destruction of plant and animal life; corrosion of metals; damage to buildings; cost of cleaning and maintenance and repairs and aesthetic nuisance. Air pollution also reduces visibility in towns. It can soil and damage clothings.

Prevention and control of air pollution

The control of air pollution is ultimately an engineering problem. The WHO has recommended the following procedures for the prevention and control of air pollution : (a) *Containment :* That is, prevention of escape of toxic substances into the ambient air. Containment can be achieved by a variety of engineering methods such as enclosure, ventilation and air cleaning. A major contribution in this field is the development of "arresters" for the removal of contaminants. (b) *Replacement :* That is, replacing a technological process causing air pollution, by a new process that does not. Increased use of electricity, solar power generation, natural gas, and central heating in place of coal have greatly helped in smoke reduction. There is a move now to reduce lead in petrol which is a cumulative poison. In India also deleaded petrol is being used. (c) *Dilution :* Dilution is valid so long as it is within the self-cleaning capacity of the environment. For example, some air pollutants are readily removed by vegetation. The establishment of "green belts" between industrial and residential areas is an attempt at dilution. The capacity for dilution is, however, limited and trouble occurs when the atmosphere is overburdened with pollutants. (d) *Legislation :* Air pollution is controlled in many countries by suitable legislation, e.g., Clean Air Acts. Legislation covers such matters as height of chimneys, powers to local authorities to carry out investigations, research and education concerning air pollution, creation of smokeless zones and enforcement of standard for ambient air quality. To decrease the nuisance of air pollution, the Government of India have enacted "The Air (Prevention and Control of Pollution) Act" in 1981. (e) *International action :* To deal with air pollution on a world-wide scale, the WHO has established an international network of laboratories for the monitoring and study of air pollution. The network consists of two international centres at London and Washington, three centres at Moscow, Nagpur and Tokyo and 20 laboratories in various parts of the world *(13)*. These centres will issue warnings of air pollution where and when necessary.

Disinfection of air

In recent years, disinfection of air has received much attention. The methods employed are : (1) MECHANICAL VENTILATION : This reduces vitiated air and bacterial density. (2) ULTRAVIOLET RADIATION : This has been found to be effective in special situations such as operation theatres and infectious disease wards. Since direct exposure to ultraviolet rays is a danger to the eyes and skin, the ultraviolet lamps are shaded and located in the upper portion of the rooms near the inlet of air. Ultraviolet rays have proved effective for general use in public assembly and school rooms. (3) CHEMICAL MISTS : Triethylene glucol vapours have been found to be effective air bactericides, particularly against droplet nuclei and dust. (4) DUST CONTROL : Application of oil to floors of hospital wards reduces the bacterial content of the air. Air disinfection is still in the experimental stage.

VENTILATION

The modern concept of ventilation implies not only the replacement of vitiated air by a supply of fresh outdoor air, but also control of the quality of incoming air with regard to its temperature, humidity and purity with a view to provide a thermal environment that is comfortable and free from risk of infection.

Standards of ventilation

The fixing of standards of ventilation is a matter of much difficulty. Most of the standards of ventilation have been based on the efficiency of ventilation in removing body odour. (1) *Cubic space :* Different workers have advocated standards for the minimal fresh air supply ranging from 300 to 3,000 c.ft. per hour per person *(1)*. The widely quoted standard is that of De Chaumont who advocated a fresh air supply of 3,000 c.ft. per person per hour on the following grounds: It was observed that so long as the amount of carbon dioxide due to respiration was not more than 2 parts in 10,000 parts of air, the air of the rooms seemed fresh and did not sensibly differ from outdoor air. Assuming that an average person expires 0.6 c.ft. of carbon dioxide per hour, and that 0.0002 c.ft. of CO_2 in one c.ft. of air as the "permissible impurity", it was calculated that 0.6/0.0002 or

3,000 c.ft. of air would be required by a man at rest per hour. This standard of ventilation is no longer followed. (2) *Air change :* It is now established that the carbon dioxide theory is not quite correct because even if the CO_2 content of air is raised to over 5 per cent and the O_2 content reduced to 18 per cent, there were no deleterious effects so long as the "cooling power" of the air was satisfactory. Air change is more important than the cubic space requirement. It is recommended that in the living rooms, there should be 2 or 3 air changes in one hour; in work rooms and assemblies 4 to 6 air changes. If the air is changed more frequently, i.e., more than 6 times in one hour, it is likely to produce a draught which should be avoided. Based on this concept, it is now considered that a space of 1,000 to 1,200 c.ft. per person is quite sufficient. The number of air changes per hour is calculated by dividing the total hourly air supply to the room by the cubic capacity of the room *(1)*. (3) *Floor space :* Floor space per person is even more important than cubic space. Heights in excess of 10 to 12 feet are ineffective from the point of view of ventilation, as the products of respiration tend to accumulate in the lower levels. Therefore, in calculating cubic space requirements, heights over 10 to 12 feet are not taken into account. The optimum floor space requirements per person vary from 50 to 100 sq.ft.

Types of ventilation

1. *NATURAL VENTILATION*

Natural ventilation is the simplest system of ventilating small dwellings, schools and offices. In this method, reliance is placed on certain forces which operate in nature. These are: (1) THE WIND : The wind is an active force in ventilation. When it blows through a room, it is called *perflation*. When there is an obstruction, it bypasses and exerts a suction action at its tail end – this is called aspiration. Doors and windows facing each other provide "cross-ventilation". Back to back houses do not permit cross ventilation and therefore, their construction is not allowed. (2) DIFFUSION : Air passes through the smallest openings or spaces by diffusion. This is a slow process and therefore, is not relied upon as the sole means of ventilation. (3) INEQUALITY OF TEMPERATURE : Air flows from high density to low density; it rises when slightly heated and escapes from openings provided high up in the room. The outside air which is cooler and more dense will enter the room through inlets placed low. The greater the temperature difference between outside and inside air, the greater the velocity of the incoming air. In the tropics the outside air may be hotter than the inside and the reverse may take place *(2)*. These properties of air are utilized to best advantage by the proper location of windows, doors, ventilators and skylights. The chief drawback of natural ventilation is that it is not possible to regulate the velocity of the incoming air nor to adjust its temperature or humidity.

2. *MECHANICAL VENTILATION*

Mechanical or artificial ventilation may be of the following types :

(1) Exhaust ventilation. (2) Plenum ventilation. (3) Balanced ventilation. (4) Air conditioning.

(1) EXHAUST VENTILATION : In this system, air is extracted or exhausted to the outside by exhaust fans usually driven by electricity. As air is exhausted, a vacuum is created which induces fresh air to enter the room through windows, doors and other inlets. Exhaust ventilation is generally provided in large halls and auditoria for removal of vitiated air. The exhaust fans are housed in apertures in the external walls, high up near the roof which facilitate removal of the upper layers of the heated light air. The ventilation may be regulated by adjusting the speed of the fans. Local exhaust ventilation is widely used in industries to remove dusts, fumes and other concentrated contaminants at their source. (2) PLENUM VENTILATION : In this system, fresh air is blown into the room by centrifugal fans so as to create a positive pressure, and displace the vitiated air. Plenum or propulsion system is used for supplying air to air-conditioned buildings and factories. Air is delivered through ducts at desired points. This system is of limited utility. (3) BALANCED VENTILATION: This is a combination of the exhaust and plenum systems of ventilation. The blowing fan must balance the exhaust fan. When this system is employed, the natural system of ventilation is entirely dispensed with. (4) AIR CONDITIONING : Air conditioning is defined as "the simultaneous control of all, or at least the first three of those factors affecting both the physical and chemical conditions of the atmosphere within any confined space or room. These factors include temperature, humidity, air movement, distribution, dust, bacteria, odours and toxic gases, most of which affect in greater or lesser degree the human health and comfort". Air conditioning is popular in large institutions, hospitals, industries and dwellings. Its use in operation theatres is of particular value in control of pathogenic organisms in the air. The air is filtered when drawn into an airconditioner system from the room. Excess humidity is removed and the air is circulated back into the room after heating or cooling it, to bring room temperature to required comfort zone. Mixing some percentage of fresh air with recirculated air is regulated. Large institutions or hospitals often install central airconditioning system for entire building, instead of installing equipments for individual rooms. Better controls and economy is achieved in central airconditioning.

Where the temperature difference is large between outside atmosphere and airconditioned room, "transition room" is sometimes provided, which maintains temperature in between the two, so as to prevent sudden exposure to high or low temperature.

LIGHT

The requirements of good lighting

Good lighting is essential for efficient vision. If the lighting conditions are not ideal, the visual apparatus is put to strain which may lead to general fatigue and loss of efficiency. For efficient vision, the following light factors are essential : (1) SUFFICIENCY: The lighting should be sufficient to enable the eye to discern the details of the object as well as the surroundings without eye strain. An illumination of 15 to 20 foot candles (1 foot candle = 10.76 Lux) is accepted as a basic minimum for satisfactory vision. The illumination requirements vary from as little as 5 foot candles in stairways and corridors to 100 foot candles in some industries. (2) DISTRIBUTION : The distribution of light should be uniform, having the same intensity, over the whole field of

work. If there are contrast differences in light, it will strain the eyes and affect adversely the visual acuity. Proper dispersal of light, without the production of shadows is therefore necessary for efficient vision. (3) ABSENCE OF GLARE : Glare is excessive contrast. The best example of glare is the automobile headlights at night, the same lights during daylight would not cause glare owing to the absence of excessive contrast. Glare may be a direct glare from a light source or reflected glare from sources such as table tops and polished furniture. Glare causes annoyance. The eye cannot tolerate glare because it causes acute discomfort and reduces critical vision. (4) ABSENCE OF SHARP SHADOWS : Slight shadows are inevitable, but sharp and contrasting shadows are disturbing. Like glare, shadows cause confusion to the eye and therefore should not be present in the field of vision. (5) STEADINESS : The source of light should be constant. It should not flicker because flickering causes eye strain and may lead to accidents. (6) COLOUR OF LIGHT : The colour of light is not very important so long as the intensity is adequate. Since natural light has a soothing effect on the eye, the artificial light should as far as possible approximate the daylight colour. (7) SURROUNDINGS : When a black object is viewed against a dark background, recognition is difficult. High levels of illumination will be required where there is little colour contrast. For efficient vision, colour schemes in rooms are important. Ceilings and roofs should have a reflection factor of 80 per cent; walls 50 to 60 per cent; furniture 30 to 40 per cent. There should not be much reflection from the floor, not more than 15 to 20 per cent. Contrasting colours are often used to prevent accidents, e.g., culverts, bridges, etc.

Measurement of light

What we perceive as light is a narrow wavelength band of electromagnetic radiation from about 380 to 780 nm (nano metre). Light containing all visible waves is perceived as white. There is considerable confusion about units of light measurement. There are four measures of importance. For each of these four measures again, there are a number of terms and also a great variety of names. These are given in Table 1. The four measures are : (1) *Luminous intensity,* which is the "power" of a light source considered as a point radiating in all directions; this is measured as candela or candle power. (2) *Luminous flux,* which is the flow of light related to a unit of solid angle measured in lumen. (3) *Illumination or illuminance,* which is the amount of light reaching a surface measured in lux per unit area; and (4) *Brightness* or *luminance* which is the amount of light reflected from a surface measured in *lamberts.*

TABLE 1
Light measurement units

Description	Quantity measured Name	Recommended Unit*	Other Units
1. Brightness of point source	Luminous intensity	Candela	Candle power
2. Flow of light	Luminous flux	Lumen	
3. Amount of light reaching surface	Illumination Illuminance	Lux	Foot candle Lumen/cm² (Phot)
4. Amount of light re-emitted by surface	Brightness Luminance	Lambert	Foot lambert Candles/cm²

* Recommended by the International Organization for Standardization

Natural lighting

Natural lighting is derived partly from the visible sky and partly from reflection. In fact, much light comes to the rooms by reflection from light coloured objects. Efficient utilization of natural light calls for careful design, location and orientation of buildings and relationship between buildings (town planning). Natural lighting also depends upon the time of the day, season, weather and atmospheric pollution. Since natural light is accompanied by radiant heat, all attempts should be made to exclude radiant heat while admitting daylight.

Suggestions for improving daylight illumination : The following general principles are taken into consideration in planning for the best utilization of daylight. (1) ORIENTATION : The brightness of the sky is not constant on the east and west and therefore the illumination is subject to variation in buildings facing east or west. Further, the direct penetration of sunlight from the east or west may heat up the rooms unduly in the tropics, especially during summer. Buildings are therefore oriented, wherever possible, towards north or south for uniform illumination. This is particularly important in respect of schools, factories and laboratories where uniform lighting is required in all the rooms. This rule may not be strictly observed with regard to dwelling houses, as uniform lighting is not required in all the rooms. When a building faces east and west, window shades are provided to protect against the direct penetration of sunlight. (2) REMOVAL OF OBSTRUCTIONS : Removal of obstructive items either wholly or partially is likely to give the most effective single improvement in lighting. (3) WINDOWS : Windows should be properly planned, as the natural lighting within any room is influenced by the amount of visible sky, the size, shape and arrangement of the window openings. A tall window gives greater penetration of light; a broad window gives greater diffusion of light. The rule that window area should not be less than 10 per cent of the floor area is now outdated. In modern practice, window area is correlated to the purpose the room is intended to serve. The usefulness of the windows is reduced by covering them unnecessarily with curtains and screens. (4) INTERIOR OF THE ROOMS : In order to obtain the full benefit of the natural illumination, the ceiling should be white; the upper portions of the walls light-tinted; and lower portions somewhat darker so as to give comfortable contrast to the eyes. The desirable reflection factors of the walls, roof and furniture have already been discussed.

Measurement of daylight

Since the intensity of daylight illumination is liable to change from moment to moment, it is not measured in terms of foot candles. Reliance is placed on a factor called the DAYLIGHT FACTOR (D.F.). It is the ratio of illumination at a given point to illumination at a point exposed simultaneously to the whole hemisphere of the sky (taken as 500 foot candles) excluding direct sunlight. The daylight factor may be summarized as follows :

$$\text{D.F.} = \frac{\text{Instantaneous illumination INDOORS}}{\text{Simultaneously occurring illumination OUTDOORS}} \times 100$$

The daylight factor in a building may be rapidly determined by a modified photo-electric meter known as a Daylight Factor Meter. It is recommended that in living

rooms, the daylight factor should be at least 8 per cent and in kitchens about 10 per cent *(4)*.

Artificial lighting

Daylight may not meet the requirements of illumination during all hours, and especially during cloudy days. It should be supplemented by artificial illumination for adequate illumination. Artificial lighting should be as close as possible to daylight in composition. There are five systems of artificial lighting : direct, semi-direct, indirect, semi-indirect and direct-indirect. (1) DIRECT LIGHTING : In direct lighting, 99 to 100 per cent of the light is projected directly towards the working area. Direct lighting is efficient, economical, but tends to cast sharp shadows. It should not fall into the eyes. (2) SEMI-DIRECT : Here 10 to 40 per cent of the light is projected upwards so that it is reflected back on the object by the ceiling. (3) INDIRECT : light does not strike a surface directly, because 90 to 100 per cent of the light is projected towards the ceiling and walls. This gives a general illumination of the whole room but not of any object. (4) SEMI-INDIRECT : Here, 60 to 90 per cent of the light is directed upwards, and the rest downwards. (5) DIRECT-INDIRECT : Here, light is distributed equally, No one system can be recommended to the exclusion of others.

Methods of artificial illumination

(1) FILAMENT LAMPS : These are widely used. The electric current heats up the tungsten filament and the light emitted depends upon the temperature. The hotter filaments produce the bluer light. Accumulation of dust on the bulbs reduces illumination by 30 to 40 per cent. The bulbs and shades therefore should be cleaned frequently. (2) FLUORESCENT LAMPS : Fluorescent lamps are economical in the use of electric current; they are cool and efficient; the light emitted simulates natural light. The lamps consist of a glass tube filled with mercury vapour and an electrode fitted at each end. The inside of the tube is coated with fluorescent chemicals, which absorb practically all the ultraviolet radiation and remit the radiation in the visible range.

The total emission of energy from the 2 lamps is as follows *(1)*.

		Light	*Heat*
Filament	.....	5%	95%
Fluorescent	.....	21%	79%

Lighting standards

The eye responds to a range of illumination ranging from 0.1 lux (full moonlight night) to 100,000 lux (bright sunshine). There is considerable confusion about standards because of the adaptability of the eye. Many standards have been published but these standards are arbitrary. The visual efficiency increases with the increase of illumination, but the curve flattens out at higher levels. The law of diminishing return applies. A useful rule of thumb is that the illumination level should be 30 times higher than the level at which the task can just be done. It is worth repeating there are no exact lighting standards and it is usually better to err on the side of too much light, provided glare can be avoided. For practical situations and various activities, the following values (in lux) have been suggested by the Illuminating Engineer Society *(1)*.

TABLE 2
Recommended illumination (the IES Code)

Visual task	Illumination (lux)
Casual reading	100
General office work	400
Fine assembly	900
Very severe tasks	1,300–2,000
Watch making	2,000–3,000

Biologic effects of light *(2, 3)*

Considerable attention has been focused on the biologic effects of light. The observation that daylight could cause the *in vitro* degradation of bilirubin is now being used as a therapeutic measure in premature infants with hyperbilirubinaemia. Other biologic effects of light include effect on biologic rhythms of body temperature, physical activity, the stimulation of melanin synthesis, the activation of precursors of vitamin D, adrenocortical secretion and food consumption.

NOISE

Noise is often defined as "unwanted sound", but this definition is subjective because of the fact that one man's sound may be another man's noise. Perhaps a better definition of noise is : "wrong sound, in the wrong place, at the wrong time". Man is living in an increasingly noisy environment. The 20th Century has been described as the "Century of Noise". Noise has become a very important "stress factor" in the environment of man. The term "Noise Pollution" has been recently coined to signify the vast cacophony of sounds that are being produced in the modern life, leading to health hazards.

Sources : The sources of noise are many and varied. These are automobiles, factories, industries, air-crafts etc. Noise levels are particularly acute near railway junctions, traffic round-abouts, bus terminuses and airports. Use of pressure horns, recreational noise of loudspeakers with full volume during festivities particularly at night are other sources of noise production. The domestic noises from the radios, transistors, T.V sets – all add to the quantum of noise in daily life.

Properties : Noise has two important properties : loudness or intensity; and frequency.

(1) LOUDNESS : Loudness or intensity depends upon the amplitude of the vibrations which initiated the noise. The loudness of noise is measured in decibels (dB). When we say that sound is 60 dB, it means that it is 60 dB more intense than the smallest distinguishable noise or the "reference" sound pressure, which is understood to be 0.0002 microbar or dynes/cm^2. A dyne is 1/1000,000th of atmospheric pressure. Normal conversation produces a noise of 60–65 dB; whispering, 20–30 dB; heavy street traffic, 60–80 dB; and boiler factories, about 120 dB. A daily exposure up to 85 dB is about the limit people can tolerate without substantial damage to their hearing. The community noise levels are given in Fig.1.

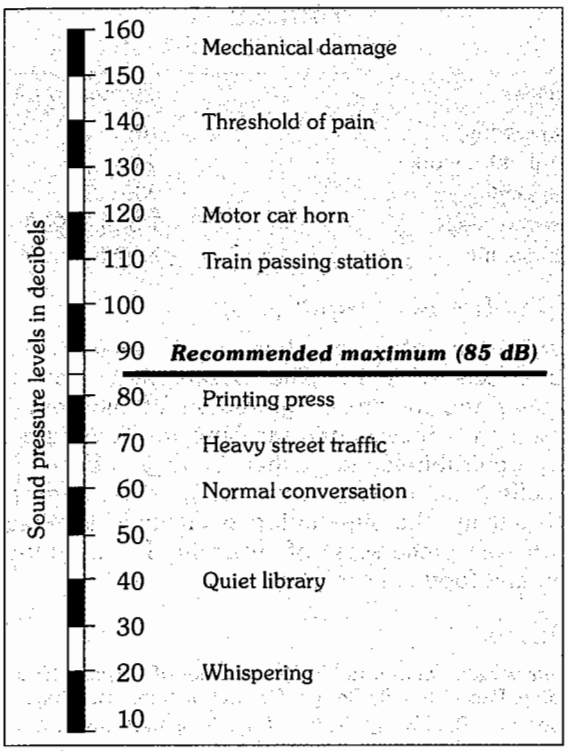

FIG.1
Community noise levels

It has been observed that the human ear responds in a non-uniform way to different sound-pressure levels, that is, it responds not to the real loudness of a sound, but to the perceived intensity. A weighting curve, called curve A has been constructed which takes into account the subjective effects of that sound. Sound-pressure levels are therefore expressed in dB (A), that is in decibels conforming to the weighting curve A, because this reflects the perception of that sound emission by the normal human ear. Acceptable noise levels are as given in Table 1.

TABLE 1

Acceptable noise levels (dBA)

Residential	Bed room	25
	Living room	40
Commercial	Office	35–45
	Conference	40–45
	Restaurants	40–60
Industrial	Workshop	40–60
	Laboratory	40–50
Educational	Class room	30–40
	Library	35–40
Hospitals	Wards	20–35

Source : *(1)*

(2) FREQUENCY : The frequency is denoted as Hertz (Hz.) One Hz is equal to one wave per second. The human ear can hear frequencies from about 20 to 20,000 Hz, but this range is reduced with age and other subjective factors. The range of vibrations below 20 Hz are infra-audible; and those above 20,000 Hz ultra-sonic. Many animals (e.g., dogs) can hear sounds inaudible to the human ear. Sometimes noise is expressed in psycho-acoustic terms – the phon. The *phon* is a psyho-acoustic index of loudness. It takes into consideration intensity and frequency.

The sound level of some of the noises are as given in Table 2.

TABLE 2

Sound levels of some noises

Source of noise	Sound level (dB)
Whisper	10
Speech, 2–3 people	73
Speech on radio	80
Music on radio	85
Children shouting	79
Children crying	80
Vacuum cleaner	76
Piano	86
Jet take-off	150

The basic instruments used in studies on noise are : (1) the "Sound Level Meter" which measures the intensity of sound in dB or dB (A); (2) the "Octave Band Frequency Analyzer," which measures the noise in octave bands. The resulting plot shows the "sound spectrum" and indicates the characteristics of the noise, whether it is mainly high-pitched, low-pitched or of variable pitch, and; (3) the "Audiometer" which measures the hearing ability. The zero line at the top in the audiogram represents normal hearing. Noise-induced hearing loss shows a characteristic dip in the curve at the 4000 Hz frequency.

Effects of noise exposure *(2,3)*

The effects of noise exposure are of two types : auditory and non-auditory. (1) AUDITORY EFFECTS. (a) *Auditory fatigue :* It appears in the 90 dB region and greatest at 4000 Hz. It may be associated with side effects such as whistling and buzzing in the ears. (b) *Deafness :* The most serious pathological effect is deafness or hearing loss. The victim is generally unaware of it in early stages. The hearing loss may be temporary or permanent. Temporary hearing loss results from a specific exposure to noise; the disability disappears after a period of time up to 24 hours following the noise exposure. Most temporary hearing loss occurs in frequency range between 4,000 to 6,000 Hz. Repeated or continuous exposure to noise around 100 decibels may result in a permanent hearing loss; in this, the inner ear damage may vary from minor changes in the hair cell endings to complete destruction of the organs of Corti. When this occurs as a result of occupation in industries, it is called 'occupational hearing loss'. Exposure to noise above 160 dB may rupture the tympanic membrane and cause permanent loss of hearing. (2) NON-AUDITORY EFFECTS : These are : (a) *Interference with speech :* Noise interferes with speech communication. In everyday life, the frequencies causing most disturbance to speech communication lie in the 300–500 Hz range. Such frequencies are commonly present in noise produced by road and air traffic. For good speech intelligibility, it is considered that the speech sound level must exceed the SIL (Speech Interference Level) by approximately 12 dB. (b) *Annoyance :* This is primarily a psychological response. Neurotic people are more sensitive to noise than balanced people. Workmen exposed to higher intensity of noise in occupational capacities, were often irritated, short tempered and impatient and more likely to resort to agitation and disrupt production. (c) *Efficiency :* Where mental

concentration is to be undertaken, a low level of noise is always desired. Reduction in noise has been found to increase work output. (d) *Physiological changes :* A number of temporary physiological changes occur in the human body as a direct result of noise exposure. These are : a rise in blood pressure, a rise in intracranial pressure, an increase in heart rate and breathing and an increase in sweating. General symptoms such as giddiness, nausea and fatigue may also occur. Noise interferes with sleep. Noise is also said to cause visual disturbance. It is said to cause a narrowing of pupil, affect colour perception and reduce night vision. (e) Besides affecting health, noise is also a significant factor in economic losses. The potential cost of noise induced hearing loss to industry is quite great.

Control of noise

A variety of approaches may be needed to control noise. These include : (1) CAREFUL PLANNING OF CITIES : In planning cities, the following measures should be taken to reduce noise; (a) division of the city into zones with separation of areas concerned with industry and transport; (b) the separation of residential areas from the main streets by means of wide green belts. House fronts should lie not less than 15 metres from the road and the intervening space should be thickly planted with trees and bushes; (c) widening of main streets to reduce the level of noise penetration into dwellings. (2) CONTROL OF VEHICLES : Heavy vehicles should not be routed into narrow streets. Vehicular traffic on residential streets should be reduced. Indiscriminate blowing of the horn and use of pressure horn should be prohibited. (3) TO IMPROVE ACOUSTIC INSULATION OF BUILDING : From the acoustic standpoint, the best arrangement is construction of detached buildings rather than a single large building or one that is continuous. Installations that produce noise or disturb the occupants within dwellings should be prohibited. Buildings should be sound-proof where necessary. (4) INDUSTRIES AND RAILWAYS : Control of noise at source is possible in industries. Special areas must be earmarked, outside residential areas, for industries, for railways, marshalling yards and similar installations. When these demands cannot be met, protective green belts must be laid down between the installations and residential areas. (5) PROTECTION OF EXPOSED PERSONS : Hearing protection is recommended for all workers who are consistently exposed to noise louder than 85 decibels in the frequency bands above 150 Hz. Workers must be regularly rotated from noisy areas to comparatively quiet posts in factories. Periodical audiogram check-ups and use of ear plugs, ear muffs are also essential as the situation demands. (6) LEGISLATION: Many states have adopted legislation providing for controls which are applicable to a wide variety of sources *(4)*. Workers have the right to claim compensation if they have suffered a loss of ability to understand speech. (7) EDUCATION : No noise abatement programme can succeed without people's participation. Therefore, their education through all available media is needed to highlight the importance of noise as a community hazard.

RADIATION

Sources of radiation exposure

Radiation is part of man's environment. The sources of radiation to which man is exposed are divided into two groups (Table 1) :

TABLE 1

Sources of radiation exposure

Natural	Man-made
(1) Cosmic rays	(1) Medical and dental: X-rays, Radioisotopes
(2) Environmental: (a) Terrestrial	(2) Occupational exposure
(b) Atmospheric	(3) Nuclear: radioactive fall-out
(3) Internal: Potassium–40 Carbon–14	(4) Miscellaneous: Television sets, Radio-active dial watches, Isotope tagged products, Luminous markers.

(1) *Natural sources :* Man is exposed to natural radiation from time immemorial. Natural background radiation arises from three sources : (a) *Cosmic rays :* The cosmic rays which originate in outer space are weakened as they pass through the atmosphere. At ordinary living altitudes, their impact is about 35 mrad a year. At altitudes above 20 km cosmic radiation becomes important. It has been calculated that a commercial jet pilot receives about 300 mrad per year from cosmic radiation *(1).* (b) *Environmental :* (i) *Terrestrial radiation :* Radioactive elements such as thorium, uranium, radium and an isotope of potassium (K_{40}) are present in man's environment, e.g., soil, rocks, buildings. It is estimated that man derives about 50 mrad per year from terrestrial radiation. Areas exist (e.g., Kerala in India) where there are rock formations containing uranium, it can be as high as 2,000 mrad a year, (ii) *Atmospheric radiation :* The external radiation dose from the radioactive gases radon and thoron in the atmosphere is rather small : about 2 mrad per year. (c) *Internal radiation :* Man is also subjected to internal radiation, i.e., from radioactive matter stored in the body tissues. These radioactive materials include minute quantities of uranium, thorium, and related substances, and isotopes of potassium (K_{40}), strontium (Sr_{90}), and carbon (C_{14}). Internal radiation is thought to inflict about 25 mrad a year on the body as a whole, but may be as high as 70 or 80. All in all, it is estimated that the total natural radiation to which the average person is subjected comes to approximately 0.1 rad a year.

(2) *Man-made sources :* In addition to natural radiation, man is exposed to artificial or man-made sources. These are : (a) *X-rays :* The greatest man-made source of radiation exposure to the general population at the present time is medical and dental X-rays. Two distinct groups are involved : (i) patients and (ii) radiologists and medical technicians. When optimum radiographic techniques are employed, the skin dose to the patient from a single X-ray film varies roughly from 0.02 to 3.0 rad. (b) *Radioactive fallout :* Nuclear explosions release a tremendous amount of energy in the form of heat, light, ionizing radiation and many radioactive substances, the important being the isotopes of carbon (C_{14}), iodine (I_{131}), cesium (Cs_{137}) and

strontium (Sr_{90}). Cs_{137} and Sr_{90} are considered most important because they are liberated in large amounts and remain radioactive for many years. The "half-life" of Sr_{90} is about 28 years and that of Cs_{137} is 30 years. These radioactive particles released into the atmosphere float down to earth for some years afterwards. Because of air currents, the particles are distributed fairly evenly over the whole human race. Measurements made in 1963 in Germany (F.R.), a country where there had been no explosions, showed that a dose of 33 mrems per person was received from this source. (c) *Miscellaneous :* Some everyday appliances (e.g., TV sets, luminous wrist watches) are radioactive. But radiation from these sources at present is too small to be important.

Types of radiation

The term "ionizing radiation" is applied to radiation which has the ability to penetrate tissues and deposit its energy within them. Ionizing radiation may be divided into two main groups : (1) *electromagnetic radiations* – X-rays and gamma rays, and (2) *corpuscular radiations* – alpha particles, beta particles (electrons) and protons. Some common types of environmental radiations are as given in Table 2.

TABLE 2

Some common environmental radiations

Type of radiation	Approximate penetrating ability		
	Air	Tissue	Lead
Alpha particles	4 cm	0.05 mm	0
Beta particles	6–300 cm	0.06–4.0 mm	0.005–0.3 mm
Gamma rays	400 metres	50 cm	40 mm
X-rays	120–240 metres	15–30 cm	0.3 mm
Cosmic rays		some components very high	

Source : *(1)*

Alpha particles are 10 times as harmful as X-rays, beta particles or gamma rays. Alpha particles, luckily, have little penetrating force. On the other hand, they are quite dangerous if radioactive substance has entered the body (by inhalation or through a wound). Gamma rays and X-rays have short wave lengths; they are deep penetrating radiations. X-rays are manmade, while gamma rays are emitted spontaneously by radioactive elements during their disintegration. Otherwise there is no material difference between gamma rays and X-rays. Cosmic rays also contain ionizing radiations.

The term "non-ionizing radiation" refers to several forms of electromagnetic radiation of wavelengths longer than those of ionizing radiation. As wavelength elongates, the energy value of electromagnetic radiation decreases. So all non-ionizing forms of radiation have less energy than cosmic, gamma, and X–radiation have. In order of increasing wavelength, non-ionizing radiation includes ultraviolet (UV) radiation, visible light, infrared radiation, microwave radiation and radio frequency radiation.

Radiation units

The activity of a radioactive material is the number of nuclear disintegration per unit of time. The unit of activity is a becquerel (Bq); 1 Bq is equal to 1 disintegration per second. Formerly, the unit of activity was curie (Ci) and 1 Bq corresponds approximately to 27 picocuries.

The potency of radiation is measured in three ways : (1) *Roentgen:* Roentgen is the unit of exposure. It is the amount of radiation absorbed in air at a given point, i.e., number of ions produced in 1 ml of air. (2) *Rad :* Rad is the unit of absorbed dose. It is the amount of radioactive energy absorbed per gram of tissue or any material. 1mrad = 0.001 rad (3) *Rem :* Rem is the product of the absorbed dose and the modifying factors. The rem indicates the degree of potential danger to health. The radiation to which the average citizen is exposed is made up almost of the fast moving, highly penetrating X-rays and gamma rays, where rem and rad are equal *(2)*.

The radiation units (viz roentgen, rad, rem) are being replaced by the new SI Units (International System of Units) which are : (a) *Coulomb per kilogram* (C/Kg) replacing the roentgen. 1 roentgen is equal to 2.58×10^{-4} C kg^{-1}. It is the unit for exposure. There is no special name for this. (b) Gray (Gy) replacing the rad. It is the unit of absorbed dose, defined as the dose of ionizing radiation that impart 1 joule of energy to 1 kg of absorbing material. 1 rad is equal to 0.01 Gy. *(1)*, and (c) Sievert (Sv) replacing the rem. It is the SI unit of dose equivalent. The dose equivalent of 1 sievert is equal to 100 rems.

Dose equivalent (H) : As all types of radiation do not produce the same biological effect per unit of energy absorbed, the concept of dose equivalent has been introduced. The dose equivalent, M (Sieverts) is equal to the absorbed dose, D (grays), multiplied by a quality factor Q which depends upon the density of ionization produced in the tissue by the radiation.

$$H = DQ$$

The factor Q for X-rays and Y-rays and electrons is equal to 1, whereas for a particle it is 20 *(3)*.

Biological effects of radiation

Biological effects of radiation are divided into two categories. The first category consists of exposure to high doses of radiation over a short period of time producing acute or short term effects. The second category represents exposure to low doses of radiation over an extended period of time producing chronic or long-term effect. High doses tend to kill cells, causing organ damage. This in tern may cause whole body response often called "Acute Radiation Syndrome". The effects of ionizing radiation can be somatic or genetic as shown below :

SOMATIC
- *Immediate*
  - (1) Radiation sickness
  - (2) Acute radiation syndrome
- *Delayed :*
  - (1) Leukaemia
  - (2) Carcinogenesis
  - (3) Foetal developmental abnormalities
  - (4) Shortening of life

GENETIC
- (1) Chromosome mutations
- (2) Point mutations

The biological response of high dose of radiation is as follows *(4)* :

< 5 rad : No immediate observable effects

~ 5 rad to 50 rad : Slight blood changes may be detected by medical evaluations

~ 50 rad to 150 rad : Slight blood changes will be noted and symptoms of nausea, fatigue, vomiting etc. likely.

~ 150 rad to 1,100 rad : Severe blood changes will be noted and symptoms appear immediately. Approximately 2 weeks later, some of those exposed may die. At about 300–500 rad, upto one half of the people exposed will die within 60 days without intensive medical attention. Death is due to destruction of the blood forming organs. Without white blood cells, infection is likely. At the lower end of the dose range, isolation, antibiotics, and transfusions may provide the bone marrow time to generate new blood cells and full recovery is possible. At the upper end of the dose range, a borne marrow transplant may be required to produce new blood cells.

~ 1,100 rad to 2,000 rad : The probability of death increases to 100% within one to two weeks. The initial symptoms appear immediately. A few days later, things get very bad, very quickly since the gastrointestinal system is destroyed. Once the GI system ceases to function, nothing can be done, and medical care is for comfort only.

>2,000 rad : Death is a certainity. At doses above 5,000 rad, the central nervous system (brain and muscles) can no longer control the body functions, including breathing and blood circulation. Everything happens very quickly. Nothing can be done, and medical care is for comfort only.

As noted, there is nothing that can be done if the dose is high enough to destroy the gastrointestinal or central nervous system. That is why bone marrow transplants don't always work.

GENETIC EFFECTS : While somatic effects are recognizable within the life span of the irradiated person, genetic effects would be manifest in the more or less remote offspring. Genetic effects result from injury to chromosomes – chromosome mutations and point mutations. Chromosome mutation is associated with sterility. Point mutation affects the genes.

Radiation protection

The amount of radiation received from outer space and background radiation has been estimated to be 0.1 rad a year. Apparently, this does not at present constitute a hazard. The additional permissible dose from man-made sources should not exceed 5 rad a year. Of the man-made sources, the X-rays constitute the greatest hazard. In routine fluoroscopy, a dose of 4 rad is delivered to a part of the body in about one minute. This implies that unnecessary X-ray examinations should be avoided, especially in the case of children and pregnant women *(5)*. It also implies adequate control and surveillance of X-ray installations, protection of workers, improvement in techniques and improvements leading to dose reduction *(6)*. Effective protective measures include proper use of lead shields and lead rubber aprons. Lead aprons (0.5 mm of lead) will reduce the intensity of scattered X-rays over 90 per cent and should be worn by all workers regularly associated with X-ray procedures *(1)*. Workers must wear a film badge or dosimeter which shows accumulated exposure to radiation since last time the instrument was charged. Besides, periodic medical examinations, regular working hours, recreation, and holidays must be ensured to workers to maintain their state of health.

Radiation protection is the youngest branch of hygiene, and is called radiation–hygiene. The International Commission on Radiological Protection (ICRP), the International Atomic Energy Agency (IAEA) and the World Health Organization (WHO) have been active in this field. The ICRP's recommendations on radiation dose levels *(7)* for occupational workers and for the general population have been adopted by many countries. It has been recommended that the genetic dose to the whole population from all sources additional to the natural background radiation, should not exceed 5 rems over a period of 30 years. The WHO has published permissible radiation levels in drinking water. The IAEA has sponsored many symposia on radioactive waste disposal and associated subjects *(8)*. Its main concern has been to promote peaceful uses of atomic energy and to assure that these uses do not imperil peace or health. In short, there has been a worldwide interest in preparing safety standards, codes of practice for the safe operation of nuclear power plants and enunciating the basic principles of radiation protection.

METEOROLOGICAL ENVIRONMENT

The elements which comprise the meteorological environment are: (1) atmospheric pressure (2) air temperature (3) humidity (4) rainfall (5) direction and speed of wind and (6) movement of clouds and character of weather *(1)*. The term "climate" is a geographical concept representing a summation of the whole range of meteorological phenomena.

Atmospheric pressure

The atmospheric pressure at earth's surface close to the sea level averages 760 mm of Hg. This is called "one atmosphere of pressure". Man is physiologically adapted to live at 760 mm of Hg pressure or close to it. The atmospheric pressure falls as altitude increases, and rises as altitude decreases. Thus, at an altitude of 100,000 feet above mean sea level, the atmospheric pressure is less than 10 mm. of Hg. The pressure increases at the rate of "one atmosphere" for each 33 feet depth below sea level.

Measurement

The instruments used for measuring atmospheric pressure are known as barometers of which there are three well-known kinds : Fortin's Barometer; the Kew Pattern Station Barometer and the Barograph. The 'Kew Pattern' Station Barometer is widely used by the Indian Meteorological Department for measuring the atmospheric pressure. Barograph is an instrument for obtaining a continuous record of atmospheric pressure. It is a circular box, the walls of which collapse or distend when the atmospheric pressure rises or falls.

Effects of atmospheric pressure on health

HIGH ALTITUDES

The air is less dense at higher altitudes, and consequently the partial pressure of oxygen is also less. Man cannot survive at an altitude of 25,000 feet without breathing equipment. When man is exposed to low pressures, the physiological effects are : (1) increase in respiration (2) increase in the concentration of haemoglobin (3) increase in cardiac output.

Two conditions have been described as a result of sudden exposure to high altitude : (1) *Acute Mountain Sickness :* This is a relatively common, harmless, and transient condition characterised by headache, insomnia, breathlessness, nausea, vomiting and impaired vision. It has not been conclusively proved whether all these symptoms are due to the effect of hypoxia or due to the various intricate biochemical and hormonal disturbances in the body. (2) *High Altitude Pulmonary Oedema :* The symptoms generally appear on about the third day at high altitude and are indistinguishable from those of ordinary mountain sickness. But as pulmonary oedema develops, the patient develops a cough, and may experience irregular or Cheyne–Stokes breathing, oligurea, mental confusion and hallucinations, stupor, seizures and coma. The condition is rare below 12,000 ft. (3,600 m.). The condition does not respond to antibiotics. The patient should be carried to lower altitudes as soon as possible. At present, the causes and mechanism of high altitude pulmonary oedema are not well understood. The main knowledge of this condition has been gained by medical officers in the Indian Army, who have seen many cases among troops transported from the lowlands to Himalayan stations *(2,3)*.

LOW ALTITUDES

The atmospheric pressure increases by one atmosphere for every 33 feet depth below sea level. The greatest depth so far reached are the equivalent of 10 atmospheres. When man is exposed to high pressure, the gases in the air namely oxygen, carbon dioxide and nitrogen are dissolved in the blood and tissues proportionately to the partial pressure of these gases. Excess concentration of nitrogen excerts a narcotic action leading to loss of mental functions and consciousness; excess of carbon dioxide increases the narcotic action of nitrogen; excess of oxygen can lead to convulsions and death. When the person comes up to the surface, the gases which are dissolved in the blood under pressure are released and cause air embolism, the effects of which are fatal. The effects of increased pressure are best observed in persons working in diving bells and compressed air chambers (Caisson disease).

AIR TEMPERATURE

The temperature of air varies in different parts of the day and also in the different seasons. The factors which influence the temperature are latitude of the place, altitude, direction of wind and proximity to sea. The temperature of the ground surface is always higher than that of the air.

MEASUREMENT

Thermometers are instruments used for measuring temperature. Mercury thermometers are widely used, as mercury boils at a high temperature, has a regular expansion and its level can be easily seen. Alcohol thermometers are also used. Alcohol has the advantage of not solidifying even at the lowest known temperature. The essential conditions for the use of the thermometers are that:- (1) the air should have free access to the bulbs of the thermometers and (2) the thermometer should be protected against radiant heat. These conditions are fulfilled by mounting the thermometers on a special approved screen called the "Stevenson Screen" which is used in all the meteorological observatories in India.

Dry bulb thermometer

This is an ordinary thermometer which measures the air temperature. For accurate readings, it is mounted on the 'Stevenson Screen', at a height of 1.20 to 1.80 m above the ground level. The screen protects against radiant heat, direct sun and rain.

Wet bulb thermometer

The wet bulb thermometer is precisely the same as the dry bulb thermometer excepting that the bulb is kept wet by a *muslin* cloth fed by water from a bottle through a wick. The evaporation of water from the muslin cloth lowers the temperature of the mercury. The wet bulb thermometer therefore shows a lower temperature reading than the dry bulb thermometer. The drier the air, the lower the wet bulb reading. If the wet and dry bulb thermometers record the same temperature, it means that the air is completely saturated with moisture, which is rare.

Maximum thermometer

This is a mercury thermometer so designed that there is a very fine constriction near the neck of the bulb. When the temperature rises, mercury expands; when the temperature falls, mercury cannot get back into the bulb. The end of the mercury thread at the distal end gives the maximum temperature reached. The thermometer is set each time by swinging briskly when the mercury retreats into the bulb.

Minimum thermometer

The liquid inside the minimum thermometer is spirit, in which is immersed a dumb-bell shaped index. When the temperature falls, the spirit drags the index towards the bulb end; when the temperature rises, the spirit expands and runs past the index.

Six's maximum and minimum thermometer

This is combination of the maximum and minimum thermometers. This instrument is not used in the Indian Meteorological Observatories.

Globe thermometer

The globe thermometer is used for the direct measurement of the mean radiant temperature of the surroundings. The instrument consists of a hollow copper bulb 6 inches (15 cm) in diameter and is coated on the outside with mattblack paint which absorbs the radiant heat from the surrounding objects. A specially calibrated mercury thermometer is inserted, with its bulb at the centre of the globe (Fig. 1). The globe thermometer registers a higher temperature than the ordinary air temperature thermometer because it is affected both by the air temperature and *radiant heat.* The difference between the globe thermometer temperature and that of the ordinary dry bulb is a measure of the radiant heat. The globe thermometer is also influenced by the velocity of air movement. The standard globe instrument reaches equilibrium with its environment in 15 to 20 minutes. A modified form of globe thermometer has been

developed by Hellon and Crockford, which reaches equilibrium in about half this time, i.e., 8 to 10 minutes. The modified globe is made up from lighter gauge metal than the standard type, i.e., half the gauge and it is also provided with an internal air stirring mechanism consisting of a small fan driven by a miniature 6 volt motor *(4)*.

Wet globe thermometer *(5)*

This instrument is designed for environmental heat measurement. It consists of a dial thermometer with the heat sensing portion enclosed by a blackened copper sphere that is completely covered with wet black cloth. The Wet Globe exchanges heat with the surroundings by conduction, convection, evaporation and radiation similar to the way a perspiring man does, so the equilibrium temperature of the globe provides a comprehensive measure of the cooling capacity of the work environment *(5)*.

Silvered thermometer

The bright metallic surface reflects as much of the incident radiant heat as possible. This gives a more accurate reading of the air temperature.

Kata thermometer

The word "kata" is a Greek word meaning "down". The Kata thermometer (Fig. 2) is an alcohol thermometer with a glass bulb 4 cm long and 1.8 cm in diameter. The readings on the stem are marked from 100 deg. to 95 deg.F. Two instruments are used, the bulb of one is covered with a wet muslin cloth, the *wet kata* and the other *dry kata*. Before taking the readings, the bulbs are immersed in hot water to warm them slightly above 130 deg.F, when the alcohol rises into a small reservoir at the top of the instrument. The bulb of the dry Kata is wiped dry. Then both the instruments are suspended in air at the point of observation. The time in seconds required for the spirit to fall from 100 deg. to 95 deg.F is noted with a stop watch. This is repeated at least 4 times. The first reading is discarded and the average of the last three is taken. The length of time depends upon the "cooling power" of the air. Each Kata has a "factor" called the Kata Factor marked on the stem. This factor is determined for each instrument by the manufacturers. This factor, divided by the average cooling time gives the rate of cooling in millicalories per sq. centimetre per second. The Kata thermometer was originally devised for measuring the "cooling power" of the air. A dry Kata reading of 6 and above, and a wet Kata reading of 20 and above were regarded as indices of thermal comfort. The Kata thermometer is now largely used as an anemometer for recording low air velocities rather than the cooling power of the air.

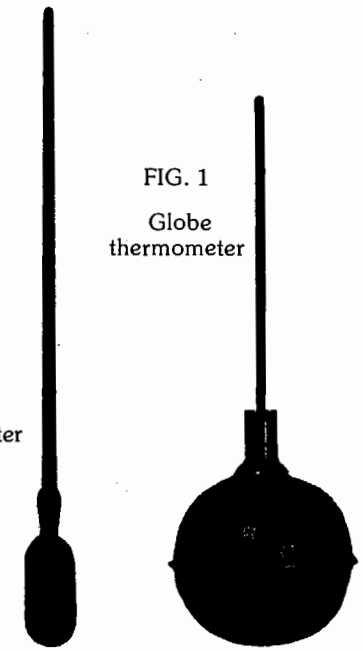

FIG. 1
Globe thermometer

FIG. 2
Kata thermometer

Kata thermometers are available to cover the following 5 deg.F cooling ranges : (1) The standard Kata – cooling range between 100 deg. – 95 deg.F. (2) the High Temperature Kata – cooling range between 130 deg. – 125 deg.F. and (3) the Extra High Temperature Kata – cooling range between 150 deg. – 145 deg.F. In tropical countries, the atmospheric temperature may be well above 100 deg.F when the standard Kata cannot be used, but the other instruments can be used. The three types of Kata are readily distinguished by the colour of the alcohol. The standard Kata is coloured red; the high temperature instrument dark blue; and the extra high instrument magenta. Kata thermometers have silvered bulbs to reduce the errors due to radiation.

Heat stress indices *(6,7)*

Heat stress is the burden or load of heat that must be dissipated if the body is to remain in thermal equilibrium. The factors which influence heat stress are metabolic rate, air temperature, humidity, air movement and radiant temperature. The amount of heat gained by the body must be equalled by the amount of heat lost from it.

Many heat stress indices have been devised, but none is adequate to be valid in all possible complexities of work rate, air temperature, air movement, etc. These include : Equatorial Comfort Index, Heat Stress Index, and Predicted Four Hour Sweat Rate (P_4SR). (a) *Equatorial comfort index :* This denotes the temperature of still and saturated air which is equivalent physiologically to the climate under consideration. (b) *Heat stress index :* This takes into consideration the metabolic rate and the principal channels of heat exchange between the human body and the environment. The heat stress index represents the percentage of the heat storage capacity of an average man. Nomograms have been provided from which the value of the heat stress index could be easily calculated. An interpretation of the HSI values are as given below :

0	.....	No thermal stress
10–30	.....	Moderate to mild heat strain
40–60	.....	Severe heat strain
70–90	.....	Very severe heat strain
100	.....	Upper limit of heat tolerance

(c) *Predicted four hour sweat rate :* The rate at which a man sweats is a good index of the heat stress to which he is subjected. A sweat rate of 4.5 litres in 4 hours is the upper limit of tolerance in health for work in hot environment. A sweat rate of 2.5 litres in 4 hours is considered optimal for a working man. P_4SR is applicable only in the situation where sweating occurs.

Effects of heat stress

As many as 14 disorders resulting from exposure to heat have been recognized and documented *(8)*. The important ones are : (1) HEAT STROKE : This is attributed to failure of the heat regulating mechanism. It is characterized by very high body temperature which may rise to 110°F (43.3°C) and profound disturbances including delirium, convulsions and partial or complete loss of consciousness. The skin is dry and hot. Classically, sweating is absent or diminished, but

many victims of clear-cut heat stroke perspire profusely. The outcome is often fatal, even when patients are brought quickly to medical attention; death/case ratios of 40 per cent or more have been reported. The treatment consists of rapidly cooling the body in ice water bath till the rectal temperature falls below 102°F (38.9°C). The rectal temperature should be monitored continuously, both to monitor the efficacy of hypothermia treatment and to guard against the development of clinically significant hypothermia, which can occur if cooling is continued too long. Further treatment is supportive and directed towards the many potential complications of hyperthermia. Hypovolaemia, hyperkalaemia, rhabdomyolysis, hypocalcaemia and bleeding diathesis may require intensive supportive treatment. The patient should be kept in bed for several days until the temperature control becomes stable. (2) HEAT HYPERPYREXIA : This is attributed to impaired functioning of the heat–regulating mechanism but without characteristic features of heat stroke. It is arbitrarily defined as a temperature above 106°F *(8)*. It may proceed to heat stroke. (3) HEAT EXHAUSTION : Unlike heat stroke, heat exhaustion is not because of failure of thermo-regulation. It is a milder illness than heat stroke and is caused primarily by the imbalance or inadequate replacement of water and salts lost in perspiration due to thermal stress. Heat exhaustion typically occurs after several days of high temperature. Body temperature may be normal or moderately elevated, but it is uncommon to exceed 102°F (38.9°C). The symptoms, primarily dizziness, weakness and fatigue, are those of circulatory distress. It may be severe enough to require hospitalization, especially in elderly patients. Treatment is directed towards normalizing fluid and electrolyte balance. (4) HEAT CRAMPS : Heat cramps occur in persons who are doing heavy muscular work in high temperature and humidity. There are painful and spasmodic contractions of the skeletal muscles. The cause of heat cramps is loss of sodium and chlorides in the blood. (5) HEAT SYNCOPE : This is a common ill-effect of heat. In its milder form, the person standing in the sun becomes pale, his blood pressure falls and he collapses suddenly. There is practically no rise in body temperature. The condition results from pooling of blood in lower limbs due to dilatation of blood vessels, with the result that the amount of blood returning to the heart is reduced, which in turn is responsible for lowering of blood pressure and lack of blood supply to the brain. This condition is quite common among soldiers when they are standing for parades in the sun *(10)*. Treatment is quite simple. The patient should be made to lie in the shade with the head slightly down; recovery usually comes within 5 to 10 minutes.

PREVENTIVE MEASURES

The ill effects of high temperature may be prevented by observing the following precautions : (1) REPLACEMENT OF WATER : Persons working under conditions of high temperature and humidity should be encouraged to drink cool water. It has been found in India that a man doing hard work in the sun requires about one litre of water per hour. For a sedentary worker, the requirement is nearly half this quantity. There is a widespread belief that extra salt intake during the summer helps prevent the ill-effects of heat. Studies have shown that the normal intake of salt in the Indian diet is far more than is actually needed. Further, salt losses through sweat are small since the concentration of salt in sweat is considerably low. Therefore, there is no need to add salt to water. However, extra salt is needed by unacclimatized persons during the first ten days of their exposure to heat *(10)*. (2) REGULATION OF WORK : The duration of exposure to a hot environment should be cut down. There should be periods of rest in between intense work. If signs, such as headache and dizziness appear, the person should be removed to a cooler environment, and the necessary treatment given. (3) CLOTHING : The clothing worn should be light, loose and of light colours. (4) PROTECTIVE DEVICES : Protective goggles, shields and helmets are helpful. (5) WORK ENVIRONMENT : The temperature and humidity in the work environment may be controlled by proper ventilation and air-conditioning.

Effects of cold stress

Injury due to cold may be general or local. In general cold injury (hypothermia), the individual is said to be suffering from exposure to cold. This is characterised by numbness, loss of sensation, muscular weakness, desire for sleep, coma and death. Local cold injury may occur at temperatures above freezing (wet–cold conditions) as in *immersion* or *trench foot*. At temperatures below freezing (dry–cold conditions) *frostbite* occurs; the tissues freeze and ice crystals form in between the cells *(11)*. Frostbite is common at high altitudes. It is extremely important to dress for the temperature with which the part will be in contact. The affected part should be warmed using water at 44 deg. C. Warming should last about 20 minutes at a time. Intake of hot fluids promotes general rewarming.

Global warming

Emission of green-house gases into the atmosphere have been increasing ever since the beginning of the industrial revolution. A major component of emission of carbon dioxide is from the combustion of fossil fuels. It is generally conceded that the main effects of this include an increase of about 3°C in the average global surface temperature by the year 2030, a rise in the sea level of 0.1–0.3 metres by 2050, and an increase in the occurrence of extreme climatic events such as cyclones, heatwaves and draughts *(12)*. The temperature rise could overwhelm the capacity of many species to adapt. A change of this magnitude would affect local, regional and global ecosystem, sea levels and ocean currents, prevailing winds, fresh water supplies, agriculture, forests, fisheries, industry, transport, urban planning, demographics and human health. Some effects are mutually reinforcing, so a small additional change in the existing trend could have massive consequences, in accordance with the mathematics of catastrophe theory *(13)*.

Changes in the configuration of jet streams, prevailing winds and ocean currents could alter the distribution of rainfall in many regions, making some wetter, others drier. The summers are becoming hotter. Temperate zone warming induces a decline in soil moisture that impairs grain production. This will also change the distribution of vegetation. The distribution of insect vectors of disease will change. The "heat island" phenomenon that makes cities warmer than surrounding rural areas will lead to longer and more severe heat waves than we are accustomed to now *(13)*.

HUMIDITY

Humidity or moisture is always present in the atmosphere. The amount of moisture which air can hold depends upon its temperature. If the air is cooled, the excessive moisture precipitates for the particular temperature. This is called *Dew Point.* Humidity may be expressed *as absolute humidity* or *relative humidity.*

(a) ABSOLUTE HUMIDITY is the weight of water vapour in a unit volume of air. It is expressed as grammes per kilogram or grammes per cubic metre of air.

(b) RELATIVE HUMIDITY: Relative humidity is the most common way of describing atmospheric moisture. It does not indicate the actual amount of water vapor in the air, instead, it tells us how close the air is to being saturated. The relative humidity (RH) is the ratio of the amount of water vapor actually in the air to the maximum amount of water vapor required for saturation at that particular temperature (and pressure). It is the ratio of the air's water vapor content to its capacity; thus

$$RH = \frac{\text{Water vapor content}}{\text{Water vapor capacity}}$$

It can also be expressed as

$$RH = \frac{\text{Actual vapor pressure}}{\text{Saturation vapor pressure}} \times 100 \text{ per cent}$$

Relative humidity is given as a per cent. Air with a 50 per cent RH actually contains one-half the amount required for saturation. Air with a RH greater than 100 per cent is said to be supersaturated. A change in RH can be brought about in two ways : (a) by changing the air's water vapor content; and (b) by changing the air temperature with a constant amount of water vapor, cooling the air raises the RH and warming the air lowers it *(14)*.

Very low RH in the house can have an adverse effect on things living inside & including house plants. Very low RH causes rapid evaporation of moisture from exposed skin causing crack, dry flake, or itch. It also irritates mucous membranes in the nose and throat, causing an itchy throat. Dry nasal passage permit inhaled bacteria to incubate, causing persistent infection. The remedy for most of these problems is to increase the RH.

(c) DEW POINT : It represents the temperature to which air would have to be cooled (with no change in air pressure or moisture content) for saturation to occur. The dew point is determined with respect to a flat surface of water. When the dew point is determined with respect to a flat surface of ice, it is called frost point. The dew point is an important measurement used to predict the formation of dew, frost, fog and even minimum temperature. High due point indicate high water vapor content; and low dew point indicate low water vapor content.

Measurement

There are several instruments which may be used for measuring humidity. The ones commonly used are described below :

DRY AND WET BULB HYGROMETER

This is the most widely used instrument for measuring humidity. The instrument consists of two similar thermometers – a dry bulb thermometer and a wet bulb thermometer, which are mounted side by side on a stand. The dry bulb measures the air temperature (DBT). The bulb of the second one is covered with a gauze or wick and is kept moist. The wet bulb temperature (WBT) is usually lower than the DBT. If both the readings are the same, it indicates that the atmosphere is 100 per cent saturated with moisture, which never occurs in reality. After obtaining the readings of the dry and wet bulb thermometers, the corresponding RH can be found from specially constructed psychrometric charts or slide rule. Humidity values are high in early morning and are near the minimum value in the afternoon at about 15.00 hours. For accurate readings of the wet bulb thermometer, the air should pass over the bulb with a speed of about 800 ft/min (5 m/sec). The sling psychrometer (described below) achieves this when rotated rapidly.

SLING PSYCHROMETER

The sling or whirling psychrometer (Fig. 3) consists of 2 mercury thermometers (wet and dry) mounted side by side, on a suitable wooden frame, and provided with a handle for rotating the instrument. The underlying principle is that by rotating, the bulbs are exposed to air at a definite velocity. The wet bulb is first moistened with distilled water and the instrument is whirled or rotated standing with the back to the sun, for about 15 seconds at the rate of 4 revolutions per second, so as to obtain the desirable air speed of about 5 metres per second. The reading of the wet bulb is then noted. The instrument is again whirled for about 10 seconds and the wet bulb reading is noted. This is repeated several times till 2 successive readings of the wet bulb are identical. The reading of the dry bulb is then noted. By use of suitable tables or charts, the relative humidity of the air may be obtained from the readings of the psychrometer.

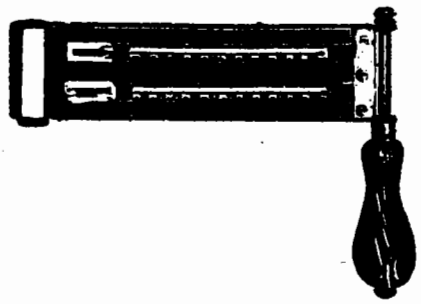

FIG.3
Sling psychrometer

ASSMANN PSYCHROMETER

This is a portable instrument specially designed to give accurate measurement of the wet and dry bulb temperature of the air. In this instrument, air is drawn at a speed higher than 5 metres per second by a clock-work fan. The bulbs of the thermometer are protected from the effects of solar radiation so that the instrument can be used even in strong sunshine.

PRECIPITATION

The term precipitation is the collective term used for rain, snow, hail, dew and frost – that is, all forms of water precipitated from the atmosphere. It is measured by rain–gauges. The rain-gauge prescribed by the Government of India for use at rainfall measuring stations in India is known as the "Symon's Rain-gauge". The funnel for receiving the rainfall has a diameter of 5 inches. Great care is exercised in selecting a suitable site for the erection of rain-gauge. The Rain-gauge should be set on a level ground, away from trees, buildings, or other obstructions. The rule which must be strictly adhered to in the erection of a Rain-gauge is that its rim should be exactly horizontal, and one foot above the ground level, the instrument having been fixed in a masonry or concrete foundation. The rainfall is measured in millimetres per a time unit (mm/day; mm/month).

AIR VELOCITY

Air velocity

The air velocity is measured by an instrument called the *anemometer.* It consists of four hemispherical cups, attached to the ends of 2 crossed metal arms. There is a vertical spindle which is attached to the 'anemometer box'. The velocity of the wind is indicated on a counter called the cyclometer, placed in the anemometer box.

Wind velocities are normally recorded in open flat country at a height of 10 m. Velocities are measured in metres per second (m/s.). When the wind speed is 0.5 m/s, it is described as complete calm with smoke rising vertically; when it is 3.3 m/s, it is described as *slight breeze* with leaves rustling; when it is 10 m/s, it is described as *strong wind* with larger branches of trees moving; when it is 15–20 m/s, it is called *storm;* when it is 25–30 m/s, it is called *gale;* and over 30–50 m/s, it is called *hurricane.*

KATA THERMOMETER : The Kata thermometer is quite sensitive to slight air movements. It can record air velocities as low as 10 feet per minute. This instrument has already been described.

Wind direction

The wind direction is observed by an instrument called the *wind vane.* There is an arrow which turns freely about a vertical axis. The wind vane is erected at a height of 10 m above ground level. If the arrow is motionless for 3 minutes, the wind is described as 'calm'. The wind direction may also be noted by letting off bits of paper in the air, which gives the approximate direction. Directions are grouped into 4 main categories (N,E,S, and W) and 8 or 16 sub-categories.

Clouds and weather observations

In all meteorological stations, clouds are observed for their form, amount, direction and height. Such observations give an insight into the sequence of weather in the particular locality. From the state of the sky and evolution of clouds, weather is described as fine weather, fair weather, unsettled weather, bad weather and thunderous sky. Meteorological satellites are now being used for automatic picture taking to give an idea of the clouds. The satellites can also measure temperature and humidity in the atmosphere.

HOUSING

"Housing", in the modern concept includes not only the 'physical structure' providing shelter, but also the immediate surroundings, and the related community services and facilities. It has become part of the concept of "human settlement", which is defined as "all places in which a group of people reside and pursue their life goals; the size of the settlement may vary from a single family to millions of people".

A WHO Expert Group (1961) on public health aspects of housing prefers to use the term "residential environment" which is defined as the physical structure that man uses and the environs of the structure including all necessary services, facilities, equipment and devices needed or desired for the physical and mental health and the social well-being of the family and the individual *(1).* The immediate surroundings of residential building are often referred to as the neighbourhood or microdistrict.

Social goals of housing

Goals are statements about desirable or projected conditions. The generally accepted goals of housing are : (1) *Shelter :* That the house should provide a sanitary shelter, which is a basic need. (2) *Family life:* That the house should provide adequate space for family life and related activities, viz preparation and storage of food, meeting, sleeping, individual activities and other basic activities. The adequacy of housing at this level has been found to have a direct impact on such things as worker productivity and family stability. (3) *Access to community facilities :* A third element of housing is accessibility to community services and facilities such as health services, schools, shopping areas, places of worship etc. (4) *Family participation in community life :* Family is part of the wider community. Community is important to family in many ways – it can offer help in times of need; it is an important source of friends. Communities are able to pool their efforts and improve their living conditions. (5) *Economic stability :* Housing is a form of investment of personal savings. It provides for economic stability and well being of the family.

The implementation of social goals in housing requires that government should (1) introduce social housing schemes; (2) establish both minimum and maximum standards; (3) create financial and fiscal institutions geared to helping low income people obtain credit for building or improving their houses.

CRITERIA FOR HEALTHFUL HOUSING

An Expert Committee of the WHO *(3)* recommended the following criteria for healthful housing similar to the Basic Principles of Healthful Housing published by the American Public Health Association *(4)* :

1. Healthful housing provides physical protection and shelter;
2. provides adequately for cooking, eating, washing, and excretory functions;
3. is designed, constructed, maintained and used in a manner such as to prevent the spread of communicable diseases;
4. provides for protection from hazards of exposure to noise and pollution;
5. is free from unsafe physical arrangements due to construction or maintenance, and from toxic or harmful materials; and

6. encourages personal and community development, promotes social relationships, reflects a regard for ecological principles, and by these means promotes mental health.

Housing standards

With the broadening concept of housing, the concept of housing standards has also changed. The standards are no longer confined to narrow health criteria like per capita space and floor space. Social and economic characteristics such as family income, family size and composition, standard of living, life style, stage in life cycle, education and cultural factors must be taken into consideration in determining housing standards. Because of cultural diversity and other factors such as climate and social traditions, standards of housing must vary from country to country and from region to region. In short, there cannot be rigid, uniform standards.

However, minimum standards are still maintained by building regulations, the aim being improvement of housing and environmental conditions for the majority of families within the limits set by available resources and objectives. The standards in India are those recommended by the EHC (1947). These are as below :

SITE : (a) The site should be elevated from its surroundings so that it is not subject to flooding during rains (b) the site should have an independent access to a street of adequate width (c) it should be away from the breeding places of mosquitoes and flies (d) it should be away from nuisances such as dust, smoke, smell, excessive noise and traffic (e) it should be in pleasing surroundings (f) the soil should be dry and safe for founding the structure and should be well drained. "Made–soil", i.e., ground that is levelled by dumping refuse is very unsatisfactory for building purposes for at least 20 to 25 years. The subsoil water should be below 10 feet (3 metres).

SET BACK : For proper lighting and ventilation, there should be an open space all round the house – this is called "set back". In rural areas it is recommended that the built-up area should not exceed one-third of the total area; in urban areas where land is costly, the built-up area may be upto two-thirds. The set back should be such that there is no obstruction to lighting and ventilation.

FLOOR : The floor should be pucca and satisfy the following criteria : (a) it should be impermeable so that it can be easily washed and kept clean and dry. Mud floors tend to break up and cause dust; they are not recommended, (b) the floor must be smooth and free from cracks and crevices to prevent the breeding of insects and harbourage of dust, (c) the floors should be damp–proof, (d) the height of the plinth should be 2 to 3 feet (0.6 to 1 metre).

WALLS : The walls should be (a) reasonably strong (b) should have a low heat capacity i.e., should not absorb heat and conduct the same (c) weather resistant (d) unsuitable for harbourage of rats and vermin (e) not easily damaged and (f) smooth. These standards can be attained by 9-inch brick–wall plastered smooth and coloured cream or white.

ROOF : The height of the roof should not be less than 10 feet (3 m) in the absence of air-conditioning for comfort. The roof should have a low heat transmittance coefficient.

ROOMS : The number of living rooms should not be less than two, at least one of which can be closed for security. The other may be open on one side if that side is a private courtyard. The number and area of rooms should be increased according to size of family, so that the recommended floor space per person may be made available.

FLOOR AREA : The floor area of a living room should be at least 120 sq.ft. (12 sq. m.) for occupancy by more than one person and at least 100 sq.ft. (10 sq. m.) for occupancy by a single person. The floor area available in living rooms per person should not be less than 50 sq.ft; the optimum is 100 sq.ft.

CUBIC SPACE : Unless means are provided for mechanical replacement of air the height of rooms should be such as to give an air space of at least 500 c.ft. *per capita, preferably 1,000 c.ft.*

WINDOWS : (a) Unless mechanical ventilation and artificial lighting are provided, every living room should be provided with at least 2 windows, and at least one of them should open directly on to an open space, (b) the windows should be placed at a height of not more than 3 feet (1 m) above the ground in living rooms (c) window area should be 1/5th of the floor area. Doors and windows combined should have 2/5th the floor area.

LIGHTING : The daylight factor should exceed 1 per cent over half the floor area.

KITCHEN : Every dwelling house must have a separate kitchen. The kitchen must be protected against dust and smoke; adequately lighted; provided with arrangements for storing food, fuel and provisions; provided with water supply; provided with a sink for washing utensils and fitted with arrangements for proper drainage. The floor of the kitchen must be impervious.

PRIVY : A sanitary privy is a MUST in every house, belonging exclusively to it and readily accessible. In the more developed areas of the world, the majority of dwelling units are equipped with water carriage systems.

GARBAGE AND REFUSE : These should be removed from the dwelling at least daily and disposed off in a sanitary manner.

BATHING AND WASHING : The house should have facilities for bathing and washing belonging exclusively to it and providing proper privacy.

WATER SUPPLY : The house should have a safe and adequate water supply available at all times.

Rural housing

In rural areas, the "approved" standards may be lower than in towns. The following minimum standards have been suggested : (1) there should be at least two living rooms (2) ample verandah space may be provided (3) the built-up area should not exceed one-third of the total area (4) there should be a separate kitchen with a paved sink or platform for washing utensils (5) the house should be provided with a sanitary latrine (6) the window area should be at least 10 per cent of the floor area (7) there should be a sanitary well or a tube well within a quarter of a mile from the house (8) it is insanitary to keep cattle and livestock in dwelling houses. Cattle sheds should be at least 25 feet away from dwelling houses. A cattle shed should be open on all sides; an area 8 ft. × 4 ft. is sufficient for each head of cattle (9) there should be adequate arrangement for the disposal of waste water, refuse and garbage *(5)*.

Housing and health

Housing is part of the total environment of man and

being a part, it is to some extent responsible for the status of man's health and well-being. It is difficult, however, to demonstrate the specific cause-and-effect relationships because housing embraces so many facets of environment. By deductive reasoning, a strong relationship can be established between poor housing and the following conditions :

(1) RESPIRATORY INFECTIONS : Common cold, tuberculosis, influenza, diphtheria, bronchitis, measles, whooping cough, etc.

(2) SKIN INFECTIONS : Scabies, ringworm, impetigo, leprosy.

(3) RAT INFESTATION : Plague.

(4) ARTHROPODS : Houseflies, mosquitoes, fleas and bugs.

(5) ACCIDENTS : A substantial proportion of house accidents are caused by some defect in the home and its environment.

(6) MORBIDITY AND MORTALITY : High morbidity and mortality rates are observed where housing conditions are sub-standard.

(7) PSYCHOSOCIAL EFFECTS : These effects must not be overlooked. The sense of isolation felt by persons living in the upper floors of high buildings is now well known to have harmful effects. Often, also, people living in densely populated urban areas feel a similar sense of isolation which may lead to neurosis and behaviour disorders.

If the definition of health given by WHO is applied, we have also to take into consideration the broader aspects of mental and social well-being of individuals and families, i.e., factors related to satisfaction of physiological, psychological and social needs.

Overcrowding

Overcrowding refers to the situation in which more people are living within a single dwelling than there is space for, so that movement is restricted, privacy secluded, hygiene impossible, rest and sleep difficult *(8)*. In general the risks as regards *physical health* are clear enough – infectious diseases spread rapidly under conditions of overcrowding. The effects on psychosocial health are not so clear-cut, viz. irritability, frustration, lack of sleep, anxiety, violence and mental disorders. Children are said to be more affected. In short, it is a psychosocial stress, leading to unhappiness and very probably to psychosomatic and mental disorders.

Overcrowding is a health problem in human dwellings. It may promote the spread of respiratory infections such as tuberculosis, influenza and diphtheria. High morbidity and mortality rates are observed where housing conditions are substandard. The accepted standards with respect to overcrowding are as below :

(1) PERSONS PER ROOM : The degree of overcrowding can best be expressed as the number of persons per room, i.e., number of persons in the household divided by the number of rooms in the dwelling. The accepted standards are :

1 room	.....	2 persons
2 rooms	.....	3 persons
3 rooms	.....	5 persons
4 rooms	.....	7 persons
5 or more rooms	.....	10 persons (additional 2 for each further room)

(2) FLOOR SPACE : The accepted standards are :

110 sq.ft. (11 sq. m.) or more	.....	2 persons
90–100 sq.ft. (9–10 sq. m.)	.....	$1^1/_2$ persons
70–90 sq.ft. (7–9 sq. m.)	.....	1 person
50–70 sq.ft. (5–7 sq. m.)	.....	$^1/_2$ person
Under 50 sq.ft (5 sq. m.)	.....	nil

(A baby under 12 months is not counted; children between 1 to 10 years counted as half a unit).

SEX SEPARATION : Overcrowding is considered to exist if 2 persons over 9 years of age, not husband and wife, of opposite sexes are obliged to sleep in the same room.

Indicators of housing

In recent years the use of indicators has become widespread for the measurement of quality of life. The indicators for housing may be classified as :

(1) *Physical :* These are based on floor space, cubic space, room height, persons per room, rooms per dwelling, environmental quality (e.g., air, light, water, noise, sewage disposal, etc).

(2) *Economic indicators :* These are cost of the building, rental levels, taxes, expenditure on housing, etc.

(3) *Social indicators :* The following were proposed at an inter-regional seminar on the Social Aspects of Housing, organized by the UN in 1975.

(a) Indicators related to prevention of illness :
- (1) Frequency of illness due to inadequate sewage and garbage collection.
- (2) Frequency of illness associated with contaminated water source.
- (3) Frequency of insect borne diseases
- (4) Frequency of illness due to overcrowding.
- (5) Frequency of illness due to accidents.
- (6) Frequency of illness due to proximity to animals.
- (7) Access to medical facility.

(b) Indicators related to comfort :
- (1) Thermal comfort
- (2) Acoustic comfort
- (3) Visual comfort
- (4) Spatial comfort.

(c) Indicators related to mental health and social well-being
- (1) Frequency of suicides in the neighbourhood
- (2) Neglected and abandoned youth in the neighbourhood
- (3) Drug abuse (including alcohol) in the neighbourhood.

Public policy

In every country where housing conditions in general are unsatisfactory the need for government intervention has been recognized. The approach to public policy on housing in India is indicated in the Five Year Plans. In 1952, a separate Ministry of Works and Housing was created at the Centre. The Government Housing Programmes consists of two categories – public sector housing and social housing schemes. The former provides mainly for government employees, while the latter attempts to provide assistance particularly to low and middle income groups through various housing schemes. For promoting housing activities, statutory Housing Boards have been established at the state

level. Four organizations, viz The National Buildings Organization (NBO), National Buildings Construction Corporation Ltd., Housing and Urban Development Corporation (HUDCO) and the Hindustan Housing Factory are functioning under the aegis of the Union Ministry of works and Housing to deal with various aspects of housing.

According to an assessment by NBO, the housing stock in 1961 was estimated to be 14.1 million in urban areas and 65.2 million in rural areas (total 79.3 million). This increased to 93 million in 1971, 116.7 million in 1981 and 148.8 million in 1991 *(6)*. In 2001 census, the total number of houses counted were 249 million *(10)* and according to 2011 census, the total number of houses counted were 330.84 million. This includes 220.7 million houses in rural areas and 110.14 million houses in urban areas *(11)*. Urban housing crisis has manifested itself in many ways of which the most significant is the growth of slums and squatter settlement. It was estimated that about 48.8 million persons were living in slums in 1990. About 40 per cent of this population was in million–plus cities. The overall rate of construction of new houses recommended by the expert body of the UN is 10 houses per 1000 persons per year *(7)*.

The Eighth and subsequent Five Year Plans have strategy for the National Housing Policy consisting of creating an enabling environment for housing activity, viewed as an important component of the national economy, by eliminating various constraints and providing direct assistance to the specially disadvantaged groups including rural and urban poor household, SC/ST, physically handicapped, widows and single women *(6)*.

House site and construction assistance : The scheme was included in the State Sector as a part of Minimum Needs Programme and formed the core of the rural housing programme during Seventh and subsequent Five Year Plans. This scheme has two components – provision of free house sites and construction assistance with varying proportion of subsidy and loan in different states. Construction assistance is planned to benefit 3.5 million families directly as part of MNP. This is exclusive of other special rural housing programmes intended for specific beneficiary groups.

Indira Awas Yojana (IAY) : The Indira Awas Yojana was introduced in the Central Sector in 1985–86 as part of the Rural Landless Employment Guarantee Programme. This type of houses have one room, one kitchen attached with latrine, bathroom and a smokeless chullah *(9)*.

DISPOSAL OF WASTES

Disposal of wastes is now largely the domain of sanitarians and public health engineers. However, health professionals need to have a basic knowledge of the subject since improper disposal of wastes constitutes a health hazard. Further the health professional may be called upon to give advice in some special situations, such as camp sanitation or coping with waste disposal problems when there is a disruption or breakdown of community health services in natural disasters. These aspects are considered in this section.

SOLID WASTES

The term "solid wastes" includes garbage (food wastes) rubbish (paper, plastics, wood, metal, throw-away containers, glass), demolition products (bricks, masonry, pipes), sewage treatment residue (sludge and solids from the coarse screening of domestic sewage), dead animals, manure and other discarded material. Strictly speaking it should not contain nightsoil. In India and similar other countries, it is not uncommon to find nightsoil in collection of refuse*(3)*. The output of daily waste depends upon the dietary habits, life styles, living standards and the degree of urbanization and industrialization. The per capita daily solid waste produced ranges between 0.25 to 2.5 kg in different countries.

Solid waste, if allowed to accumulate, is a health hazard because:

a. it decomposes and favours fly breeding
b. it attracts rodents and vermin
c. the pathogens which may be present in the solid waste may be conveyed back to man's food through flies and dust.
d. there is a possibility of water and soil pollution, and
e. heaps of refuse present an unsightly appearance and nuisance from bad odours.

There is a correlation between improper disposal of solid wastes and incidence of vector-borne diseases. Therefore, in all civilized countries, there is an efficient system for its periodic collection, removal and final disposal without risk to health.

Sources of refuse

(1) Refuse that is collected by the street cleansing service or scavenging is called *street refuse*. It consists of leaves, straw, paper, animal droppings and litter of all kinds. (2) Refuse that is collected from markets is called *market refuse*. It contains a large proportion of putrid vegetable and animal matter. (3) Refuse that is collected from stables is called *stable litter*. It contains mainly animal droppings and left–over animal feeds. (4) *Industrial refuse* comprises a wide variety of wastes ranging from completely inert materials such as calcium carbonate to highly toxic and explosive compounds. (5) The *domestic refuse* consists of ash, *rubbish* and *garbage*. Ash is the residue from fire used for cooking and heating. Rubbish comprises paper, clothing, bits of wood, metal, glass, dust and dirt. Garbage is waste matter arising from the preparation, cooking and consumption of food. It consists of waste food, vegetable peelings and other organic matter. *Garbage* needs quick removal and disposal because it ferments on storage.

Storage

The first consideration should be given to the proper storage of refuse, while awaiting collection. The galvanized steel dust bin with close fitting cover is a suitable receptacle for storing refuse. The capacity of a bin will depend upon the number of users and frequency of collection. The output of refuse per capita per day in India is estimated to vary from $^1/_{10}$ to $^1/_{20}$ c.ft. For a family of 5 members, a bin having a capacity of 5/10 or 1/2 c.ft. would be needed. If collection is done once in 3 days, a bin having a capacity of $1^1/_2$ or 2 c.ft. would be adequate. A recent innovation in the western countries is the "paper sack." Refuse is stored in the paper sack, and the sack itself is removed with the contents for disposal and a new sack is substituted. *Public bins :* Public bins cater for a larger number of people. They are usually without cover in India because people do not like to touch them. They are kept on a concrete platform raised 2 to 3 inches above ground level to prevent flood water entering the bins. In bigger municipalities, the bins are handled and emptied mechanically by lorries fitted with cranes.

Collection

The method of collection depends upon the funds available. House-to-house collection is by far the best method of collecting refuse. Only at some places in the urban areas this kind of facility is available. In majority of places in India, there is no house-to-house collection system. People are expected to dump the refuse in the nearest public bin, which is usually not done. Refuse is dispersed all along the street, and some is thrown out in front and around the house. As a result, an army of sweepers is required for sweeping the streets in addition to the gang for collecting the refuse from public bins. The refuse is then transported in refuse collection vehicles to the place of ultimate disposal. Dead animals are directly transported to the place of disposal.

The collection methods normally practised in this country need drastic revision and improvement in the interest of better hygiene. The Environmental Hygiene Committee (1949) recommended that municipalities and other local bodies should arrange for collection of refuse not only from the public bins but also from individual houses *(4)*. A house-to-house collection will result in a simultaneous reduction in the number of public bins *(5)*. The open refuse cart should be abandoned and replaced by enclosed vans. Mechanical transport should be used wherever possible as it is more practical and economical than the 19th century methods. There is a wide variety of refuse collection vehicles of all shapes and sizes. The latest arrival in the western countries is the "Dustless Refuse Collector" which has a totally enclosed body.

Methods of disposal

There is no single method of refuse disposal which is equally suitable in all circumstances. The choice of a particular method is governed by local factors such as cost and availability of land and labour. The principal methods of refuse disposal are :–

(a) Dumping
(b) Controlled tipping or sanitary land-fill
(c) Incineration
(d) Composting
(e) Manure pits
(f) Burial.

(a) Dumping

Refuse is dumped in low lying areas partly as a method of reclamation of land but mainly as an easy method of disposal of dry refuse. As a result of bacterial action, refuse decreases considerably in volume and is converted gradually into humus. Kolkata disposes of its refuse by dumping and the reclaimed land is leased out for cultivation. The drawbacks of open dumping are : (1) the refuse is exposed to flies and rodents, (2) it is a source of nuisance from the smell and unsightly appearance, (3) the loose refuse is dispersed by the action of the wind, and (4) drainage from dumps contributes to the pollution of surface and ground water. A WHO Expert Committee (1967) condemned dumping as "a most insanitary method that creates public health hazards, a nuisance, and severe pollution of the environment". Dumping should be outlawed and replaced by sound procedures *(6)*.

(b) Controlled tipping

Controlled tipping or sanitary landfill is the most satisfactory method of refuse disposal where suitable land is available. It differs from ordinary dumping in that the material is placed in a trench or other prepared area, adequately compacted, and covered with earth at the end of the working day. The term "modified sanitary landfill" has been applied to those operations where compaction and covering are accomplished once or twice a week *(7)*.

Three methods are used in this operation : the trench method, the ramp method and the area method *(7, 8)*.

(1) *The trench method :* Where level ground is available, the trench method is usually chosen. A long trench is dug out – 2 to 3 m (6–10 ft.) deep and 4 to 12 m, (12–36 ft.) wide, depending upon local conditions. The refuse is compacted and covered with excavated earth. Where compacted refuse is placed in the fill to a depth of 2 m (6 ft.), it is estimated that one acre of land per year will be required for 10,000 population *(7)*.

(2) *The ramp method :* This method is well suited where the terrain is moderately sloping. Some excavation is done to secure the covering material.

(3) *The area method :* This method is used for filling land depressions, disused quarries and clay pits. The refuse is deposited, packed and consolidated in uniform layers up to 2 to 2.5 m (6–8 ft.) deep. Each layer is sealed on its exposed surface with a mud cover at least 30 cm (12 inches) thick. Such sealing prevents infestation by flies and rodents and suppresses the nuisance of smell and dust. This method often has the disadvantage of requiring supplemental earth from outside sources.

Chemical, bacteriological and physical changes occur in buried refuse. The temperature rises to over 60 deg. C within 7 days and kills all the pathogens and hastens the decomposition process. Then it takes 2 to 3 weeks to cool down. Normally it takes 4 to 6 months for complete decomposition of organic matter into an innocuous mass. The tipping of refuse in water should not be done as it creates a nuisance from odours given off by the decomposition of organic matter. The method of controlled tipping has been revolutionized by mechanization. The bulldozer achieves the tasks of spreading trimming and spreading top soil.

(c) Incineration

Refuse can be disposed of hygienically by burning or

incineration. It is the method of choice where suitable land is not available. Hospital refuse which is particularly dangerous is best disposed of by incineration. Incineration is practised in several of the industrialized countries, particularly in large cities due to lack of suitable land. Incineration is not a popular method in India because the refuse contains a fair proportion of fine ash which makes the burning difficult. A preliminary separation of dust or ash is needed. All this involves heavy outlay and expenditure, besides manipulative difficulties in the incinerator. Further, disposal of refuse by burning is a loss to the community in terms of the much needed manure. Burning, therefore, has a limited application in refuse disposal in India.

(d) Composting

Composting is a method of combined disposal of refuse and nightsoil or sludge. It is a process of nature whereby organic matter breaks down under bacterial action resulting in the formation of relatively stable humus–like material, called the compost which has considerable manurial value for the soil. The principal by-products are carbon dioxide, water and heat. The heat produced during composting, about 60 deg C or higher, over a period of several days, destroys eggs and larvae of flies, weed seeds and pathogenic agents. The end–product – compost – contains few or no disease producing organisms, and is a good soil builder containing small amounts of the major plant nutrients such as nitrates and phosphates *(9)*. The following methods of composting are now used :

(1) Bangalore method (Anaerobic method)

(2) Mechanical composting (Aerobic method)

(1) BANGALORE METHOD *(Hot fermentation process)*

As a result of investigations carried out under the auspices of the Indian Council of Agricultural Research at the Indian Institute of Science, Bangalore, a system of anaerobic composting, known as *Bangalore method* (hot fermentation process) has been developed. It has been recommended as a satisfactory method of disposal of town wastes and nightsoil *(10)*.

Trenches are dug 90 cm (3 ft.) deep, 1.5 to 2.5 m (5–8 ft.) broad and 4.5 to 10 m (15–30 ft.) long, depending upon the amount of refuse and nightsoil to be disposed of. Depths greater than 90 cm (3 ft.) are not recommended because of slow decomposition. The pits should be located not less than 800 m (1/2 mile) from city limits. The composting procedure is as follows : First a layer of refuse about 15 cm (6 in) thick is spread at the bottom of the trench. Over this, nightsoil is added corresponding to a thickness of 5 cm (2 in). Then alternate layers of refuse and nightsoil are added in the proportion of 15 cm (6 in) and 5 cm (2 in) respectively, till the heap rises to 30 cm (1 ft.) above the ground level. The top layer should be of refuse, at least 25 cm (9 in) thickness. Then the heap is covered with excavated earth. If properly laid, a man's legs will not sink when walking over the compost mass *(10)*.

Within 7 days as a result of bacterial action considerable heat (over 60 deg C) is generated in the compost mass. This intense heat which persists over 2 or 3 weeks, serves to decompose the refuse and nightsoil and to destroy all pathogenic and parasitic organisms. At the end of 4 to 6 months, decomposition is complete and the resulting manure is a well decomposed, odourless, innocuous material of high manurial value ready for application to the land. The Environmental Hygiene Committee (1949) did not recommend composting by municipalities with a population of over 100,000 *(4)*. Bigger municipalities should install underground sewers to transport human excreta.

(2) MECHANICAL COMPOSTING

Another method of composting known as 'Mechanical composting' is becoming popular. In this, compost is literally manufactured on a large scale by processing raw materials and turning out a finished product. The refuse is first cleared of salvageable materials such as rags, bones, metal, glass and items which are likely to interfere with the grinding operation. It is then pulverised in a pulverising equipment in order to reduce the size of articles to less than 2 inches. The pulverised refuse is then mixed with sewage, sludge or nightsoil in a rotating machine and incubated. The factors which are controlled in the operation are a certain carbon-nitrogen ratio, temperature, moisture, pH and aeration. The entire process of composting is complete in 4 to 6 weeks. This method of composting is in vogue in some of the developed countries, e.g., Holland, Germany, Switzerland, Israel. The Government of India is considering the installation of mechanical composting plants in selected cities. Cities such as Delhi, Nagpur, Mumbai, Chennai, Pune, Allahabad, Hyderabad, Lucknow and Kanpur have offered to join the Government for setting up pilot plants for mechanical composting *(3)*.

(e) Manure pits

In rural areas in India, there is no system for collection and disposal of refuse. Refuse is thrown around the houses indiscriminately resulting in gross pollution of the soil. The problem of refuse disposal in rural areas can be solved by digging 'manure pits' by the individual householders. The garbage, cattle dung, straw, and leaves should be dumped into the manure pits and covered with earth after each day's dumping. Two such pits will be needed, when one is closed, the other will be in use. In 5 to 6 month's time, the refuse is converted into manure which can be returned to the field. This method of refuse disposal is effective and relatively simple in rural communities.

(f) Burial

This method is suitable for small camps. A trench 1.5 m wide and 2 m deep is excavated, and at the end of each day the refuse is covered with 20 to 30 cm of earth. When the level in the trench is 40 cm from ground level, the trench is filled with earth and compacted, and a new trench is dug out. The contents may be taken out after 4 to 6 months and used on the fields. If the trench is 1 m in length for every 200 persons, it will be filled in about one week *(8)*.

Public education

Refuse disposal cannot be solved without public education. People have very little interest in cleanliness outside their homes. Many municipalities and corporations usually look for the cheapest solution, especially in regard to refuse disposal. What is needed is public education on these matters, by all known methods of health education, viz., pamphlets, newspapers, broadcasting, films etc. Police enforcement of the laws may also be needed at times.

Economics and finance

If refuse disposal is to be carried out efficiently, hygienically and economically, heavy capital outlay will be needed whatever system of disposal is adopted. In the highly

industrialized countries up to 20 per cent of municipal budgets are spent on the collection and disposal of solid wastes, and even more will be required if the job is to be done adequately *(6)*.

International cooperation

An organization was formed – the International Solid Wastes and Public Cleansing Association (ISWA) in 1970, to assist countries in the general endeavour to improve sanitary services. A WHO International Reference Centre has also been set up in Switzerland to collect, evaluate and disseminate information on wastes–disposal practices and to foster research *(9)*.

EXCRETA DISPOSAL

Public health importance

Human excreta is a source of infection. It is an important cause of environmental pollution. Every society has a responsibility for its safe removal and disposal so that it does not constitute a threat to public health. The HEALTH HAZARDS of improper excreta disposal are : (1) soil pollution, (2) water pollution, (3) contamination of foods, and (4) propagation of flies. The resulting diseases are typhoid and paratyphoid fever, dysenteries, diarrhoeas, cholera, hookworm disease, ascariasis, viral hepatitis and similar other intestinal infections and parasitic infestations. These diseases are not only a burden on the community in terms of sickness, mortality and a low expectation of life, but a basic deterrent to social and economic progress. Proper disposal of human excreta, therefore, is a fundamental environmental health service without which there cannot be any improvement in the state of community health.

Extent of the problem in India

In many areas of the world, including India, excreta disposal is a problem of grave importance. Nearly 70 per cent of India's population live in rural areas and the majority of them "go to the fields" for defecation and thereby pollute the environment with human excrement.

Statistics indicate that the intestinal group of diseases claim about 5 million lives every year while another 50 million people suffer from these infections *(1)*. Surveys carried out in the community development block areas in Andhra Pradesh, Assam, Bihar, Madhya Pradesh, Manipur, Orissa, Rajasthan and West Bengal show that the enteric group of fevers is very common in rural areas *(2)*. Hookworm disease is also known to be highly prevalent : about 45 million people are estimated to be infested with hookworms *(3)*. The solution to the problem is only through hygienic disposal of human excreta which is the corner-stone of all public health services.

How disease is carried from excreta

Let us consider how the faecal–borne diseases are transmitted to a new host. The human excreta of a sick person or a carrier of disease is the main focus of infection. It contains the disease agent which is transmitted to a new host through various channels : (1) water, (2) fingers, (3) flies, (4) soil and (5) food. These events are as shown in Fig. 1.

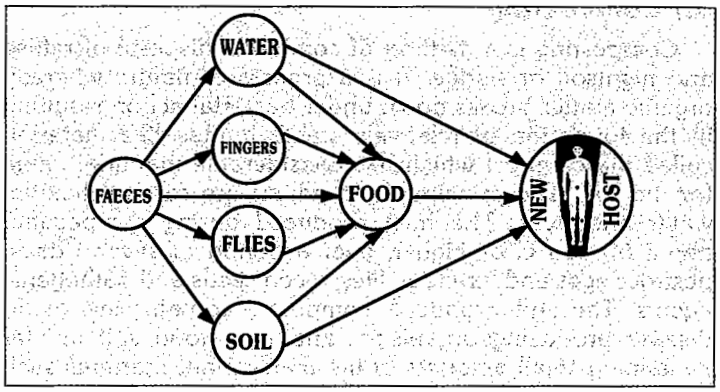

FIG. 1

Transmission of faecal-borne diseases *(13)*

Sanitation barrier

Community medicine aims at breaking the disease cycle at vulnerable points. The disease cycle (Fig. 1) may be broken at various levels : segregation of faeces, protection of water supplies, protection of foods, personal hygiene and control of flies. Of these, the most effective step would be to segregate the faeces and arrange for its proper disposal so that the disease agent cannot reach the new host, directly or indirectly. Fig. 2 shows the segregation of the excreta by imposing a barrier called the "sanitation barrier". In simple terms, this barrier can be provided by a 'sanitary latrine' and a disposal pit. The more elaborate schemes envisage installation of a sewerage system and sewage treatment plants.

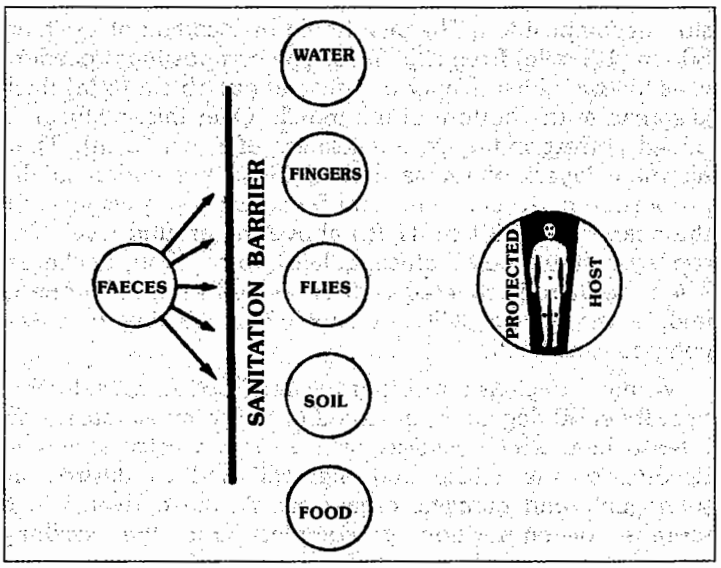

FIG. 2

Sanitation barrier to transmission of faecal-borne diseases *(13)*

Methods of excreta disposal

There are a number of methods of excreta disposal. Some are applicable to unsewered areas, and some to sewered areas. A classification and description of the various methods of excreta disposal is given below :

I. Unsewered areas

1. SERVICE TYPE LATRINES (CONSERVANCY SYSTEM)

Nightsoil is collected from pail or bucket type of latrines by human agency, and later disposed of by burying or composting.

2. NON-SERVICE TYPE (SANITARY LATRINES)

(a) Bore hole latrine
(b) Dug well or pit latrine
(c) Water-seal type of latrines
  (i) P.R.A.I. type
  (ii) R.C.A. type
  (iii) Sulabh Shauchalaya.
(d) Septic tank
(e) Aqua privy.

3. LATRINES SUITABLE FOR CAMPS AND TEMPORARY USE

(a) Shallow trench latrine
(b) Deep trench latrine
(c) Pit latrine
(d) Bore hole latrine

II. Sewered areas

1. WATER–CARRIAGE SYSTEM AND SEWAGE TREATMENT

(a) *Primary treatment*
  Screening
  Removal of grit
  Plain sedimentation
(b) *Secondary treatment*
  Trickling filters
  Activated sludge process
(c) *Other methods*
  (i) Sea outfall
  (ii) River outfall
  (iii) Sewage farming
  (iv) Oxidation ponds.

I. Excreta disposal in unsewered areas

1. SERVICE TYPE (CONSERVANCY SYSTEM)

The collection and removal of nightsoil from bucket or pail latrines by human agency is called the service type or conservancy system, and the latrines are called service latrines. The nightsoil is transported in "nightsoil carts" to the place of final disposal, where it is disposed off by (i) composting or (ii) burial in shallow trenches. Service latrines are a source of filth and insanitation. They have all the drawbacks and faults which tend to perpetuate the disease cycle of faecal-borne diseases in the community (Fig. 1). The night soil is exposed to flies; there is always the possibility of water and soil pollution. The buckets and pans are subject to corrosion and require frequent replacement. The emptying operation of the buckets is not always satisfactory. It is also difficult to recruit adequate staff needed for the collection of nightsoil. If the sweepers go on strike, the entire machinery collapses with dire consequences to public health. Furthermore, the employment of human labour for the collection of nightsoil is not consistent with human dignity and is no longer pardonable. The Environmental Hygiene Committee (1949) therefore, recommended that in unsewered areas the service latrines should be replaced by sanitary latrines which require no service, and in which excreta can be disposed off at the site of the latrine in a hygienic manner *(4)*.

2. NON-SERVICE TYPE OF LATRINES (SANITARY LATRINES)

A sanitary latrine is one which fulfils the following criteria :

(1) Excreta should not contaminate the ground or surface water
(2) Excreta should not pollute the soil
(3) Excreta should not be accessible to flies, rodents, animals (pigs, dogs, cattle, etc.) and other vehicles of transmission.
(4) Excreta should not create a nuisance due to odour or unsightly appearance.

A brief description of some of the well-known types of sanitary latrines is given below :

BORE HOLE LATRINE

The bore hole latrine is the forerunner of the non-service type of latrines in this country. It was first introduced by the Rockefeller foundation during 1930's in campaigns of hookworm control. The latrine consists of a circular hole 30 to 40 cm (12–16 in.) in diameter, dug vertically into the ground to a depth of 4 to 8 m (13–26 ft.), most commonly 6 m (20 ft.). A special equipment known as *auger* is required to dig a bore hole. In loose and sandy soils, the hole is lined with bamboo matting or earthen–ware rings to prevent caving in of the soil (1). A concrete squatting plate with a central opening and foot rests is placed over the hole. A suitable enclosure is put up to provide privacy. For a family of 5 or 6 people, a bore hole of the above description serves well for over a year. Bore hole is essentially a family type of installation and is not recommended as a public convenience because of its small capacity. When the contents of the bore hole reach within 50 cm (20 in.) of the ground level, the squatting plate is removed and the hole is closed with earth.

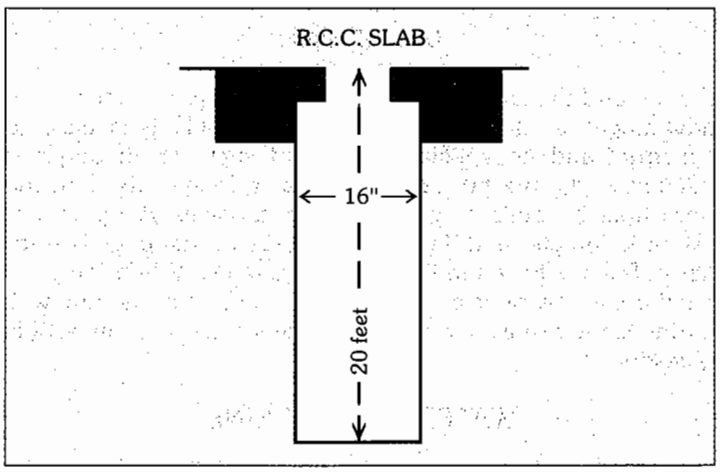

FIG. 3
Bore hole latrine

A new hole is dug and similarly used. The nightsoil undergoes purification by *anaerobic digestion* and is eventually converted into a harmless mass. The amount of sludge that accumulates has been estimated to amount to 2.1 to 7.3 cubic feet per 1,000 users days *(1)*. The merits of a bore hole latrine are : (1) there is no need for the services of a sweeper for daily removal of nightsoil, (2) the pit is dark and unsuitable for fly breeding, (3) if located 15 m (50 ft.) away from a source of water supply, there should be no danger of water pollution. In spite of these merits, bore hole latrines are not considered a very suitable type of latrine today. The reasons are : (a) the bore hole fills up rapidly because of its small capacity, (b) a special equipment, the auger, is required for its construction which may not be readily available, (c) in many places, the subsoil water is high and the soil loose, with the result it may be difficult to dig a hole deeper than 3 m (10 ft.). The bore hole latrine is therefore, not very much in use today. It has been superseded by better innovations.

DUG WELL LATRINE

Dug well latrine or pit latrine (Fig. 4) was first introduced in Singur, West Bengal in 1949–1950 *(1)*. It is an improvement over the bore hole latrine. A circular pit about 75 cm (30 in.) in diameter and 3 to 3.5 m (10–12 ft.) deep is dug into the ground for the reception of the nightsoil. In sandy soil, the depth of the pit may be reduced to 1.5 to 2 m (6–7 ft.). The pit may be lined with pottery rings, and as many rings as necessary to prevent caving in of the soil may be used. A concrete squatting plate is placed on the top of

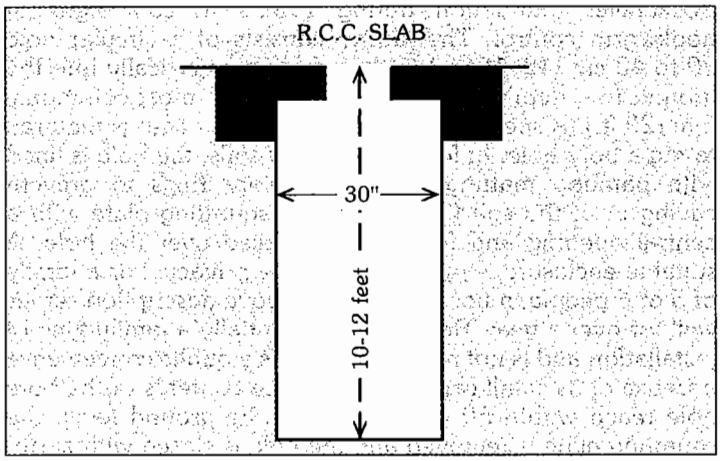

FIG. 4
Dug well latrine

the pit, and the latrine is enclosed with a superstructure. The advantages of this type of latrine are : (1) it is easy to construct and no special equipment such as an auger is needed to dig the pit, (2) the pit has a longer life than the bore hole because of greater cubic capacity. A pit 75 cm (30 in.) diameter and 3 to 3.5 m (10–12 ft.) deep will last for about 5 years for a family of 4 to 5 persons. When the pit is filled up, a new pit is constructed. The action of the dug well latrine is the same as in the bore hole latrine, i.e., anaerobic digestion.

WATER SEAL LATRINE

A further improvement in the designing of sanitary latrines for rural families is the hand-flushed "water seal" type of latrine (Fig. 5). Here, the squatting plate is fitted with

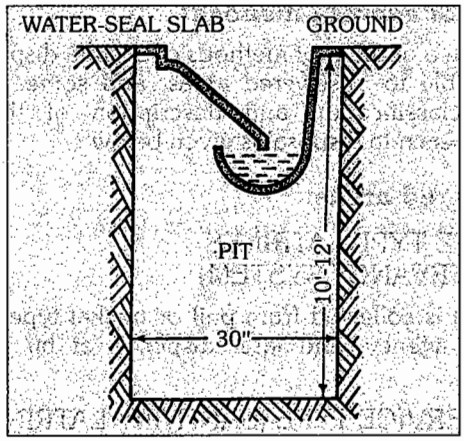

FIG. 5
Water seal latrine (direct type)

a *water seal*. The water seal performs two important functions : (1) it prevents access by flies. That is, the nightsoil is sealed off from flies, by a small depth of water contained in a bent pipe called the trap, (2) it prevents escape of odours and foul gases and thereby eliminates the nuisance from smell. Once the latrine is flushed, nightsoil is no longer visible. These merits have rendered the water seal type of latrine more acceptable to rural people than the bore hole or pit privy without water seal. Several designs of water seal latrines have been tested in the field, and two types have gained recognition for wide use. These are : (1) the P.R.A.I. type, evolved by the Planning, Research and Action Institute, Lucknow (Uttar Pradesh) and (2) the RCA type, designed by the Research–cum–Action Projects in Environmental Sanitation of the Ministry of Health, Government of India. Of these two types, the RCA latrine has been accepted as a suitable design for wide adoption in different parts of the country *(1)*. A brief description of the RCA latrine is given below :

The parts of a water-seal latrine, whether RCA type or PRAI type, are essentially the same (Fig. 5 & 9). The differences are in matters of minor engineering detail. The *essential features* of a RCA latrine and its installation are described below :

RCA LATRINE

(1) LOCATION

The safe distance between the latrine and a source of water supply will depend upon the porosity of the soil, level of ground water, its slope and direction of flow. In general, it may be stated, that latrines of any kind should not be located within 15 m (50 ft) from a source of water supply, and should be at a lower elevation to prevent the possibility of bacterial contamination of the water supply. Where possible, latrines should not be located in areas usually subject to flooding.

(2) SQUATTING PLATE

The squatting plate or slab (Fig. 6) is an important part of a latrine. It should be made of an impervious material so that it can be washed and kept clean and dry. If kept dry, it will not facilitate the survival of hookworm larvae. In recommending squatting plates, due consideration should be paid to the habits of Indian people who defecate in the squatting position and use water for anal washing. The slab of the RCA latrine has been designed to meet the above

needs. It is made of cement concrete with minimum dimensions of 90 cm (3 ft) square and 5 cm (2 in.) thickness at the outer edge. There is a slope 1/2 inch towards the pan. This allows drainage into the latrine of the water used for ablution or cleansing purposes. A circular squatting plate of 90 cm (3 ft.) diameter and of 5 cm (2 in.) uniform thickness, has also been found satisfactory. For the convenience of the users, raised footrests are included in the squatting plate.

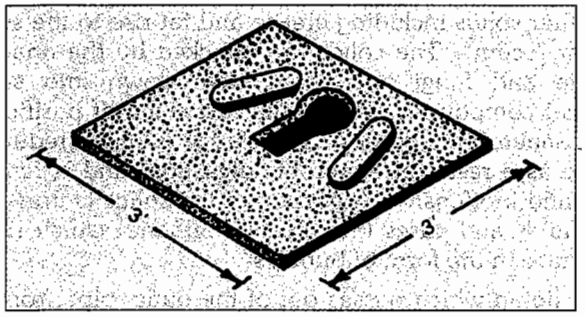

FIG. 6
Squatting plate

(3) PAN

The pan (Fig. 7) receives the nightsoil, urine and wash water. The length of the pan is 42.5 cm (17 in.). The width of the front portion of the pan has a minimum of 12.5 cm (5 in.) and the width at its widest portion is 20 cm (8 in.). There is a uniform slope from front to back of the pan. The pan is given a smooth finish.

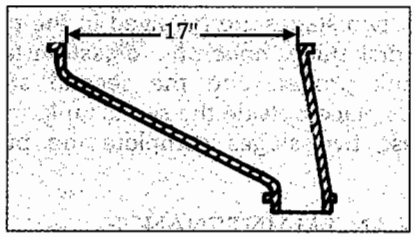

FIG.7
Latrine pan

(4) TRAP

The trap (Fig. 8) is a bent pipe, about 7.5 cm (3 in.) in diameter and is connected with the pan. It holds water and provides the necessary 'water seal'. The water seal is the distance between the level of water in the trap and the lowest point in the concave upper surface of the trap. The depth of the water seal (AB) in the RCA latrine is 2 cm (3/4 in.) (Fig. 8). The water seal prevents the access by flies and suppresses the nuisance from smell.

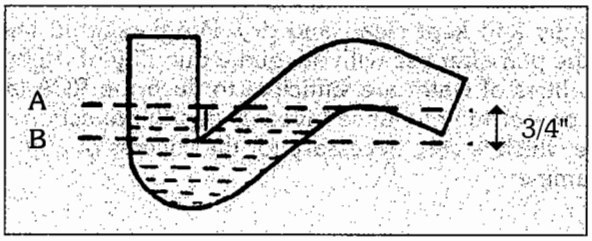

FIG. 8
Trap

(5) CONNECTING PIPE

When the pit is dug, away from the squat plate, the trap is connected to the pit by a short length of connecting pipe 7.5 cm (3 in.) in diameter and at least 1 m (3 ft.) in length with a bend at the end (Fig. 9).

A latrine of this type is called the Indirect type because the pit is sited away from the squatting plate. In the direct type there is no need for a connecting pipe (Fig. 5). The direct type is best suited for areas where the ground is hard and does not easily cave in. The direct type is cheaper and easier to construct and occupies less space *(1)*. An advantage with the indirect type is that when the pit fills up, a second pit can be put into operation by merely changing the direction of the connecting pipe. Therefore, the indirect type is usually preferred.

(6) DUG WELL

The dug well or pit is usually 75 cm (30 in.) in diameter, and 3 to 3.5 m (10–12 ft.) deep and is covered. In loose soil and where the water table is high a lining of earthenware rings or bamboo matting can be used to prevent caving in of the pit *(1)*. When the pit fills up, a second pit is dug nearby and the direction of the connecting pipe is changed into the second pit. When the second pit fills up, the first one may be emptied and reused.

(7) SUPERSTRUCTURE

The desired type of superstructure may be provided for privacy and shelter. An attractive superstructure with a neat finish is desirable as this will be generally well maintained.

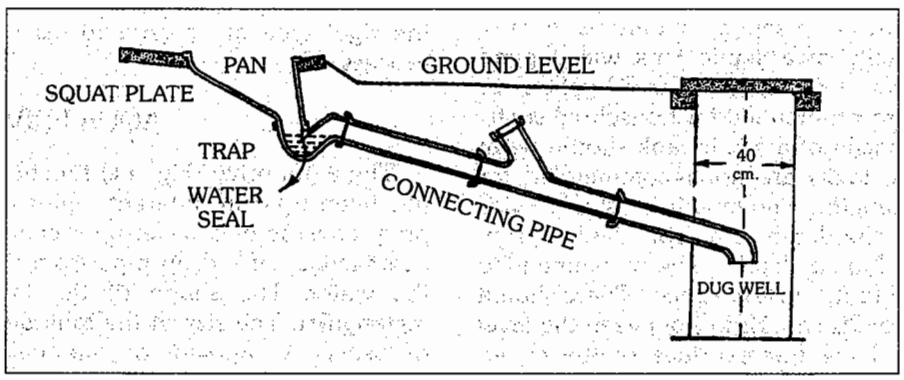

FIG. 9
RCA Latrine (Indirect type)

(8) MAINTENANCE

The life of a latrine will depend upon several factors such as care in usage and maintenance. The latrine should be used only for the purpose intended and not for disposal of refuse or other debris. The squatting plate should be washed frequently and kept clean and dry. People should learn to flush the pan after use with adequate quantity of water. One to two litres of water are sufficient to flush the RCA latrine. Thus, proper maintenance involves *health education* of the people which is very necessary for the success of any latrine programme.

SEPTIC TANK

The septic tank (Fig. 10) is water-tight masonry tank into which household sewage is admitted for treatment. It is a satisfactory means of disposing excreta and liquid wastes from individual dwellings, small groups of houses and institutions which have adequate water supplies but do not have access to a public sewerage system.

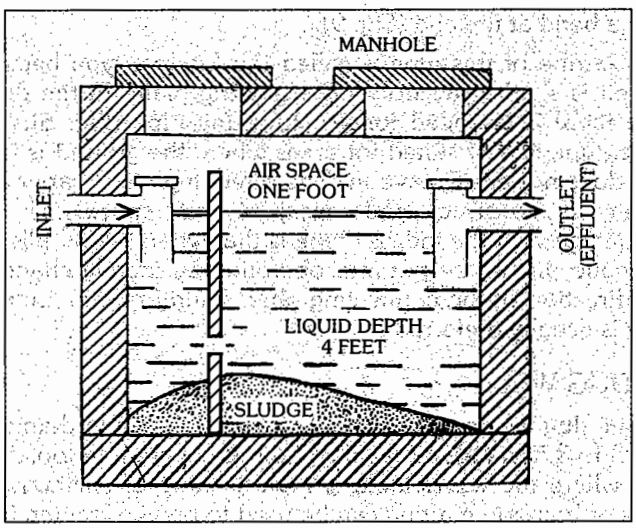

FIG. 10
Septic tank

DESIGN FEATURES

There are various designs in septic tanks. Some are double chambered and some single chambered. A single chambered septic tank has been found satisfactory for small installations. Tanks with more than two compartments are expensive and have shown little advantage over the two or multiple chambered septic tank *(5)*.

The main design features of a septic tank are as follows. (1) *Capacity :* The capacity of a septic tank will depend upon the number of users. A capacity of 20–30 gallons or $2^1/_2$–5 c.ft. per person is recommended for household septic tanks. The minimum capacity of a septic tank should be at least 500 gallons. Septic tanks are not recommended for large communities. (2) *Length :* The length is usually twice the breadth. (3) *Depth :* The depth of a septic tank is from 1.5 to 2 m (5–7 ft.). (4) *Liquid depth :* The recommended liquid depth is only 1.2 m (4 ft.). (5) *Air space :* There should be a minimum air space of 30 cm (12 in.) between the level of liquid in the tank and the undersurface of the cover. (6) *Bottom :* In some septic tanks, the bottom is sloping towards the inlet end. This facilitates retention of solids. (7) *Inlet and outlet :* There is an inlet and outlet pipe, which are submerged. (8) *Cover :* The septic tank is covered by a concrete slab of suitable thickness and provided with a manhole. (9) *Retention Period :* Septic tanks are designed in this country to allow a retention period of 24 hours. Too long a retention period will result in undue septicity of the effluent whereas too short a period gives insufficient treatment.

WORKING OF A SEPTIC TANK

The solids settle down in the tank, to form "sludge", while the lighter solids including grease and fat rise to the surface to form "scum". The solids are attacked by the anaerobic bacteria and fungi and are broken down into simpler chemical compounds. This is the first stage of purification, called anaerobic digestion. The sludge is much reduced in volume as a result of anaerobic digestion, and is rendered stable and inoffensive. A portion of the solids is transferred into liquids and gases (principally methane) which rises to the surface in the form of bubbles.

The liquid which passes out of the outlet pipe from time to time is called the "effluent". It contains numerous bacteriae, cysts, helminthic ova and organic matter in solution or fine suspension. The effluent is allowed to percolate into the sub–soil. It is dispersed by means of perforated or open-jointed pipes laid in trenches 90 cm (3 ft.) deep and the trenches are then covered with soil. The effluent percolates into the surrounding soil. There are millions of aerobic bacteria in the upper layers of the soil, which attack the organic matter present in the effluent. As a result, the organic matter is oxidized into stable end-products, i.e., nitrates, carbon dioxide and water. This stage of purification is called *aerobic oxidation.*

To sum up, two stages are involved in the purification of sewage. The first stage, *anaerobic digestion* takes place in the septic tank proper, and the second stage, aerobic oxidation takes place outside the septic tank, in the sub-soil. Together, these two stages complete the purification of sewage.

OPERATION AND MAINTENANCE

(1) The use of soap water and disinfectants such as phenol should be avoided as they are injurious to the bacterial flora in the septic tank. (2) Undue accumulation of sludge reduces the capacity of the septic tank and interferes with proper working. Therefore, the contents of the septic tank should be bailed out at least once a year. This operation is called "desludging". The bailed out sludge is disposed of by trenching. (3) Newly built septic tanks are first filled with water up to the outlet level and then seeded with ripe sludge drawn from another septic tank, to provide the right type of bacteria to carry out the decomposition process.

AQUA PRIVY

The aqua privy (Fig. 11) functions like a septic tank and has been used in different regions in the country *(1)*. The privy consists of a water-tight chamber filled with water. A short length of a drop pipe from the latrine floor dips into the water. The shape of the tank may be circular or rectangular. The size of the tank depends upon the number of users. A capacity of one cubic metre (35 cu.ft.) is recommended for a small family, allowing 6 years or more for cleansing purposes. Aqua privies are designed for public use also.

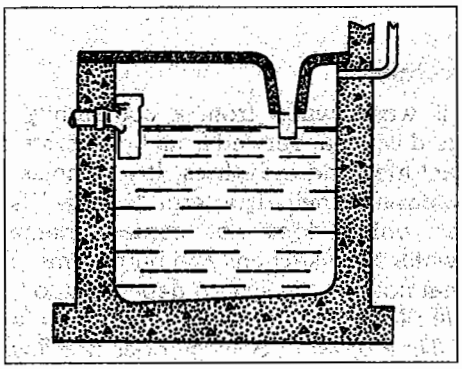

FIG. 11
Aqua privy

Night soil undergoes purification by anaerobic digestion. Since there is evolution of gases, a vent should be provided for the escape of gases into the atmosphere, the vent should be open above the roof of dwellings. The effluent is far from innocuous. It contains finely divided faecal matter in suspension and may carry parasitic and infective agents. It should be treated in the same manner as the effluent from a septic tank by sub-soil irrigation or absorption. The digested sludge which accumulates in the tank should be removed at intervals.

SULABH SHAUCHALAYA

The "Sulabh Shauchalaya" model, the invention of a Patna–based firm, is a low cost pour-flush, water-seal type of latrine, which is now being used in many parts of India. Basically it is an improved version of the standard handflush latrine (e.g., RCA type). It consists of a specially designed pan and a water–seal trap. It is connected to a pit 3 feet square and as deep. Excreta undergoes bacterial decomposition and is converted to manure (compost). The method requires very little water.

Sulabh International, the investors, not only build but also maintain the system of Sulabh **Community Latrines**. Their usual structure is a lavatory block of several dozen seats, with a bathing block adjoining. The system is to charge Rs. 5 per user. Delhi has opted for this system in all its slums. This system has drawn praise from ecologists and planners.

CHEMICAL CLOSET

It has very limited use under Indian conditions. The closet consists of a metal tank containing a disinfectant fluid. The active ingredients of the fluid are formaldehyde and quaternary ammonium compounds. In addition, a harmless water dye and a deodorizing substance are usually incorporated *(6)*. A seat with a cover is placed directly over the tank. Nothing except the toilet paper should be thrown into the chemical closet.

SHALLOW TRENCH LATRINE

This is simply a trench dug with ordinary tools. The trench is 30 cm (1 ft.) wide and 90–150 cm (3–5 ft.) deep. Its length depends on the number of users : 3–3.5 m (10–12 ft.) are necessary for 100 people. Separate trenches should be provided for men and women. The earth from the trench should be piled up at the side. People should be instructed to cover faeces with earth each time they use the latrine. However, these instructions may not be carried out, and it will be necessary to post sweepers in attendance to do this work. Ablution water should be provided. The shallow trench is a rudimentary arrangement for a short period (upto one week). When the trench is filled to 30 cm (12 in.) below ground level, it must be covered with earth, heaped above ground level and compacted; if necessary, a new trench must be dug *(8)*.

DEEP TRENCH LATRINE

This type of latrine is intended for camps of longer duration, from a few weeks to a few months. The trench is 1.8 to 2.5 m (6–8 ft.) deep and 75–90 cm (30–35 in.) wide. Depending upon the local customs, a seat or a squatting plate is provided. A superstructure is built for privacy and protection. Other requirements are the same as for shallow trench latrine *(8)*.

WATER CARRIAGE SYSTEM

The water carriage system or sewerage system implies collecting and transporting of human excreta and waste water from residential, commercial and industrial areas, by a net–work of underground pipes, called *sewers* to the place of ultimate disposal. It is the method of choice for collecting and transporting sewage from cities and towns where population density is high. There are two types in water carriage system – the combined sewer system and the separate sewer system. In the *combined* system, the sewers carry both the sewage and surface water. In the separate system, surface water is not admitted into sewers. The *separate system* is considered the system of choice today. Although the first sewers were laid in 1867 in Calcutta, the Mudaliar Committee (1962) reported that not more than 15 per cent of the urban population in India had the amenity of a sewerage system. The problem is one of economics – a heavy outlay of capital is needed to install a water-carriage system. Since water is needed for flushing the toilets and for conveying the human wastes, there can be no sewerage system without a piped water supply.

A water carriage system consists of the following elements.

1. Household sanitary fittings (plumbing system of buildings)
2. House sewers
3. Street sewers or trunk sewers
4. Sewer appurtenances : manholes, traps, etc.

1. Household sanitary fittings

Where sewers exist, every house is expected to be connected to the nearest sewer. The usual household sanitary fittings are : (i) water closet, (ii) urinal and (iii) wash basin.

WATER CLOSETS may be broadly divided into two types : Indian squatting type (Fig. 6) and the Western commode type. An ideal water closet bowl (western type) is shown in Fig. 12. It is recommended that for efficient performance : (a) the water seal area should not be more than 7.5 cm *(2)*. (b) there should not be any sharp corners in the trap design. (c) the volume of water in trap should be as little as possible, preferably not exceeding 1.75 litres to maintain a minimum of 50 mm deep water seal, and (d) the interior of the bowl should be vertical at least 50 to 75 mm just above the surface of water seal *(9)*. The water closets are provided with a 'flushing rim'. Human excreta is directly

received into the water in the closet without soiling the sides. The flushing removes all traces of excreta from the sides and keeps the closet clean. The closet is connected to a small cistern by a pipe 2.5 to 3.75 cm (1–1.5 in.) in diameter. The flushing cistern normally holds 15 litres (3 gallons) of water and works by syphonic action. The flushing cisterns can be classified as high level, low level and integrated depending upon the height of location above the water closet bowl or pan. The Indian squatting type W.C. pans are used with a high level flushing cisterns.

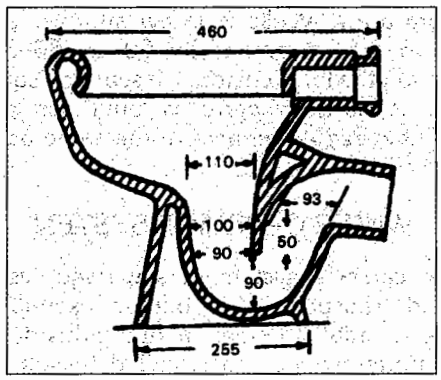

FIG. 12
An ideal water closet (western type)

2. House drain

The house drain is usually 10 cm (4 in.) in diameter and is laid in the courtyard about 15 cm (6 in.) below the ground level on a bed of cement concrete with sufficient gradient towards the main drain. The house drain empties the sewage into the main sewer or public drain.

3. Public sewer

The trunk sewers are not less than 22.5 cm (9 in.) in diameter; bigger ones may be 2 to 3 m (8–10 ft.) in diameter. They are laid on a bed of cement concrete, about 3 m (10 ft.) below the ground level, with sufficient gradient to ensure what is known as "self-cleansing" velocity; this varies from 2 to 3 feet per second. The trunk sewers collect sewage from several houses and transport to the main outfall or place of final disposal.

4. Sewer appurtenances

These are (a) manholes and (b) traps which are installed in the sewerage system. MANHOLES are openings built into the sewerage system. They are placed (a) whenever there is a change in the direction of sewers, (b) at the meeting point of two or more sewers, and (c) at distances of 100 metres in long straight runs. These openings permit a man to enter the sewer for inspection, repairs and cleaning. Workers entering the manholes are liable to gas poisoning and asphyxiation. Due precautions should be taken to ensure their safety. TRAPS are of various kinds, these are devices designed to prevent foul gases entering the houses and to remove sand, grit and grease from sewage. Traps are placed in three situations : (a) under the basin of water closets, (b) where the house drain joins the public drain (intercepting trap), and (c) where surface waste water enters the drains.

The installation of a sewerage system is a huge engineering problem. It involves considerable planning, designing, construction, operation, maintenance and administration – each calling for specialized skills. Sewer systems are designed, like water supplies, for service for one generation (30 years).

Sewage

What is sewage ?

Sewage is waste water from a community, containing solid and liquid excreta, derived from houses, street and yard washings, factories and industries. It resembles dirty water with an unpleasant smell. The term "sullage" is applied to waste water which does not contain human excreta, e.g., waste water from kitchens and bathrooms. The amount of sewage that flows in the sewers depends upon : (a) *Habits of the people :* If people use more water, there will be more sewage. (b) *Time of day :* Sewage does not flow uniformly throughout the day. It is subject to variations depending upon the time of day and during different seasons. In the morning, when people tend to use more water there is greater quantity and flow; in mid-day the flow is less, and again there is a slight increase in the evening. The average amount of sewage which flows through the sewerage system in 24 hours is called the "dry weather flow."

Health aspects

Unless prompt measures are taken to provide proper means of sewage disposal, the following environmental problems may be created :

a. creation of nuisance, unsightliness and unpleasant odours.
b. breeding of flies and mosquitoes
c. pollution of soil and water supplies
d. contamination of food, and
e. increase in the incidence of disease, especially enteric and helminthic diseases.

Composition of sewage

Sewage contains 99.9 per cent of water. The solids which comprise barely 0.1 per cent are partly organic and partly inorganic; they are partly in suspension and partly in solution. The offensive nature of the sewage is mainly due to the organic matter which it contains. The organic matter decomposes according to the laws of nature during which process it gives off offensive odours. In addition, sewage is charged with numerous living organisms derived from faeces, some of which may be agents to disease. It is estimated that one gram of faeces may contain about 1,000 million of *E. coli,* 10 to 100 million of faecal streptococci, and 1 to 10 million spores of *Cl. perfringens* besides several others. The average adult person excretes daily some 100 grams of faeces.

Aim of sewage purification

Raw sewage or inadequately treated sewage should not be discharged into rivers, sea or other sources of water supply. This is because, the oxygen in the water supply is used up by the numerous aerobic bacteria found in the sewage. Depletion of oxygen may lead to the death of the plant and animal life in water. Furthermore, the water may yield an offensive smell because of the release of hydrogen sulphide.

The aim of sewage treatment is to "stabilize" the organic matter so that it can be disposed off safely; and, to convert the sewage water into an effluent of an acceptable standard of purity which can be disposed off in to land, rivers or sea. A standard test which is an indicator of the organic content of the sewage is biochemical oxygen demand (BOD).

The "strength" of the sewage is expressed in terms of (a) BIOCHEMICAL OXYGEN DEMAND (BOD) : It is the most important test done on sewage. It is defined as the amount of oxygen absorbed by a sample of sewage during a specified period, generally 5 days, at a specified temperature, generally 20 deg.C for the aerobic destruction or use of organic matter by living organisms *(10)*. BOD values range from about 1 mg per litre for natural waters to about 300 mg per litre for untreated domestic sewage. If the BOD is 300 mg/L and above, sewage is said to be "strong"; if it is 100 mg/L, it is said to be "weak" (b) CHEMICAL OXYGEN DEMAND (COD) : The COD test measures the oxygen equivalent of that portion of the organic matter in a sample which is susceptible to oxidation by a strong chemical oxidiser. If wastes contain toxic substances, this test may be the only practical method for determining the organic load. (c) SUSPENDED SOLIDS : The suspended solids are yet another indicator of the "strength" of sewage. The amount of suspended solids in domestic sewage may vary from 100 to 500 p.p.m. (mg/L). If the amount of suspended solids is 100 mg/L, the sewage is said to be weak : if the amount is 500 mg/L the sewage is said to be strong.

Decomposition of organic matter

The decomposition of organic matter in sewage takes place by two processes : aerobic and anaerobic processes.

(1) *Aerobic process :* It is the most efficient method of reducing the organic matter in sewage. The process requires a continuous supply of free dissolved oxygen. The organic matter is broken down into simpler compounds namely CO_2, water, ammonia, nitrites, nitrates and sulphates by the action of bacterial organisms including fungi and protozoa.

(2) *Anaerobic process :* Where the sewage is highly concentrated and contains plenty of solids, the anaerobic process is highly effective. The end-products of decomposition are methane, ammonia, CO_2 and H_2. In anaerobic decomposition, the reactions are slower and the mechanism of decomposition extremely complex.

MODERN SEWAGE TREATMENT

Modern sewage treatment plants are based on biological principles of sewage purification, where the purification is brought about by the action of *anaerobic* and *aerobic* bacteria. Fig. 13 shows the flow diagram of a modern sewage treatment plant. The treatment of sewage may be divided into two stages, primary treatment and secondary treatment. In primary treatment, the solids are separated from the sewage partly by screening and partly by sedimentation and subjected to anaerobic digestion which is the first stage in purification; in secondary treatment, the effluent is subjected to aerobic oxidation, which is the second stage in purification.

a. PRIMARY TREATMENT

1. Screening

Sewage arriving at a disposal work is first passed through a metal screen which intercepts large floating objects such as pieces of wood, rags, masses of garbage and dead animals. Their removal is necessary to prevent clogging of the treatment plant. The screen consists of vertical or inclined steel bars usually set 5 cm (2 in) apart. In some plants, the screens are of the fixed type while in others, the screens are of the moving type. The screenings are removed from time to time either manually or mechanically, and disposed off by trenching or burial.

2. Grit chamber

Sewage is then passed through a long narrow chamber called the *grit chamber* or detritus chamber. This chamber is approximately 10 to 20 metres in length; it is so designed as to maintain a constant velocity of about 1 foot per second, with a detention period of 30 seconds to 1 minute *(10)*. The function of the grit chamber is to allow the settlement of heavier solids such as sand and gravel, while permitting the organic matter to pass through. The grit which collects at the bottom of the chamber is removed periodically or continuously, and disposed off by plain dumping or trenching.

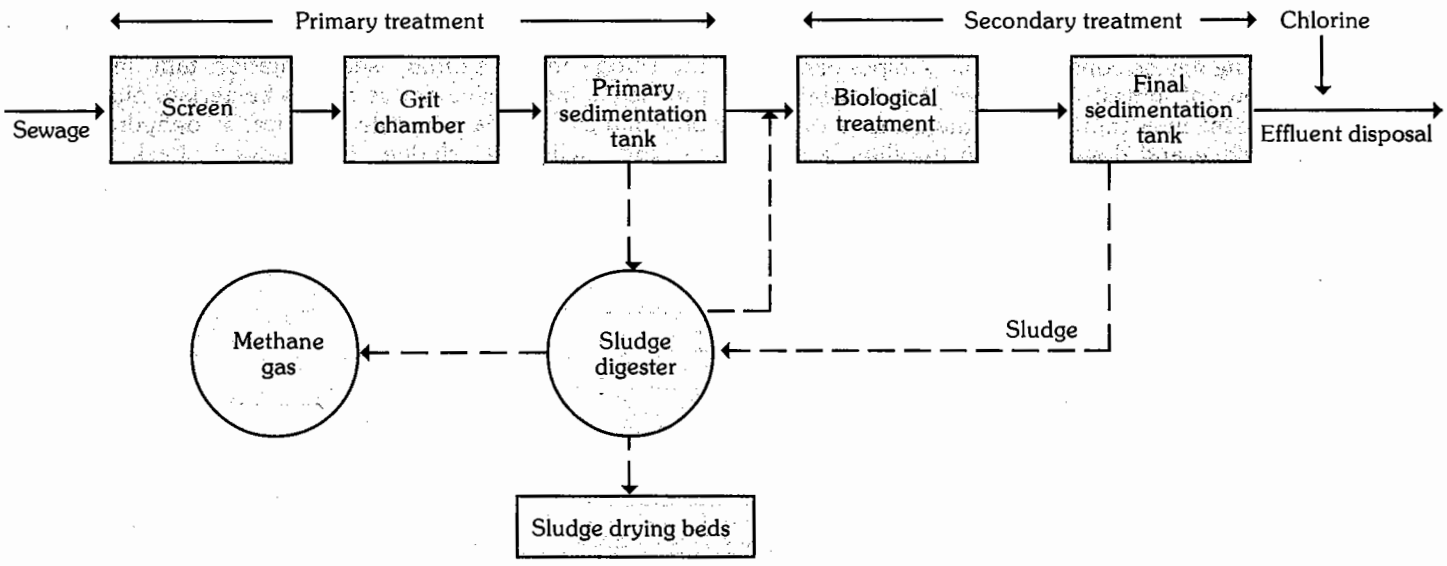

FIG. 13
Flow diagram of a modern sewage treatment plant

3. Primary sedimentation

Sewage is now admitted into a huge tank called the *primary sedimentation tank*. It is a very large tank, holding from $^1/_4$ to $^1/_3$ the dry weather flow. There are various designs in primary sedimentation tank. By far the commonest is the rectangular tank. Sewage is made to flow very slowly across the tank at a velocity of 1–2 feet per minute. The sewage spends about 6–8 hours in the tank. During this long period of relatively still conditions in the tank, a very considerable amount of purification takes place mainly through sedimentation of suspended matter. Nearly 50–70 per cent of the solids settle down under the influence of gravity. A reduction of between 30 to 40 per cent in the number of coliform organisms is obtained *(11)*. The organic matter which settles down is called *sludge* and is removed by mechanically operated devices, without disturbing the operation in the tank. While this is going on, a small amount of biological action also takes place in which the microorganisms present in the sewage attack complex organic solids and break them down into simpler soluble substances and ammonia. A certain amount of fat and grease rise to the surface to form *scum* which is removed from time to time and disposed of. When the sewage contains organic trade wastes, it is treated with chemicals such as lime, aluminium sulphate and ferrous sulphate. Addition of one of these chemicals precipitates the animal protein material quickly.

b. SECONDARY TREATMENT

The effluent from the primary sedimentation tank still contains a proportion of organic matter in solution or colloidal state, and numerous living organisms. It has a high demand for oxygen and can cause pollution of soil or water. It is subjected to further treatment, aerobic oxidation, by one of the following methods :

(a) Trickling filter method

(b) Activated sludge process.

(a) TRICKLING FILTER METHOD

The trickling filter or percolating filter is a bed of crushed stones or cinker, 1 to 2 m (4–8 ft.) deep and 2 to 30 m (6–100 ft.) in diameter, depending upon the size of the population. The effluent from the primary sedimentation tank is sprinkled uniformly on the surface of the bed by a revolving device. The device consists of hollow pipes each of which have a row of holes. The pipes keep rotating, sprinkling the effluent in a thin film on the surface of the filter. Over the surface and down through the filter, a very complex biological growth consisting of algae, fungi, protozoa and bacteria of many kinds occurs. This is known as the "zoogleal layer". As the effluent percolates through the filter bed, it gets oxidized by the bacterial flora in the zoogleal layer. The action of the filter is thus purely a biological one, and not one of filtration as the name suggests. The term "filter" is a misnomer. The trickling filters are very efficient in purifying sewage. They do not need rest pauses, because wind blows freely through the beds supplying the oxygen needed by the zoogleal flora. The biological growth or zoogleal layer lives, grows and dies. The dead matter sloughs off, breaks away and is washed down the filter. It is a light green, flocculent material and is called "humus". The oxidized sewage is now led into the secondary sedimentation tanks or humus tanks.

(b) ACTIVATED SLUDGE PROCESS

Activated sludge process (Fig. 14) is the modern method of purifying sewage, in place of the trickling filter. The "heart" of the activated sludge process is the aeration tank. The effluent from the primary sedimentation tank is mixed with sludge drawn from the final settling tank (also known as activated sludge or return sludge; this sludge is a rich culture of aerobic bacteria). The proportion of activated sludge to the incoming effluent is of the order of 20 to 30 per cent. The mixture is subjected to aeration in the aeration chamber for about 6 to 8 hours *(10)*. The aeration is accomplished either by mechanical agitation or by forcing compressed air continuously from the bottom of the aeration tank. This latter method, also known as 'diffuse aeration' is considered a better method of aeration. During the process of aeration, the organic matter of the sewage gets oxidized into carbon dioxide, nitrates and water with the help of the aerobic bacteria in the activated sludge. The typhoid and cholera organisms are definitely destroyed, and the coliforms greatly reduced. Activated sludge plants occupy less space, require skilled operations. One acre of activated sludge plant does the work of 10 acres of percolating filter. Activated sludge process is therefore, best suited for larger cities and the percolating filter for smaller towns because they are cheaper to install and easier to operate.

Secondary sedimentation

The oxidized sewage from the trickling filter or aeration chamber is led into the secondary sedimentation tank where it is detained for 2–3 hours. The sludge that collects in the secondary sedimentation tank is called 'aerated sludge' or activated sludge, because it is fully aerated. It differs from the sludge in the primary sedimentation tank in that it is practically inoffensive and is rich in bacteriae, nitrogen and phosphates. It is a valuable manure, if dehydrated. Part of the activated sludge is pumped back into the "aeration tanks" in the activated sludge process and the rest pumped into the sludge digestion tanks for treatment and disposal.

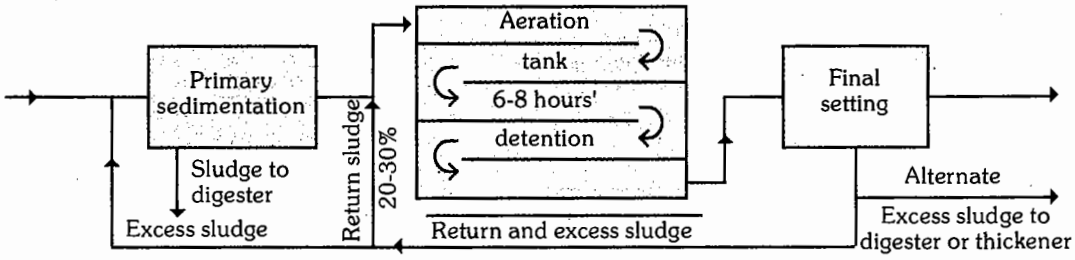

FIG. 14

Activated sludge process

Sludge digestion

One of greatest problems associated with sewage treatment is the treatment and disposal of the resulting sludge. One million gallons of sewage produces 15–20 tons of sludge. The sludge is a thick, black mass containing 95 per cent of water, and it has a revolting odour. There are a number of methods of sludge disposal : (a) *Digestion :* Modern sewage treatment plants employ digestion of sludge as the method of treatment. If sludge is incubated under favourable conditions of temperature and pH, it undergoes anaerobic auto-digestion in which complex solids are broken down into water, carbon dioxide, methane and ammonia. The volume of sludge is also considerably reduced. It takes 3–4 weeks or longer for complete sludge digestion. The residue is in-offensive, sticky and tarry mud which will dry readily and form an excellent manure. Sludge digestion is carried out in special tanks known as "sludge digestion tanks". Methane gas, which is a by–product of sludge digestion, can be used for heating and lighting purposes. (b) *Sea disposal:* Sea coast towns and cities can dispose of sludge by pumping it into the sea (c) *Land :* Sludge can be disposed of by composting with town refuse.

Disposal of effluent

(a) *Disposal by dilution :* Disposal into water courses such as rivers and streams is called 'disposal by dilution'. The effluent is diluted in the body of water and the impurities are oxidized by the dissolved oxygen in water. The diluting capacity of the river or the receiving body of water and its dissolved oxygen contents, are important considerations before discharging the effluent into a river or any body of water. Since people use river water for drinking purpose, the effluent must be rendered free from pathogenic organisms by adequate chlorination. The Royal Commission in England in its Fifth Report (1908) recommended that an effluent from a sewage treatment plant should not have more than 30 mg/litre of suspended solids and the 5 day B.O.D. of the effluent including the suspended matter, should not exceed 20 mg/litre. These standards assumed that the river or body of water into which the effluent passed would provide an 8 :1 dilution. These standards have been the backbone of subsequent work on the purity of sewage effluent. During the past few years, industry has developed hundreds of new chemicals which are released into the sewerage system. Some of these chemicals are not removed by biological treatment. Consequently, the effluent may contain substances toxic to man, or substances that can kill fish, damage agriculture or interfere with the normal functioning of a stream. In many places in the UK, effluent standards have been raised from the original Royal Commission values of 30 mg per litre of suspended solids and 20 mg per litre of B.O.D. to 10 mg per litre of each *(11)*. The World Health Organization is seized with this problem, and is fostering research in "tertiary" methods of treatment or "polishing" the effluent further. (b) *Disposal on land :* If suitable land is available the effluent can be used for irrigation purposes (e.g., the Okhla Sewage Treatment Plant in Delhi).

OTHER METHODS OF SEWAGE DISPOSAL

(a) Sea outfall
(b) River outfall
(c) Land treatment
(d) Oxidation ponds
(e) Oxidation ditches.

(a) Sea outfall

Sea coast towns and cities may dispose of their sewage by discharging it into the sea. For instance, nearly two-thirds of untreated sewage of Greater Mumbai is discharged every day into the Arabian Sea. Purification takes place by dilution in the large body of sea water, and the solids get slowly oxidized. The drawback of this method is that the offensive solid matter may be washed back to the shore and create public nuisance. In order to prevent this, the sewage outfall is designed to discharge the sewage into deep water at many points.

(b) River outfall

Raw sewage should never be discharged into rivers. The present day practice is to purify the sewage before it is discharged into rivers. How far the sewage should be purified depends upon the dilution the river provides to carry on aeration and self–purification.

(c) Land treatment (sewage farming)

If sufficient and suitable land (porous soil) is available, sewage may be applied to the land after grit removal, screening and a short period of settlement. This type of treatment is practised in some Indian towns and cities and is known as *Sewage Farming* or *Broad Irrigation.* An acre of land would be required to treat the sewage of 100–300 persons. The land is first laid into ridges and furrows. Sewage is fed into the furrows *intermittently* and crops are grown on the ridges. The crops that are found suitable to grow are those which do not come in contact with sewage and likely to be eaten raw. Fodder grass and potatoes seem to be the most paying crops. Fruit trees whose fruits are high above the ground (e.g., plantain) can be grown. But sugar cane, coriander, cuccumber, tomato, onion, etc. should not be grown. The farm should be under the direction of a competent agricultural expert. During the rainy season, it may not be possible to operate the sewage farms. Badly managed farms stink, a condition described as "sewage sickness" because of lack of sufficient aeration and rest pauses to the land. Alternate methods of disposal may have to be provided during the rainy season.

(d) Oxidation pond *(12)*

A cheap method of sewage treatment is the *oxidation pond* which has been referred to by many different names – waste stabilization pond, redox pond, sewage lagoons, etc. The term "waste stabilization pond" is more appropriate. The term 'waste' includes both sewage and industrial wastes. Although an old method of purifying sewage, oxidation pond has attracted the attention of public health engineers only recently. Over 50 ponds are working at present in India. The first large-scale installation was the one at Bhilai where it serves a population of 100,000.

The oxidation pond is an open, shallow pool 1 to 1.5 m (3–5 ft.) deep with an inlet and outlet (Fig. 15). To qualify as an oxidation pond, there must be the presence of (1) algae (2) certain types of bacteria which feed on decaying organic matter, and (3) sun-light. The organic matter contained in the sewage is oxidized by bacteria (hence oxidation pond) to simple chemical compounds such as carbon dioxide, ammonia and water. The algae, with the help of sunlight, utilize the carbon dioxide, water and inorganic minerals for their growth, Thus there is a mutually beneficial biological balance between the algae and bacteria in oxidation ponds. Oxygen that is needed for oxidation is derived to a small

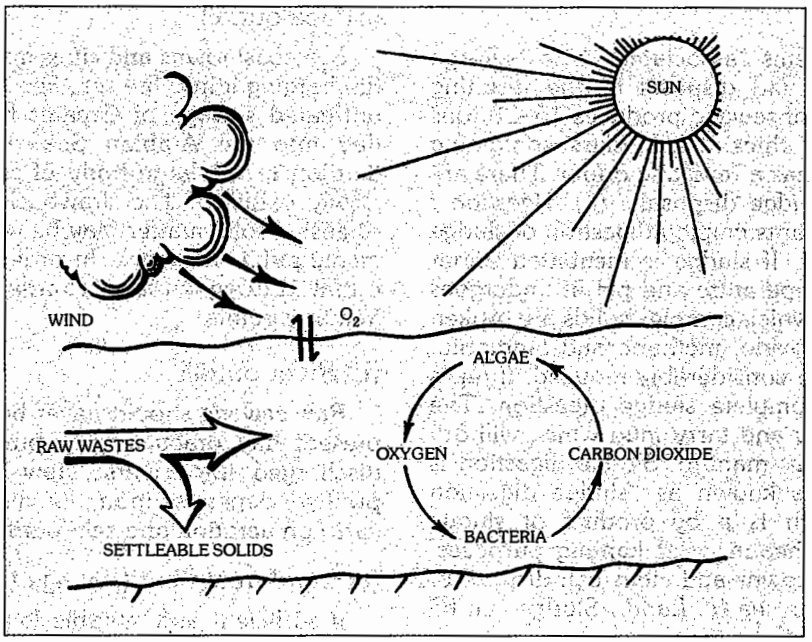

FIG. 15
Oxidation pond

extent from the atmosphere but mostly from the algae which liberates oxygen under the influence of sunlight. Consequently, sunlight is an important factor in the proper functioning of oxidation ponds. Cloudy weather definitely lowers the efficiency of the process.

The oxidation ponds are predominantly aerobic during sunshine hours as well as some hours of the night. In the remaining hours of the night, the bottom layers are generally *anaerobic*. Thus the sewage purification in oxidation ponds is brought about by a combination of aerobic and anaerobic types of bacteria. The effluent may be used for growing vegetable crops (land irrigation) or may be discharged into a river or other water courses after appropriate treatment. Mosquito nuisance is avoided by keeping weed growth in the neighbourhood of oxidation ponds to a minimum and the water line free from marginal vegetation. There is no odour nuisance associated with these ponds when they are properly maintained. Oxidation ponds have become an established method of purifying sewage for small communities.

(e) Oxidation ditches

Other methods recommended are (1) oxidation ditches and (2) aerated lagoons. These methods make use of mechanical rotors for extended aeration. For treatment of the wastes of a population between 5,000 to 20,000 an oxidation ditch requires an area of one acre as compared to 22 acres for an oxidation pond and 2.5 acres for an aerated lagoon. These are low-cost treatment methods for the purification of sewage.

SOCIAL ASPECTS OF EXCRETA DISPOSAL IN INDIA

India is a land of villages and about 70 per cent of its population lives in villages. The problem of sanitation therefore is one of "Rural sanitation". Surveys have shown that substantial per cent of the population "go to the open fields" for defecation. This habit of indiscriminate fouling of the surroundings with human excrement is generations–old, and rooted firmly in the cultural behaviour of the village people.

In urban areas, the latrine is considered a necessary part of a house. In rural areas, by and large, people have not accepted latrines with any enthusiasm, and even when installed only a few used them regularly. The problem in rural sanitation is how to overcome the resistance of the village people, and induce them to use sanitary latrines. Research studies have indicated that there is only one way to solve the problem, i.e., through *health education*. Social scientists have listed the reasons why villagers do not accept latrines. Some of the reasons found in the surveys are : (1) latrines are associated with bad smell (2) they are the breeding places of flies (3) they are something foul and dirty so that one should not have them close to houses (4) latrines are costly and beyond their means to install, and (5) they do not know how faecal-borne diseases are spread. Secondly, using a latrine goes against a DAILY habit pattern of going to the fields. The use of latrines involves a drastic change in the day to day behaviour of a large number of people.

The solution to the problem lies in teaching the people first the reasons why latrines are important. The teaching should be undertaken by all known methods of health education – direct discussion, group discussion, latrine demonstration, and use of visual aids and above all service facilities. The ultimate goal of health education will be to *motivate* the rural people towards acceptance and use of sanitary latrines.

Surface water drainage in urban areas

Many low income communities in developing countries consider stormwater drainage to be their most urgent need as far as urban infrastructure is concerned. It is the coastal regions of the world that have the highest average rainfall, but the flat estuarine terrain and often impermeable alluvial soil make drainage difficult. Even in the arid areas where average rainfall is low, tropical rainfall – when it comes – is more intense than in temperate climates, and the lack of vegetation and of adequate drainage means that torrents of water can form in minutes, causing damage to homes and

property, which will take years to repair. The lack of drainage is especially serious where the ground is either steeply sloping, as in Hongkong or very flat as in Kolkata, Bangkok and Manila.

Deaths due to drowning in floods or burial beneath landslides or collapsing homes are perhaps the most dramatic signs of the suffering that drainage can help to alleviate. Less noticeable to an outsider, but of greater impact on the residents living in a poor community, is the steady toll of disease, disability and death by standing water.

First in public health importance are the many "faecal-oral" infections acquired by consumption of contaminated food and drink. Children are particularly exposed to infection when playing or bathing in surface water. Surface water becomes contaminated with pathogens from blocked sewers and overflowing septic tanks. This contaminated surface water can infect people in many ways.

Another important group of diseases related to poor drainage is transmitted by mosquitoes, and malaria is the best example. Transmission can be particularly intense in urban areas where there are relatively few animals to divert the vector species of mosquito from human blood meals. Drainage construction is an effective mosquito control measure. It is cheaper than application of insecticides and does not have to be repeated regularly. Unlike insecticides, it can have no detrimental effect on the environment; on the contrary, it constitutes an environmental improvement.

Urban poor may often build on land with drainage problems, but good urban planning can help to avoid making these problems worse. One of the simplest planning measure is to set out regular plots before house building starts in an area, leaving space for well-aligned roads. Adequate road width and alignment will make it much easier to build drains when they are needed later.

MEDICAL ENTOMOLOGY

Arthropods comprise the most numerous and varied of the living things in the environment of man. Some of them are man's allies helping in the fertilization of flowers, but the majority of arthropods, in general, are either of no use to man or are his most dangerous enemies. They destroy man's crops and his food reserves; and some which live close to man act as *vectors* or carriers of disease. A study of the arthropods of medical importance is known as medical entomology which is an important branch of preventive medicine.

Arthropods of medical importance

The arthropods of medical importance are as given in Table 1.

TABLE 1

Arthropods of medical importance

Class: Insecta	Class: Arachnida	Class: Crustacea
1. *Mosquitoes:* Anophelines Culicines	1. *Ticks:* Hard ticks Soft ticks	1. *Cyclops*
2. *Flies:* Houseflies Sandflies Tsetse flies Blackflies	2. *Mites (Chiggers):* Leptotrombidium and trombiculid mites; Itch mite	
3. *Human Lice:* Head and body lice; Crab lice		
4. *Fleas:* Rat fleas Sand fleas		
5. *Reduviid bugs*		

Distinctive characters

The distinctive characters of the above arthropods are as given in Table 2.

TABLE 2

Distinctive characters of arthropods of medical importance

	Insecta	Arachnida	Crustacea
1. Body divisions	Head. thorax abdomen	Cephalothorax and abdomen (no division) in some cases	Cephalothorax and abdomen
2. Legs	3 pairs	4 pairs	5 pairs
3. Antennae	1 pair	None	2 pairs
4. Wings	One or two pairs; some are wingless	None	None
5. Where found	On land	On land	In water

Arthropod-borne diseases

Arthropod–borne diseases constitute a major health problem in India. Malaria continues to be an important vector–borne disease with an annual morbidity of 4 to 5 million cases. Filaria is another important arthropod-borne disease with an estimated 236 million people living in filaria-endemic areas. About 5 million people are estimated to be living in areas where guinea-worm disease is endemic. Scabies is a widespread disease, especially in rural areas. Dengue, haemorrhagic fever, Japanese encephalitis and KFD are also among the important arthropod-borne virus diseases in India. The prevalence rates for trachoma which is a major cause of blindness in India vary from 0.5 per cent in West Bengal to 79 per cent in Punjab and Haryana. Thus,

arthropods are responsible for much ill-health and deaths (Table 3).

TABLE 3

Arthropod-borne diseases

Arthropod	Diseases transmitted
1. Mosquito	Malaria, filaria, viral encephalitis (e.g., Japanese encephalitis), viral fevers (e.g., dengue, West Nile, viral haemorrhagic fevers (e.g., yellow fever, dengue haemorrhagic fever)
2. Housefly	Typhoid and paratyphoid fever, diarrhoea, dysentery, cholera, gastro–enteritis, amoebiasis, helminthic infestations, poliomyelitis, conjunctivitis, trachoma, anthrax, yaws, etc.
3. Sandfly	Kala-azar, oriental sore, sandfly fever, oraya fever.
4. Tsetse fly	Sleeping sickness
5. Louse	Epidemic typhus, relapsing fever, trench fever, pediculosis
6. Rat flea	Bubonic plague, endemic typhus, chiggerosis, hymenolepis diminuta.
7. Blackfly	Onchocerciasis.
8. Reduviid bug	Chagas disease.
9. Hard tick	Tick typhus, viral encephalitis, viral fevers, viral haemorrhagic fever, (e.g., Kyasanur forest disease), tularemia, tick paralysis, human babesiosis.
10. Soft tick	Q fever, relapsing fever.
11. Trombiculid mite	Scrub typhus, Rickettsial-pox.
12. Itch-mite	Scabies.
13. Cyclops	Guinea-worm disease, fish tapeworm (D. latus).
14. Cockroaches	Enteric pathogens.

Transmission of arthropod-borne diseases

Three types of transmission cycles are involved in the spread of arthropod-borne disease : (1) DIRECT CONTACT : In this method of spread, the arthropods are directly transferred from man to man through close contact, e.g., scabies and pediculosis, (2) MECHANICAL TRANSMISSION : The disease agent is transmitted mechanically by the arthropod. The transmission of diarrhoea, dysentery, typhoid, food poisoning and trachoma by the housefly – are examples of mechanical transmission of the disease agent by the vector. (3) BIOLOGICAL TRANSMISSION : When the disease agent multiplies or undergoes some developmental change with or without multiplication in the arthropod host, it is called biological transmission. This may be of three types : (a) *Propagative :* When the disease agent undergoes no cyclical change, but multiplies in the body of the vector, transmission is said to be propagative, e.g., plague bacilli in rat fleas (b) *Cyclo-propagative :* The disease agent undergoes cyclical change, and multiplies in the body of the arthropod, e.g., malaria parasite in anopheline mosquito (c) *Cyclo-developmental :* When the disease agent undergoes cyclical change but does not multiply in the body of the arthropod, e.g., filarial parasite in culex mosquito and guineaworm embryo in cyclops.

In communicable disease terminology, the word vector means an "arthropod or other invertebrate which transmits infection by inoculation into or through the skin or mucous membrane by biting, or by deposit of infective materials on the skin or on food or other objects". The period of time necessary for the development of the disease agent in the arthropod host is called *extrinsic incubation period.* For example, the extrinsic incubation periods in malaria and filaria are from 10 to 14 days or longer depending upon the environmental temperature. The host in which the sexual cycle of the agent occurs is called the *definitive host,* e.g., mosquito is the definitive host in malaria. The host in which the asexual cycle of the agent occurs is called the *intermediate host* e.g., mosquito in filaria and cyclops in guinea-worm disease. By *infestation* is meant the lodgement, development and reproduction of arthropods on the surface of the body or in the clothing e.g., louse infestation.

Principles of arthropod control

The general principles of arthropod control are :

1. Environmental control
2. Chemical control
3. Biological control
4. Genetic control.

(1) *Environmental control :* This offers the best approach to the control of arthropods, because the results are likely to be permanent. Examples of environmental manipulation are : elimination of breeding places (source reduction); filling and drainage operation; carefully planned water management; provision of piped water supply; proper disposal of refuse and other wastes; cleanliness in and around houses, etc. Intensive health education of the public as well as political support are essential prerequisites. (2) *Chemical control :* A wide range of insecticides belonging to the organochlorine, organo-phosphorus and carbamate groups of compounds (Fig. 17, page 784) are available for vector control. It must be mentioned that vector control by insecticides alone is no longer fully effective because resistance has appeared in over 100 species of arthropods of public health importance. This coupled with the danger of environmental contamination has led to restricted use of many insecticides in some countries. To avoid undue environmental pollution, it is now considered essential to replace gradually the highly persistent compounds such as DDT with compounds which are readily "biodegradable" and less toxic to man and animals such as methoxychlor, abate and dursban *(1).* As there is no alternate control method which is as efficient and economical as the insecticides, it is postulated that most of the developing countries will have to depend, for sometime to come, on the organochlorine compounds for the control of vectors. (3) *Biological control :* To minimize environmental pollution with toxic chemicals, great emphasis is now being placed on biological control. The use of larvivorous fish especially Gambusia is well known in mosquito control. Fungi of the genus Coelomomyces are also known to be pathogenic to mosquitoes. A variety of other biological agents (e.g., bacteria, fungi, nematodes, protozoa and viruses) are under study for the control of insects. But the fear exists that the introduction of biological agents for the control of arthropods may pose a direct hazard to the health of man himself *(2).* (4) *Genetic control :* Much progress has taken place in recent years in the theoretical and applied

aspects of genetic control of arthropods. The WHO/ICMR Research Unit at New Delhi has contributed massively to the techniques of genetic control of mosquitoes *(3)*. Techniques such as sterile male technique, cytoplasmic incompatibility and chromosomal translocations have been found to be effective in small field trials. In conclusion, it may be stated that these methods are nowhere near the stage where they can be used large-scale in an effective way. (5) *Newer methods* : New and innovative methods are being sought for pest control. These are (a) insect growth regulators (b) chemosterilants, and (c) sex attractants or pheromones *(4)*.

Integrated approach

Since no single method of control is likely to provide a solution in all situations, the present trend is to adopt an "integrated approach" for vector control combining two or more methods with a view to obtain maximum results with the minimum effort and to avoid the excessive use of any one method *(5)*.

MOSQUITO

General description

Mosquitoes constitute the most important single family of insects from the standpoint of human health. They are found all over the world. The four important groups of mosquitoes in India which are related to disease transmission are the *Anopheles, Culex, Aedes* and *Mansonia*.

The body of a mosquito consists of three parts : head, thorax and abdomen, (a) HEAD : The head is semi-globular in outline, and bears the following structures :– (i) a pair of large compound eyes (ii) a long needle-like structure, called the *proboscis* with which the mosquito bites (iii) a pair of *palpi*, each a four–jointed structure, situated on either side of the proboscis and (iv) a pair of *antennae* or feelers. The antennae are bushy in the male, and not quite so in the female. They provide an easy means of distinguishing the male from the female (b) THORAX : The thorax is large and rounded in appearance and bears :– (i) a pair of wings dorsally (ii) three pairs of legs ventrally. The wings of the mosquito are characterised by a fringe of scales on the posterior border and the first, third and sixth veins on the wings are not branched. When the mosquito is at rest, the wings are folded. The buzzing noise which the mosquitoes produce is due to the beating of their wings, and not to "singing". (c) ABDOMEN : The abdomen is long and narrow and is composed of 10 segments, the last two of which are modified to form the external genitalia.

Life history

There are four stages in the life history of mosquitoes (Fig. 1): egg, larva, pupa and adult. Metamorphosis is complete.

(1) EGG : Eggs are laid on the surface of water, 100–250 at a time. The *Anopheles* lays her eggs singly; the eggs are boat-shaped and possess lateral floats. The *Culex* lays her eggs in small clusters or rafts; the eggs do not possess lateral floats. The *Aedes* lays her eggs singly; the eggs are cigar-shaped and do not possess lateral floats. The *Mansonia* lays her eggs in star-shaped clusters attached to the under-surface of the leaves of certain aquatic plants, notably the pisita plant. Under favourable conditions, the egg stage of mosquitoes lasts for 1–2 days. The period that elapses from the moment a blood meal is taken until the eggs are laid is called the "gonotrophic cycle", it is about 48 hours in hot and humid tropical areas.

(2) LARVA : The larva is a free swimming creature with an elongated body divisible into head, thorax and abdomen. It feeds on algae, bacteria and vegetable matter and passes through four stages of growth called "instars" with moulting between each stage. The larva of the *Anopheles* floats horizontally in the water, and has no siphon tube at the tip of its abdomen. The *Culicine* (e.g., Culex, Aedes, and Mansonia) larvae, in contrast, are suspended in water with their heads downwards; they all possess a siphon tube, which is situated on the 8th abdominal segment. The larvae of the *Mansonia* are peculiar in the respect that they are attached to the rootlets of certain aquatic plants by their siphon tubes; they obtain air from the plant rootlets. The larval stage occupies 5–7 days.

(3) PUPA : The pupa is comma-shaped in appearance, with a large rounded cephalothorax and a narrow abdomen. Two small respiratory tubes or trumpets project from the upper surface of the thorax. The pupa represents the resting stage in the life history of the mosquito; it does not feed but prefers to stay quiet at the water surface. But when disturbed it swims rapidly downwards into the water. The pupal stage lasts for 1–2 days.

(4) ADULT : When the development is complete, the

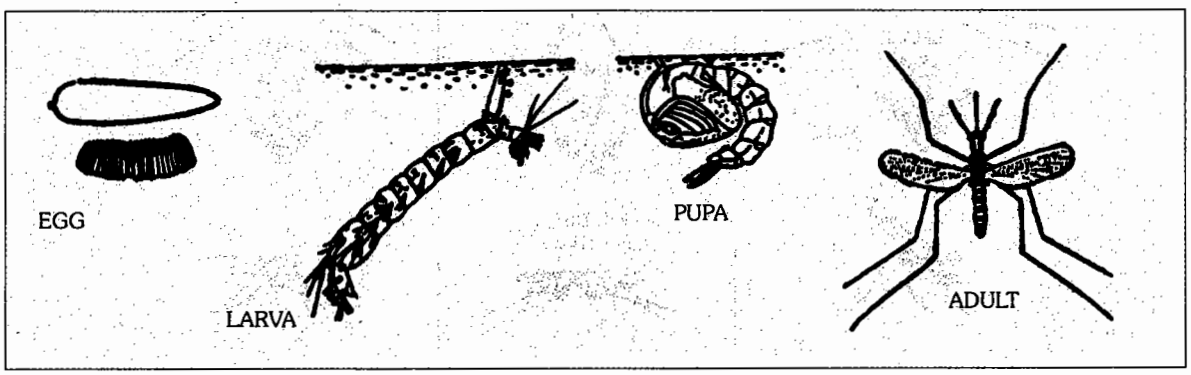

FIG. 1
Life cycle of a mosquito

pupal skin splits along the back and the adult mosquito or imago emerges. It rests for a while on the pupal skin to allow its wings to expand and harden and then flies away. Under favourable conditions of temperature and food supply the life cycle from the egg to adult is complete in 7–10 days. Normally the adult mosquito lives for about 2 weeks. The males are generally short-lived.

Differentiation between anophelines and culicines

There are two main *tribes* of mosquitoes – Tribe *Anophelini* and Tribe *Culicini*. The tribe anophelini contains only one genus, *Anopheles*. The tribe *Culicini* is represented in India by 15 genera of which the important ones are *Culex, Aedes* and *Mansonia*. The main points of difference between the two tribes, *Anophelini* and *Culicini* are as given in Table 4 (See Fig. 2).

(1) Anopheles

Some 45 species of anopheles mosquitoes have been found in India but only a few of them have been incriminated as vectors or carriers of malaria. They are (1) An. *culicifacies* (2) *An. fluviatilis* (3) *An. minimus* (4) *An. philippinensis* (5) *An. stephensi* (6) *An. sundaicus* and (7) *An. leucosphyrus*. The areas of distribution of these mosquitoes are different : *An. fluviatilis* and *An. minimus* are found in the foot-hill regions; *An. sundaicus* and *An.stephensi* are found in the coastal regions; and *An. culicifacies* and *An. philippinensis* are found in the plains. An accurate guide to the identification of the known species of anopheles mosquitoes in India may be found in Health Bulletin No.10 entitled : "Synoptic Table for the Identification of the Anopheles Mosquitoes in India *(6)*."

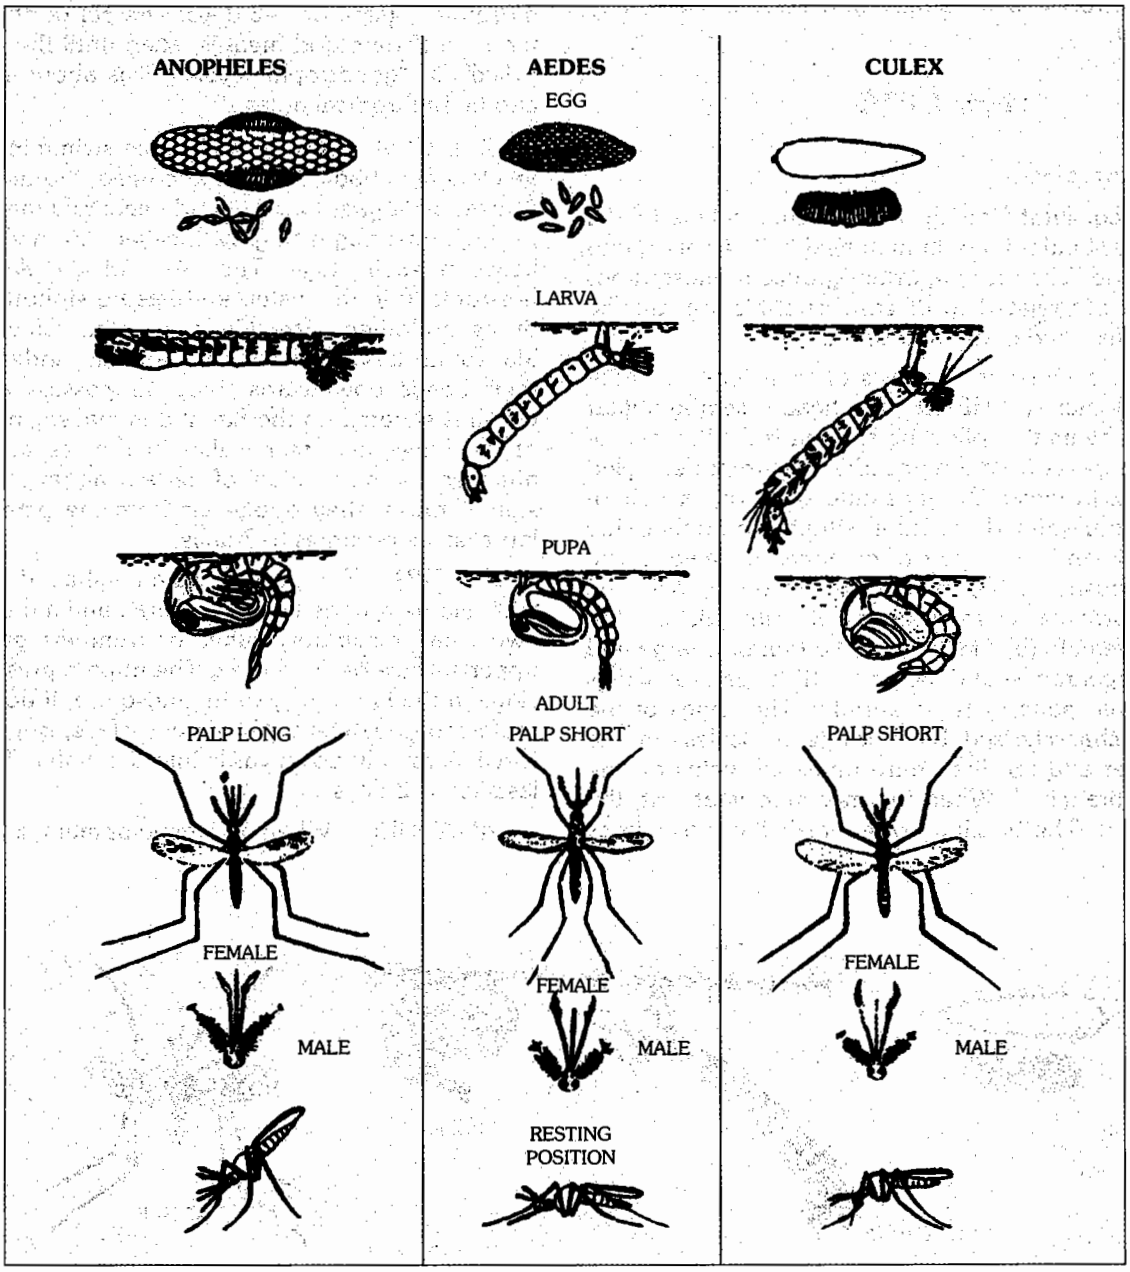

FIG. 2
Characteristics of anopheles, aedes and culex

TABLE 4

Differentiation between anophelini and culicini

Tribe → Genus →	Anophelini-anopheles	Culicini, Culex, Aedes, Mansonia
EGGS	(1) Laid singly.	(1) Laid in clusters or rafts, each raft containing 100–250 eggs (except–Aedes).
	(2) Eggs are boat-shaped, and provided with lateral floats.	(2) Eggs are oval-shaped, and not provided with lateral floats.
LARVAE	(1) Rest parallel to water surface.	(1) Suspended with head downwards at an angle to water surface.
	(2) No siphon tube.	(2) Siphon tube present.
	(3) Palmate hairs present on abdominal segments.	(3) No palmate hairs.
PUPAE	Siphon tube is broad and short.	Siphon tube is long and narrow.
ADULTS	(1) When at rest, inclined at an angle to surface.	(1) When at rest, the body exhibits a hunch back.
	(2) Wings spotted.	(2) Wings unspotted.
	(3) Palpi long in both sexes.	(3) Palpi short in female.

(2) Culex

Mosquitoes of the genus *Culex* are the common "nuisance mosquitoes" which are terrible pests of man. An important member of this group is *Culex fatigans,* the vector of Bancroftian filariasis in India. *Culex fatigans* is essentially a domestic species and is found everywhere in India in and around dwellings. Rapid urbanization and industrialization without adequate drainage facilities are responsible for its increased spread. It breeds profusely in dirty water collections, viz. stagnant drains, cesspools, septic tanks, burrow pits, and in fact, in all types of water collection. *Culex fatigans* is a strong–winged mosquito; its dispersal has been found to be 11 km in the rural areas of Delhi *(7)*. The species is highly anthrophilic. It enters the houses at dusk and reaches maximum density by midnight. The peak biting time is about midnight. Legs, particularly below the knee are the preferred biting sites. During day, it may be seen resting indoors on walls, underneath furniture, inside empty pots and in dark corners.

(3) Aedes (Stegomyia)

Aedes mosquitoes are easily distinguished by white stripes on a black body. Because of the striped or banded character of their legs they are sometimes referred to as "tiger mosquitoes". Important members of this group of mosquitoes are : *Aedes aegypti, Aedes vittatus* and *Aedes albopictus*. Aedes mosquitoes are most abundant during rainy season.

Aedes aegypti occupies a very special position in preventive medicine. It is the first proved vector of a virus disease – yellow fever. Aedes aegypti is widely distributed in India. It breeds in artificial accumulations of water in and around human dwellings, such as water found in discarded tins, broken bottles, fire buckets, flower pots, coconut shells, earthen pots, tree holes and the like. It lays eggs singly, and the eggs are cigar–shaped. The females are fearless biters, and they bite chiefly during the day. They do not fly over long distances – usually less than 100 metres (110 yards). This factor facilitates its eradication. Under the WHO International Health Regulations (IHR), all international airports and seaports are kept free from all types of mosquitoes for a distance of 400 metres around the perimeter of the ports. Under the International Health Regulations, *Aedes aegypti index* is defined as "the ratio, expressed as percentage, between the number of houses in a limited well-defined area on the premises of which actual breeding of *Aedes aegypti* are found, and the total number of houses examined in that area" *(8)*. This index is kept at zero at all ports.

(4) Mansonia

The mosquitoes of this genus are big, black or brown mosquitoes with speckling on their wings and legs. The common Indian species are : *M.annulifera, M.uniformis, M. indiana* and *M. longipalpis*. The *mansonoides mosquitoes* are peculiar in their breeding habits. They breed in ponds and lakes containing certain aquatic plants, especially the floating types like *Pistia stratiotes* and water hyacinth. The eggs are laid in star-shaped clusters on the under-surface of the leaves of these aquatic plants. The larvae and pupae are found attached to the rootlets of these plants by their siphon tubes; they obtain their air supply from these rootlets. When about to become adults, the pupae come to the surface of water and the fully formed adults emerge and escape. The control of mansonoides mosquitoes is easy by the removal or destruction of the aquatic host plants by herbicides.

Habits of mosquitoes

The habits of mosquitoes have been extensively studied by entomologists. A knowledge of these habits is essential from the point of view of controlling the mosquitoes as well as for a proper understanding of the part they play in disease transmission. The following are some of their important habits : (1) FEEDING HABITS : The males never bite : they subsist on plant juices. The females on the contrary are haematophagous. They require a blood meal, once in 2–3 days for the development of eggs. The females differ in their feeding habits. Some species (anthrophilic) prefer human blood, some (zoophillic) prefer animal blood, and some indifferent in their choice and feed on both man and animals. (2) TIME OF BITING : In general mosquitoes bite in the evening or in the early part of the night, but there are great variations among the species. (3) RESTING HABITS : Mosquitoes obscure themselves during the day in dark and cool corners. Some rest indoors (endophilia), and some outdoors (exophilia). The indoor resting places are usually the dark corners of houses, upper part of walls, behind pictures and under furniture. The outdoor resting places are usually the vegetation, shrubs, tree holes, cattle sheds and wells. (4) BREEDING HABITS : In general, the *anophelines* prefer clean water for breeding; the *culicines* prefer dirty and polluted water; the *aedes* prefer artificial collections of water. The *mansonia* breed in water containing certain types of aquatic vegetation. (5) HIBERNATION : Mosquitoes are known to hibernate in the adult stage when the environmental conditions are not favourable. Severe winters are tided over by hibernation. (6) DISPERSAL : Mosquitoes do not generally fly far from the place where they breed unless swept by currents of wind. The range of flight varies with the species, and may range upto 11 kms. Aircrafts and ships have increased the possibility of the dispersal of mosquitoes from country to country, and have created fresh problems of public health. The danger of introduction of mosquitoes infected with yellow fever into

India where the population have no past experience of the disease is well recognised. (7) LIFE SPAN : The life of a mosquito is influenced by temperature and humidity. Both high and low temperatures are fatal. The normal life span of mosquitoes varies from 8 to 34 days. The males, as a rule, are short-lived.

Mosquito-borne diseases

Apart from their pestiferous nature, mosquitoes play an important role in the transmission of human disease. They act as vectors of many diseases in India : (Table 5).

TABLE 5

Mosquito-borne diseases in India

Type of mosquito	Disease
1. Anopheles	Malaria Filaria (not in India)
2. Culex	Bancroftian filariasis Japanese encephalitis West Nile fever Viral arthritis (epidemic/polyarthritis)
3. Aedes	Yellow fever (not in India) Dengue Dengue haemorrhagic fever Chikungunya fever Chikungunya haemorrhagic fever Rift valley fever Filaria (not in India)
4. Mansonoides	Malayan (Brugian) filariasis Chikungunya fever

MOSQUITO CONTROL MEASURES

While there are many methods of mosquito control, experts now recommend an "integrated approach", that is, an approach which avoids the excessive use of any one method (e.g., insecticides) but tries to combine one or more methods with a view to obtain maximum results with minimum inputs and also to prevent environmental pollution with toxic chemicals and development of insecticide resistance. The various methods of mosquito control may be classified as below :

1 ANTI-LARVAL MEASURES
- (a) Environmental control
- (b) Chemical control
- (c) Biological control.

2 ANTI-ADULT MEASURES
- (a) Residual sprays
- (b) Space sprays
- (c) Genetic control.

3 PROTECTION AGAINST MOSQUITO BITES
- (a) Mosquito net
- (b) Screening
- (c) Repellents.

1. ANTI-LARVAL MEASURES

(a) Environmental control

The most important step in reducing the numbers of mosquitoes is to eliminate their breeding places. This is known as "source reduction", and comprises minor engineering methods such as filling, levelling and drainage of breeding places; and water management (such as intermittent irrigation). These are proven methods of larval control. Source reduction also implies rendering the water unsuitable for mosquito breeding, as for example, changing the salinity of water. Source reduction requires an accurate knowledge of the breeding habits of mosquitoes. If *Culex* mosquitoes are a problem, there should be a programme for the abolition of domestic and peridomestic sources of breeding such as cesspools and open ditches; and arrangements should be made for adequate collection, removal and disposal of sewage and waste water. If *Aedes* mosquitoes are a problem, the environment should be cleaned up and got rid of water holding containers such as discarded tins, empty pots, broken bottles, coconut shells and similar other artificial collections of water. If *Anopheles* mosquitoes are a problem, their breeding places should be looked for and abolished by appropriate engineering measures such as filling and drainage. If *Mansonia* mosquitoes are a problem, the aquatic plants to which the larvae attach themselves should be removed or destroyed by herbicides. Source reduction methods generally produce results that are permanent.

(b) Chemical control

The commonly used larvicides are :

(i) Mineral oils
(ii) Paris green
(iii) Synthetic insecticides.

(i) *Mineral oils :* The application of oil to water is one of the oldest known mosquito control measure. The oils most widely used are the diesel oil, fuel oil, kerosene and various fractions of crude oils. Special oils (e.g., Mosquito Larvicidal Oil) are also available. Oil kills larvae and pupae within a short time after application. When applied on water, oil spreads and forms a thin film, which cuts off the air supply to the mosquito larvae and pupae. Oil probably has also a specific toxic action on these insect stages. The usual application rate for oils is 40 to 90 litres per hectare *(9)*. Since the life cycle of a mosquito occupies about 8 days, it is customary to apply oil once a week on all breeding places. Oil has also certain disadvantages, it renders water unfit for drinking; it kills fish. Nevertheless, oil is eminently suited for the control of mosquito larvae.

(ii) *Paris green :* Paris green or copper acetoarsenite is an emerald green, micro-crystalline powder practically insoluble in water. A good sample of paris green must contain 50 per cent arsenious oxide. Paris green is a stomach poison and to be effective it must be ingested by the larvae. Paris green kills mainly the *Anopheles* larvae because they are surface–feeders. Bottom-feeding larvae are also killed when paris green is applied as a special granular formulation *(9)*. Paris green is applied as 2 per cent dust which is prepared by mixing 2 kg of paris green and 98 kg of a diluent such as soapstone powder or slaked lime in a "rotary mixer". The resulting mixture must be fine with the size of the particles ranging from 20–25 microns. The dusting is accomplished by hand blowers or rotary blowers. The recommended dose is 1 kg of actual paris green per hectare of water surface *(9)*. In the dosage applied, paris green does not harm fish, man or domestic animals.

(iii) *Synthetic insecticides* : Fenthion, Chlorpyrifos, and Abate are the most effective larvicides *(10)*. These organophosphorous compounds hydrolyze quickly in water. Abate at a concentration of 1.0 ppm has been found to be a very effective larvicide, and also the least toxic. Dosage of these toxicants are given in Table 6. The organochlorine compounds (e.g., DDT, HCH) are not recommended for larviciding operations because of their long residual effect, water contamination and increased risk of developing resistance in the vector mosquitoes.

TABLE 6

Toxicants employed as larvicides in mosquito control

Toxicant	Dosage (g/ha)
Abate	56–112
Malathion	224–672
Fenthion	22–112
Chloropyrifos	11–16

Biological control

A wide range of small fish feed readily on mosquito larvae. The best known are the *Gambusia affinis* and *Lebister reticulatus* (sometimes known as Barbados Millions). These fish can be used in burrow pits, sewage oxidation ponds, ornamental ponds, cisterns and farm ponds. In recent years, there has been a revival of interest in the biological control of mosquitoes through the use of fish *(11)*. It is however recognized that biological control can be effective only when used in conjunction with other methods.

2. ANTI-ADULT MEASURES

(a) Residual sprays

Adult mosquitoes are most commonly controlled by spraying houses with residual insecticides. DDT is the insecticide of choice and dosages of 1–2 grams of pure DDT per sq. metre are applied 1–3 times a year to walls and other surfaces where mosquitoes rest. In areas where DDT resistance is encountered, malathion and propoxur (OMS–33), and to a lesser extent gamma–HCH (lindane) are recommended *(12)*. Dosages and average duration of effectiveness are as given in Table 7.

TABLE 7

Toxicants suitable against malaria vectors as residual spray applications

Toxicant	Dosage in g/m²	Average duration of effectiveness (months)
DDT	1 to 2	6 to 12
Lindane	0.5	3
Malathion	2	3
OMS–33	2	3

Resistance to insecticides has become common among mosquitoes, especially after several years of exposure. Resistance to organophosphorus insecticides is also becoming widespread. It is essential that periodic tests should be made to determine the susceptibility of different species of mosquitoes to the various insecticides so that only potent insecticides can be applied.

(b) Space sprays

Space sprays are those where the insecticidal formulation is sprayed into the atmosphere in the form of a mist or fog to kill insects. The common space sprays are : (i) *Pyrethrum extract* : An extract of pyrethrum flowers is an excellent space spray. The active principle (pyrethrin) is a nerve poison and kills insects instantly on mere contact. Pyrethrum is sprayed at a dosage of 1 oz of the spray solution (containing 0.1 per cent of the active principle, pyrethrin) per 1,000 C. ft. of space. The doors and windows are kept closed for half an hour. For domestic purposes, the hand gun with a fine nozzle is all that is necessary, but for application on a large scale, power sprayers or "aerosol" dispensers may be needed. Pyrethrum sprays are effective in reducing the number of mosquitoes but the reduction is only temporary since it has no residual action. Reinfestation from outside sources generally occurs within a short time. (ii) *Residual Insecticides* : New equipment has been developed for ULV (ultra low volume) space spraying. The most extensively used insecticides are malathion and fenitrothion for ULV fogging *(13)*.

(c) Genetic control *(14, 15)*

In recent years, control of mosquitoes by genetic methods such as sterile male technique, cytoplasmic incompatibility, chromosomal translocations, sex distortion, and gene replacement have been explored. Their use is still in the "Research Phase". These techniques have great potential in mosquito control *(3)*. They also have certain advantages over chemical methods, being cheaper and potentially more efficient and above all not subject to vector resistance.

3. PROTECTION AGAINST MOSQUITO BITES

(a) Mosquito net

The mosquito net offers protection against mosquito bites during sleep. The material of the net should be white, to allow easy detection of mosquitoes. The top as well as the sides of the net should be of netting. The best pattern is the rectangular net. There should not be a single hole or rent in the net. The size of the openings in the net is of utmost importance – the size should not exceed 0.0475 inch in any diameter. The number of holes in one square inch is usually 150.

(b) Screening

Screening of buildings with copper or bronze gauze having 16 meshes to the inch is recommended. The aperture should not be larger than 0.0475 inch. Screening of buildings is costly, but gives excellent results.

(c) Repellents

Diethyltoluamide (deet) has been found to be an outstanding all–purpose repellent *(10)*. It has been found to remain active against *C. fatigans* for 18–20 hours. There are others also which are effective: indalone, dimethyl phthalate, dimethyl carbate, ethyl hexanediol, etc. Repellents or *culicifuges* are used mainly for application on the skin, and their chief advantage is the short duration of protection.

HOUSEFLIES

Houseflies are the commonest and most familiar of all insects which live close to man. They occur in abundance all the year round in India. The majority of house–frequenting flies in India are non-biting. The most important of these are : *Musca domestica, M. vicinia, M. nebulo* and *M. sorbens (16)*. Houseflies should be regarded as a sign of insanitation, and their number as an index of that insanitation.

General characters

The common housefly (*M. domestica*) is mouse-grey in colour. The body is divided into head, thorax and abdomen. (1) HEAD : The head bears a pair of antennae, a pair of large compound eyes and a retractile proboscis, which is adapted for sucking liquid foods. The eyes of the male are close together; those of the female are set apart widely. (2) THORAX : The thorax is marked with 2 to 4 dark longitudinal stripes, which is characteristic of the genus, *musca*. The thorax bears a pair of wings and three pairs of legs. Each leg is provided with a pair of pads which enables the fly to walk on highly polished surfaces. The legs and the body are covered with numerous short and stiff hairs, called the *tenent hairs* which secrete a sticky substance. (3) ABDOMEN : The abdomen is segmented and shows light and dark markings.

Life history

The housefly undergoes a complete metamorphosis with four stages in its life cycle : egg, larva (maggot), pupa and adult (Fig. 3).

(1) EGG : The female lays from about 120 to 150 eggs at one sitting in moist decaying organic matter such as human and animal excreta, manure heaps, garbage and vegetable refuse. The Indian *M. domestica* and *M. vicinia* breed profusely in human excreta. The eggs are pearly-white in colour and about 1 mm long. They can be readily seen by the naked eye. The fly lays from 600 to 900 eggs during her life time. The eggs hatch in 8 to 24 hours; during summer, in India, they may hatch within 3 hours. (2) LARVA : The larvae or maggots measure 1 to 2 mm in length at birth. They are white, segmented and footless with a narrow anterior end, and a broad posterior end. They eat voraciously and moult twice in the course of development. The full grown larva may measure up to 12 mm in length. The larvae resent light; they bury themselves under manure heaps. When about to pupate, they migrate to dry outer regions. The larval period lasts from 2 to 7 days, but this stage may be prolonged in cold weather. (3) PUPA : The pupa are dark-brown and barrel shaped and measure about quarter of an inch. The pupal stage in the tropics occupies 3 to 6 days. In winter months, the pupal stage may be considerably prolonged. (4) ADULT : The complete life cycle from egg to adult may take 5 to 6 days during summer in India, but at other times it may take 8 to 20 days. Flies do not generally live longer than 15 days in summer and 25 days during winter.

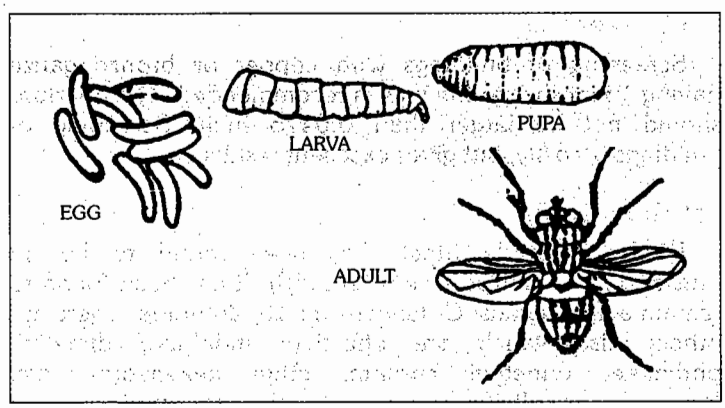

FIG. 3
Life cycle of housefly

Habits

The habits of housefly make it eminently suited for the spread of disease. (1) BREEDING HABITS : The most important breeding places of flies in order of importance are (a) fresh horse manure (b) human excreta (c) manure of other animals (d) garbage (e) decaying fruits and vegetables (f) rubbish dumps containing organic matter and (g) ground where liquid wastes are spilled. (2) FEEDING HABITS : The housefly does not bite. It is attracted to food by its sense of smell. It cannot eat solid foods; it vomits on solid food to make a solution of it and sucks in a liquid state. Adult flies delight in sputum, faeces, discharges from wounds and open sores. (3) RESTLESSNESS : The fly is a restless insect and moves back and forth between food and filth. This helps in the spread of infection mechanically. (4) VOMIT DROP : The fly vomits frequently. The "vomit drop" is often a culture of disease agents. (5) DEFECATION : The housefly has the habit of defecating constantly all the day. Thus it deposits countless bacteria on exposed food. (6) RESTING HABITS : Flies have a tendency to rest on vertical surfaces and hanging objects. They have a tendency to fly towards light. (7) DISPERSAL : Normally houseflies remain close to their breeding places, but they disperse frequently up to 4 miles, and sometimes even more from the point of their origin.

Transmission of disease

Flies are potential vectors of many diseases : typhoid and paratyphoid fevers, diarrhoeas and dysenteries, cholera, and gastroenteritis, amoebiasis, helminthic infestations, poliomyelitis, conjunctivitis, trachoma, anthrax, yaws, in fact, most diseases that can be spread by mechanical transmission.

Flies transmit disease in the following ways : (1) MECHANICAL TRANSMISSION : Houseflies are exceptionally efficient mechanical spreaders of disease. They transport microorganisms on their feet and hairy legs. Pathogenic organisms, ova and cysts have been recovered from the bodies of the common housefly. Houseflies are therefore called "porters of infection". (2) VOMIT DROP : The regurgitated stomach contents or "vomit drop" is a rich bacterial culture. By its habit of frequent vomiting, the housefly infects food and thereby transmits disease. (3) DEFECATION : The excrement of housefly has been found to contain numerous microorganisms as well as cysts and ova of intestinal parasites. By its habit of constant defecation, the housefly spreads these diseases.

FLY CONTROL MEASURES

1. Environmental control

The best way to control houseflies is to eliminate their breeding places and to bring about an overall improvement in the environmental sanitation on a community-wide basis. This, in effect, implies the following : (1) storing garbage, kitchen wastes and other refuse in bins with tight lids, pending disposal. (2) efficient collection, removal and disposal of refuse by incineration, composting or sanitary landfill. (3) provision of sanitary latrines, e.g., pit privies,

septic tanks, water-seal latrines and sanitary system. (4) stopping open air defecation. (5) sanitary disposal of animal excreta, and (6) stepping up general sanitation. A clean house with clean surroundings is the best answer to the fly problem.

2. Insecticidal control *(17,18)*

(1) RESIDUAL SPRAYS : Since it first showed resistance to DDT in 1948, *M. domestica* has developed resistance to the other organo-chlorine compounds as well as to organophosphorus and carbamate pesticides. Susceptible flies may be killed by DDT (5%), methoxychlor (5%), lindane (0.5%), or chlordane (2.5%) sprayed at about 5 litres per 100 square metres of surface; for flies resistant to these, diazinon (2%) dimethoate (2.5%), fenthion (2.5%), malathion (5%), or ronnel (5%) may be used. The addition of sugar to insecticidal formulations enhances their effectiveness. Special care should be taken to prevent contamination of food or water during spraying operations. (2) BAITS : Baits may be solid or liquid. Poisoned baits containing 1 or 2 per cent diazinon, malathion, dichlorvos, ronnel and dimethoate have been tried with success. Liquid baits containing 0.1 to 0.2 per cent of the same insecticides and 10 per cent sugar water have given good results. The cheapest bait is one that is made by mixing 3 teaspoons of commercial formalin with one pint of water or milk to which is added a little sugar, (3) CORDS AND RIBBONS : Cords and strips impregnated with diazinon, fenthion, or dimethoate have been tried with success. These are hung like festoons from ceilings. The period of effectiveness ranges from 1 to 6 months. (4) SPACE SPRAYS : Space sprays containing pyrethrin and DDT or HCH are available commercially. These may be applied indoors or outdoors using hand or power sprayers. Space sprays in general have little or no residual action. They produce only a temporary effect on adult fly populations; consequently, repeated applications are necessary. (5) LARVICIDES: Insecticides such as 0.5% diazinon, 2% dichlorovos, 2% dimethoate or 1% ronnel applied at the rate of 28–56 litres per 100 sq. metres have been used for the treatment of fly breeding places, but it is found that they cause or accelerate the development of resistance. In summary, it may be stated that insecticides, at best, are only a supplement, but not a substitute for sanitation.

3. Fly papers

Sticky fly papers are useful adjuncts to other methods of control. These papers can be easily made by mixing 2 lbs of resin and one pint of castor oil which should be heated together until the mixture resembles molasses. This should, while hot, be smeared on paper by using an ordinary paint brush. The adhesive mixture can also be applied to strips of wire and hung up in places where flies abound. Although a slight reduction of flies may occur, no lasting benefits will result from the use of fly papers.

4. Protection against flies

Screening of houses, hospitals, food markets, restaurants and all other similar establishments will give considerable relief from houseflies. Screens with 14 meshes to the inch will keep out houseflies but finer screens will also keep out the other insects. Screening is expensive for general use.

5. Health education

It is difficult to achieve fly control without the willing co-operation of the people. A "fly consciousness" should be created among the people, through health education. Fly control campaigns require *organized individual* and *community effort* which is the basis of a successful public health programme. It is only through health education that people can be motivated with a desire to get rid of flies permanently.

SANDFLIES

Sandflies are small insects, light or dark–brown in colour. They are smaller than mosquitoes, measuring 1.5 to 2.5 mm in length with their bodies and wings densely clothed with hair. Some 30 species of sand-flies have been recorded in India. The important ones are : *Phlebotomus argentipes, P. papatasii, P. sergenti,* and *Sergentomyia punjabensis.* Our knowledge of the Indian sandflies is meagre, and needs more studies *(19)*.

General characters

The body of a sandfly is divided into head, thorax and abdomen, (1) HEAD : The head bears a pair of long, slender and hairy antennae; palpi and a proboscis. Only the females bite, the males live on vegetable juices. (2) THORAX : The thorax bears a pair of wings and three pairs of legs. The wings are upright, lanceolate in shape and densely hairy. The second longitudinal vein on the wings branches twice, the first branching takes place in the middle of the wing. This is a characteristic feature of the genus, Phlebotomus. The legs are long and slender and out of proportion to the size of the body. (3) ABDOMEN : The abdomen has 10 segments and is covered with hair. In the female, the tip of the abdomen is rounded; in the male, there are claspers, which are conspicuous and attached to the last abdominal segment.

Sandflies may be distinguished from mosquitoes by the following characteristics : (1) *Size :* Sandflies are smaller than mosquitoes. (2) *Wings :* The wings of the sandfly are up-right and lanceolate in shape; the second longitudinal vein branches twice, the first branching taking place in the middle of the wing. (3) *Legs :* The legs of the sandfly are longer compared with the size of the body. (4) *Hairs :* Sandfly is a hairy insect. (5) *Hopping:* Sandflies hop about, and do not fly by choice.

Life history

The life history of the sandfly is characterised by complete metamorphosis, having four stages : egg, larva, pupa and adult (Fig. 4).

(1) EGG : The eggs are laid in damp dark places in the vicinity of cattle sheds and poultry. The eggs are comparatively large, and torpedo-shaped with longitudinal wavy lines on the outside. The eggs hatch within 7 days. (2) LARVA : The larvae are hairy maggots with a distinct head, thorax and abdomen. The last abdominal segment carries two pairs of long stout hairs; one pair is remarkably long. The larva feeds on decaying organic matter and becomes a pupa in about 2 weeks. (3) PUPA : The pupal stage lasts for about 1 week. (4) ADULT : The average life of a sandfly is about 2 weeks.

Habits

Sandflies are troublesome noctural pests. Their bite is irritating and painful, while their presence is scarcely observed. They infest dwellings during night, and take shelter during day in holes and crevices in walls, holes in trees, dark rooms, stables and store rooms. The females

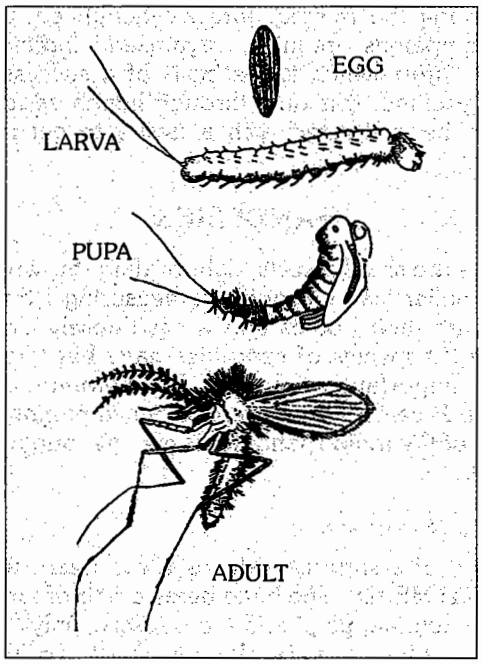

FIG. 4
Life cycle of a sandfly

alone bite, as they require a blood meal every third or fourth day for oviposition. Sandflies are incapable of flying over long distances; they merely hop about from one place to another. Sandflies are generally confined to within 50 yards of their breeding places.

Diseases transmitted

SPECIES	DISEASES CARRIED
Phlebotomus argentipes	Kala-azar
Phlebotomus papatasii	Sandfly fever Oriental sore
Phlebotomus sergenti	Oriental sore
S. punjabensis	Sandfly fever

Control of sandflies

Sandflies are easily controlled because they do not move long distances from the place of their breeding. (1) INSECTICIDES : Resistance to DDT has not been demonstrated. A single application of 1 to 2 g/m^2 of DDT or 0.25 g/m^2 of lindane has been found effective in reducing sandflies. DDT residue may remain effective for a period of 1 to 2 years, and lindane only for a period of 3 months *(17)*. Spraying should be done in the human dwellings, cattle sheds and other places. (2) SANITATION : Sanitation measures such as removal of shrubs and vegetation within 50 yards of human dwellings, filling up cracks and crevices in walls and floors, and location of cattle sheds and poultry houses at a fair distance from human habitations should receive attention.

TSETSE FLIES

Tsetse flies or the Glossinae are bloodsucking flies, which present a general resemblance to the common housefly. They are yellow or dark–brown in colour, and measure about half an inch long. Their wings, when folded, overlap each other like the blades of a scissors. They have a proboscis which is rigid and non-retractile and adapted for piercing the skin and sucking blood. Tsetse flies are only found in African continent. Regions infested with tsetse flies are called "fly belts". For centuries, the tsetse fly has ravaged vast areas of tropical Africa, and hampered economic and social progress; it continues to be a menace even today.

Life history

The life history of the tsetse fly is somewhat abnormal. The female does not lay eggs, but gives birth to a living larva, one at a time, at 10–day intervals. The female produces only a few offspring in its life time. Soon after birth the larva crawls away to a suitable place and buries itself in the earth, usually at a depth of an inch or so beneath the surface. Pupation then takes place, within a few hours. The pupal stage lasts for 20–40 days. At the end of the pupal stage, the adult fly emerges. The tsetse lives less than 100 days.

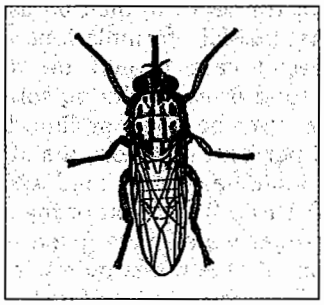

FIG. 5
Tsetse fly

Species and habits

More than 30 species of the *Glossinae* have been recognised, but only four species are dangerous to man. They are : *G.palpalis, G.tachinoides, G.morsitans,* and *G.pallidepes.* The first two species are sometimes called "riverine species" because they inhabit the woodland vegetation near water courses; the latter two are called "savannah species" because they prefer to live and breed in woodland vegetation in savannah country.

Tsetse flies attack man, animals, wild game of all kinds, birds, lizards and snakes. Both the sexes bite, mainly during day. The riverine species (e.g., *G. palpalis* and *G. tachinoides*) have a distinct attraction to man; the savannah species prefer to feed on game rather than man. Tsetse flies rarely enter houses, but they are known to follow travellers both by road and rail for considerable distance in order to obtain a blood meal. Tsetse flies are vectors of trypanosomiasis or "sleeping sickness". The disease affects man, domestic animals and wildgame – being particularly lethal to man, and his domestic stock.

Control of tsetse flies

There are four main techniques in the control of tsetse flies : (1) INSECTICIDES : Resistance to insecticides has not been reported in *Glossina.* At present, DDT (25%) and dieldrin (18–20%) are the most commonly used pesticides for tsetse fly control *(17)*. The insecticide is applied from aircraft when large areas are to be covered quickly. (2) CLEARING OF VEGETATION : Clearing of vegetation where tsetse flies live and breed is now the technique most widely adopted for controlling tsetse flies. Used alone, this method gives slow results, but in conjunction with the application of residual insecticides, it has given a speedy reduction of flies. (3) GAME DESTRUCTION : Large tracts of Africa have been cleared of the tsetse flies by the destruction of wild game. This method is now given up. (4) GENETIC CONTROL : Currently, research is centred

round genetic control of tsetse flies using the "sterile male release" technique *(20)*.

BLACKFLIES

Blackflies or *simuliidae* are small robust flies with short stout legs, large broad wings and a short proboscis (Fig. 6). They are very often all black. *Simulum indicum* is the Indian species *(21)*. Blackflies attack domestic animals and man and suck blood. They are vectors of onchocerciasis in Africa, Mexico, and Central and South America. The eggs are laid on submerged stones and water weeds. The larvae are aquatic; they fix themselves to stones or plants, usually at a depth of 1 foot. The larval stage occupies 3 to 4 weeks. They pupate in water; the pupal stage occupies 1 to 3 weeks. In India, *simuliidae* breed in hill streams. Control of the adult fly is difficult, because the range of the fly is about 100 miles. Therefore, the attack is levelled at the larvae. Abate is used which kills the blackfly larvae without causing harmful effects to mammals or other aquatic fauna. It is added to river water in weekly doses of 0.05 to 0.1 mg/litre over a period of 10 minutes *(22)*.

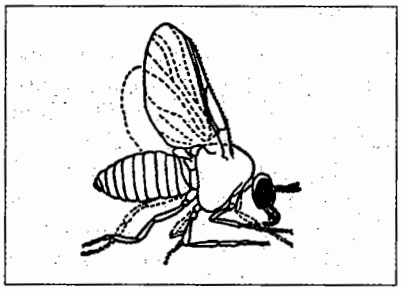

FIG. 6
Simulum

LICE

Lice are small wingless ectoparasites of mammals and birds. They bite severely and are annoying pests. The lice that infest man are of three kinds : head louse (*Pediculus capitis*), body louse (*Pediculus corporis*), and pubic or crab louse (*Phthirus pubis*). Human lice occur in all parts of the world wherever standards of hygiene are low, but people in colder climates are affected more frequently than those in warmer regions. Infestation by lice is called *pediculosis*.

Head and body lice

The head and body lice differ very little in structure except in their habitat. The head lice inhabit the hairs of the scalp, and the body lice occur mainly in the seams of clothing and on the bodies of the hosts. The body of a louse is flattened dorso-ventrally, and is divided into head, thorax and abdomen. (1) HEAD : The head is pointed in front and bears a pair of 5–jointed antennae. The mouth parts are adapted for sucking blood. (2) THORAX : The thorax is a fused mass and is shaped somewhat like a square. Three pairs of legs are attached ventrally to the thorax. The legs are strongly developed and are provided with claws which help the insect to cling to the hair and clothing. (3) ABDOMEN : The abdomen is elongated and consists of 9 segments. The last abdominal segment is pointed in the case of males, and bilobed in the case of females.

Life history

There are three stages in the life history of lice : egg, larva and adult. Metamorphosis is gradual (Fig. 7).

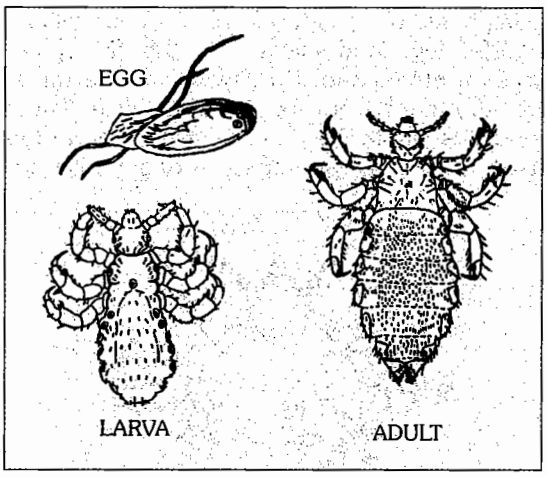

FIG. 7
Life cycle of a louse

(1) EGG : The eggs, called "nits" are laid singly or in groups, firmly attached to the hair or seams of clothing by a cementing substance. The eggs are small, white ovoid bodies, pointed at one end and truncated and pitted at the other end. A female lays up to 300 eggs, at the rate of 4 to 9 eggs a day. Under favourable conditions of temperature, the eggs will hatch in 6 to 9 days. The eggs will not hatch if the temperature is below 22 deg. C (71.6 deg.F). (2) LARVA OR NYMPH : The larva looks very much like an adult, except for its smaller size. It feeds on the host and develops into an adult after passing through 3 moults. The larval stage may take 10 to 15 days. (3) ADULT : The entire life cycle from the laying of an egg to the appearance of the adult louse takes about 15 to 17 days under favourable conditions. Adult lice lives from 30 to 50 days.

Dissemination

(1) DIRECT CONTACT : Lice are disseminated by close contact with lousy or infested persons. Overcrowding provides an excellent opportunity for the direct transference of lice from one person to another. Children get easily infested at school when their heads come together at work or play. (2) INDIRECT CONTACT : Lice may also be acquired from clothing, bedding, combs or brushes used by lousy persons. Lice have been seen to be blown by puffs of wind from heavily infested persons. Lice tends to leave the host whose temperature rises above or falls below the normal.

Lice and disease

Lice are vectors of the following diseases :

DISEASE		CAUSATIVE AGENT
1. Epidemic typhus	.....	Rickettssia prowazeki
2. Relapsing fever	.....	Borrelia recurrentis
3. Trench fever	.....	Rickettssia quintana
4. Dermatitis	.....	Due to scratching and secondary infection

Crab louse

The crab louse or pubic louse (*Phthirus pubis*) is generally found in the pubic and perineal region, but at times it may occur in the other parts of the body as well. It adheres close to the skin, and its removal is a matter of difficulty. The crab louse has a characteristic body form, and is readily recognized by (1) its small size and square body,

(2) head impacted on the thorax, (3) the relatively enormous and powerful legs and claws, (4) the first pair of legs slenderer than others and, (5) its extreme inertness. It does not move very much from the site of its birth. The life cycle of crab louse is similar to that of head or body louse. The crab louse has not been proved to carry any disease (Fig. 8).

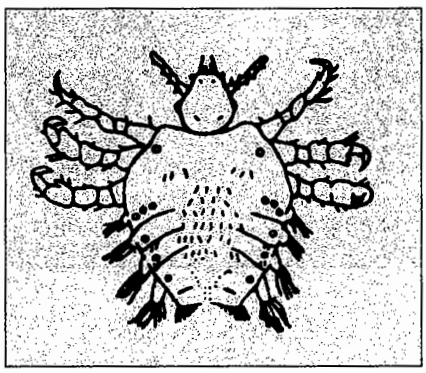

FIG. 8
Phthirus pubis

Control of lice *(17,18)*

(1) INSECTICIDAL CONTROL : Insecticides appear to be the only means at present for the control of lice. There are reports that lice have become resistant in many areas to DDT and HCH, and there are some reports of resistance to malathion. It is of utmost importance to monitor periodically louse susceptibility to insecticides to assess which insecticide should be used *(13)*. (a) *Head and crab lice :* The present recommended treatment is a lotion containing 0.5 per cent malathion. The lotion should be left on for 12 to 24 hours when the hair can be washed. Malathion, if correctly used, will kill lice and nits. Dust containing carbaryl is also effective as louse powder. (b) *Body Lice :* Since lice have become resistant to DDT and HCH, a powder containing 1 per cent malathion will obviously be the treatment of choice. Dust containing carbaryl may also be used. The powder is applied to the inner surface of the clothing as well as socks and the body of the persons. "Mass delousing" of large numbers of people is carried out with hand operated dusters. The powder is blown down the neck of the shirt, up the sleeves, and into the loosened trousers from several angles at the front and back. With this type of treatment, the clothing is not removed and about 50 g. (2 ozs.) of the insecticidal powder are required for one person. Normally a single application will eradicate an infestation, but a second application may be made in 7 days to kill late-hatching lice.

(2) PERSONAL HYGIENE : Delousing procedures should be accompanied by improvements in personal hygiene. Lice require very close contact with humans, frequent blood meals and a relatively constant temperature. They cannot survive in communities where people regularly bathe, change and launder their clothes. A daily bath with soap and water is essential in a country like India to prevent lice infestation. Women with long hair should wash and clean their hair frequently. Clothing, towels and sheets should be washed in hot water and soap and pressed with hot iron. Autoclaving of clothes and bedding in steam sterilizers may be required for body louse control. The long-term control policy should be based on improvement of personal hygiene, partly by simple health education and also by improving living standards.

FLEAS

Fleas are small, bilaterally compressed, wingless insects with a hard chitinous exoskeleton and covered with backwardly directed strong bristles. They are blood sucking ecto-parasites of mammals and birds. The fleas found on one particular kind of animal host will not usually seek the blood of another species of animal, unless compelled by necessity.

Types of fleas

More than a thousand different species of fleas have been described; some 37 species are known to occur in India. The fleas of importance in public health are :

1.	Rat fleas *(Oriental)*	–	*Xenopsylla cheopis*
		–	*Xenopsylla astia*
		–	*Xenopsylla braziliensis*
2.	Rat fleas *(Temperate zone)*	–	*Nosopsylla fasciatus*
3.	Human fleas	–	*Pulex irritans*
4.	Dog and cat fleas	–	*Ctenocephalus canis*
		–	*Ctenocephalus felis*
5.	Sand fleas *(Jigger or chigoe fleas)*	–	*Tunga penetrans*

The rat fleas are of greatest importance because they are vectors of plague and typhus. *Nosopsylla fasciatus* is rare in India; it occurs in temperate zones. The human flea, *Pulex irritans* has a wide host range; in addition to man, it infests commensal rats, pigs, cats, dogs and foxes. The *cat* and *dog fleas* occur almost everywhere. They occur not only on the specific hosts, the cat and dog, but also on other animals. They are prone to attack man. The sand flea, *Tunga penetrans* occurs in the tropical regions of Africa and America.

Rat fleas

The body of a flea is divided into head, thorax and abdomen. (1) HEAD : The head is conical in shape and is attached to the thorax without a neck. The head bears short, piercing mouth parts which are conspicuous and project downwards from the head. The mouth parts are adapted for piercing and sucking blood. (2) THORAX : The thorax is composed of three segments – the prothorax, mesothorax and metathorax. There are three pairs of strong legs attached to the thorax. The flea has no wings. (3) ABDOMEN : The abdomen consists of 10 segments. The sexes are easily distinguished. In the male, there is a coiled structure, the penis, in the abdomen. In the female, there is a short, stumpy structure, the *spermatheca*, in the posterior part of the abdomen. The shape of the *spermatheca* helps in the identification of the species.

Life history

There are four stages in the life history of fleas : egg, larva, pupa and adult. Metamorphosis is complete (Fig. 9).

(1) EGG : The eggs are small (0.5mm), ovoid and white in colour. They are deposited among the hairs of the animal host or in and near the nest or haunts of its host. A female may lay 300–400 eggs in its life time – 2 to 6 or even more at a time. The eggs hatch in 2 to 7 days, depending upon temperature. (2) LARVA : The larvae are small, legless caterpillars, whitish in colour, and bear sparse long hair on their bodies. They are found in the dust and debris, in on near the nests or lairs of the host. They feed on organic matter and the blood in the faeces of the adult flea. There are three larval stages; the last stage spins a cocoon, to which dust particles adhere. The duration of the larval stage is about 2 weeks. (3) PUPA : The

pupa develops inside the cocoon. The pupal stage lasts for 1 to 2 weeks, depending upon temperature and other environmental influences. (4) ADULT : The life cycle of a flea may be completed within 3 weeks, under favourable conditions. The fleas live normally for a month or so under tropical conditions. Infected fleas may live for one year, and certain species may survive in the burrow microclimate for as long as 4 years *(17)*.

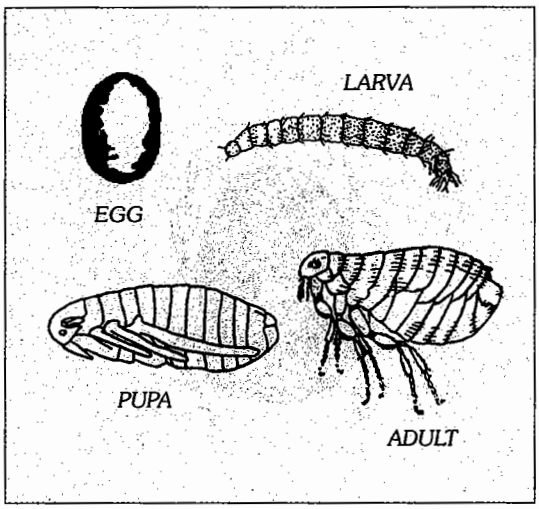

FIG. 9
Life cycle of rat flea

Habits

Fleas are found on their normal hosts and in the nests, burrows and lairs of their hosts. They are also found in the dwellings, on the ground, in cracks and crevices, and under carpets. Both the sexes bite and suck blood. They feed at frequent intervals, usually once a day and sometimes more often. Fleas cannot fly, but they are capable of making vertical jumps of about 4 inches when starved, and about 3 inches when gorged. The distance they can cover by horizontal jumps is less than 6 inches. Fleas are passively transported by (a) their hosts (b) transport vehicles (c) humans – on the person or in the luggage, and (d) the movement of goods like grain, raw cotton, gunny bags, rags and hides.

Flea indices

The following indices are used in flea surveys : (1) GENERAL FLEA INDEX : It is the average number of fleas of all species per rodent. (2) SPECIFIC FLEA INDEX : (*X.cheopis index; X.astia index, etc.*) It is the average number of fleas of each species, found per rodent. (3) PERCENTAGE INCIDENCE OF FLEA SPECIES : It is the percentage of fleas of each species, found per rodent. (4) RODENT INFESTATION RATE : It is the percentage of rodents infested with the various flea species.

Flea indices do not in themselves indicate an imminent plague epidemic. But flea indices serve as useful indicators of the potential explosiveness of the situation, should a plague outbreak occur in an endemic area *(23)*. Specific flea indices are more significant than are overall flea indices.

Fleas and human disease

Fleas are known to transmit the following diseases : (1) Plague (bubonic), (2) Endemic or murine typhus, (3) Chiggerosis, and (4) Hymenolepis diminuta.

MODE OF TRANSMISSION : Fleas convey disease by (1) *Biting* : The chief method of transmission, in the case of plague, is by the bite of hungry 'blocked' fleas. Some fleas which ingest plague bacilli become blocked due to the multiplication of plague bacilli in their proventriculus or stomach. Fleas affected in this way are called 'blocked' fleas. The blockage of the food passage renders the flea unable to obtain further blood feeds. Because of hunger, the flea begins to bite more ferociously and makes frantic efforts to suck blood. Each time it bites, instead of sucking blood, it injects plague bacilli into the wound. Such 'blocked' fleas play a great role in the spread of plague. (2) *Mechanical transmission* : Mechanical transmission takes place from the proboscis of the fleas, which had recently fed on an infected rodent. (3) *Faeces* : The fleas are apt to defecate while feeding. The faecal drop of infected fleas may contain numerous bacilli. When the host scratches over the flea-bitten area, there is direct inoculation of the infective agent into the angry spot.

Control of fleas *(17, 18)*

(1) INSECTICIDAL CONTROL : The cheapest and most widely used formulation has been 10 per cent DDT dust. As the rodents pass over the dust, they pick it up on their fur where it kills the fleas. In a number of plague areas, the rat fleas have developed resistance to DDT and/or to gamma–HCH and dieldrin. In such areas, carbaryl or diazinon (2%) or malathion (5%) should prove effective *(9)*. The sprays should be applied to floors and walls up to a height of about 1 ft. *Patch dusting* with insecticides has also been found to be an effective method of controlling fleas. The insecticidal powder is dusted over rat runs, under gunny bags, and other harbourage areas. The insecticidal dust should also be blown into the rodents' burrows with the help of dust–blowers at about 30 g. per burrow. Animal hosts like cats and dogs and their quarters and premises should also be treated with insecticidal dusts, sprays or dips. (2) REPELLENTS : Diethyltoluamide is an efficient flea repellent. Clothing impregnated with diethyltoluamide repels fleas for more than a week. Benzyl benzoate is also a good flea repellent. (3) RODENT CONTROL : Flea control should be followed by rodent control. This subject is treated elsewhere in this chapter.

SAND FLEA

Sand fleas occur in the tropical regions of Africa and America. They are also known as Jigger or Chigoe fleas. Of particular importance is the sand flea, *Tunga penetrans*. The fertilized female burrows into the skin of the feet, often beneath the nail and causes ulcers. Tetanus and gas gangrene frequently occur because of secondary infection. *T. penetrans* has been recorded in the western parts of India; it has not yet been able to gain foothold in India. It flourishes best in sandy soil. Its hosts are usually domestic animals (Fig. 10).

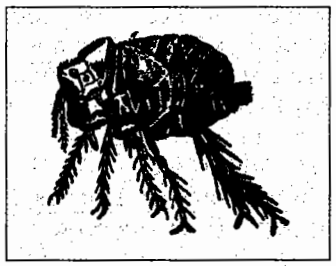

FIG. 10
Sand flea

REDUVIID BUGS

Reduviid bugs, also known as cone-nose bugs, are vectors of Chagas' disease in Mexico and Central and South America. All are of large size, about an inch or more in length. Adults have wings. These bugs live exclusively on the blood of animals including man and transmit *Trypanosoma cruzi,* the causative agent of Chagas' disease. These bugs occur in India *(21),* but are not incriminated in the transmission of any disease. These bugs frequently attack man and their bites may cause intense itching, nausea, flushed face, palpitation of the heart, etc. (Fig. 11).

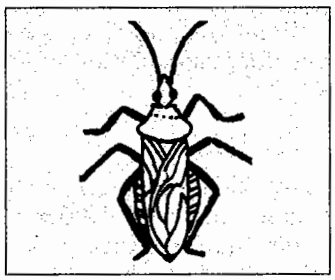

FIG. 11
Reduviid bug

Reduviid bugs live in cracks, fissures and other hiding places in walls and ceilings of human dwellings and in animal habitations and nests. They emerge only to feed and then retreat into their hiding places. Where housing is primitive, conditions may be ideal for these bugs. Residual spraying with HCH (0.5 g/m^2 or dieldrin (1 g/m^2) is commonly used for control of these bugs *(17).*

TICKS AND MITES

Ticks and mites comprise one of the largest and most important orders (acarina) of the phylum Arthropod. They are ectoparasites of vertebrate animals, and they all suck blood.

Ticks

Ticks are of two kinds : hard ticks (*ixodidae*) and soft ticks *(argasidae)*

The body of a tick is oval in shape and is not distinctly separated into head, thorax and abdomen. They have four pairs of legs, and no antennae. The hard ticks are covered on their dorsal surface by a chitinous shield, called scutum , this in the male covers the entire back, and in the female only a small part in front. The scutum or dorsal shield is absent in soft ticks. Hard ticks have a "head" or capitulum at anterior end; soft ticks have a head on underside, which is entirely invisible from above (Fig. 12 & 13). The males are generally smaller than females. The hard ticks feed both night and day and cannot stand starvation; the soft ticks, on the other hand, feed at night and can withstand starvation for several months. The hard ticks are always found on their hosts; the soft ticks hide in cracks and crevices during the day and emerge at night to feed on the host. The common hard ticks which infest domestic animals such as dogs and cattle in India are : *Dermacentor, Haemophysalis, Hyalomma, Rhipecephalus* and *Boophilus.* From the medical standpoint, the soft tick of importance is *Ornithodorus moubata,* which transmits relapsing fever.

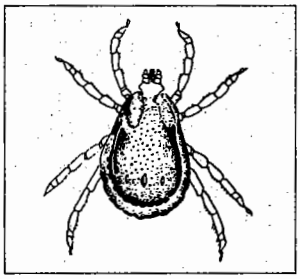

FIG. 12
Hard tick

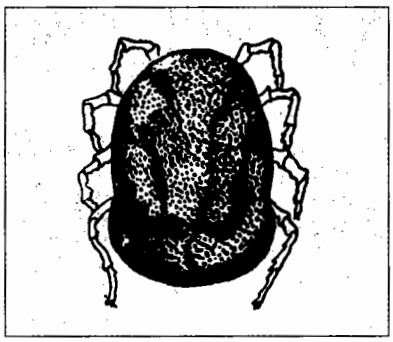

FIG. 13
Soft tick

Life history

There are four stages in the life history of ticks; egg, larva, nymph and adult. (1) EGG : Hard ticks lay eggs in a few hundreds or even thousands, all at one time, after which the female is exhausted and dies. The soft ticks lay eggs in batches of 20 to 100 over a long period. The eggs are deposited on the ground and hatch in 1 to 3 weeks. (2) LARVA : The larva of the tick possesses 3 pairs of legs. It lies in wait among grass and herbiage till a suitable host appears to which it attaches itself. After a blood meal, it drops off, and in course of time it moults to become a nymph. The duration of the larval stage may vary from 3 to 13 days. (3) NYMPH : The nymph resembles the adult in having 4 pairs of legs, but it has no genital pore. The nymphs are all blood suckers, and they attach themselves to suitable hosts for a blood meal. There are 5 nymphal stages in the life history of soft ticks. (4) ADULT : The duration of the life cycle from egg to adult is about 2 months in the case of hard ticks, and from 9 to 10 months in the case of soft ticks. Adult ticks may live for a year or more. Soft ticks live longer than hard ticks.

Public health importance

Hard ticks transmit the following diseases :

(a) Tick typhus (Rocky mountain spotted fever)
(b) Viral encephalitis (e.g., Russian spring-summer encephalitis)
(c) Viral fevers (e.g., Colorado tick fever)
(d) Viral haemorrhagic fevers (e.g. KFD in India)
(e) Tularaemia
(f) Tick paralysis, and
(g) Human babesiosis.

Soft ticks transmit :

(a) Q fever
(b) Relapsing fever, and
(c) KFD.

The tick attaches itself to its host by means of its mouth parts. The rostrum is burrowed into skin to enable it to suck blood. At the same time saliva is secreted, which contains a neurotoxin. Mature ticks, especially gravid female ticks, may remain attached for a comparatively long time but the male usually drops off the body after a few days. As the tick feeds, it gradually becomes engorged with blood.

Ticks transmit disease by biting; The larva and nymph are also capable of transmitting disease by biting (i.e., infection is maintained trans-stadially). Experiments have also shown transovarian transmission of infection through successive generations.

Hard and soft ticks compared

Hard and soft ticks are compared as shown in Table 8.

TABLE 8
Comparison of hard and soft ticks

	Hard ticks (Ixodidae)	Soft ticks (Argasidae)
1. Scutum	Covers the entire back in males; only a small portion in front in females	Absent
2. Head	Situated at anterior end	Lies ventrally; not seen from above
3. Spiracles	Situated behind IV coxa	Situated between III and IV coxa
4. Eggs	Several hundreds or thousands laid at one sitting	Laid in batches of 20–100 over a long period
5. Nymphal stages	One	Five
6. Habits	Cannot stand starvation; feed night and day	Can stand starvation for a year or more
7. Diseases transmitted	Tick typhus Viral encephalitis Haemorrhagic fever Tularaemia Tick paralysis Human babesiosis	Relapsing fever
8. Important species	Dermacentor andersoni Haemophysalis spinigera	Ornithodorus moubata

Mites (Chiggers)

Mites (chiggers) resemble ticks in their general appearance, having 4 pairs of legs and a body not well demarcated into head, thorax and abdomen. From the public health standpoint, two mites are important; (1) the trombiculid mite, and (2) the itch mite (*Acarus scabiel*).

TROMBICULID MITES

These are spider-like arthropods. The important species are *Leptotrombidium deliense* and *L. akamushi* which are vectors of scrub typhus in Asia and South Pacific.

Life History

The *life history* of a mite consists of 4 stages (Fig. 14) : egg, larva nymph and adult. (1) EGG : Eggs are laid singly; they hatch in about a week. (2) LARVA : The larva is very small, pale orange in colour, and has 3 pairs of legs. It attacks vertebrate hosts (rodents or man). When gorged with blood, it drops down to the ground for moulting. The larval stage lasts for 1 to 2 weeks. (3) NYMPH : The nymph is brick-red in colour and has 4 pairs of legs. It lives on vegetable juices. The nymphal stage lasts for 1 to 3 weeks. (4) ADULT : The adult male lives in soil. It has 4 pairs of legs, the first pair being the largest. The mite lives for about 6 months.

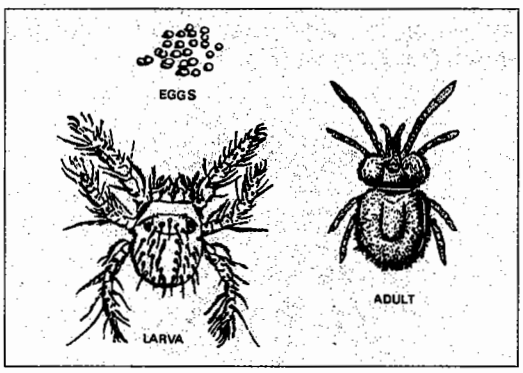

Fig. 14
Life cycle of a mite

Control of ticks and mites

(1) INSECTICIDAL CONTROL ; Great success has been obtained in destroying ticks and mites by the use of modern insecticides. DDT, chlordane, dieldrin, lindane, malathion and toxaphane at rates of 1 to 2 lbs per acre give effective control. Either dusting or spray formulations can be employed. A thorough knowledge of the habits of a given species of tick must be obtained before planning a control programme. Animals like dogs may be freed of ticks by treating them with insecticidal sprays or dusts. Not only the animals, but also the premises which they frequent should be treated with insecticides (2) ENVIRONMENTAL CONTROL : Cracks and crevices in ground particularly near buildings and paths should be filled up. Animal hosts such as wild rodents and dogs should be reduced. (3) PROTECTION OF WORKERS : Exposed workers should be encouraged to wear protective clothing impregnated with an insect-repellent. The best repellents against ticks and mites are indalone, diethyltoluamide and benzyl benzoate. Further, persons working in tick-infested areas should be trained to examine themselves for ticks both during the lunch hour and at the end of work and to remove promptly any ticks found on their person. This is achieved by painting the tick with petrol paraffin or a camel-hair brush with which the dead tick can be brushed off the skin *(25)*. It may be necessary to extract the head gently with forceps and in that event care should be taken not to break the mouth parts.

ITCH MITE

The discovery in 1687 of the itch mite marks scabies as the first disease of man with known cause *(26)*. The itch mite (*Sarcoptes scabiei* or *Acarus scabiei*) is an extremely small, globular arthropod just visible to the naked eye. The female parasite burrows into the epidermis where it breeds and causes the condition known as scabies or itch. Species of the genus *sarcoptes* also infest animals such as dog, cattle and horse. The human acarus is morphologically indistinguishable from the animal variety but it is quite distinct physiologically. Therefore, animal scabies cannot flourish on the human skin.

General description

The itch mite is just visible to the naked eye, measuring 0.4 mm in size and has a body shaped like a tortoise, rounded above and flattened below. The body shows no demarcation into cephalothorax or abdomen. The body surface is thrown into folds and is covered with short bristles. The parasite has two pairs of legs in front, and two pairs behind. The front legs end in long tubular processes known as suckers and the hind legs end in long bristles. The male has suckers on all the legs excepting the third pair, which distinguishes it from female (Fig. 15).

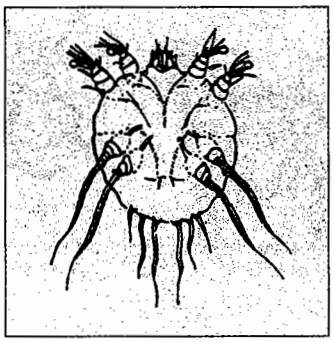

Fig. 15
Itch mite

Life history

There are four stages in the life history of an itch mite : egg, larva, nymph and adult. (1) EGG : The female burrows within the stratum corneum, and lays eggs in the burrow. A single female may lay up to 30 eggs at the rate of 2 to 3 per day, and ultimately dies at the end of the burrow. The eggs hatch into larvae in 3 to 4 days. (2) LARVA : The larvae are three–legged. They leave the burrows, come to the surface and bore into the hair follicles where vesicles form. The larvae mature into nymphs in about 3 days. (3) NYMPH : The nymphs develop into adults in 6 to 8 days. (4) ADULT : The life cycle from egg to adult may take 10 to 15 days. The adult mites live for 1 to 2 months.

Mode of spread

(1) CLOSE CONTACT : Scabies is usually transmitted by close contact with an infested person. This is often due to sleeping in the same bed or by children playing with each other or nursing an infested person. Because of close contact, the disease tends to spread through families. Scabies is therefore called a familial or household infection. (2) CONTAMINATED CLOTHES : the disease may be acquired sometimes from contaminated clothes and bed linen.

Site of lesions

The disease classically affects the hands and wrist (63%), The extensor aspect of elbows being next (10.9%). The axillae, buttocks, lower abdomen, feet and ankles, palms in infants are all common sites of infestation. The disease also affects the breasts in women and the genitals in men.

Diagnosis of scabies

The main diagnostic features of scabies are : (1) the patient complains of itching which is worse at night, (2) examination reveals follicular lesions at the affected site, (3) secondary infection leads to crusted papules and pustules, (4) the diagnosis is probable if the other members of the household are affected, (5) confirmation of the diagnosis may be made by searching for the parasite in the skin debris under microscope.

Control of scabies

In the control of scabies, it is essential to treat all members of the affected household simultaneously whether or not they appear to be infested. Before commencing the treatment the patient is given a good scrub with soap and hot water. (1) BENZYL BENZOATE : Benzyl benzoate (25 per cent) is an effective sarcopticide. It should be applied with a paint brush or shaving brush to every inch of the body below the chin including the soles of the feet and allowed to dry. In the case of babies, the head must also be treated, The application should be repeated after 12 hours, and after a further 12 hours a bath given and all underclothes, clothes and sheets changed and washed. Not more than two applications of benzyl benzoate should be given per week as excessive use can cause an irritant dermatitis *(27)*. (2) HCH : 0.5 to 1.0 per cent strength of gamma-HCH (lindane) in coconut oil or any vegetable oil or vanishing cream is an efficient sarcopticide. The preparation should be rubbed on the affected parts of the skin on one or two occasions separated by an interval of 2 to 3 days. (3) TETMOSOL : A 5 per cent solution of tetmosol is also an efficient sarcopticide, three daily applications are recommended (4) SULPHUR OINTMENT : 2.5 to 10 per cent daily for 4 days is a cheap remedy.

CYCLOPS

Cyclops or water flea is a crustacean present in most collections of fresh water. It is a tiny arthropod, not more than 1 mm in length and just visible to the trained eye. It has a pear–shaped semi-transparent body, a forked tail, 2 pairs of antennae, 5 pairs of legs and a small pigmented eye (Fig. 16). It swims in water with characteristic jerky movements. The average life of a cyclops is about 3 months.

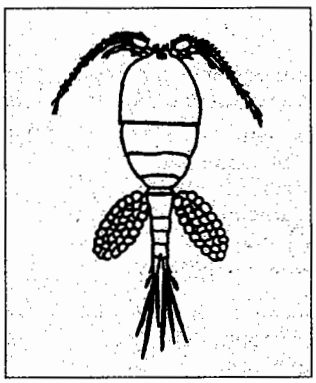

FIG. 16
Cyclops

Public health importance

(1) Cyclops is the intermediate host of Dracunculiasis or guinea-worm disease. Man acquires infestation by drinking water containing infected cyclops.

(2) Cyclops mediates also as one of the intermediate hosts of fish tape worm, *Diphyllobothrium latum* infestation. The disease is rare in India.

Control of cyclops

Cyclops may be controlled by the use of physical, chemical or biological methods *(29)*. (1) PHYSICAL : (a) *Straining :* Straining of water through a piece of fine cloth is sufficient to remove cyclops. (b) *Boiling :* Cyclops is readily killed by heat at 60°C. The physical methods are useful for individual prophylaxis. (2) CHEMICAL : (a) *Chlorine :* Chlorine destroys

cyclops and larvae of guinea worm in a strength of 5 ppm. This high concentration of chlorine gives an objectionable smell and taste to drinking water. The excess chlorine needs to be removed by dechlorinating agents *(21)*. (b) *Lime :* Lime at a dosage of 4 gram per gallon of water is found to be very efficient for killing cyclops. (c) *Abate :* The organophosphorus insecticide, *Abate* (OMS – 786) has been found effective in killing cyclops at a concentration of 1 mg/litre *(30)*. This indicates that Abate is potentially useful in the chemical control of the guinea-worm infection. (3) BIOLOGICAL : Certain kinds of small fish, e.g., barbel fish and gambusia fish have been found to feed on cyclops. These fish were used successfully in eradicating guinea-worm in parts of Karnataka State *(31)*. The most satisfactory and permanent method of controlling cyclops in drinking water is to provide piped water supply or tube wells. Abolition of step wells and provision of sanitary wells should receive attention in rural areas.

INSECTICIDES

Insecticides are substances which are used to kill insects. The word pesticide is a general term that includes insecticides, fungicides rodenticides, herbicides, disinfectants, repellents, and other chemicals used for the control of pests. The control of arthropod borne diseases by insecticides is one of the greatest triumphs of public health during the 20th century. Insecticides have not only controlled malaria, plague, typhus and other diseases transmitted by insects, but also brought vast economic and social benefits through better health and increased food production.

Insecticides are classified into three groups : contact poisons, stomach poisons and fumigants. CONTACT POISONS are those which kill insects primarily by contact e.g., pyrethrum, DDT, HCH, dieldrin. STOMACH POISONS are those which when ingested cause the death of the insects, e.g., paris green, sodium fluoride. FUMIGANTS are those which give off vapours which have a lethal effect on the insects, e.g., sulphur dioxide. This classification is by no means a rigid one, because a contact poison can also be a stomach poison.

Most of the present-day insecticides available for vector control (excluding inorganic chemicals and larvicidal oils) may be classified conveniently into 3 groups *(10)* :

Group I – *Organochlorine compounds :* DDT, HCH, dieldrin, chlordane, methoxychlor, etc.
Group II – *Organophosphorous compounds :* malathion, fenthion, chlorpyrifos, abate, etc.
Group III – *Carbamates :* Propoxur, carbaryl.

A detailed list of insecticides in public health use is given in Fig. 17. The problem of insecticide resistance and environmental contamination has restricted the use of many insecticides. A brief description of the insecticides in current use is given below :

1. DDT

DDT (Dichloro–diphenyl–trichloroethane) was first synthesized in 1874, by a German chemist, Ziedler. It was in 1939, its insecticidal properties were discovered by the Swiss scientist, Paul Muller. (a) PROPERTIES : DDT is a white

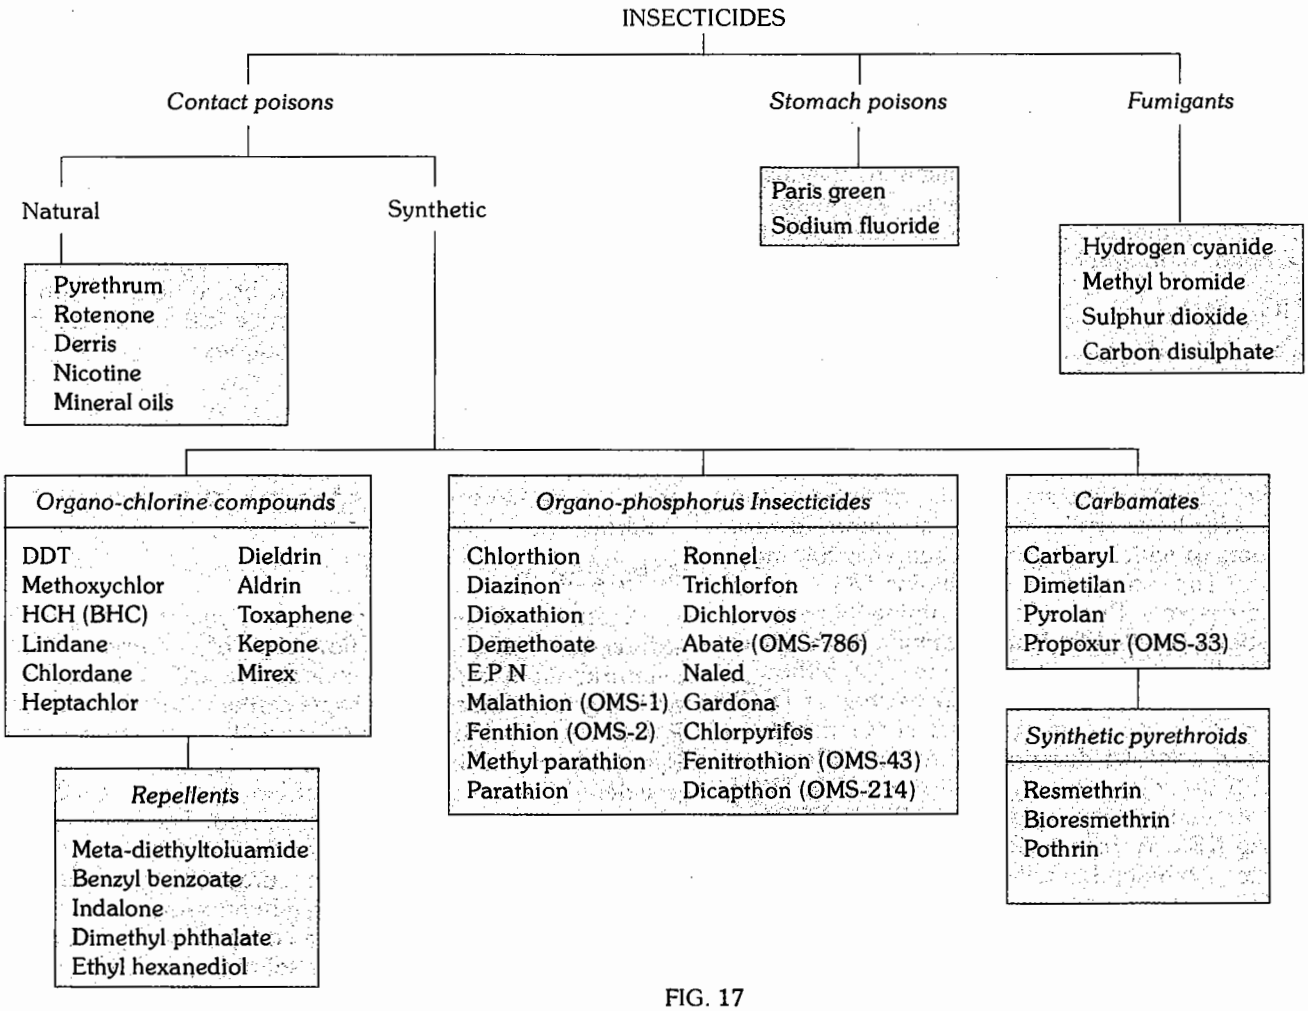

FIG. 17
Chemical control of arthropods of public health importance

amorphous powder with a mild, but not unpleasant smell. It is insoluble in water but dissolves in most organic solvents. The 'technical' DDT contains 70–80 per cent of the *para–para isomer,* which is the most active fraction of DDT. (b) ACTION : DDT is primarily a contact poison. It acts on the nervous system of insects. It permeates into the insect body through the cuticle, after dissolving in the waxy covering of the feet, and causes paralysis of legs and wings, convulsions and finally death. DDT does not cause immediate death, but it takes several hours to kill. The residual action of DDT may last as long as 18 months depending upon the treated surface. On mud walls, the prolonged action however, is decreased by absorption. DDT has no repellent action on insects. (c) APPLICATION : As a residual spray, DDT is applied at a dosage of 100–200 mg. per square foot area. The formulation of choice is a 5 per cent suspension of DDT, which when sprayed at a rate of 1 gallon over an area of 1,000 sq. feet, gives a dosage of 200 mg. per sq. ft. As a dust, DDT is used in 5 to 10 per cent strength for the control of lice, fleas, ticks and bugs. In aerosol or space sprays, DDT is one of the main constituents. DDT is still one of the most widely used insecticides.

In recent years DDT has earned the reputation of being an "environmental pollutant". Its persistence in the living organisms and plants and also its adverse effects on certain species of wild animals have led to the controversy on its use. Many developed countries (e.g., U.K., Sweden, Norway) have restricted the use of DDT because of its potential danger to ecosystems of wild life in the environment. But the benefits from the application of DDT in health programmes far outweigh the hazards. It has been responsible for saving millions of lives throughout the world. No toxic effects have been reported in the past 20 years among 200,000 spraymen employed in malaria campaigns nor among the 600 to 1,000 million people living in repeatedly sprayed houses. A WHO Expert Committee pointed out that "there is no valid reason to discontinue the use of DDT, for application in houses, against malaria or other diseases because its safety for human use still remains unchallenged despite the tremendous amount of research" *(32)*.

2. HCH (BHC)

Benzene hexachloride or hexachlorocyclo–hexane or gammexane or hexidol was synthesized much earlier than DDT by Michael Faraday in 1825. Even its insecticidal activity was discovered before that of DDT – in the USA in 1933. (a) PROPERTIES : HCH is a white or chocolate coloured powder with a musty smell. It is irritating to the eyes, nose and skin. In its crude form, it is composed of a number of isomers of which the *gamma isomer* is the most active constituent. The *technical* HCH contains 13 to 16 per cent of the gamma isomer. Pure HCH containing 99 per cent of the gamma isomer is called *lindane* or *gamma HCH*. HCH is slightly volatile. It is more insecticidal than DDT, although its insecticidal action is not as prolonged as that of DDT. (b) ACTION : HCH kills insects by direct contact, but its residual action is of a shorter duration, up to 3 months or so as compared with the longer residual action of DDT. HCH kills insects by its vapour effect also. (c) APPLICATION : HCH is used like DDT. A dose of 25 to 50 mg of gamma-HCH per sq. ft. is recommended for residual treatment.

3. Malathion

Malathion has the least toxicity of all organophosphorous compounds. The technical product is a yellow or clear-brown liquid with an unpleasant smell. Commercially, water-dispersible powders are available. Malathion is used in doses of 100–200 mg. per sq. ft., every 3 months. Because of its low toxicity, malathion has been recommended as an alternative insecticide to DDT. As a low volume (ULV) spray, malathion has been widely used for killing adult mosquitoes to prevent or interrupt dengue–haemorrhagic fever, and mosquito-borne encephalitis epidemics *(9)*.

4. Abate

Abate (Temephos) is an organophosphorus compound. It is a brown viscous liquid, soluble in petroleum solvents. Because of its low toxicity, it has been extensively used in India for the control of *A.stephensi* in wells and in domestic water containers with good results at a dosage not greater than 1.0 ppm. Abate is less effective as adulticide *(9)*.

5. Diazinon

Diazinon is a liquid product. Being volatile, it kills insects not only by direct contact, but also by fumigant action. It has proved effective in the control of DDT– resistant insects. At a dosage of 60 to 100 mg per sq. foot, it has given satisfactory control of flies and mosquitoes. Diazinon is more toxic to man than malathion or fenthion.

6. Fenthion

Fenthion or baytex is a brown liquid smelling slightly of garlic. It is practically insoluble in water. Water dispersible powders are available containing 20 to 40 per cent fenthion. Fenthion is found to be as effective as DDT. The usual dosage for residual sprays is 100 mg./sq ft. As a larvicide, fenthion is reported to be very powerful. Granules containing 2 per cent fenthion have been used in anti-larval work. The WHO Filariasis Research unit in Rangoon found fenthion, applied at the rate of 1 ppm, highly effective in controlling the larvae of *C. fatigans*.

7. Dichlorovos

Dichlorovos or DDVP is highly volatile liquid insecticide, which kills insects by fumigant action. It has been successfully used for disinfecting aircraft. A special advantage of DDVP is that it can be combined with solid substances such as wax, which can be fashioned into tablets or bricks from which it slowly evaporates.

8. Propoxur

The new carbamate insecticide, propoxur has been recommended as a substitute for DDT in areas where the anophelines have developed resistance to both DDT and dieldrin.

9. Pyrethrum

Pyrethrum is an insecticide of vegetable origin. It is extracted from the flowers of *Chrysanthemum cinerariafolium,* a plant which is cultivated in Kashmir, Simla and Nilgiris in India. The flowers contain 4 active principles : Pyrethrins I and II, cinerins I and II – all nerve poisons. Pyrethrum extract is prepared by soaking 1/2 to 1 lb of dried, powdered flowers in 1 gallon of kerosene oil for 72 hours, when the active principles are extracted. The ready-to-spray solution contains up to 0.1 per cent of pyrethrins. Pyrethrum extract is an excellent space spray. It has been used extensively in the past for killing adult mosquitoes, and other insects. It kills instantly on mere contact. It is sprayed at the rate of 1/2 to 1 oz. of the spray solution per 1,000 cu. ft. of space. As a space spray, fine atomization of the spray solution is necessary and the doors and windows should be

kept closed for 1/2 hour after spraying. Pyrethrum suffers from the disadvantage that it does not possess the residual action of DDT and other synthetic insecticides.

10. Pyrethrum and DDT

Most space sprays contain pyrethrum and DDT or other synthetic insecticides, which are added for synergistic action. The standard reference aerosol recommended by the WHO consists of (a) pyrethrum extract (25% pyrethrins) – 1.6 per cent, and (b) DDT technical – 3 per cent to be dispersed at the rate of 10 g. per 1,000 cu. ft. of space in the treatment of aircraft. About one–third of this dosage, 3.3 g. per 1,000 cu. ft. may be used for routine treatment of dwellings.

11. Synthetic pyrethroids

Synthetic pyrethroids are now being developed to replace natural pyrethrins. Some of the newly developed synthetic pyrethroids have been found to be as much as 10 times as effective as naturally occurring pyrethrins. Among the synthetic pyrethroids developed so far, tetramethrin, resethrin, prothrin and proparthin seem to be the most promising ones *(33)*.

12. Rotenone

Rotenone is obtained from the roots of a plant, *Derris elliptica*. The roots are dried and powdered and then are blended to give a rotenone content between 4 to 5 per cent and used as insecticidal dust. An extract of rotenone may be made in organic solvents such as chloroform. Rotenone was once widely used in the control of lice, fleas, mites and ticks.

13. Mineral oils

Oils such as kerosene, crude oil, malariol have been extensively used to kill mosquito larvae and pupae. Oils suffocate and poison the aquatic stages of the mosquito. The killing power of oil is increased greatly by the addition of DDT, HCH and other chemicals. Oils are injurious to vegetation and fish when improperly used.

14. Paris green

Paris green or copper aceto-arsenite is an emerald green microcrystalline powder, practically insoluble in water but soluble in ammonia and concentrated acids. A good sample of paris green contains over 50 per cent of arsenious oxide. Paris green is a stomach poison. Till the advent of DDT, paris green was extensively used in the control of anopheline larvae, by spraying as a 2 per cent dust over breeding places once a week. The use of paris green was largely responsible for the eradication of *A. gambiae* from Brazil in 1940, and the near–eradication of the same species in Egypt in 1944.

INSECTICIDE RESISTANCE

The widespread use of synthetic insecticides has given rise to the serious problem of insecticide resistance practically all over the world. The magnitude of the problem can be appreciated from the fact that, whereas in 1946 resistance to insecticides was reported in only 2 species of insects of public health importance, in 1962, the number rose to 81 species and in 1980 to 134. Evidence has accumulated to show that resistance in many vectors has been caused as a side effect of agricultural pesticide usage.

Resistance has been defined by WHO (1957) as "the development of an ability in strain of insects to tolerate doses of toxicants which would prove lethal to the majority of individuals in normal population of the same species" *(34)*. Resistance is due to *biochemical* and *genetic* factors. In the former, the toxicant is converted into a non-toxicant form in the body of the insect by various enzymes; in the latter, resistance is transmitted through genes, single or multiple.

A knowledge of insecticide resistance is important from the point of view of proper selection of insecticides. Generally speaking, organo-chlorine insecticide resistance is divided into two groups : resistance to DDT and its analogues; and the other to HCH–dieldrin group of insecticides. Resistance to DDT amounts to resistance to a number of DDT analogues such as methoxychlor, but not to HCH–dieldrin group. Similarly resistance to HCH amounts to resistance to dieldrin but not to DDT. Many insects now have developed "double resistance", that is, resistance to the two groups of organochlorine insecticides. When an insect develops resistance to DDT and HCH, the only effective action that can be taken is to change over to organo-phosphorus and carbamate insecticides. The change to organo-phosphorus and carbamate compounds involves substantial increase in cost, as these are all costly insecticides. Furthermore, cases of resistance towards them have already appeared. There is cross resistance between most carbamates and most organo-phosphorus compounds. To sum up, the problem of insecticide resistance which is growing in magnitude, is no doubt, steadily diminishing the choice of effective insecticides for vector control.

TOXICITY OF INSECTICIDES

1. Organo-chlorine compounds

DDT and its chemical relations are all nerve poisons. They increase the nervous excitability, and cause tremors and convulsions. Of the three commonly used compounds namely DDT, HCH and dieldrin, DDT is the least toxic. The median lethal dose for the humans is about 250 mg per kg. of body weight. Gamma–HCH is about twice as toxic as DDT, and dieldrin is about 5 to 8 times as toxic as DDT. Dieldrin poisoning is met with more frequently than DDT or HCH poisoning : the reason is, dieldrin is absorbed through the skin whereas DDT and HCH are not absorbed through the skin in the solid state. TREATMENT : Poisoning with chlorinated hydrocarbons is treated with barbiturates, specially phenobarbitone. Stomach washouts are generally necessary, purgative may be useful but no oils or fats should be given.

2. Organophosphorus compounds and carbamates

These insecticides interfere with the mechanism of transmission of nerve impulses. They act by inhibiting cholinesterase, the enzyme which catalyses the degradation of acetyl choline in the synapse of striated muscle. Consequently there is accumulation of acetyl choline. The effects of poisoning are headache, giddiness, apprehension, restlessness, cold sweating, salivation, uncontrolled urination and defecation, unconsciousness and in extreme cases, ataxia and paralysis of respiratory centre. TREATMENT : Atropine is the specific antidote for poisoning by organo-phosphorus insecticides. It should be injected in doses of 1 to 2 mg intramuscularly and repeated if necessary at 30 minutes interval. Three more specific drugs are available at present – 2 PAM iodine, 2 PAM chloride, and P2S *(35)*. Atropine should be combined with one of these compounds. It is necessary that drugs be supplemented by other measures such as removal of the contaminated clothes, and washing of the exposed skin with soap and water.

Cases of poisoning due to organophosphorus compounds are on the increase in India. Those who are called upon to

render First Aid and/or treat cases of pesticide poisoning would do well to refer to "Instructions for Safe use of Pesticides" issued by the Plant Protection Advisor to Government of India, Faridabad, Haryana wherein specific antidotes for groups of pesticides are given. The passing of "Indian Insecticide Act" by Parliament with a view to regulating the manufacture, transport, distribution, sale and use of pesticides is a step in the right direction.

A summary of treatment of poisoning with insecticides may be found in the WHO Publication "Safe Use of Pesticides" Technical Report Series No. 513 on page 52.

RODENTS

Rats and mice are part of man's environment. Often their numbers exceed human population. A female rat can have 100 offsprings each year. By living in close proximity to man, they not only cause substantial economic loss by damaging buildings, consuming and contaminating foodstuffs (36%) and other commodities, but also act as sources or reservoirs of some important communicable diseases such as plague and typhus fever. It implies therefore, that destruction of rats and elimination of their habitat is an important environmental health measure.

Rodents may be classified into two distinct groups : domestic and wild. (1) DOMESTIC RODENTS : The rodents of chief public health concern are those that live in close association with man, namely the black rat (*Rattus rattus*) and the Norway rat (*R. norvegicus*) and the house mouse (*Mus musculus*). Rattus rattus is a domestic animal whose area of movement is usually restricted. It readily infests ships, and therefore its public health importance is considerable. *Rattus rattus* is also a good climber and infestation generally occurs in the roofs of houses, though in some places it does burrow. *R. norvegicus*, on the other hand is a semidomestic animal which frequents sewers, drains as well as houses. Characteristics which are easily ascertainable of *R. rattus* and *R. norvegicus* are illustrated in Fig. 1.

(2) WILD RODENTS : The common wild rodents in India are *Tatera indica, Bandicota bengalensis varius (Gunomys kok), B.indica, Millardia meltada, M. gleadowi* and *Mus booduga.* In India, *Tatera indica* has been found to be the natural reservoir of plague.

Rodents and disease *(36)*

A number of diseases are associated with rodents. Broadly these are : (1) *Bacterial :* plague, tularaemia, salmonellosis; (2) *Viral :* Lassa fever, haemorrhagic fever, encephalitis (3) *Rickettsial :* scrub typhus, murine typhus, rickettsial pox; (4) *Parasitic :* hymenolepis diminuata, leishmaniasis, amoebiasis, trichinosis, Chagas disease; and (5) *Others :* rat bite fever, leptospirosis, histoplasmosis, ring worm etc.

The mode of transmission may be directly through rat bite (e.g., rat bite fever); some through contamination of food or water (e.g., salmonellosis, leptospirosis) and some through rat fleas (e.g., plague and typhus).

Antirodent measures

1. *Sanitation measures :* Sound environmental sanitation is the most effective weapon in deratization campaign. Rats require three things : food, water and shelter. If these are denied, rats will naturally decrease in density. The environmental sanitation measures comprise : (1) proper storage, collection and disposal of garbage, (2) proper storage of food–stuffs, (3) construction of rat-proof buildings, godowns and warehouses, and (4) elimination of rat burrows by blocking them with concrete. Sanitation is therefore essential to the permanent control of rats and mice, and all measures should be regarded as supplementary to sanitation.

2. *Trapping :* Trapping of rats is a simple operation. But it causes temporary reduction in the number of commensal rodents. It is recommended that the number of traps laid should be at least 5 per cent of the human population. The 'wonder trap' developed by the Haffkine Institute, Mumbai is credited to trap as many as 25 rats at a time. The traps are

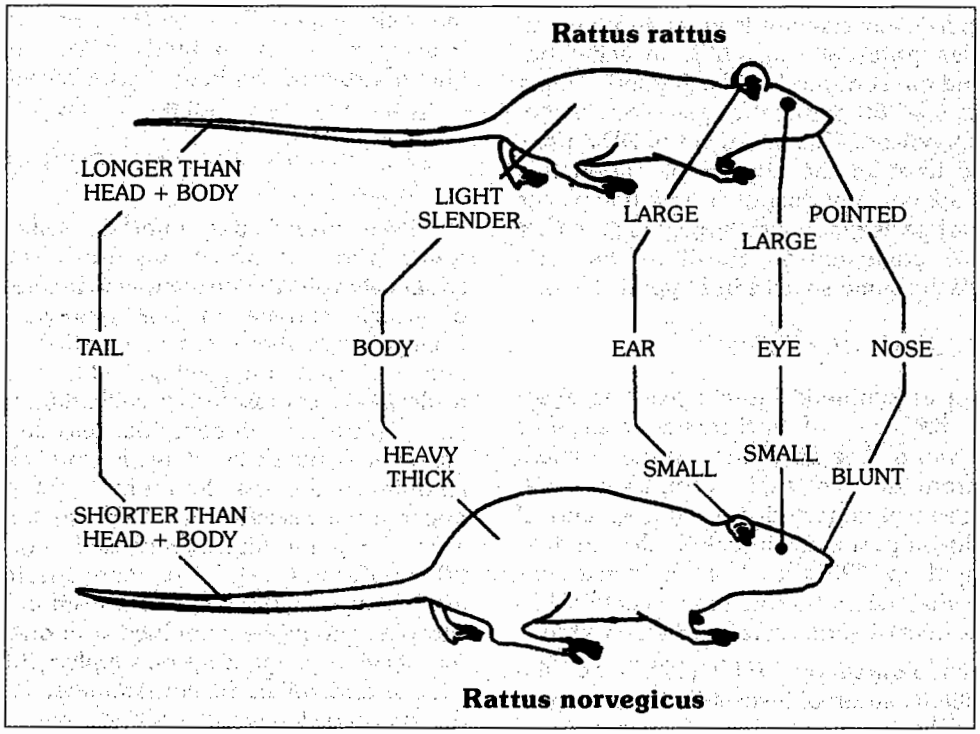

FIG. 1
Norway and roof rats

usually baited with indigenous foods of the locality. The captured rats must be destroyed which may be done by drowning them in water. Rats by nature are suspicious animals, and will soon become "trap-wise" and avoid baited traps. Trapping therefore should be considered supplementary to other methods of rodent control.

3. *Rodenticides :* Rodenticides are of two main types – single-dose (acute) and multiple-dose (cumulative). The former are lethal to the rat after a single feeding, while the latter require repeated feedings over a period of 3 more days *(17)*.

An Expert Committee of the WHO *(37)* grouped the "acute" rodenticides as below :

1. *Those requiring ordinary care*
   - Red squill
   - Norbromide
   - Zinc phosphide
2. *Those requiring maximal precaution*
   - Sodium fluorocetate
   - Fluoroacetamide
   - Strychnine
3. *Too dangerous for use*
   - Arsenic trioxide
   - Phosphorus
   - Thallium sulphate
   - ANTU
   - Gophacide.

The commonly used poisons in this country are : (i) *Barium carbonate :* This is a white tasteless powder, and is very cheap. It is mixed with wheat or rice flour in the ratio of 1 part to 4 parts of flour. The mixed material is moistened with water and made into small round marbles. The poisoned baits are placed near the rat burrows and in dark, secluded places. On eating the pills, rats are killed in 2 to 24 hours. Barium carbonate is a weak rodenticide of uneven performance, and probably easily detected by rats in many baits. In the opinion of many workers, in view of the availability of more efficient rodenticides, barium carbonate should not be used any more *(38)*. (ii) *Zinc phosphide :* Zinc phosphide is an efficient rodenticide. When moist, the chemical slowly gives off phosphine whose garlic odour is repellent to man and domestic animals, but seems to have no adverse effect on rats. Zinc phosphide is now extensively used in India. It is used in the ratio of 1 part to 10 parts of wheat or rice flour and mixed with a few drops of edible oil in order to render it more attractive to rats. Rats are killed in about three hours. The use of rubber gloves is recommended in handling zinc phosphide as it is highly poisonous. Special bait boxes have been designed for the administration of very toxic compounds such as zinc phosphide to eliminate the risk to man and domestic animals. Because of its good safety record, low cost and reasonably high effectiveness, Zinc phosphide is recommended for large scale use against rats *(38)*.

The *multiple-dose* (cumulative) poisons are : warfarin, diphacinone, coumafuryl and pindone *(17)*. As anticoagulants, they cause internal haemorrhage and slow death in 4 to 10 days. The continued use of anticoagulant rodenticides has led to the appearance of resistant Norway rat populations in several European countries. In some countries, the use of chronic rodenticides has been given up. All rodent poisons are toxic to mammals including man and call for the utmost care in their use.

(4) *Fumigation :* Fumigation is an effective method of destroying, both rats and rat fleas. The fumigants used in anti-rat campaigns are calcium cyanide (often called cyanogas or cymag), carbon disulphide, methyl bromide, sulphur dioxide, etc. Cyanogas has been extensively used in India for the fumigation of rat burrows. This chemical is prepared in powder form and is pumped into rat burrows by a special foot pump called the "Cyanogas pump" (Fig. 2). About 2 ounces of the poison are pumped into each rat burrow after closing the exit openings and the burrow is then promptly sealed with wet mud. On contact with moisture, the cynogas powder gives off hydrogen cyanide gas which is lethal to both rats and their fleas. Trained personnel are required to carry out fumigation because of its extreme danger to man and livestock. For the eradication of rats from ships, either cyanogas or sulphur dioxide is used.

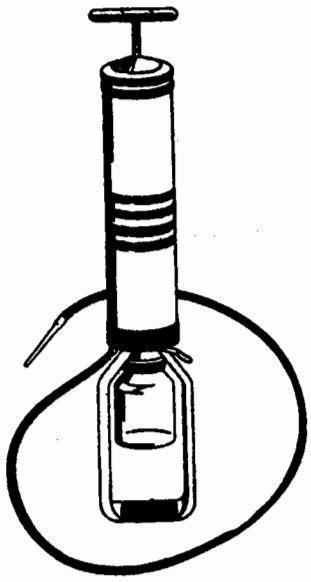

FIG. 2
Cyanogas foot pump

(5) *Chemosterilants :* A chemosterilant is a chemical that can cause temporary or permanent sterility in either sex or both sexes. Rodent chemosterilants are still in the experimental stage *(39)*.

ZOONOSES

Animals are part of man's biological environment. Some of them act as reservoir hosts of a number of diseases. The WHO records more than 150 diseases and infections of animals communicable to man *(40)* – these are termed "zoonoses". The Joint FAO/WHO Expert Committee (1967) defined zoonoses as "those diseases and infections which are naturally transmitted between vertebrate animals and man".

Zoonotic diseases may be due to viruses, bacteriae, rickettisiae, fungi, helminths, protozoa, arthropods or insects. The WHO (1967) classified zoonoses into different groups *(40)*. Some of the important zoonoses are as given in Table 1.

India has the largest animal population in the world which is nearly 11 per cent of the total world animal population. Being an agricultural country the relationship between man and animals is the closest in this country. It is not uncommon to see animals and human beings living under the same roof. The available information indicates that a large number of zoonotic infections (e.g., brucellosis, rabies, tuberculosis, leptospirosis, hydatid disease) occur in different parts of the country. Except for rabies, the prevalence of other diseases in human being is not well mapped out. The National Institute of Communicable Diseases, Delhi is making efforts to organize systematic and collaborative studies with other Institutions on different zoonotic infections. The WHO has a section of Veterinary Public Health in its Division of Communicable Diseases. The control of zoonoses is a challenge facing the veterinary public health today.

TABLE 1
Partial list of zoonoses

Disease in man	Animal principally involved
A. Bacterial infections	
Anthrax	Herbivores, pigs
Brucellosis	Cattle, sheep, goats, camels, pigs, dogs, horses, buffaloes
Ornithosis	Wild and domestic birds
Q fever	Cattle, sheep, goats, wild animals
Leptospirosis	Rodents, mammals
Tuberculosis	Cattle, sheep, goats, pigs, cats, dogs
Plague	Rodents
B. Viral infections	
Cowpox	Cattle
Monkeypox	Monkeys, rodents
Easternequine encephalitis	Horses, rodents
Ross river fever	Horses, cattle, goats, sheep, dogs, rats, bats, pigs
Yellow fever	Monkeys
Japanese encephalitis	Wild birds
Lassa fever	Multi-mammate rat
Rabies	Dog, fox, shunk, mongoose, bat and jackal
C. Protozoan infections	
Leishmaniasis	Dogs, cats, swine
Toxoplasmosis	Cats, mammals, birds
Trypanosomiasis	Game animals, cattle
Babesiosis	Cattle
D. Helminthic infections	
Clonorchiasis	Dogs, cats, swine, wild mammals, fish
Fasciolopsis	Swine, dogs
Schistosomiasis	Rodents
Echinococcosis	Dogs, wild carnivores, domestic and wild ungulates
Taeniasis	Cattle
Trichinellosis	Swine, rodents, wild carnivores, marine mammals

Source : *(41, 42)*

Control of zoonoses

The principal components of control are : (a) *Control in animals :* The measure comprise diagnosis of the zoonotic condition, treatment, destruction, quarantine and immunization. (b) *Control of vehicles of transmission :* These include establishment of food hygiene practices, ensuring safety of animal products such as wool, hides, horn, bones, fat, etc.; proper disposal of animal carcasses and wastes, and disinfection procedures. (c) *Prevention and treatment in man :* This involves protection of high risk groups, by immunization, chemoprophylaxis, monitoring of health status including occupational health programmes, prevention of spread by man, early diagnosis and treatment of the condition in man, health education, prevention of environmental contamination, prevention of food contamination, and improvement of diagnostic facilities *(42)*.

During the past 50 years, the concept of environment has become broad-based. Modern ecologists use the term in its widest sense. The concept of environment covers first the general environment, for instance water and air pollution, to which an individual is exposed. Secondly, it refers to the personal environment created by the individual himself – including such cultural habits as cigarette smoking, alcohol, drug addiction. This has been described as "chemical environment". The concept that the general everyday chemical environment could also be dangerous to human health developed slowly. Evidence is accumulating that environmental factors, especially factors in the chemical environment, play a major role in carcinogenesis, and that many cancers may be theoretically preventable *(43)*.

It is now current jargon to advocate an "integrated" approach to the environmental problems where all aspects of a given problem are looked at from all angles. It implies an unprecedented cooperation between different services and disciplines. The United Nations Environmental Programme (UNEP), UNESCO's Man and Biosphere (MAB) Programme, WHO's Environmental Health Criteria Programme, and the UN's International Drinking Water Supply and Sanitation Decade, 1981–1990 are efforts in the direction to promote health in the human environment.

13 Hospital Waste Management

Let the wastes of "the sick" not contaminate the lives of "the healthy"

The waste produced in the course of health-care activities carries a higher potential for infection and injury than any other type of waste. Therefore, it is essential to have safe and reliable method for its handling. Inadequate and inappropriate handling of health-care waste may have serious public health consequences and a significant impact on the environment. Appropriate management of health-care waste is thus a crucial component of environmental health protection, and it should become an integral feature of health-care services.

Definition

According to Bio-Medical Waste (Management and Handling) Rules, 1998 of India, "Bio-medical waste" means any waste, which is generated during the diagnosis, treatment or immunization of human-beings or animals, or in research activities pertaining thereto or in the production or testing of biologicals, and including categories as mentioned in schedule I in Table 4 *(1)*.

TABLE 1
Classification of health-care waste

Waste category	Description and examples
Infectious waste	Waste suspected to contain pathogens e.g. laboratory cultures; waste from isolation wards; tissues (swabs), materials, or equipments that have been in contact with infected patients; excreta.
Pathological waste	Human tissues or fluids e.g. body parts; blood and other body fluids; fetuses.
Sharps	Sharp waste e.g. needles; infusion sets; scalpels; knives; blades; broken glass.
Pharmaceutical waste	Waste containing pharmaceuticals e.g. pharmaceuticals that are expired or no longer needed; items contaminated by or containing pharmaceuticals (bottles, boxes).
Genotoxic waste	Waste containing substances with genotoxic properties e.g. waste containing cytostatic drugs (often used in cancer therapy); genotoxic chemicals.
Chemical waste	Waste containing chemical substances e.g. laboratory reagents; film developer; disinfectants that are expired or no longer needed; solvents.
Wastes with high content of heavy metals	Batteries; broken thermometers; blood–pressure gauges; etc.
Pressurized containers	Gas cylinders; gas cartridges. aerosol cans.
Radioactive waste	Waste containing radioactive substances e.g. unused liquids from radiotherapy or laboratory research; contaminated glassware, packages, or absorbent paper; urine and excreta from patients treated or tested with unsealed radionucleides; sealed sources.

Source : *(2)*

Between 75 to 90 per cent of the waste produced by the health-care providers is non-risk or "general" health-care waste, comparable to domestic waste. It comes mostly from administrative and house keeping functions of the health-care establishments, and may also include waste generated during maintenance of health-care premises. The remaining 10–25 per cent health-care waste is regarded as hazardous and may create a variety of health risk *(2)*. The classification of health-care waste is summarized in Table 1.

Sources of health-care waste

The institutions involved in generation of bio-medical waste are :

- Government hospitals.
- Private hospitals.
- Nursing homes.
- Physician's office/clinics.
- Dentist's office/clinics.
- Dispensaries.
- Primary health centres.
- Medical research and training establishments.
- Mortuaries.
- Blood banks and collection centres.
- Animal houses.
- Slaughter houses.
- Laboratories.
- Research organizations.
- Vaccinating centres, and
- Bio-technology institutions/production units.

All these health-care establishments generate waste and are therefore, covered under Bio-Medical Waste (BMW) Rules *(1)*.

Health-care waste generation

Several surveys have provided an indication of typical health-care waste generation, and it shows that this differs not only from country to country but also within the country. Waste generation depends on numerous factors such as established waste management methods, type of health-care establishment, hospital specializations, proportion of reusable items employed in health-care, and proportion of patients treated on a day-care basis.

In middle and low income countries, health-care waste generated is lower than in high-income countries. Developing countries that have not performed their own

surveys of health-care waste, find the following estimates for an average distribution of health-care wastes useful for preliminary planning of waste management *(2)*.

- 80 per cent general health-care waste, which may be dealt with by the normal domestic, and urban waste management system;
- 15 per cent pathological and infectious waste;
- 1 per cent sharps waste;
- 3 per cent chemical and pharmacological waste;
- Less than 1 per cent special waste, such as radio-active or cytotoxic waste, pressurized containers, or broken thermometers and used batteries.

Table 2 shows average composition of waste obtained from 10 large hospitals in Mumbai, Kolkata, Delhi, and Nagpur during the period 1993–1996.

TABLE 2

Average composition of hospital waste in India

Material	Percentage (wet-weight basis)
Paper	15
Plastics	10
Rags	15
Metal (sharps etc.)	1
Infectious waste	1.5
Glass	4.0
General waste (food waste, sweepings from hospital premises etc.)	53.5

Source : (National Environmental Engineering Research Institute 1997)

A survey done in Bangalore revealed that the quantity of solid wastes generated in hospitals and nursing homes generally varies from 1/2 to 4 kg per bed per day in Govt. hospitals, 1/2 to 2 kg per bed per day in private hospitals, and 1/2 to 1 kg per bed per day in nursing homes. The total quantity of hospital wastes generated in Bangalore is about 40 tonnes per day. Out of this nearly 45 to 50 per cent is infectious. Segregation of infectious wastes from non-infectious wastes is done only in about 30 per cent of hospitals *(3)*.

Health hazards of health-care waste

Exposure to hazardous health-care waste can result in disease or injury due to one or more of the following characteristics :

(a) it contains infectious agents; (b) it contains toxic or hazardous chemicals or pharmaceuticals; (c) it contains sharps; (d) it is genotoxic; and (e) it is radio-active.

All individuals exposed to such hazardous health-care waste are potentially at risk, including those who generate the waste or those who either handle such waste or are exposed to it as a consequence of careless management. The main groups at risk are :

- medical doctors, nurses, health-care auxilliaries, and hospital maintenance personnel;
- patients in health-care establishments;
- visitors to health-care establishments;
- workers in support service allied to health-care establishments such as laundries, waste handling and transportation; and
- workers in waste disposal facilities such as land-fills or incinerators including scavengers.

1. Hazards from infectious waste and sharps

Pathogens in infectious waste may enter the human body through a puncture, abrasion or cut in the skin, through mucous membranes by inhalation or by ingestion. There is particular concern about infection with HIV and hepatitis virus B and C, for which there is a strong evidence of transmission *via* health-care waste. Bacterias resistant to antibiotics and chemical disinfectants, may also contribute to the hazards created by poorly managed waste.

2. Hazards from chemical and pharmaceutical waste

Many of the chemicals and pharmaceuticals used in health-care establishments are toxic, genotoxic, corrosive, flammable, reactive, explosive or shock-sensitive. Although present in small quantity they may cause intoxication, either by acute or chronic exposure, and injuries, including burns. Disinfectants are particularly important members of this group. They are used in large quantities and are often corrosive, reactive chemicals may form highly toxic secondary compounds.

3. Hazards from genotoxic waste

The severity of the hazards for health-care worker responsible for handling or disposal of genotoxic waste is governed by a combination of the substance toxicity itself and the extent and duration of exposure. Exposure may also occur during the preparation of or treatment with particular drug or chemical. The main pathway of exposure is inhalation of dust or aerosols, absorption through the skin, ingestion of food accidentally contaminated with cytotoxic drugs, chemicals or wastes etc.

4. Hazards from radio-active waste

The type of disease caused by radio-active waste is determined by the type and extent of exposure. It can range from headache, dizziness and vomiting to much more serious problems. Because it is genotoxic, it may also affect genetic material.

5. Public sensitivity

Apart from health hazards, the general public is very sensitive to visual impact of health-care waste particularly anatomical waste.

Treatment and disposal technologies for health-care waste *(2)*

Incineration, used to be the method of choice for most hazardous health-care wastes, and is still widely used. However, recently developed alternative treatment methods are becoming increasingly popular. The final choice of treatment should be made on the basis of factors, many of which depend on local conditions.

I. Incineration

Incineration is a high temperature dry oxidation process, that reduces organic and combustible waste to inorganic incombustible matter and results in a very significant reduction of waste-volume and weight. The process is usually selected to treat wastes that cannot be recycled, reused or disposed off in a land fill site.

The flow diagram of incinerator is as shown in Fig. 1.

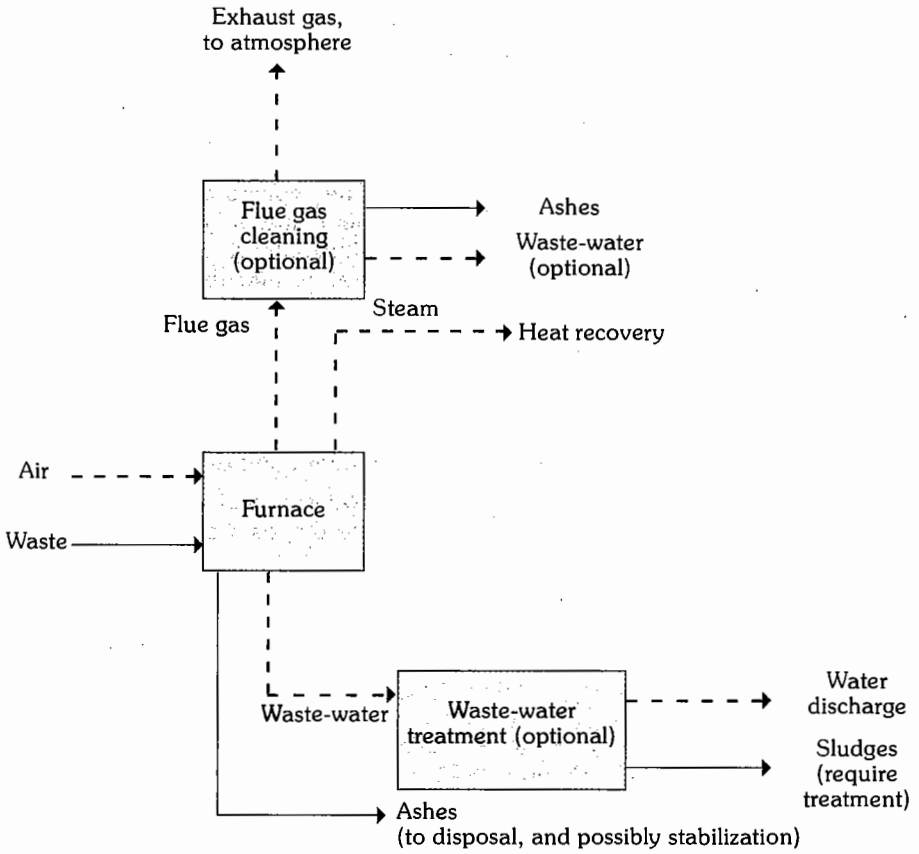

FIG. 1
Simplified flow scheme of incinerator

Source : *(2)*

Incineration requires no pre-treatment, provided that certain waste types are not included in the matter to be incinerated. Characteristics of the waste suitable for incineration are : (a) low heating volume – above 2,000 kcal/kg for single–chamber incinerators, and above 3,500 kcal/kg for pryolytic double-chamber incinerators; (b) content of combustible matter above 60 per cent; (c) content of non-combustible solids below 5 per cent; (d) content of non-combustible fines below 20 per cent; and (e) moisture content below 30 per cent *(2)*.

Waste types not to be incinerated are : (a) pressurized gas containers; (b) large amount of reactive chemical wastes; (c) silver salts and photographic or radiographic wastes; (d) Halogenated plastics such as PVC; (e) waste with high mercury or cadmium content, such as broken thermometers, used batteries, and lead-lined wooden panels; and (f) sealed ampules or ampules containing heavy metals *(2)*.

TYPES OF INCINERATORS

Incinerators can range from very basic combustion unit that operates at much lower temperature to extremely sophisticated, high temperature operating plants. It should be carefully chosen on the basis of the available resources, the local situation, and the risk-benefit consideration.

Three basic kinds of incineration technology are of interest for treating health-care waste :

(a) Double-chamber pyrolytic incinerators which may be especially designed to burn infectious health-care waste; (b) Single-chamber furnaces with static grate, which should be used only if pyrolytic incinerators are not affordable; and (c) Rotary kilns operating at high temperatures, capable of causing decomposition of genotoxic substances and heat-resistant chemicals.

II. **Chemical disinfection**

Chemicals are added to waste to kill or inactivate the pathogens it contains, this treatment usually results in disinfection rather than sterilization. Chemical disinfection is most suitable for treating liquid waste such as blood, urine, stools or hospital sewage. However, solid wastes including microbiological cultures, sharps etc. may also be disinfected chemically with certain limitations.

III. **Wet and dry thermal treatment**

WET THERMAL TREATMENT : Wet thermal treatment or steam disinfection is based on exposure of shredded infectious waste to high temperature, high pressure steam, and is similar to the autoclave sterilization process. The process is inappropriate for the treatment of anatomical waste and animal carcassess, and will not efficiently treat chemical and pharmaceutical waste.

SCREW-FEED TECHNOLOGY : Screw-feed technology is the basis of a non–burn, dry thermal disinfection process in which waste is shredded and heated in a rotating auger. The waste is reduced by 80 per cent in volume and by 20–35 per cent in weight. This process is suitable for treating infectious waste and sharps, but it should not be used to process pathological, cytotoxic or radio-active waste.

IV. **Microwave irradiation**

Most microorganisms are destroyed by the action of

microwave of a frequency of about 2450 MHz and a wave length of 12.24 nm. The water contained within the waste is rapidly heated by the microwaves and the infectious components are destroyed by heat conduction. The efficiency of the microwave disinfection should be checked routinely through bacteriological and virological tests.

V. **Land disposal**

MUNICIPAL DISPOSAL SITES : If a municipality or medical authority genuinely lacks the means to treat waste before disposal, the use of a landfill has to be regarded as an acceptable disposal route. There are two types of disposal land–open dumps and sanitary landfills. Health-care waste should not be deposited on or around open dumps. The risk of either people or animals coming into contact with infectious pathogens is obvious.

Sanitary landfills are designed to have at least four advantages over open dumps : geological isolation of waste from the environment, appropriate engineering preparation before the site is ready to accept waste, staff present on site to control operations, and organized deposit and daily coverage of waste.

VI. **Inertization**

The process of "inertization" involves mixing waste with cement and other substances before disposal, in order to minimize the risk of toxic substances contained in the wastes migrating into the surface water or ground water. A typical proportion of the mixture is: 65 per cent pharmaceutical waste, 15 per cent lime, 15 per cent cement and 5 per cent water. A homogeneous mass is formed and cubes or pellets are produced on site and then transported to suitable storage sites.

The main advantages and disadvantages of various treatment and disposal options are listed in Table 3.

National legislation is the basis for improving health-care waste disposal practices in any country. It establishes legal

TABLE 3

Main advantages and disadvantages of treatment and disposal options

Treatment / disposal method	Advantages	Disadvantages
Rotary kiln	Adequate for all infectious waste, most chemical waste and pharmaceutical waste.	High investment and operating costs.
Pyrolytic incineration	Very high disinfection efficiency. Adequate for all infectious waste and most pharmaceutical and chemical waste.	Incomplete destruction of cytotoxics. Relatively high investment and operating costs.
Single-chamber incineration	Good disinfection efficiency. Drastic reduction of weight and volume of waste. The residues may be disposed off in landfills. No need for highly trained operators. Relatively low investment and operating costs.	Significant emissions of atmospheric pollutants. Need for periodic removal of slag and soot. Inefficiency in destroying thermally resistant chemicals and drugs such as cytotoxics.
Drum or brick incinerator	Drastic reduction of weight and volume of the waste. Very low investment and operating costs.	Destroys only 99% of microorganisms. No destruction of many chemicals and pharmaceuticals. Massive emission of black smoke, fly ash, toxic flue gas, and odours.
Chemical disinfection	Highly efficient disinfection under good operating conditions.	Requires highly qualified technicians for operation of the process.
	Some chemical disinfectants are relatively inexpensive.	Uses hazardous substances that require comprehensive safety measures.
		Inadequate for pharmaceutical, chemical and some types of infectious waste.
Wet thermal treatment*	Environmentally sound.	Shredders are subject to frequent breakdowns and poor functioning.
	Relatively low investment and operating costs.	Operation requires qualified technicians.
		Inadequate for anatomical, pharmaceutical, chemical waste and waste that is not readily steam-permeable.
Mircowave irradiation	Good disinfection efficiency under appropriate operating conditions.	Relatively high investment and operating costs.
	Drastic reduction in waste volume. Environmentally sound.	Potential operation and maintenance problems.
Encapsulation	Simple, low-cost, and safe. May also be applied to pharmaceuticals.	Not recommended for non-sharp infectious waste.
Safe burying	Low costs. Relatively safe if access to site is restricted and where natural infiltration is limited.	Safe only if access to site is limited and certain precautions are taken.
Inertization	Relatively inexpensive.	Not applicable to infectious waste.

* May not apply to more sophisticated, self-contained, commercial methods.

Source : *(2)*

control, and permits the national agency responsible for the disposal of health-care waste, usually the Ministry of Health, to apply pressure for their implementation. The Ministry of Environment may also be involved. There should be a clear designation of responsibilities before the law is enacted.

The United Nations Conference on the Environment and Development (UNCED) in 1992 recommended the following measures :

(a) Prevent and minimize waste production
(b) Reuse or recycle the waste to the extent possible
(c) Treat waste by safe and environmentally sound methods, and
(d) Dispose off the final residue by landfill in confined and carefully designed sites.

Bio-Medical Waste Management in India *(1, 4, 5)*

Bio-Medical Waste (Management and Handling) Rule 1998, prescribed by the Ministry of Environment and Forests, Government of India, came into force on 28th July 1998. This rule applies to those who generate, collect, receive, store, dispose, treat or handle bio-medical waste in any manner. Table 4 shows the categories of bio-medical waste, types of waste and treatment and disposal options under Rule 1998.

The bio-medical waste should be segregated into containers/bags at the point of generation of the waste. The colour coding and the type of containers used for disposal of waste are as shown in Table 5. Fig. 2 shows the label for bio-hazards symbol and cytotoxic hazard symbol which should be prominently visible and non-washable.

TABLE 4

Schedule I
Categories of bio-medical waste in India

Option	Waste category	Treatment and disposal
Category No. 1	Human anatomical waste (human tissues, organs, body parts).	incineration[2] / deep burial.
Category No. 2	Animal waste (animal tissues, organs, body parts carcasses, bleeding parts, fluids, blood and experimental animals used in research, waste generated by veterinary hospitals colleges, discharge from hospital, animal house).	incineration[2] / deep burial.
Category No. 3	Microbiology and bio-technology waste (waste from laboratory cultures, stocks or specimens of micro-organisms, live or attenuated vaccines, human and animal cell culture used in research and infectious agents from research and industrial laboratories, waste from production of biologicals, toxins, dishes and devices and for transfer of cultures).	local autoclaving / microwaving / incineration[2].
Category No. 4	Waste sharps (needles, syringes, scalpels, blades, glass, etc. that may cause puncture and cuts. This includes both used and unused sharps).	disinfection (chemical treatment@/ autoclaving/ microwaving and mutilation shredding).
Category No. 5	Discarded medicines and cytotoxic drugs (wastes comprising of outdated, contaminated and discarded medicines).	incineration@ destruction and drugs disposal in secured landfills.
Category No. 6	Solid waste (Items contaminated with blood, and fluids including cotton, dressings, soiled plaster casts, linen, beddings, other material contaminated with blood).	incineration@ autoclaving / microwaving.
Category No. 7	Solid waste (wastes generated from disposable items other than the waste sharps such as tubings, catheters, intravenous sets etc.).	disinfection by chemical treatment@@ autoclaving/ microwaving and mutilation / shredding ##.
Category No. 8	Liquid waste (waste generated from laboratory and washing, cleaning, house-keeping and disinfecting activities).	disinfection by chemical treatment @@ and discharge into drains.
Category No. 9	Incineration ash (ash from incineration of any bio-medical waste).	disposal in municipal landfill.
Category No. 10	Chemicals used in production of biologicals, chemicals used in disinfection, as insecticides, etc.	chemical treatment@@ and discharge into drains for liquids and secured landfill for solids.

@ @ Chemical treatment using at least 1% hypochlorine solution or any other equipment chemical reagent. It must be ensured that chemical treatment ensures disinfection.
Mutilation / shredding must be such so as to prevent unauthorized reuse.
@ There will be no chemical pre-treatment before incineration. Chlorinated plastics shall not be incinerated.
[2] Deep burial shall be an option available only in towns with population less than five lakhs and in rural areas.

TABLE 5

Schedule II

Colour coding and type of container for disposal of bio-medical wastes

Colour coding	Type of container	Waste category	Treatment options as per Schedule I
Yellow	Plastic bag	Cat. 1, Cat. 2, and Cat. 3, Cat. 6	Incineration/deep burial
Red	Disinfected container/ plastic bag	Cat. 3, Cat. 6, Cat. 7	Autoclaving/Microwaving/Chemical treatment
Blue / white translucent	Plastic bag/puncture proof container	Cat. 4, Cat. 7.	Autoclaving/Microwaving/Chemical treatment and Destruction/Shredding
Black	Plastic bag	Cat. 5 and Cat. 9 and Cat. 10 (solid)	Disposal in secured landfill

Notes :

1. Colour coding of waste categories with multiple treatment options as defined in Schedule I, shall be selected depending on the treatment option chosen, which shall be as specified in Schedule I.
2. Waste collection bags for waste types needing incineration shall not be made of chlorinated plastics.
3. Categories 8 and 10 (liquid) do not require containers/bags.
4. Category 3 if disinfected locally need not be in containers/bags.

Bio-hazard Symbol

Bio-hazard

Cytotoxic Hazard Symbol

14 Disaster Management

A stitch in time, saves nine

A *"disaster"* can be *defined* as "any occurrence that causes damage, ecological disruption, loss of human life or deterioration of health and health services on a scale sufficient to warrant an extraordinary response from outside the affected community or area" *(1)*.

A *"hazard"* can be defined as any phenomenon that has the potential to cause disruption or damage to people and their environment *(2)*.

Emergencies and disasters do not only affect health and well-being of people; frequently, large number of people are displaced, killed or injured, or subjected to greater risk of epidemics. Considerable economic harm is also common. Disasters cause great harm to the existing infrastructure and threaten the future of sustainable development.

Disasters are not confined to a particular part of the world ; they can occur any where and at any time. Major emergencies and disasters have occurred throughout history and as the world's population grows and resources become more limited, communities are increasingly becoming vulnerable to the hazards that cause disaster. Statistics gathered since 1969 show a rise in the number of people affected by disasters. Since there is little evidence that the actual events causing disasters are increasing in either intensity or frequency, it can only be concluded that vulnerability to disaster is growing. For each disaster listed in officially recognized disaster database, there are some 20 other smaller emergencies with destructive impact on local communities that are unacknowledged.

There are many types of disasters such as earthquakes, cyclones, floods, tidal waves, land-slides, volcanic eruptions, tornadoes, fires, hurricanes, snow storms, severe air pollution (smog), heat waves, famines, epidemics, building collapse, toxicologic accidents (e.g. release of hazardous substances), nuclear accidents and warfare etc. Warfare is a special category, because damage is the intended goal of action. Every catastrophic event has its own special features. Some can be predicted several hours or days before-hand, as in the case of cyclones or floods, others such as earthquakes occur without warning.

The relative number of injuries and deaths differ, depending on a number of factors such as the type of disaster, the density and distribution of the population, condition of the environment, degree of the preparedness and opportunity of the warning. Injuries usually exceed death in explosions, earthquakes, typhoons, hurricanes, fires, tornadoes etc. Death frequently exceeds injuries in landslides, avalanches, volcanic eruptions, tidal waves, floods etc. *(3)*.

The types of emergency vary according to the kind of disaster, and how and when it strikes. In *earthquakes*, there is a high level of mortality, as a result of people being crushed by falling objects. The risk is greater inside or near dwellings but is very small in the open. Consequently earthquakes at night are more deadly. During the night fractures of pelvis, thorax and spine are common, because earthquake strikes while people are lying in bed. In the daytime injuries to the arms and skull are common. In *volcanic eruptions* mortality is high in the case of mudslides (e.g., 23,000 deaths in Colombia in 1985) and glowing clouds (e.g., 30,000 deaths at Saint – pierre in Martinique). There may be injuries, burns and suffocation. In *floods*, mortality is high only in case of sudden flooding e.g., flash floods, collapse of dams or tidal waves. Fractures, injuries and bruises may occur. If weather is cold, cases of accidental hypothermia may occur. In *cyclones* and *hurricanes*, mortality is not high unless tidal waves occur. The combined, effect of wind and rain may cause houses to collapse. A large number of objects may be lifted in the air and carried along by the wind. This may give rise to injuries. In *draughts*, mortality may increase considerably in areas where drought cause famines, in which case there may be protein–calorie malnutrition and vitamin deficiencies particularly vitamin A deficiency, leading to xerophthalmia and blindness. In famine conditions measles, respiratory infections, diarrhoea accompanied by dehydration may bring about a massive increase in infant mortality. When people migrate and settle down on the outskirts of famine hit areas, poor hygiene and overcrowding may facilitate the spread of endemic communicable diseases e.g., tuberculosis, parasitic diseases and malaria *(4)*.

On the whole, morbidity which results from a disaster situation can be classified into four types :

a. Injuries;
b. Emotional stress;
c. Epidemic of disease; and
d. Increase in indigenous diseases.

The short-term effects of major disasters are summarized in Table 1.

DISASTER MANAGEMENT

There are three fundamental aspects of disaster management :

a. disaster response ;
b. disaster preparedness ; and
c. disaster mitigation.

These three aspects of disaster management correspond to different phases in the so-called *"disaster cycle"* as shown in Fig. 1.

TABLE 1
Short-term effects of major disasters

Effect	Earthquakes	High winds (without flooding)	Tidal waves / flash floods	Slow - onset floods	Landslides	Volcanoes / Lahars
Death[a]	Many	Few	Many	Few	Many	Many
Severe injuries requiring extensive treatment	Many	Moderate	Few	Few	Few	Few
Increased risk of communicable diseases	Potential risk following all major disasters (Probability rising with overcrowding and deteriorating sanitation)					
Damage to health facilities	Severe (structure and equipment)	Severe	Severe but localized	Severe (equipment only)	Severe but localized	Severe (structure and equipment)
Damage to water systems	Severe	Light	Severe	Light	Severe but localized	Severe
Food shortage	Rare (may occur due to economic and logistic factors)		Common	Common	Rare	Rare
Major population movements	Rare (may occur in heavily damaged urban areas)		Common (generally limited)			

[a] Potential lethal impact in absence of preventive measures.

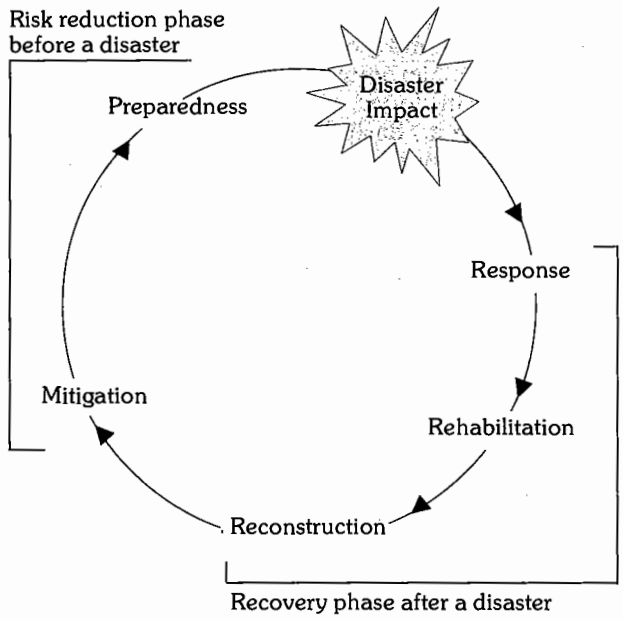

FIG. 1
Management sequence of a sudden-onset disaster

Source : *(5)*

Disaster impact and response

Medical treatment for large number of casualties is likely to be needed only after certain types of disaster. Most injuries are sustained during the impact, and thus, the greatest need for emergency care occurs in the first few hours. The management of mass casualties can be further divided into search and rescue, first aid, triage and stabilization of victims, hospital treatment and redistribution of patients to other hospitals if necessary.

Search, rescue and first-aid

After a major disaster, the need for search, rescue and first aid is likely to be so great that organized relief services will be able to meet only a small fraction of the demand. Most immediate help comes from the uninjured survivors.

Field care

Most injured persons converge spontaneously to health facilities, using whatever tansport is available, regardless of the facilities, operating status. Providing proper care to casualties requires, that the health service resources be redirected to this new priority. Bed availability and surgical services should be maximized. Provisions should be made for food and shelter. A centre should be established to respond to inquiries from patient's relatives and friends. Priority should be given to victim's identification and adequate mortuary space should be provided.

Triage (5)

When the quantity and severity of injuries overwhelm the operative capacity of health facilities, a different approach to medical treatment must be adopted. The principle of "first come, first treated", is not followed in mass emergencies. Triage consists of rapidly classifying the injured on the basis of the severity of their injuries and the likelyhood of their survival with prompt medical intervention. It must be adopted to locally available skills. Higher priority is granted to victims whose immediate or long-term prognosis can be dramatically affected by simple intensive care. Moribund patients who require a great deal of attention, with questionable benefit, have the lowest priority. Triage is the only approach that can provide maximum benefit to the greatest number of injured in a major disaster situation.

Although different triage systems have been adopted and are still in use in some countries, the most common classification uses the internationally accepted four colour code system. Red indicates high priority treatment or transfer, yellow signals medium priority, green indicates ambulatory patients and black for dead or moribund patients.

Triage should be carried out at the site of disaster, in order to determine transportation priority, and admission to the hospital or treatment centre, where the patient's needs and priority of medical care will be reassessed. Ideally, local health workers should be taught the principles of triage as part of disaster training.

Persons with minor or moderate injuries should be treated at their own homes to avoid social dislocation and

the added drain on resources of transporting them to central facilities. The seriously injured should be transported to hospitals with specialized treatment facilities.

Tagging

All patients should be identified with tags stating their name, age, place of origin, triage category, diagnosis, and initial treatment.

Identification of dead

Taking care of the dead is an essential part of the disaster management. A large number of dead can also impede the efficiency of the rescue activities at the site of the disaster. Care of the dead includes : (1) removal of the dead from the disaster scene; (2) shifting to the mortuary; (3) identification; (4) reception of bereaved relatives. Proper respect for the dead is of great importance.

The health hazards associated with cadavers are minimal if death results from trauma, and corps are quite unlikely to cause outbreaks of disease such as typhoid fever, cholera or plague. If human bodies contaminate streams, wells, or other water sources as in floods etc., they may transmit gastroenteritis or food poisoning to survivors. The dead bodies represent a delicate social problem.

Relief phase

This phase begins when assistance from outside starts to reach the disaster area. The type and quantity of humanitarian relief supplies are usually determined by two main factors : (1) the type of disaster, since distinct events have different effects on the population, and (2) the type and quantity of supplies available locally.

Immediately following a disaster, the most critical health supplies are those needed for treating casualties, and preventing the spread of communicable diseases. Following the initial emergency phase, needed supplies will include food, blankets, clothings, shelter, sanitary engineering equipment and construction material. A rapid damage assessment must be carried out in order to identify needs and resources. Disaster managers must be prepared to receive large quantities of donations. There are four principal components in managing humanitarian supplies : (a) acquisition of supplies; (b) transportation; (c) storage; and (d) distribution.

Epidemiologic surveillance and disease control

Disasters can increase the transmission of communicable diseases through following mechanisms :

1. Overcrowding and poor sanitation in temporary resettlements. This accounts in part, for the reported increase in acute respiratory infections etc. following the disasters.
2. Population displacement may lead to introduction of communicable diseases to which either the migrant or indigenous populations are susceptible.
3. Disruption and the contamination of water supply, damage to sewerage system and power systems are common in natural disasters.
4. Disruption of routine control programmes as funds and personnel are usually diverted to relief work.
5. Ecological changes may favour breeding of vectors and increase the vector population density.
6. Displacement of domestic and wild animals, who carry with them zoonoses that can be transmitted to humans as well as to other animals. Leptospirosis cases have been reported following large floods (as in Orissa, India, after super cyclone in 1999). Anthrax has been reported occasionally.
7. Provision of emergency food, water and shelter in disaster situation from different or new source may itself be a source of infectious disease.

Outbreak of gastroenteritis, which is the most commonly reported disease in the post-disaster period, is closely related to first three factors mentioned above. Increased incidence of acute respiratory infections is also common in displaced population. Vector-borne diseases will not appear immediately but may take several weeks to reach epidemic levels.

Displacement of domesticated and wild animals increases the risk of transmission of zoonoses. Veterinary services may be needed to evaluate such health risks. Dogs, cats and other domestic animals are taken by their owners to or near temporary shelters. Some of these animals may be reservoirs of infections such as leptospirosis, rickettsiosis etc. Wild animals are reservoirs of infections which can be fatal to man such as equine encephalitis, rabies, and infections still unknown in humans.

The principals of preventing and controlling communicable diseases after a disaster are to – (a) implement as soon as possible all public health measures, to reduce the risk of disease transmission; (b) organize a reliable disease reporting system to identify outbreaks and to promptly initiate control measures; and (c) investigate all reports of disease outbreaks rapidly *(5)*.

Vaccination *(5)*

Health authorities are often under considerable public and political pressure to begin mass vaccination programmes, usually against typhoid, cholera and tetanus. The pressure may be increased by the press media and offer of vaccines from abroad.

The WHO does not recommend typhoid and cholera vaccines in routine use in endemic areas. The newer typhoid and cholera vaccines have increased efficacy, but because they are multidose vaccines, compliance is likely to be poor. They have not yet been proven effective, as a large-scale public health measure. Vaccination programme requires large number of workers who could be better employed elsewhere. Supervision of sterilization and injection techniques may be impossible, resulting in more harm than good. And above all, mass vaccination may lead to false sense of security about the risk of the disease and to the neglect of effective control measures. However, these vaccinations are recommended for health workers. Supplying safe drinking water and proper disposal of excreta continue to be the most practical and effective strategy.

Significant increase in tetanus incidence have not occurred after natural disasters. Mass vaccination of population against tetanus is usually unnecessary. The best protection is maintenance of a high level of immunity in the general population by routine vaccination before the disaster occurs, and adequate wound cleaning and treatment. If tetanus immunization was received more than 5 years ago in a patient who has sustained an open wound, a tetanus toxoid booster is an effective preventive measure. In previously unimmunized injured patients, tetanus toxoid should be given only at the discretion of a physician. If

routine vaccination programmes are being conducted in camps with large number of children, it is prudent to include vaccination against tetanus.

Natural disasters may negatively affect the maintenance of on going national or regional eradication programmes against polio and measles. Disruption of these programmes should be monitored closely.

If cold-chain facilities are inadequate, they should be requested at the same time as vaccines. The vaccination policy to be adopted should be decided at senior level only.

Nutrition

A natural disaster may affect the nutritional status of the population by affecting one or more components of food chain depending on the type, duration and extent of the disaster, as well as the food and nutritional conditions existing in the area before the catastrophe. Infants, children, pregnant women, nursing mothers and sick persons are more prone to nutritional problems after prolonged drought or after certain types of disasters like hurricanes, floods, land or mudslides, volcanic eruptions and sea surges involving damage to crops, to stocks or to food distribution systems.

The immediate steps for ensuring that the food relief programme will be effective include : (a) assessing the food supplies after the disaster ; (b) gauging the nutritional needs of the affected population ; (c) calculating daily food rations and need for large population groups ; and (d) monitoring the nutritional status of the affected population.

Rehabilitation

The final phase in a disaster should lead to restoration of the pre-disaster conditions. Rehabilitation starts from the very first moment of a disaster. Too often, measures decided in a hurry, tend to obstruct re-establishment of normal conditions of life. Provisions by external agencies of sophisticated medical care for a temporary period has negative effects. On the withdrawal of such care, the population is left with a new level of expectation which simply cannot be fulfilled.

In first weeks after disaster, the pattern of health needs, will change rapidly, moving from casualty treatment to more routine primary health care. Services should be reorganized and restructured. Priorities also will shift from health care towards environmental health measures. Some of them are as follows :

Water supply

A survey of all public water supplies should be made. This includes distribution system and water source. It is essential to determine physical integrity of system components, the remaining capacities, and bacteriological and chemical quality of water supplied.

The main public safety aspect of water quality is microbial contamination. The first priority of ensuring water quality in emergency situations is chlorination. It is the best way of disinfecting water. It is advisable to increase residual chlorine level to about 0.2–0.5 mg/litre. Low water pressure increases the risk of infiltration of pollutants into water mains. Repaired mains, reservoirs and other units require cleaning and disinfection.

Chemical contamination and toxicity are a second concern in water quality and potential chemical contaminants have to be identified and analyzed.

The existing and new water sources require the following protection measures : (1) restrict access to people and animals, If possible, erect a fence and appoint a guard; (2) ensure adequate excreta disposal at a safe distance from water source; (3) prohibit bathing, washing and animal husbandry, upstream of intake points in rivers and streams; (4) upgrade wells to ensure that they are protected from contamination; and (5) estimate the maximum yield of wells and if necessary, ration the water supply.

In many emergency situations, water has to be trucked to disaster site or camps. All water tankers should be inspected to determine fitness, and should be cleaned and disinfected before transporting water.

Food safety

Poor hygiene is the major cause of food-borne diseases in disaster situations. Where feeding programmes are used (as in shelters or camps) kitchen sanitation is of utmost importance. Personal hygiene should be monitored in individuals involved in food preparation.

Basic sanitation and personal hygiene

Many communicable diseases are spread through faecal contamination of drinking water and food. Hence, every effort should be made to ensure the sanitary disposal of excreta. Emergency latrines should be made available to the displaced, where toilet facilities have been destroyed. Washing, cleaning and bathing facilities should be provided to the displaced persons.

Vector control

Control programme for vector-borne diseases should be intensified in the emergency and rehabilitation period, especially in areas where such diseases are known to be endemic. Of special concern are dengue fever and malaria (mosquitoes), leptospirosis and rat bite fever (rats), typhus (lice, fleas), and plague (fleas). Flood water provides ample breeding opportunities for mosquitoes.

A major disaster with high mortality leaves a substantial displaced population, among whom are those requiring medical treatment and orphaned children. When it is not possible to locate the relatives who can provide care, orphans may become the responsibility of health and social agencies. Efforts should be made to reintegrate disaster survivors into the society, as quickly as possible through institutional programmes coordinated by ministries of health and family welfare, social welfare, education, and NGOs.

Disaster mitigation in health sector

Emergency prevention and mitigation involves measures designed either to prevent hazards from causing emergency or to lessen the likely effects of emergencies. These measures include flood mitigation works, appropriate land-use planning, improved building codes, and reduction or protection of vulnerable population and structures.

In most cases mitigation measures aim to reduce the vulnerability of the system. Medical casualties can be drastically reduced by improving the structural quality of houses, schools and other public and private buildings. Although mitigation in these sectors has clear health implications, the direct responsibility of the health sector is limited to ensuring the safety of health facilities and public health services, including water supply and sewerage systems. When water supplies are contaminated or

interrupted, in addition to the social cost of such damage, the cost of rehabilitation and reconstruction severely strains the economy. Mitigation complements the disaster preparedness and disaster response activities.

Disaster preparedness

Emergency preparedness is "a programme of long-term development activities whose goals are to strengthen the overall capacity and capability of a country to manage efficiently all types of emergency. It should bring about an orderly transition from relief through recovery, and back to sustained development" *(1)*.

The objective of disaster preparedness is to ensure that appropriate systems, procedures and resources are in place to provide prompt effective assistance to disaster victims, thus facilitating relief measures and rehabilitation of services.

The individuals are responsible for maintaining their well–being. Community members, resources, organizations, and administration should be the cornerstone of an emergency preparedness programme. The reasons of community preparedness are : (a) Members of the community have the most to lose from being vulnerable to disasters and the most to gain from an effective and appropriate emergency preparedness programme; (b) Those who first respond to an emergency come from within the community. When transport and communications are disrupted, an external emergency response may not arrive for days ; (c) Resources are most easily pooled at the community level and every community possesses capabilities. Failure to exploit these capabilities is poor resource management ; (d) Sustained development is best achieved by allowing emergency-affected communities to design, manage, and implement internal and external assistance programme *(2)*.

Disaster preparedness is an on-going multisectoral activity. It forms an integral part of the national system responsible for developing plans and programmes for disaster management, prevention, mitigation, preparedness, response, rehabilitation and reconstruction. The system, known by a variety of names depending on the country, depends on the coordination of a variety of sectors to carry out the following tasks *(5)* :

1. Evaluate the risk of the country or particular region to disaster ;
2. Adopt standards and regulations ;
3. Organize communication, information and warning systems ;
4. Ensure coordination and response mechanisms ;
5. Adopt measures to ensure that financial and other resources are available for increased readiness and can be mobilized in disaster situation ;
6. Develop public education programmes ;
7. Coordinate information sessions with news media ; and
8. Organize disaster simulation excercises that test response mechanisms.

The emergency preparedness and emergency management do not exist in a vacuum. To succeed, emergency programmes must be appropriate to their context. This context will vary from country to country and from community to community.

Policy development *(2)*

The policy development is "the formal statement of a course of action". Policy is strategic in nature and performs the following functions :

(a) establish long-term goals;
(b) asign responsibilities for achieving goals;
(c) establish recommended work practice; and
(d) determine criteria for decision making.

While policies tend to be "top-down" that is authorized by higher levels, implementation of the strategies that arise from a policy tend to be "bottom-up", with the higher levels assisting lower levels. The form of emergency preparedness policy varies from country to country. Six sectors are required for response and recovery strategies. These sectors are communication, health, social welfare, police and security, search and rescue and transport.

Personal protection in different types of emergencies *(2)*

In addition to considering action by rescuers, thought must be given to personal protection measures in different types of emergencies. Making people aware of what is expected of them in case of an emergency can make large difference to the organized management efforts. By taking precautions, the individual assists the collective effort to reduce the effects of an emergency.

A number of measures must be observed by all persons in all types of emergency:

- Do not use the telephone, except to call for help, so as to leave telephone lines free for the organization of response.
- Listen to the messages broadcast by radio and the various media so as to be informed of development.
- Carry out the official instructions given over the radio or by loudspeaker.
- Keep a family emergency kit ready.

In all the different types of emergency, it is better:

- to be prepared than to get hurt;
- to get information so as to get organized;
- to wait rather than act too hastily.

FLOODS

What to do before-hand

While town planning is a government responsibility, individuals should find out about risks in the area where they live. For example, people who live in areas downstream from a dam should know the special signals (such as foghorns) used when a dam threatens to break. Small floods can be foreseen by watching the water level after heavy rains and regularly listening to the weather forecasts.

Forecasting of floods or tidal waves is very difficult, but hurricanes and cyclones often occur at the same time of year, when particular vigilance must be exercised. They are often announced several hours or days before they arrive.

During a flood

- Turn off the electricity to reduce the risk of electrocution.
- Protect people and property:
  - as soon as the flood begins, take any vulnerable people (children, the old, the sick, and the disabled) to an upper floor;

  - whenever possible, move personal belongings upstairs or go to raised shelters provided for use in floods.
- Beware of water contamination – if the taste, colour, or smell of the water is suspicious, it is vital to use some means of purification.
- Evacuate danger zones as ordered by the local authorities it is essential to comply strictly with the evacuation advice given. Authorities will recommend that families take with them the emergency supplies they have prepared.

After a flood

When a flood is over, it is important that people do not return home until told to do so by the local authorities, who will have ensured that buildings have not been undermined by water. From then on it is essential to:

  - wait until the water is declared safe before drinking any that is untreated;
  - clean and disinfect any room that has been flooded;
  - sterilize or wash with boiling water all dishes and kitchen utensils;
  - get rid of any food that has been in or near the water, including canned foods and any food kept in refrigerators and freezers;
  - get rid of all consumables (drinks, medicines, cosmetics, etc.).

STORMS, HURRICANES AND TORNADOES

What to do before-hand

Above all, it is vital that people find out about the kinds of storm liable to strike their region so that they can take optimum preventive measures, and:

  - choose a shelter in advance, before the emergency occurs – a cellar, a basement, or an alcove may be perfectly suitable;
  - minimize the effects of the storm – fell dead trees, prune tree branches, regularly check the state of roofs, the state of the ground, and the drainage around houses;
  - take measures against flooding;
  - prepare a family emergency kit.

During an emergency

- Listen to the information and advice provided by the authorities.
- Do not go out in a car or a boat once the storm has been announced.
- Evacuate houses if the authorities request this, taking the family emergency package.
- If possible, tie down any object liable to be blown away by the wind; if there is time, nail planks to the doors and shutters, open the windows and doors slightly on the side opposite to the direction from which the wind is coming so as to reduce wind pressure on the house.
- If caught outside in a storm, take refuge as quickly as possible in a shelter; if there is no shelter, lie down flat in a ditch.
- In a thunderstorm keep away from doors, windows, and electrical conductors, unplug electrical appliances and television aerials. Do not use any electrical appliances or the telephone.
- Anyone who is outside should
  - look for shelter in a building (never under a tree);
  - if out in a boat, get back to the shore;
  - keep away from fences and electric cables;
  - kneel down rather than remain standing.

After an emergency

After the storm has subsided

  - follow the instructions given by the authorities;
  - stay indoors and do not go to the stricken areas;
  - give the alert as quickly as possible;
  - give first aid to the injured;
  - make sure the water is safe to drink and check the contents of refrigerators and freezers;
  - check the exterior of dwellings and call for assistance if there is a risk of falling objects (tiles, guttering, etc.).

EARTHQUAKES

What to do before-hand

The movement of the ground in an earthquake is rarely the direct cause of injuries; most are caused by falling objects or collapsing buildings. Many earthquakes are followed (several hours or even days later) by further tremors, usually of progressively decreasing intensity. To reduce the destructive effects of earthquakes a number of precautions are essential for people living in risk areas:

- Build in accordance with urban planning regulations for risk areas.
- Ensure that all electrical and gas appliances in houses, together with all pipes connected to them, are firmly fixed.
- Avoid storing heavy objects and materials in high positions.
- Hold family evacuation drills and ensure that the whole family knows what to do in case of an earthquake.
- Prepare a family emergency kit.

During an earthquake

- Keep calm, do no panic.
- People who are indoors should stay there but move to the central part of the building.
- Keep away from the stairs, which might collapse suddenly.
- People who are outside should stay there, keeping away from buildings to avoid collapsing walls and away from electric cables.
- Anyone in a vehicle should park it, keeping away from bridges and buildings.

After an earthquake

- Obey the authorities' instructions.
- Do not go back into damaged buildings since tremors may start again at any moment.
- Give first-aid to the injured and alert the emergency services in case of fire, burst pipes, etc.
- Do not go simply to look at the stricken areas: this will hamper rescue work.
- Keep emergency packages and a radio near at hand.
- Make sure that water is safe to drink and food stored at home is fit to eat (in case of electricity cuts affecting refrigerators and freezers).

CLOUDS OF TOXIC FUMES

What to do before-hand

People in a risk area should:

- find out about evacuation plans and facilities;
- familiarize themselves with the alarm signals used in case of emergency;
- equip doors and windows with the tightest possible fastenings;
- prepare family emergency kits.

During an emergency

- Do not use the telephone; leave lines free for rescue services.
- Listen to the messages given by radio and other media.
- Carry out the instructions transmitted by radio or loudspeaker.
- Close doors and windows.
- Stop up air intakes.
- Seal any cracks or gaps around windows and doors with adhesive tape.
- Organize a reserve of water (by filling wash basins, baths, etc.).
- Turn off ventilators and air conditioners.

After an emergency

- Comply with the authorities' instructions and do not go out until there is no longer any risk.
- Carry out necessary decontamination measures.

MAN-MADE DISASTERS

There are many disasters which have large elements of human causation either accidental or intended. These can also be divided into three categories. (a) Sudden disasters such as Bhopal Gas Tragedy in India on 3rd December 1984 in which a leakage in the storage tank of Union Carbide Pesticide Plant released tons of methyl isocyanate into the air. Wind conditions and an atmospheric inversion, along with delayed warning and a population that had not been taught the nature of risks and the appropriate response increased the impact. About 2 million people were exposed to the gas leaving about 3,000 dead. People are still suffering from the adverse effects of the gas. The second example is the accident at reactor 4 of the Chernobyl nuclear power station in the Soviet Union on April 26, 1986, which resulted in the largest reported accidental release of radioactive material in the history of nuclear power. It deposited more than 7 million curies of Iodine 131, Cesium 134 and 137, Strontium 90 and other isotopes throughout the northern hemisphere, *(3)*; (b) Insidious disasters, such as insidious chemical exposure and insidious radiation exposure, as in nuclear weapons production factories, research laboratories resulting in release of radioactive substances into the air, soil and underground water. Chemical plants releasing their toxic by-products into rivers and other water sources is another example. Other form of long term and continuing human-made disaster include global warming (the "green house effect") caused by the heat–trapping gases in the atmosphere released by burning of fossil fuels, and depletion of ozone layer due to the use of the aerosolized chlorofluorohydrocarbons etc. ; and (c) Wars and civil conflicts. The latest example is the attack on twin buildings of World Trade Centre in New York in which about 6000 people lost their lives and thousands were injured.

Since World War II, there have been about 127 wars and 21.8 million war-related deaths involving more than 50 per cent of civilians *(3)*. Recently the proportion of civilians among dead has been increasing. Air-borne power and wide–ranging nature of modern war puts an entire population at risk, disrupting food production and supply routes, imperiling fragile ecosystem and forcing refugees by hundred of thousands to flee. More than half of the civilian deaths in current hostilities resulted from war-related famines. As for causes of most wars, most frequent objectives were gain of land assets, and independence. However, civil wars, representing power conflicts within nations, have increased sharply in the twentieth century, and are now, by far the major form of warfare.

The public health response to man-made disaster is the primary prevention, i.e., prevention of occurrence of the disaster. Much can be done to prevent not only the consequences but also the occurrences of fires, explosions, crashes, and sudden chemical and radiation exposures. This includes tighter regulations of chemical plants and other hazardous facilities and insistance that the chemical plants be built away from dense populous areas. Other measures include appropriate engineering and technological measures (like building codes, dam designs, containment of toxic materials), early warning, if possible, and protection against human errors.

During the first half of the twentieth century, two world wars and many regional conflicts provided the experience for governments, to develop civil defence programmes. They were reshaped after the introduction of nuclear weapons and massive air attacks occuring with little warning. Weapons of mass destruction are indiscriminate, killing and injuring civilians as well as military personnel, and destroying and contaminating ecosystem over wide areas. People around the world have turned towards efforts to stop the arms race and prevent nuclear war.

Disasters in India

With a wide range of topographic and climatic conditions, India is the highly disaster-prone country in Asia–Pacific region with an average of 8 major natural calamities a year. While floods, cyclones, draughts, earthquakes and epidemics are frequent from time to time, major accidents happen in railways, mines and factories causing extensive damage to human life and property.

Northern mountain regions, including the foot hills are prone to snow-storms, land-slides and earthquakes. The eastern coastal areas are prone to severe floods and cyclones (Andhra Pradesh, West Bengal, Orissa, etc.). Bihar, Assam and Uttar Pradesh get major floods almost every year. Western desert areas are prone to draughts. There is hardly a year when some or the other part of the country does not face the spectre of drought, floods or cyclone. Orissa had super cyclone on 29th October 1999, when thousands lost their lives and many more became homeless. Gujarat had a severe earthquake in which about 16,480 people died and lacs became homeless. Indian ocean tsunami killed more than 200,000 persons in India in Dec. 2004 and major earthquake in Jammu & Kashmir (7.4 RS) left 2,100 dead and 30,000 injured, more recently, in June 2013 in Uttarakhand, cloudburst causing floods that killed about 5,748 people in Kedarnath, and the floods in Kashmir vally in 2014. India also saw world's worst man-made disaster in 1984, when methyl isocyanate gas leaked at

Union Carbide Pesticide Plant in Bhopal killing about 3,000 people. People are still suffering from variety of diseases, as an after effect of this tragedy.

In the federal structure of India, the state governments are responsible for the execution of relief work in wake of natural disasters. Government of India plays a supportive role, in terms of supplementation of final resources to the states. An administrative system has been developed to combat and minimize the adverse impact of the natural disasters. At the centre, the Ministry of Agriculture is the nodal ministry for coordination of all activities during a natural disaster. Since health is an important part of disaster management, in the DGHS under the ministry of Health and Family Welfare there is a special wing called the Emergency Medical Relief Wing which coordinates all activities related to health.

In a vast country like India, it is not practicable for the government machinery alone, to undertake disaster reduction programmes without involvement of NGOs. Public education and community involvement plays a vital role here. As part of the International Decade for Natural Disaster Reduction activities, every year, the second wednesday of October has been designated as *World Disaster Reduction Day*.

Indian Meteorological Department (IMD) plays a key role in forwarning the disaster. It has five centres in Kolkata, Bhubaneshwar, Vishakhapatnam, Chennai and Mumbai for detection and tracing of cyclone storms. Satellite imagery facilities and cyclone warning radars are provided to various Cyclone Warning Centres. In addition, it has 31 special observation posts set up along east coast of India. For all ships out at sea, warnings are issued six times a day. Insat Disaster Warning System (DWS) receivers have been installed primarily in the coastal areas of Tamil Nadu and Andhra Pradesh. This has proved very reliable form of communication system. The Snow and Avalanche Study Establishment (SASE) in Manali has been issuing warning to people about avalanches 24 to 48 hours in advance.

INTERNATIONAL AGENCIES PROVIDING HEALTH HUMANITARIAN ASSISTANCE

Every country is a potential source of health humanitarian assistance for some other disaster–striken nation. Bilateral assistance, whether personnel, supplies or cash is probably the most important source of external aid. Several international or regional agencies have established special funds, procedures and offices to provide humanitarian assistance. United Nation's Agencies are United Nations Office for the Coordination of Humanitarian Affairs (OCHA), World Health Organization (WHO), UNICEF, World Food Programme (WFP), Food and Agriculture Organization (FAO). Inter–governmental organizations are European Community Humanitarian Office (ECHO), Organization of American States (OAS), Centre of Coordination for Prevention of Natural Disasters in Central America, Caribbean Disaster Emergency Response Agency. Some Non-Governmental Organizations are CARE, International Committee of Red Cross, International Council of Voluntary Agencies (ICVA), International Federation of Red Cross and Red Crescent Societies (IFRC) etc.

15 Occupational health

"Prevention is better than cure"

Occupational health is essentially preventive medicine. The Joint ILO/WHO Committee on Occupational Health, in the course of its first session, held in 1950, gave the following definition: "Occupational health should aim at the *promotion* and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations; the *prevention* among workers of departures from health caused by their working conditions; the protection of workers in their employment from risks resulting from factors adverse to health; the placing and maintenance of the worker in an occupational environment adapted to his physiological and psychological equipment, and, to summarize, the adaptation of work to man and of each man to his job *(1)*.

Preventive medicine and occupational health have the same aim – the prevention of disease and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations; the levels of application of preventive measures are the same – health promotion, specific protection, early diagnosis and treatment, disability limitation and rehabilitation; the tools are the same – epidemiologic approach, statistics, health screening, health education etc. *(2)*. Occupational health, therefore, is the application of preventive medicine in all places of employment.

In the past, it was customary to think of occupational health entirely in relation to factories and mines; hence the terms "industrial hygiene" or "industrial health" were in vogue. Modern concepts of occupational health now embrace all types of employment including mercantile and commercial enterprises, service trades, forestry and agriculture and includes the subjects of industrial hygiene, industrial diseases, industrial accidents, toxicology in relation to industrial hazards, industrial rehabilitation and occupational psychology. Occupational health in agriculture and ergonomics (human engineering) are relatively new concepts *(3,4)*.

ERGONOMICS is now a well recognized discipline and constitutes an integral part of any advanced occupational health service. The term "ergonomics" is derived from the Greek *ergon,* meaning work and *nomos,* meaning law. It simply means: "fitting the job to the worker". Training in ergonomics involves designing of machines, tools, equipment and manufacturing processes, lay-out of the places of work, methods of work and environment in order to achieve greater efficiency of both man and machine *(5)*. The object of ergonomics is "to achieve the best mutual adjustment of man and his work, for the improvement of human efficiency and well-being". The application of ergonomics has made a significant contribution to reducing industrial accidents and to the overall health and efficiency of the workers *(5)*.

HEALTH OF THE WORKER

Industrial workers constitute only a segment of the general population, and the factors that influence the health of the population also apply equally to industrial workers, i.e., housing, water, sewage and waste disposal, nutrition, and education. A detailed consideration of these factors can be found in Chapter 2. In addition to these factors, the health of the industrial workers, in a large measure, will also be influenced by conditions prevailing in their work place. One of the declared aims of occupational health is to provide a safe 'occupational environment' in order to safeguard the health of the workers and to step up industrial production.

Occupational environment

By "occupational environment" is meant the sum of external conditions and influences which prevail at the place of work and which have a bearing on the health of the working population. The industrial worker today is placed in a highly complicated environment which is getting more complicated as man is becoming more ingenious. Basically, there are three types of interaction in a working environment:

(a) Man and physical, chemical and biological agents

(b) Man and machine

(c) Man and man.

MAN AND PHYSICAL, CHEMICAL AND BIOLOGICAL AGENTS

(1) *Physical agents:* The physical factors in the working environment which may be adverse to health are heat, cold, humidity, air movement, heat radiation, light, noise, vibrations and ionizing radiation. The factors act in different ways on the health and efficiency of the workers, singly or in different combinations. The amount of working and breathing space, toilet, washing and bathing facilities are also important factors in an occupational environment. (2) *Chemical agents:* These comprise a large number of chemicals, toxic dusts and gases which are potential hazards to the health of the workers. Some chemical agents cause disabling respiratory illnesses, some cause injury to skin and some may have a deleterious effect on the blood and other organs of the body. (3) *Biological agents:* The workers may be exposed to viral, rickettsial, bacterial and parasitic agents which may result from close contact with animals or their products, contaminated water, soil or food.

MAN AND MACHINE

An industry or factory implies the use of machines driven by power with emphasis on mass production. The

unguarded machines, protruding and moving parts, poor installation of the plant, lack of safety measures are the causes of accidents which is a major problem in industries. Working for long hours in unphysiological postures is the cause of fatigue, backache, diseases of joints and muscles and impairment of the worker's health and efficiency.

MAN AND MAN

There are numerous psychosocial factors which operate at the place of work. These are the human relationships amongst workers themselves on the one hand, and those in authority over them on the other. Examples of psychosocial factors include the type and rhythm of work, work stability, service conditions, job satisfaction, leadership style, security, workers participation, communication, system of payment, welfare conditions, degree of responsibility, trade union activities, incentives and a host of similar other factors, all entering the field of human relationships. In modern occupational health, the emphasis is upon the people, the conditions in which they live and work, their hopes and fears and their attitudes towards their job, their fellow-workers and employers *(2)*.

The occupational environment of the worker cannot be considered apart from his *domestic environment*. Both are complementary to each other. The worker takes his worries home, and brings to his work disturbances which arise in his domestic environment. Stress at work may disturb his sleep, just as stress at home may affect his work. Severe prolonged stress, no matter where it has been aroused, may produce serious physical or mental symptoms which do not allow man to work efficiently. According to ecological approach, occupational health represents a dynamic equilibrium or adjustment between the industrial worker and his occupational environment.

OCCUPATIONAL HAZARDS

An industrial worker may be exposed to five types of hazards, depending upon his occupation:

(a) Physical hazards
(b) Chemical hazards
(c) Biological hazards
(d) Mechanical hazards
(e) Psychosocial hazards.

a. Physical hazards

(1) HEAT AND COLD: The common physical hazard in most industries is heat. The direct effects of heat exposure are burns, heat exhaustion, heat stroke and heat cramps; the indirect effects are decreased efficiency, increased fatigue and enhanced accident rates. Many industries have local "hot spots" – ovens and furnaces, which radiate heat. Radiant heat is the main problem in foundry, glass and steel industries, while *heat stagnation* is the principal problem in jute and cotton textile industry *(7)*. High temperatures are also found in mines for instance in the Kolar Gold Mines of Mysore which is the second deepest mine of the world (11,000 feet), temperatures as high as 65 deg. C are recorded *(8)*. Physical work under such conditions is very stressful and impairs the health and efficiency of the workers. For gainful work involving sustained and repeated effort, a reasonable temperature must be maintained in each work room. The Indian Factories Act has not laid down any specific temperature standard. However, the work of Rao (1952, 1953) and Mookerjee et al. (1953) indicate that a corrected effective temperature of 69 to 80 deg. F (20°C to 27°C) is the comfort zone in this country and temperatures above 80 deg. F (27°C) cause discomfort *(7)*.

Important hazards associated with cold work are chilblains, erythrocyanosis, immersion foot, and frostbite as a result of cutaneous vasoconstriction. General hypothermia is not unusual *(9)*.

(2) LIGHT: The workers may be exposed to the risk of poor illumination or excessive brightness. The *acute* effects of poor illumination are eye strain, headache, eye pain, lachrymation, congestion around the cornea and eye fatigue. The *chronic* effects on health include "miner's nystagmus". Exposure to excessive brightness or "glare" is associated with discomfort, annoyance and visual fatigue. Intense direct glare may also result in blurring of vision and lead to accidents. There should be sufficient and suitable lighting, natural or artificial, wherever persons are working.

(3) NOISE: Noise is a health hazard in many industries. The effects of noise are of two types: (i) *Auditory effects* which consist of temporary or permanent hearing loss. (ii) *Non-auditory effects* which consist of nervousness, fatigue, interference with communication by speech, decreased efficiency and annoyance. The degree of injury from exposure to noise depends upon a number of factors such as intensity and frequency range, duration of exposure and individual susceptibility.

(4) VIBRATION: Vibration, especially in the frequency range 10 to 500 Hz, may be encountered in work with pneumatic tools such as drills and hammers. Vibration usually affects the hands and arms. After some months or years of exposure, the fine blood vessels of the fingers may become increasingly sensitive to spasm (white fingers). Exposure to vibration may also produce injuries of the joints of the hands, elbows and shoulders *(9)*.

(5) ULTRAVIOLET RADIATION : Occupational exposure to ultraviolet radiation occurs mainly in arc welding. Such radiation mainly affects the eyes, causing intense conjunctivitis and keratitis (welder's flash). Symptoms are redness of the eyes and pain, these usually disappear in a few days with no permanent effect on the vision or on the deeper structures of the eye *(9)*.

(6) IONIZING RADIATION : Ionizing radiation is finding increasing application in medicine and industry, e.g., X-rays and radio-active isotopes. Important radio-isotopes are cobalt 60 and phosphorus 32. Certain tissues such as bonemarrow are more sensitive than others and from a genetic standpoint, there are special hazards when the gonads are exposed. The radiation hazards comprise genetic changes, malformation, cancer, leukaemia, depilation, ulceration, sterility and in extreme cases death. The International Commission of Radiological Protection has set the maximum permissible level of occupational exposure at 5 rem per year to the whole body *(10)*.

b. Chemical hazards

There is hardly any industry which does not make use of chemicals. The chemical hazards are on the increase with the introduction of newer and complex chemicals. Chemical agents act in three ways : local action, inhalation and ingestion. The ill-effects produced depend upon the duration of exposure, the quantum of exposure and individual susceptibility.

(1) LOCAL ACTION : Some chemicals cause dermatitis, eczema, ulcers and even cancer by *primary irritant action;* some cause dermatitis by an allergic action. Some

chemicals, particularly the aromatic nitro and amino compounds such as TNT and aniline are *absorbed* through the skin and cause systemic effects. Occupational dermatitis is a big problem in industry. Rao and Banerji (1952) were the first to draw attention in India to the prevalence of occupational dermatitis due to machine oil, rubber, X-rays, caustic alkalies and lime *(7)*.

(2) INHALATION : (i) *DUSTS :* Dusts are finely divided solid particles with size ranging from 0.1 to 150 microns. They are released into the atmosphere during crushing, grinding, abrading, loading and unloading operations. Dusts are produced in a number of industries – mines, foundry, quarry, pottery, textile, wood or stone working industries. Dust particles larger than 10 microns settle down from the air rapidly, while the smaller ones remain suspended indefinitely. Particles smaller than 5 microns are directly inhaled into the lungs and are retained there. This fraction of the dust is called "respirable dust", and is mainly responsible for pneumoconiosis. Dusts have been classified into *inorganic* and *organic* dusts; *soluble* and *insoluble dusts*. The inorganic dusts are silica, mica, coal, asbestos dust, etc.; the organic dusts are cotton, jute and the like. The soluble dusts dissolve slowly, enter the systemic circulation and are eventually eliminated by body metabolism. The insoluble dusts remain, more or less, permanently in the lungs. They are mainly the cause of pneumoconiosis. The most common dust diseases in this country are silicosis and anthracosis. (ii) *GASES :* Exposure to gases is a common hazard in industries. Gases are sometimes classified as *simple gases* (e.g., oxygen, hydrogen), *asphyxiating gases* (e.g. carbon monoxide, cyanide gas, sulphur dioxide, chlorine) and *anaesthetic gases* (e.g., chloroform, ether, trichlorethylene). Carbon monoxide hazard is frequently reported in coal-gas manufacturing plants and steel industry. (iii) *METALS AND THEIR COMPOUNDS:* A large number of metals, and their compounds are used throughout the industry. The chief mode of entry of some of them is by inhalation as dust or fumes. The industrial physician should be aware of the toxic effects of lead, antimony, arsenic, beryllium, cadmium, cobalt, manganese, mercury, phosphorus, chromium, zinc and others. The ill-effects depend upon the duration of exposure and the dose or concentration of exposure. Unlike the pneumoconiosis, most chemical intoxications respond favourably to cessation, exposure and medical treatment.

(3) INGESTION: Occupational diseases may also result from ingestion of chemical substances such as lead, mercury, arsenic, zinc, chromium, cadmium, phosphorus etc. Usually these substances are swallowed in minute amounts through contaminated hands, food or cigarettes. Much of the ingested material is excreted through faeces and only a small proportion may reach the general blood circulation.

c. Biological hazards

Workers may be exposed to infective and parasitic agents at the place of work. The occupational diseases in this category are brucellosis, leptospirosis, anthrax, hydatidosis, psittacosis, tetanus, encephalitis, fungal infections, schistosomiasis and a host of others. Persons working among animal products (e.g., hair, wool, hides) and agricultural workers are specially exposed to biological hazards.

d. Mechanical hazards

The mechanical hazards in industry centre round machinery, protruding and moving parts and the like. About 10 per cent of accidents in industry are said to be due to mechanical causes.

e. Psychosocial hazards

The psychosocial hazards arise from the workers' failure to adapt to an alien psychosocial environment. Frustration, lack of job satisfaction, insecurity, poor human relationships, emotional tension are some of the psychosocial factors which may undermine both physical and mental health of the workers. The capacity to adapt to different working environments is influenced by many factors such as education, cultural background, family life, social habits, and what the worker expects from employment.

The health effects can be classified in two main categories: (a) Psychological and behavioural changes : including hostility, aggressiveness, anxiety, depression, tardiness, alcoholism, drug abuse, sickness, absenteeism; (b) Psychosomatic illhealth : including fatigue, headache; pain in the shoulders, neck and back; propensity to peptic ulcer, hypertension, heart disease and rapid aging.

Reports from various parts of the world indicate that physical factors (heat, noise, poor lighting) also play a major role in adding to or precipitating mental disorders among workers. The increasing stress on automation, electronic operations and nuclear energy may introduce newer psychosocial health problems in industry. Psychosocial hazards are therefore, assuming more importance than physical or chemical hazards.

OCCUPATIONAL DISEASES

There is no internationally accepted definition for the term "occupational disease" *(3)*. However, occupational diseases are usually defined as diseases arising out of or in the course of employment. For convenience, they may be grouped as under:

I. Diseases due to physical agents

(1) Heat : Heat hyperpyrexia, heat exhaustion, heat syncope, heat cramps, burns and local effects such as prickly heat.

(2) Cold : Trench foot, frost bite, chilblains

(3) Light : Occupational cataract, miner's nystagmus

(4) Pressure : Caisson disease, air embolism, blast (explosion)

(5) Noise : Occupational deafness

(6) Radiation : Cancer, leukaemia, aplastic anaemia, pancytopenia

(7) Mechanical factors : Injuries, accidents

(8) Electricity : Burns.

II. Diseases due to chemical agents

(1) Gases: CO_2, CO, HCN, CS_2, NH_3, N_2, H_2S, HCI, SO_2 – these cause gas poisoning.

(2) Dusts (Pneumoconiosis)

(i) Inorganic dusts :

(a) Coal dust .. Anthracosis

(b) Silica .. Silicosis

(c) Asbestos .. Asbestosis, cancer lung

(d) Iron .. Siderosis

(ii) Organic (vegetable) dusts

(a) Cane fibre .. Bagassosis

(b) Cotton dust .. Byssinosis
(c) Tobacco .. Tobacossis *(11)*
(d) Hay or grain dust .. Farmers' lung

(3) Metals and their compounds

Toxic hazards from lead, mercury, cadmium, manganese, beryllium, arsenic, chromium etc.

(4) Chemicals : Acids, alkalies, pesticides

(5) Solvents : Carbon bisulphide, benzene, trichloroethylene, chloroform, etc.

III. Diseases due to biological agents

Brucellosis, leptospirosis, anthrax, actinomycosis, hydatidosis, psittacosis, tetanus, encephalitis, fungal infections, etc.

IV. Occupational cancers

Cancer of skin, lungs, bladder.

V. Occupational dermatosis

Dermatitis, eczema.

VI. Diseases of psychological origin

Industrial neurosis, hypertension, peptic ulcer, etc.

PNEUMOCONIOSIS

Dust within the size range of 0.5 to 3 micron, is a health hazard producing, after a variable period of exposure, a lung disease known as pneumoconiosis, which may gradually cripple a man by reducing his working capacity due to lung fibrosis and other complications. The hazardous effects of dusts on the lungs depend upon a number of factors such as (a) chemical composition (b) fineness (c) concentration of dust in the air (d) period of exposure and (e) health status of the person exposed. Therefore, the threshold limit values for different dusts are different. In addition to the toxic effect of the dust on the lung tissues, the super-imposition of infections like tuberculosis may also influence the pattern of pneumoconiosis. The important dust diseases are silicosis, anthracosis, byssinosis, bagassosis, asbestosis and farmer's lung. As no cure for the pneumoconiosis is known, it is essential to prevent these diseases from arising. A brief account of these conditions is given below :

1. Silicosis

Among the occupational diseases, silicosis is the major cause of permanent disability and mortality. It is caused by inhalation of dust containing free silica or silicon dioxide (SiO_2). It was first reported in India from the Kolar Gold Mines (Mysore) in 1947. Ever since, its occurrence has been uncovered in various other industries, e.g., mining industry (coal, mica, gold, silver, lead, zinc, manganese and other metals), pottery and ceramic industry, sand blasting, metal grinding, building and construction work, rock mining, iron and steel industry and several others.

In the mica mines of Bihar, out of 329 miners examined, 34.1 per cent were found suffering from silicosis. In a ceramic and pottery industry, the incidence of silicosis was found to be 15.7 per cent *(12)*. The incidence of silicosis depends upon the chemical composition of the dust, size of the particles, duration of exposure and individual susceptibility. The higher the concentration of free silica in the dust, the greater the hazard. Particles between 0.5 to 3 micron are the most dangerous because they reach the interior of the lungs with ease. The longer the duration of exposure, the greater the risk of developing silicosis. It is found that the incubation period may vary from a few months up to 6 years of exposure, depending upon the above factors.

The particles are ingested by the phagocytes which accumulate and block the lymph channels. Pathologically, silicosis is characterized by a dense "nodular" fibrosis, the nodules ranging from 3 to 4 mm in diameter. Clinically the onset of the disease is insidious. Some of the early manifestations are irritant cough, dyspnea on exertion and pain in the chest. With more advanced disease, impairment of total lung capacity (TLC) is commonly present. An X-ray of the chest shows "snow-storm" appearance in the lung fields. Silicosis is progressive and what is more important is that silicotics are prone to pulmonary tuberculosis, a condition called "silico-tuberculosis." In recent years doubts have been raised, whether silico-tuberculotics are really tubercular or purely silicotics. It is because, sputum in silico-tuberculotics rarely shows tubercle bacilli; children and women of silico–tuberculotics do not develop tuberculosis; post-mortems on silico-tuberculotics failed to prove the existence of tuberculosis disease, but showed them to be cases of pure silicosis. The radiological evidence in the two conditions is so similar that one is apt to mistake a case of silicotic to be a case of tuberculosis of lungs *(13)*. The final answer to this question is still awaited.

There is no effective treatment for silicosis. Fibrotic changes that have already taken place cannot be reversed. The only way that silicosis can be controlled (if not altogether eliminated) is by (a) rigorous dust control measures, e.g., substitution, complete enclosure, isolation, hydroblasting, good house-keeping, personal protective measures and (b) regular physical examination of workers *(14)*.

Silicosis was made a notifiable disease under the Factories Act 1948 and the Mines Act 1952.

2. Anthracosis

Previously it was thought that pulmonary "anthracosis" was inert. Studies *(15)* indicate that there are two general phases in coal miners pneumoconiosis – (1) the first phase is labelled *simple pneumoconiosis* which is associated with little ventilatory impairment. This phase may require about 12 years of work exposure for its development (2) the second phase is characterised by *progressive massive fibrosis* (PMF); this causes severe respiratory disability and frequently results in premature death. Once a background of simple pneumoconiosis has been attained in the coal worker, a progressive massive fibrosis may develop out of it without further exposure to it. From the point of view of epidemiology, the risk of death among coal miners has been nearly twice that of the general population *(15)*. Coal-miners' pneumoconiosis has been declared a notifiable disease in the Indian Mines Act of 1952, and also compensatable in the Workmen's Compensation (Amendment) Act of 1959.

3. Byssinosis

Byssinosis is due to inhalation of cotton fibre dust over long periods of time. The symptoms are chronic cough and progressive dyspnoea, ending in chronic bronchitis and emphysema. India has a large textile industry employing nearly 35 per cent of the factory workers. Incidence of byssinosis is reported to be 7 to 8 per cent in three independent surveys carried out in Mumbai, Ahmedabad and Delhi *(12)*.

4. Bagassosis

Bagassosis is the name given to an occupational disease of the lung caused by inhalation of bagasse or sugarcane dust. It was first reported in India by Ganguli and Pal in 1955 in a cardboard manufacturing firm near Kolkata. India has a large cane-sugar industry. The sugarcane fibre which earlier went to waste, is now utilized in the manufacturing of paper, cardboard and rayon.

Bagassosis has been shown to be due to a thermophilic actinomycete for which the name *Thermoactinomyces sacchari* was suggested *(18)*. The symptoms consist of breathlessness, cough, haemoptysis and slight fever. Initially there is acute diffuse bronchiolitis. Skiagram may show mottling in lungs or shadow. There is impairment of pulmonary function *(17)*. If treated early, there is resolution of the acute inflammatory condition of the lung. If left untreated, there is diffuse fibrosis, emphysema and bronchiectasis.

PREVENTIVE MEASURES : (1) *DUST CONTROL :* Measures for the prevention and suppression of dust such as wet process, enclosed apparatus, exhaust ventilation etc., should be used. (2) PERSONAL *PROTECTION :* Personal protective equipment (masks or respirators with mechanical filters or with oxygen or air supply) may be necessary. (3) *MEDICAL CONTROL :* Initial medical examination and periodical medical check-ups of the workers are indicated. (4) *BAGASSE CONTROL :* By keeping the moisture content above 20 per cent and spraying the bagasse with 2 per cent propionic acid, a widely used fungicide, bagasse can be rendered safe for manufacturing use *(18)*.

5. Asbestosis

Asbestos is the commercial name given to certain types of fibrous materials. They are silicates of varying composition; the silica is combined with such bases as magnesium, iron, calcium, sodium and aluminium. Asbestos is of two types – serpentine or chrysolite variety and the amphibole type. Ninety per cent of the world's production of asbestos is of the serpentine variety, which is hydrated magnesium silicate, the amphibole type contains little magnesium. The amphibole type occurs in different varieties, e.g., crocidolite (blue), amosite (brown), and anthrophyllite (white) *(9)*. Asbestos fibres are usually from 20 to 500 μ in length and 0.5 to 50 μ in diameter. Asbestos is used in the manufacture of asbestos cement, fire-proof textiles, roof tiling, brake lining , gaskets and several other items. Asbestos is mined in Andhra Pradesh (Cudappah), Bihar, Jharkhand, Karnataka, and Rajasthan – but most of it is imported from USSR, Canada, US and South Africa.

Asbestos enters the body by inhalation, and fine dust may be deposited in the alveoli. The fibres are insoluble. The dust deposited in the lungs causes pulmonary fibrosis leading to respiratory insufficiency and death; carcinoma of the bronchus; mesothelioma of the pleura or peritoneum; and cancer of the gastro-intestinal tract. In Great Britain, an association was reported between mesothelioma and living within 1 km of an asbestos factory *(19)*. The risk of bronchial cancer is reported to be high if occupational exposure to asbestos is combined with cigarette smoking. Mesothelioma, a rare form of cancer of the pleura and peritoneum, has been shown to have a strong association with the crocidolite variety of asbestos *(9)*. The disease does not usually appear until after 5 to 10 years of exposure *(20)*. The fibrosis in asbestosis is due to mechanical irritation, and is peri-bronchial, diffuse in character, and basal in location in contrast to silicosis in which the fibrosis is nodular in character and present in the upper part of the lungs. Clinically the disease is characterized by dyspnoea which is frequently out of proportion to the clinical signs in the lungs. In advanced cases, there may be clubbing of fingers, cardiac distress and cyanosis. The sputum shows "asbestos bodies" which are asbestos fibres coated with fibrin. An X-ray of the chest shows a ground-glass appearance in the lower two-thirds of the lung fields. Once established, the disease is progressive even after removal of the worker from contact *(2)*.

The *preventive measures* consists of : (1) use of safer types of asbestos (chrysolite and amosite); (2) substitution of other insulants: glass fibre, mineral wool, calcium silicate, plastic foams, etc.; (3) rigorous dust control; (4) periodic examination of workers; biological monitoring (clinical, X-ray, lung function), and (5) continuing research.

6. Farmer's lung

Farmer's lung is due to the inhalation of mouldy hay or grain dust *(22)*. In grain dust or hay with a moisture content of over 30 per cent bacteria and fungi grow rapidly, causing a rise of temperature to 40 to 50 deg. C. This heat encourages the growth of thermophilic actinomycetes, of which *Micropolyspora faeni* is the main cause of farmer's lung *(23)*. The acute illness is characterized by general and respiratory symptoms and physical signs. Repeated attacks cause pulmonary fibrosis and inevitable pulmonary damage and corpulmonale. It is quite possible that this condition might be widespread in India considering the bulk of the population engaged in agricultural work.

LEAD POISONING

More industrial workers are exposed to lead than to any other toxic metal. Lead is used widely in a variety of industries because of its properties : (1) low boiling point (2) mixes with other metals easily to form alloys (3) easily oxidised and (4) anticorrosive. All lead compounds are toxic – lead arsenate, lead oxide and lead carbonate are the most dangerous; lead sulphide is the least toxic.

INDUSTRIAL USES : Over 200 industries are counted where lead is used – manufacture of storage batteries; glass manufacture; ship building; printing and potteries; rubber industry and several others.

NON-OCCUPATIONAL SOURCES : The greatest source of environmental (non-occupational) lead is gasoline. Thousands of tons of lead every year is exhausted from automobiles. Lead is one of the few trace metals that is abundantly present in the environment. Lead exposure may also occur through drinking water from lead pipes; chewing lead paint on window sills or toys in case of children.

MODE OF ABSORPTION : Lead poisoning may occur in three ways : (1) *INHALATION :* Most cases of industrial lead poisoning is due to inhalation of fumes and dust of lead or its compounds. (2) *INGESTION :* Poisoning by ingestion is of less common occurrence. Small quantities of lead trapped in the upper respiratory tract may be ingested. Lead may also be ingested in food or drink through contaminated hands. (3) *SKIN :* Absorption through skin occurs only in respect of the organic compounds of lead, especially tetraethyl lead. Inorganic compounds are not absorbed through the skin.

BODY STORES : The body store of lead in the average adult population is about 150 to 400 mg and blood levels

average about 25µg/100 ml. An increase to 70µg/100 ml blood is generally associated with clinical symptoms. Normal adults ingest about 0.2 to 0.3 mg of lead per day largely from food and beverages *(24)*.

DISTRIBUTION IN THE BODY: Ninety per cent of the ingested lead is excreted in the faeces. Lead absorbed from the gut enters the circulation, and 95 per cent enters the erythrocytes. It is then transported to the liver and kidneys and finally transported to the bones where it is laid down with other minerals. Although bone lead is thought to be 'metabolically inactive', it may be released to the soft tissues again under conditions of bone resorption. Lead probably exerts its toxic action by combining with essential SH-groups of certain enzymes, for example some of those involved in prophyrin synthesis and carbohydrate metabolism. Lead has an effect on membrane permeability and potassium leakage has been demonstrated from erythrocytes exposed to lead *(25)*.

CLINICAL PICTURE : The clinical picture of lead poisoning or plumbism is different in the inorganic and organic lead exposures. The toxic effects of *inorganic* lead exposure are abdominal colic, obstinate constipation, loss of appetite, blue-line on the gums, stippling of red cells, anaemia, wrist drop and foot drop. The toxic effects of *organic* lead compounds are mostly on the central nervous system – insomnia, headache, mental confusion, delirium, etc.

DIAGNOSIS *(26, 27)*

Diagnosis of lead poisoning is based on : (1) HISTORY : a history of lead exposure (2) CLINICAL FEATURES : such as loss of appetite, intestinal colic, persistent headache, weakness, abdominal cramps and constipation, joint and muscular pains, blue line on gums, anaemia, etc. (3) LABORATORY TESTS : (a) *Coproporphyrin in urine (CPU) :* Measurement of CPU is a useful screening test. In non-exposed persons, it is less than 150 microgram/litre. (b) *Amino levulinic acid in urine (ALAU) :* If it exceeds 5 mg/ litre, it indicates clearly lead absorption. (c) *Lead in blood and urine :* Measurement of lead in blood or urine requires refined laboratory techniques. They provide quantitative indicators of exposure. Lead in urine of over 0.8 mg/litre (normal is 0.2 to 0.8 mg) indicates lead exposure and lead absorption. A blood level of 70µg/100 ml is associated with clinical symptoms. (d) *Basophilic stipling of RBC :* Is a sensitive parameter of the haematological response.

PREVENTIVE MEASURES

(1) *Substitution :* That is, where possible lead compounds should be substituted by less toxic materials. (2) *Isolation :* All processes which give rise to harmful concentration of lead dust or fumes should be enclosed and segregated. (3) *Local exhaust ventilation:* There should be adequate local exhaust ventilation system to remove fumes and dust promptly (4) *Personal protection :* Workers should be protected by approved respirators. (5) *Good house-keeping :* Good house-keeping is essential where lead dust is present. Floors, benches, machines should be kept clean by wet sweeping. (6) *Working atmosphere :* Lead concentration in the working atmosphere should be kept below 2.0 mg per 10 cu. metres of air, which is usually the permissible limit or threshold value. (7) *Periodic examination of workers :* All workers must be given periodical medical examination. Laboratory determination of urinary lead, blood lead, red cell count, haemoglobin estimation and coproporphyrin test of urine should be done periodically. Estimation of basophilic stippling may also be done. An Expert Committee of the WHO states that in the case of exposure to lead, it is not only the average level of lead in the blood that is important, but also the number of subjects whose blood level exceeds a certain value (e.g., 70µg/ml or whose ALA in the urine exceeds 10 mg/litre) (8) *Personal hygiene :* Hand-washing before eating is an important measure of personal hygiene. There should be adequate washing facilities in industry. Prohibition on taking food in work places is essential. (9) *Health education :* Workers should be educated on the risks involved and personal protection measures.

MANAGEMENT : The major objectives in management of lead poisoning are the prevention of further absorption, the removal of lead from soft tissues and prevention of recurrence. Early recognition of cases will help in removing them from further exposure. A saline purge will remove unabsorbed lead from the gut. The use of d-penicillamine has been reported to be effective. Like Ca–EDTA, it is a chelating agent and works by promoting lead excretion in urine. Lead poisoning is a notifiable and compensatable disease in India since 1924.

OCCUPATIONAL CANCER

Occupational cancer is a serious problem in Industry. The sites of the body most commonly affected are skin, lungs, bladder, and blood-forming organs.

1. Skin cancer

Percival Pott was first to draw attention to cancer of scrotum in chimney sweeps in 1775. It was subsequently found that cancer of the scrotum and of the skin in other parts of the body was caused by coal tar, X-rays, certain oils and dyes. Statistics now show that nearly 75 per cent of occupational cancers are skin cancer *(28)*. Skin cancers are an occupational hazard among gas workers, coke oven workers, tar distillers, oil refiners, dye-stuff makers, road makers and in industries associated with the use of mineral oil, pitch, tar and related compounds.

2. Lung cancer

Lung cancer is a hazard in gas industry, asbestos industry, nickel and chromium work, arsenic roasting plants and in the mining of radio-active substances (e.g., uranium). Nickel, chromates, asbestos, coal tar (presumably 3–4 benzpyrene), radio-active substances and cigarette-smoking are proved carcinogens for the lungs. Arsenic, beryllium and isopropyl oil are suspected carcinogens. More than nine-tenths of lung cancer are attributed to tobacco smoking, air pollution and occupational exposure.

3. Cancer bladder

Cancer bladder was first noted in man in aniline industry in 1895. In more recent years, it was noted in the rubber industry. It is now known that cancer bladder is caused by aromatic amines, which are metabolized in the body and excreted in the urine. The industries associated with cancer bladder are the dye-stuffs and dyeing industry, rubber, gas and the electric cable industries. The following have been mentioned as possible bladder carcinogens. : Beta-naphthylamines, benzidine, para-amino-diphenyl, auramine and magenta *(28)*.

4. Leukaemia

Exposure to benzol, roentgen rays and radio-active

substances give rise to leukaemia. Benzol is a dangerous chemical and is used as a solvent in many industries. Leukaemia may appear long after exposure has ceased.

The characteristics of occupational cancer are : (1) they appear after prolonged exposure, (2) the period between exposure and development of the disease may be as long as 10 to 25 years, (3) the disease may develop even after the cessation of exposure, (4) the average age incidence is earlier than that for cancer in general, (5) the localization of the tumours is remarkably constant in any one occupation *(29)*.

Personal hygiene is very important in the prevention of occupational cancer.

Control of industrial cancer

The control measures comprise the following : (1) elimination or control of industrial carcinogens. Technical measures like exclusion of the carcinogen from the industry, well-designed building or machinery, closed system of production, etc., (2) medical examinations, (3) inspection of factories, (4) notification, (5) licensing of establishments, (6) personal hygiene measures, (7) education of workers and management, and (8) research *(30)*.

OCCUPATIONAL DERMATITIS

Occupational dermatitis is a big health problem in many industries. The causes may be; *Physical* – heat, cold, moisture, friction, pressure, X-rays and other rays; *Chemical* – acids, alkalies, dyes, solvents, grease, tar, pitch, chlorinated phenols etc. *Biological* – living agents such as viruses, bacteria, fungi and other parasites; *Plant products* – leaves, vegetables, fruits, flowers, vegetable dust, etc.

The dermatitis-producing agents are further classified into : (1) primary irritants, and (2) sensitizing substances. Primary irritants (e.g. acids, alkalies, dyes, solvents, etc.) cause dermatitis in workers exposed in sufficient concentration and for a long enough period of time. On the other hand, allergic dermatitis occurs only in small percentage of cases, due to sensitization of the skin.

PREVENTION : Occupational dermatitis is largely preventable if proper control measures are adopted : (1) *Pre-selection :* The workers should be medically examined before employment, and those with an established or suspected dermatitis or who have a known pre-disposition to skin disease should be kept away from jobs involving a skin hazard. (2) *Protection :* The worker should be given adequate protection against direct contact by protective clothing, long leather gloves, aprons and boots. The protective clothing should be frequently washed and kept in good order. There are also, what are known as *barrier creams* which must be used regularly and correctly. There is no barrier cream so far invented which will prevent dermatitis in all occupations. (3) *Personal hygiene :* There should be available a plentiful supply of warm water, soap and towels. The worker should be encouraged and educated to make frequent use of these facilities. Adequate washing facilities in industry are a statutory obligation under the Factories Act. (4) *Periodic inspection :* There should be a periodic medical check-up of all workers for early detection and treatment of occupational dermatitis. If necessary, the affected worker may have to be transferred to a job not exposing him to risk. The worker should be educated to report any skin irritation, no matter how mild or insignificant.

RADIATION HAZARDS

A number of industries use radium and other radio-active substances, e.g., painting of luminous dials for watches and other instruments, manufacture of radio-active paints. Exposure to radium also occurs in mining of radio-active ores, monozite sand workers and handling of their products. X-rays are used both in medicine and industry. Exposure to ultraviolet rays occurs in arc and other electric welding processes. Infrared rays are produced in welding, glass blowing, foundry work and other processes where metal and glass are heated to the molten state, and in heating and drying of painted and lacquered objects.

Effects of radiation

Occupational hazards due to ionizing radiation may be acute burns, dermatitis and blood dyscrasias; chronic exposure may cause malignancies and genetic effects. Lung cancer may develop in miners working in uranium mines due to inhalation of radio-active dust.

Preventive measures

(1) Inhalation, swallowing or direct contact with the skin should be avoided. (2) In case of X-rays, shielding should be used of such thickness and of such material as to reduce the exposure below allowable exposures. (3) The employees should be monitored at intervals not exceeding 6 months by use of the film badge or pocket electrometer devices. (4) Suitable protective clothing to prevent contact with harmful material should be used. (5) Adequate ventilation of work-place is necessary to prevent inhalation of harmful gases and dusts. (6) Replacement and periodic examination of workers should be done every 2 months. If harmful effects are found, the employees should be transferred to work not involving exposure to radiation, and (7) Pregnant women should not be allowed to work in places where there is continuous exposure.

OCCUPATIONAL HAZARDS OF AGRICULTURAL WORKERS

Occupational health in agriculture sector is a new concept. From the standpoint of capital investment and number of persons employed, agriculture may be termed as "big industry". Agricultural workers have a multitude of health problems – a fact which is often forgotten because of the widespread misconception that occupational health is mainly concerned with industry and industrialized countries. The health problems of workers in agriculture may be enumerated as below *(3, 31)*.

(1) ZOONOTIC DISEASES : The close contact of the agricultural worker with animals or their products increases the likelihood of contracting certain zoonotic diseases such as brucellosis, anthrax, leptospirosis, tetanus, tuberculosis (bovine) and Q fever. The extent of the occupational occurrence of these diseases in most parts of the world is not known.

(2) ACCIDENTS : Agricultural accidents are becoming more frequent, even in developing countries, as a result of the increasing use of agricultural machinery. Insect and snake bites are an additional health problem in India.

(3) TOXIC HAZARDS : Chemicals are being used increasingly in agriculture either as fertilizers, insecticides or pesticides. Agricultural workers are exposed to toxic hazards from these chemicals. Associated factors such as malnutrition and parasitic infestation may increase

susceptibility to poisoning at relatively low levels of exposure.

(4) PHYSICAL HAZARDS : The agricultural worker may be exposed to extremes of climatic conditions such as temperature, humidity, solar radiation, which may impose additional stresses upon him. He may also have to tolerate excessive noise and vibrations, inadequate ventilation and the necessity of working in uncomfortable positions for long periods of time.

(5) RESPIRATORY DISEASES : Exposure to dusts of grains, rice husks, coconut fibres, tea, tobacco, cotton, hay and wood are common where these products are grown. The resulting diseases – e.g., byssinosis, bagassosis, farmer's lung and occupational asthma, appear to be widespread.

ACCIDENTS IN INDUSTRY

Accidents are a common feature in most industries. In fact, some industries are known for accidents, e.g., coal and other mining industries, quarries, construction work. It was estimated that nearly 3 million mandays are lost yearly in India because of accidents. To the worker, the loss is in terms of his wages, apart from human suffering; to the industry, it is in terms of compensation costs, provision of medical care, lowered morale, lowered production and damage to machinery and goods; to the nation in terms of lost production.

CAUSES

The causes of accidents are several and may be grouped under two headings : human and environmental *(33)*.

(a) HUMAN FACTORS : Most authorities consider human factors much more important than environmental factors in accident causation, the former being responsible for 85 per cent of all accidents *(34)*. These factors are : (1) *PHYSICAL* : The physical capabilities of the worker may not meet the job requirements; his visual acuity may be inadequate; his hearing may be inadequate. (2) *PHYSIOLOGICAL FACTORS* : (a) *Sex* : Studies have shown that women are known to have less accidents than men, doing comparative jobs. In a study from the Physiological and Industrial Hygiene Section of the All India Institute of Hygiene and Public Health, Kolkata the ratio was 5:24 reportable accidents in Bengal (b) *Age* : Younger ages are known to be involved more in accidents than older age groups. The very old again are more prone to accidents. (c) *Time* : Accidents are minimum at the beginning of the day and increase gradually as fatigue sets in. (d) *Experience* : Approximately 50 per cent of the employees had accidents in their first 6 months of employment, 23 per cent in the next 6 months and only 3 per cent subsequently in certain industrial undertakings. Thus experience is an important factor in the occurrence of accidents. (e) *Working hours* : An increase in accidents is found whenever the daily or weekly working hours increase. (3) *PSYCHOLOGICAL* : These are mental factors that might involve a person in accidents – carelessness, inattentiveness, overconfidence, slow cerebration, ignorance, inexperience, emotional stress and accident proneness. Psychological factors appear to be more important factors than physiological factors.

(b) ENVIRONMENTAL FACTORS : Amongst the environmental factors known to influence the incidence of accidents are the temperature, poor illumination, humidity, noise and unsafe machines. Causes directly attributable to unsafe machines account for 10–20 per cent of all accidents.

Prevention

Accident prevention is a fascinating problem. Studies have shown that 98 per cent of the accidents are preventable. The principles of accident prevention are : (1) adequate preplacement examination. (2) adequate job training. (3) continuing education. (4) ensuring safe working environment. (5) establishing a safety department in the organization under a competent safety engineer. (6) periodic surveys for finding out hazards. (7) careful reporting, maintenance of records and publicity.

SICKNESS ABSENTEEISM

Sickness absence is an important health problem in industry. It may seriously impede production with serious cost repercussions, both direct as well as indirect. As the production techniques become more sophisticated, absenteeism tends to increase the adverse repercussions. Absenteeism is a useful index in industry to assess the state of health of workers, and their physical, mental and social well-being.

INCIDENCE : India has a working force of 5 million in registered factories. Research undertaken by the National Productivity Council (N.P.C.) into absenteeism showed a marked increase from around 8 to 13 per cent in the early 1950s to around 15 to 20 per cent or even more in recent years *(35)*. The rate of absenteeism was reported to be 8 to 10 days per head per year *(36)*.

CAUSES : The causes of sickness-absenteeism may not be entirely due to sickness : (a) *Economic causes* : Studies have shown that if the worker is entitled to sick leave with pay, he tends to avail of this privilege by reporting sick. It is so well remarked that in industry the workers declare themselves fit or unfit for work, at their choice *(37)*. (b) *Social causes* : Certain social factors appear to influence sickness absenteeism in India. These are the social and family obligations such as weddings, festivals, repair and maintenance of ancestral house and similar other causes. Some of the workers who come from rural areas go back to their villages, for short or long periods, during sowing and harvest seasons. (c) *Medical causes* : About 10 per cent of the days lost were found to be due to occupational accidents. Respiratory and alimentary illnesses have also been found to be important causes. (d) *Non-occupational causes* : Certain non-occupational causes such as nutritional disorders, alcoholism and drug addiction have also been found to be responsible for sickness-absenteeism.

PREVENTION: The prevention/reduction of sickness absenteeism would result in better utilization of resources and maximising the production. The methods for reducing sickness absenteeism include : (1) good factory management and practices (2) adequate preplacement examination (3) good human relations and (4) application of ergonomics.

HEALTH PROBLEMS DUE TO INDUSTRIALIZATION

Industrialization implies the transformation of a peasant society into a community dependent upon the industries. It involves individual and collective technical skills for the manufacture of particular goods through highly specialized processes. There is division of work under the same roof with emphasis on mass production and community profit. In short, industrialization means a social and economic revolution in the culture of a nation. Any such revolution is bound to carry with it some associated hazards.

The community health problems arising out of industrialization may be enumerated as follows. (1) ENVIRONMENTAL SANITATION PROBLEMS (a) HOUSING : A rise in the number of slums and insanitary dwellings is one of the chief problems in all industrial areas due to migration of people from the country-side for employment. The effect of sub-standard housing on the health of the population is discussed elsewhere in detail. (b) WATER POLLUTION : Water pollution is one of the tragic aftermath of rapid industrialization due to discharge of industrial wastes without treatment, into water courses. *Industrial wastes* may contain acids, alkalies, oils and other organic and inorganic chemicals, some of which may be toxic; synthetic detergents and radioactive substances. It requires legal, administrative and technical measures to deal with the situation. Pollution control measures should be instituted in the planning stage itself in the process of industrialization. (c) AIR POLLUTION : This is an important problem in industrial areas which may have an adverse effect on the health of the population. Air pollution is due to the discharge of toxic fumes, gases, smoke and dusts into the atmosphere. It requires proper town planning and zoning to eliminate this hazard. (d) SEWAGE DISPOSAL : There is bound to be pressure on the existing sanitation services if proper planning is not undertaken before locating industries. Lack of facilities for the disposal of sewage leads to pollution of water supply, contamination of soil with parasites and their ova. (2) COMMUNICABLE DISEASES : The main problems in industrial areas are tuberculosis, venereal diseases, and food and water borne infections. These are in addition to the specific diseases associated with specific industries. Industrial areas without proper sewage disposal have become hot-beds for filariasis owing to the breeding of the mosquito vectors in contaminated water. (3) FOOD SANITATION : The standards of food sanitation are bound to be lowered due to industrialization, if proper precautions are not taken. Food-borne infections such as typhoid fever and viral hepatitis are all too common in India. (4) MENTAL HEALTH : Mental health problems are due to altered living conditions. People are removed from the warmth of village community life and are transplanted in an alien environment which calls for certain adjustments. Failure of adjustment leads to mental illness, psychoneurosis, behaviour disorders, delinquency. etc. (5) ACCIDENTS : Accidents are a public health problem in industrial areas due to congestion, vehicular traffic and the increased tempo of life. These accidents are in addition to those that occur in the factories. (6) SOCIAL PROBLEMS : Alcoholism, drug addiction, gambling, prostitution, increased divorces, breaking up of home, juvenile delinquency, higher incidence of crime are some of the social problems due to industrialization. (7) MORBIDITY AND MORTALITY : Vital statistical rates indicate that industrial areas are characterized by high morbidity and mortality from certain diseases. For example the incidence of chronic bronchitis and lung cancer is higher in industrialized areas than in rural areas. The crude death rate and infant mortality rate tend to be high in industrial areas. India has special problems due to industrialization. It is because the level of public health is generally low, the average expectation of life is less than that in industrially advanced countries.

MEASURES FOR HEALTH PROTECTION OF WORKERS

The aim of occupational health is "the promotion and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations". The measures for the general health protection of workers was the subject of discussion by an ILO/WHO Committee on Occupational Health in 1953. The Committee recommended the following *(38)*.

1. Nutrition

In many developing countries, malnutrition is an important factor contributing to poor health among workers and low work output. Malnutrition may also affect the metabolism of toxic agents and also the tolerance mechanisms. Under the Indian Factories Act, it is obligatory on the part of the industrial establishments to provide a canteen when the number of employees exceed 250. The aim is to provide balanced diets or snacks at reasonable cost under sanitary control. It is important to combine this action with the education of the workers on the value of a balanced diet. If the worker carries his own lunch to work, provision should be made for a safe and uncontaminated place to store the food before it is eaten to avoid spoilage or contamination. Likewise, some place separate from the workroom should be provided so that the meal may be eaten in sanitary surroundings.

2. Communicable disease control

The industry provides an excellent opportunity for early diagnosis, treatment, prevention and rehabilitation. It is a general objective everywhere, to detect cases of communicable disease and to render them non-infectious to others by treatment or removal from the working environment, or both. The communicable diseases of special importance in India are tuberculosis, typhoid fever, viral hepatitis, amoebiasis, intestinal parasites, malaria and venereal diseases. There should be an adequate immunization programme against preventable communicable diseases. Anthrax, undulant fever, and Q fever are examples of communicable diseases which may be of occupational origin. Their control calls for special sanitary measures in the handling of working materials and substances.

3. Environmental sanitation

Within the industrial establishment, the following needs attention for the prevention of the spread of communicable diseases by water, food or other means : (1) WATER SUPPLY : A sufficient supply of wholesome drinking water is one of the basic requirements in all industrial establishments. The common glass tumbler for drinking water should be abandoned as it spreads infection. Installation of drinking water fountains, at convenient points should be encouraged. (2) FOOD : If food is sold, its sanitary preparation, storage and handling are essential. Education of food handlers and other measures may be necessary to prevent outbreaks of gastro-intestinal disease. (3) TOILET : There should be sufficient number of latrines and urinals of the sanitary type, separate for males and females, conveniently situated. It is recommended that there should be at least one sanitary convenience for every 25 employees (males and females separate) for the first 100 employees, and thereafter one for every 50. Garbage and waste disposal should be such as to avoid the breeding of flies and vermin. (4) GENERAL PLANT CLEANLINESS : The walls, ceilings and passages should be painted with water washable paint and repainted at least once in 3 years and washed at least once in every 6 months. The dust which settles down on the floor and machinery should be promptly

removed by vacuum cleaners or by wetting agents before it is redistributed into the atmosphere by the vibration of the machinery or buildings. A high standard of general cleanliness is one of the fundamentals of accident prevention. It also contributes to the efficiency and high morale of the workers. (5) SUFFICIENT SPACE : Sufficient floor space and cubic space are essential to prevent not only respiratory infections but also to ensure a comfortable working environment. The recommended standard is a minimum of 500 Cu. ft. of space for every worker; space more than 14 feet above the floor level is not to be taken into consideration. (6) LIGHTING : The results of poor industrial illumination are workers' eye fatigue, increased accidents, decreased production and more rejections of finished products. Furthermore, defective illumination over a long period of time may result in permanent impairment of vision. There should be sufficient and suitable lighting, natural or artificial or both, in every part of a factory where workers are working or passing through. The standards of illumination for different kinds of work have been set out – precision work for a high degree of accuracy may require 50–75 foot candles; where people work regularly, 6 to 12 foot candles may be sufficient. Illumination in corridors and passages should be at least 0.5 foot candles. (7) VENTILATION, TEMPERATURE: Poor ventilation not only increases the chances of infection from person to person, but also affects the mental and physical efficiency of the workers. Proper ventilation is also needed for the control of noxious vapours, fumes and dusts and prevention of fatigue and industrial accidents. Effective and suitable provision should be made for maintaining adequate ventilation by circulation of fresh air in every work room; and such a temperature which will secure to workers therein, reasonable conditions of comfort and prevent injury to health. (8) PROTECTION AGAINST HAZARDS: There should be adequate environmental controls designed to protect the workers against exposure to dusts, fumes and other toxic hazards. (9) HOUSING: There is usually an acute shortage of housing in industrial areas. Most workers come from rural areas. The housing of workers near a plant must be correlated to essential community amenities and to social and sanitary facilities. Town planning and zoning are highly desirable.

4. Mental health

The objective of an occupational health service is not only to keep the workers physically healthy, but mentally and psychologically stable. Industrial workers are susceptible to the effects of love, recognition, rejection, job satisfaction, rewards and discipline. The master-servant era is now disappearing from industry. The workers, individually and collectively, like to be recognized, like to have a measure of control over their own affairs, like to have the opportunity to develop skills appropriate to their individual capacity.

The goals of mental health in industry are : (1) to promote the health and happiness of the workers, (2) to detect signs of emotional stress and strain and to secure relief of stress and strain where possible, (3) the treatment of employees suffering from mental illness, and (4) the rehabilitation of those who become ill.

5. Measures for women and children

Women workers require special protection because (1) the developing embryo may be more susceptible to noxious agents than the exposed mother (e.g., in the case of methylmercury poisoning, (2) females may be less suited for some work tasks than men; pregnancy may decrease the capacity to cope with many work factors, (3) women tend to feed themselves less substantially than men and also restrict their nourishment in difficult economic circumstances, (4) the infant mortality is higher amongst children of women employed in industrial work.

The following types of protection are available for women workers in India : (1) Expectant mothers are given maternity leave for 12 weeks, of which 6 weeks precede the expected date of confinement; during this period they are allowed 'maternity benefit', which is a cash payment, under the Employees State Insurance Act, 1948. (2) Provision of free antenatal, natal and postnatal services. (3) The Factories Act (Section 66) prohibits night work between 7 p.m. and 6 a.m.; Section 34 prohibits carrying of excessive weights beyond a certain schedule which has been laid down. (4) The Indian Mines Act (1923) prohibits work underground. (5) The Factories Act, 1976 provides for creches in factories where more than 30 women workers are employed, and also prohibits the employment of women and children in certain dangerous occupations. Regarding protection of children, the Constitution of India declared: "No child below the age of fourteen shall be employed to work in any factory or mine or engaged in any other hazardous employment" (Chapter III, Fundamental Rights – Article 24).

6. Health education

Health education is a basic health need. It is an important health promotional measure. Health education in the industrial setting should be envisaged at all levels – the management, the supervisory staff, the worker, the trade union leaders and the community. The content varies from matters of personal hygiene and protection to participation of the workers in the planning and operation of the total health service programme in industry.

7. Family planning

Family planning is now recognized a decisive factor for the quality of life, and this applies to industrial workers also. The workers must adopt the small family norm.

PREVENTION OF OCCUPATIONAL DISEASES

The various measures for the prevention of occupational diseases may be grouped under three heads: medical, engineering and statutory or legislative.

1. MEDICAL MEASURES

1. Pre-placement examination

Pre-placement examination is the foundation of an efficient occupational health service. It is done at the time of employment and includes the worker's medical, family, occupational and social history; a thorough physical examination and a battery of biological and radiological examinations, e.g., chest X-ray, electro-cardiogram, vision testing, urine and blood examination, special tests for endemic disease. A fresh recruit may either be totally rejected or given a job suited to his physical and mental abilities. The purpose of preplacement examination is to place the right man in the right job, so that the worker can perform his duties efficiently without detriment to his health. This is ergonomics. The following is a list of some occupations in which it is risky to employ men suffering from certain diseases *(39)*.

Hazard	*Undesirable conditions*
(1) Lead	Anaemia, hypertension, nephritis, peptic ulcer
(2) Dyes	Asthma; skin, bladder and kidney diseases; precancerous lesions
(3) Solvents	Liver and kidney disease, dermatitis, alcoholism
(4) Silica	Healed or active tuberculosis of lungs, chronic lung disease
(5) Radium and X-rays	Signs of ill-health, especially any blood disease.

Pre-placement examination will also serve as a useful bench-mark for future comparison. It may be mentioned that in most countries, many workers start employment without the benefit of a pre-employment medical examination. This is particularly true of workers in small-scale industries and mines and those engaged in construction and agricultural work in the developing countries.

2. Periodical examination

Many diseases of occupational origin require months or even years for their development. Their slow development, very often, leads to their non-recognition in the early stages and this is harmful to the worker. This is the reason why a periodical medical check-up of workers is very necessary when they handle toxic or poisonous substances.

The frequency and content of periodical medical examinations will depend upon the type of occupational exposure. Ordinarily workers are examined once a year. But in certain occupational exposures (e.g., lead, toxic dyes, radium) monthly examinations are indicated. Sometimes, even daily examinations may be needed such as when irritant chemicals like dichromates are handled *(39)*. The periodical examinations may be supplemented, where necessary by biological and radiological examinations. Particular care should be given to workers returning from medical leave, to assess the nature and degree of any disability and to assess suitability or otherwise of returning to the same job.

3. Medical and health care services

The medical care of occupational diseases is a basic function of an occupational health service. In India, the Employees State Insurance Scheme provides medical care not only for the worker but also his family. Within the factory, first aid services should be made available. Properly applied first aid can reduce suffering and disability and hasten recovery. Immunization is another accepted function of an occupational health service.

4. Notification

National Laws and Regulations (Factories Act, 1976; Mines Act, 1952; Dock Labourers Act, 1948; etc.) require the notification of cases and suspected cases of occupational disease. In the Factories Act, a list of 22 diseases is included while in the Mines Act 3 diseases and in the Dock Regulations 8 diseases are listed. These diseases are recognized internationally for the purpose of workmen's compensation. The main purpose of notification in industry is to initiate measures for prevention and protection and ensuring their effective application; and to investigate the working conditions and other circumstances which have caused or suspected to have caused occupational diseases *(26)*.

5. Supervision of working environment

Periodic inspection of working environment provides information of primary importance in the prevention of occupational disabilities. The physician should pay frequent visits to the factory in order to acquaint himself with the various aspects of the working environment such as temperature, lighting, ventilation, humidity, noise, cubic space, air pollution and sanitation which have an important bearing on the health and welfare of the workers. He should be acquainted with the raw materials, processes and products manufactured. He should also study the various aspects of occupational physiology such as occurrence of fatigue, night–work, shift-work, weight carried by the workers and render advice to the factory management on all matters connected with the health and welfare of the workers. For studies of this kind the physician should enlist the cooperation of safety engineers, industrial hygienists and psychologists.

6. Maintenance and analysis of records

Proper records are essential for the planning, development and efficient operation of an occupational health service. The worker's health record and occupational disability record must be maintained. Their compilation and review should enable the service to watch over the health of the workers, to assess the hazards inherent in certain types of work and to devise or improve preventive measures.

7. Health education and counselling

Ideally, health education should start before the worker enters the factory. All the risks involved in the industry in which he is employed and the measures to be taken for personal protection should be explained to him. The correct use of protective devices like masks and gloves should also be explained. Simple rules of hygiene – hand-washing, paring the nails, bodily cleanliness and cleanliness of clothes, should be impressed upon him. He should be frequently reminded about the dangers in industry through the media of health education such as charts, posters and hand bills. The purpose of health education is to assist the worker in his process of adjustment to the working, home and community environment.

2. ENGINEERING MEASURES

1. Design of building

Measures for the prevention of occupational diseases should commence in the blue-print stage. The type of floor, walls, height, ceiling, roof, doors and windows, cubic space are all matters which should receive attention in the original plan of the building which is put up by the industrial architect. Once the building is constructed, it would be difficult to introduce alterations without much trouble and expense.

2. Good house-keeping

Good house-keeping is a term often applied to industry, and means much the same as when used domestically. It covers general cleanliness, ventilation, lighting, washing, food arrangements and general maintenance. Good housekeeping is a fundamental requirement for the control or elimination of occupational hazards. It also contributes to efficiency and morale in industry. The walls, ceilings, and passages should be white-washed at least once a year. The

dust which settles down on the floor, ledges, beams, machinery and other stationery objects should be promptly removed by vacuum cleaners or by wetting agents. Masks, gloves, aprons and other protective equipment should be kept clean and in a state of good repair. To prevent accidents, the right thing should be in the right place. Not only the inside, but the outside of the plant should also be kept clean and tidy.

3. General ventilation

There should be good general ventilation in factories. It has been recommended that in every room of a factory, ventilating openings shall be provided in the proportion of 5 sq. feet for each worker employed in such room, and the openings shall be such as to admit a continued supply of fresh air. In rooms where dust is generated there should be an efficient exhaust ventilation system. Good general ventilation decreases the air-borne hazards to the workers, especially hazards from dusts and gases. The Indian Factories Act has prescribed a minimum of 500 cu. ft. of air space for each worker.

4. Mechanization

The plant should be mechanized to the fullest possible extent to reduce the hazard of contact with harmful substances. Dermatitis can be prevented if hand-mixing is replaced by mechanical devices. Acids can be conveyed from one place to another through pipes. There may be other similar situations where mechanisation can be substituted to hand-operation.

5. Substitution

By substitution is meant the replacement of a harmful material by a harmless one, or one of lesser toxicity. A classical example is the substitution of white phosphorus by phosphorus sesquisulphide in the match industry, which resulted in the elimination of necrosis of jaw (Phossy jaw). Zinc or iron paints can be used in place of harmful lead paints; silver salts can be used in place of mercury salts; acetone can be used in place of benzene. But substitution is not always possible in industry. Where possible, it should be used to the fullest possible extent.

6. Dusts

Dusts can be controlled at the point of origin by water sprays, e.g., wet drilling of rock. Inclusion of a little moisture in the materials will make the processes of grinding, sieving and mixing comparatively dust-free. Wet methods should be tried to combat dust before more elaborate and expensive methods are adopted.

7. Enclosure

Enclosing the harmful materials and processes will prevent the escape of dust and fumes into the factory atmosphere. For example, grinding machinery can be completely enclosed. Such enclosed units are generally combined with exhaust ventilation.

8. Isolation

Sometimes it may be necessary to isolate the offensive process in a separate building so that workers not directly connected with the operation are saved from exposure. Isolation may not be only in space, but also in the fourth dimension of time. Certain operations can be done at night in the absence of the usual staff.

9. Local exhaust ventilation

By providing local exhaust ventilation dusts, fumes and other injurious substances can be trapped and extracted "at source" before they escape into the factory atmosphere. The heart of the local exhaust ventilation is the hood which is placed as near as possible to the point of origin of the dust or fume or other impurity. Dusts, gases and fumes are drawn into the hood by suction and are conveyed through ducts into collecting units. In this way, the breathing zone of workers may be kept free of dangerous dust and poisonous fumes.

10. Protective devices

Respirators and gas masks are among the oldest devices used to protect workers against air-borne contaminants and they are still used for that purpose. There are two classes of respirators : (i) those which remove contaminants from air, (ii) those to which fresh air is supplied. The workers should know what kinds to use, and when and how to use. Respiratory devices should not be used as substitute for other control methods. The other protective devices comprise ear plugs, ear muffs, helmets, safety shoes, aprons, gloves, gum boots, barrier creams, screens and goggles. The worker should be instructed in the correct use of protective devices.

11. Environmental monitoring

An important aspect of occupational health programme is environmental monitoring. It is concerned with periodical environmental surveys, especially sampling the factory atmosphere to determine whether the dusts and gases escaping into the atmosphere are within the limits of permissible concentration. The use of "permissible limits" has played an important part in reducing occupational exposure to toxic substances. Thermal environment, ventilation, lighting would also have to be monitored. Such monitoring should be done by joint collaboration of doctors and engineers.

12. Statistical monitoring

Statistical monitoring comprises review at regular intervals of collected data on health and environmental exposure of occupational groups. The main objective of these reviews is to evaluate the adequacy of preventive measures and occupational health criteria, including permissible exposure levels.

13. Research

Research in occupational health offers fertile ground for study which can provide a better understanding of the industrial health problems. There are two kinds of research – pure research and research for the improvement of, or in connection with a manufactured product. Both are important. Study of the permissible limits of exposure to dusts and toxic fumes, occupational cancer, accident prevention, industrial fatigue and vocational psychology are some aspects of research in occupational health.

3. LEGISLATION

Society has an obligation to protect the health of the worker engaged in diverse occupations. It has grown out of the realisation that the worker is more important than the machine which he operates. The worker cannot be permitted to endanger his life and limb in an occupation,

while the employer makes a fortune. Factory laws, therefore, have been framed in every country to govern the conditions in industry and to safeguard the health and welfare of the worker. The most important factory laws in India today are:

(1) The Factories Act, 1948

(2) The Employees' State Insurance Act, 1948

There are other specialized Acts adapted to the particular circumstances of the industry, e.g., the Mines Act, the Plantation Act, the Minimum Wages Act, the Maternity Benefit Act, etc. All these Acts lay down certain standards to which the employer must comply to ensure health and safety to workers.

The Factories Act, 1948

The first Indian Factories Act dates as far back as 1881. The Act was revised and amended several times, the latest being the Factories (Amendment) Act, 1987. A brief description of the Act is given below:

(1) SCOPE: The Act defines factory as an establishment employing 10 or more workers where power is used, and 20 or more workers where power is not used. There is no distinction between perennial and seasonal factories. The 1976 amendment modifies the definition of the term 'worker' so as to include within its meaning contract labour employed in the manufacturing process. The Act applies to the whole of India except the State of Jammu and Kashmir. The State Governments are authorized to appoint besides the Chief Inspector of Factories as many Additional Chief Inspectors, Joint Chief Inspectors, Deputy Chief Inspectors and Inspectors as they think fit to enforce the provisions of the law.

(2) HEALTH, SAFETY AND WELFARE : (Chapter III, IV, IVA, & V). Elaborate provisions have been made in the Act with regard to health, safety and welfare of the workers. In addition to such matters as cleanliness, lighting and ventilation, the Act provides for the treatment of wastes and effluents so as to render them innocuous, and for their disposal, the elimination of dusts and fumes, the provision of spittoons, control of temperature, supply of cool drinking water during summer and for the employment of cleaners to keep the water closets clean. A minimum of 500 Cu.ft of space for each worker has been prescribed (not taking into account space more than 14 feet above the ground level). For factories installed before the 1948 Act, a minimum of 350 Cu.ft of space has been prescribed.

The Act also prescribes in detail the precautions which should be taken for ensuring the safety of workers. Some of the safety provisions relate to the casing of new machinery, devices for cutting off the power, hoists and lifts, cranes and other lifting devices, protection of the eyes and precautions against dangerous fumes, explosive and inflammable material. The Act provides that no worker shall be required to lift or carry loads which are likely to cause him injury. The State Governments are empowered to prescribe maximum weights which may be lifted or carried by men, women and children. The 1976 amendment (Section 40 B) provides for the appointment of 'Safety Officers' in every factory wherein 1,000 or more workers are ordinarily employed.

The Act contains a separate Chapter (Chapter V) relating to specific welfare measures, e.g., washing facilities, facilities for storing and drying clothes, facilities for sitting, first-aid appliances, shelters, rest-rooms and lunch rooms, canteens and creches. The Act specifies that wherein more than 250 workers are ordinarily employed, a canteen shall be provided. The 1976 amendment provides for creches in every factory wherein more than 30 women workers are ordinarily employed. In every factory, wherein 500 or more workers are ordinarily employed, there should be a Welfare Officer.

(3) EMPLOYMENT OF YOUNG PERSONS: The Act prohibits employment of children below the age of 14 years and declares persons between the ages 15 and 18 to be adolescents. Adolescents should be duly certified by the "Certifying Surgeons" regarding their fitness for work. Restrictions have been laid down on employment of women and children in certain dangerous occupations. Child who has not completed his fourteenth year of age has been restricted from employment in any factory. Adolescent employee is allowed to work only between 6 A.M. & 7 P.M.

(4) HOURS OF WORK: The Act has prescribed a maximum of 48 working hours per week, not exceeding 9 hours per day with rest for at least $^1/_2$ hour after 5 hours of continuous work. For adolescents, the hours of work have been reduced from 5 to $4^1/_2$ per day. The 1976 amendment makes a provision to increase the spread-over period of work (including rest intervals) of an employee in a factory upto 12 hours from the existing $10^1/_2$ hours. The total number of hours of work in a week including overtime shall not exceed 60.

(5) LEAVE WITH WAGES: The Act lays down that besides weekly holidays, every worker will be entitled to leave with wages after 12 month's continuous service at the following rate; adult – one day for every 20 days of work, children – one day for every 15 days of work. The leave can be accumulated up to 30 days in case of adults and 40 days in case of children.

(6) OCCUPATIONAL DISEASES: It is obligatory on the part of the factory management to give information regarding specified accidents which cause death, serious bodily injury or regarding occupational diseases contracted by employees. The Act gives a schedule of notifiable diseases. The 1976 amendment includes Byssinosis, Asbestosis, occupational dermatitis and noise-induced hearing loss among the list of notifiable diseases and provides for enquiry in every case of a fatal accident. Provision has also been made in the 1976 amendment for safety and occupational health surveys in factories and industries.

(7) EMPLOYMENT IN HAZARDOUS PROCESSES : The Central Govt. has incorporated a new Chapter IV-A by the Factories (Amendment) Act, 1987, relating to hazardous processes. Site Appraisal Committee consisting of Chief Inspector and other members, not more than 14 in number, for examination of service conditions of employees in a factory, involving hazardous processes, is to be constituted for recommendations. Specific responsibility of the occupier in relation to hazardous processes were also made with workers' participation in safety management. List of industries involving hazardous processes is prescribed in 1st schedule of the Act.

The Employees State Insurance Act, 1948 *(40)*

The ESI Act passed in 1948 (amended in 1975, 1984, 1989 and 2010) is an important measure of social security and health insurance in this country. It provides for certain *cash* and *medical benefits* to industrial employees in case of sickness, maternity and employment injury.

SCOPE

The Act extends to the whole of India. The ESI Act of 1948 covered all power-using factories other than seasonal factories wherein 10 or more persons were employed (excluding mines, railways and defence establishments). The provisions of the ESI (Amendment) Act of 1975 were extended to the following new classes of establishments :

a) Small factories employing 10 or more persons, whether power is used in the process of manufacturing or not.
b) Shops;
c) Hotels and restaurants;
d) Cinemas and theatres;
e) Road-motor transport establishments; and
f) Newspaper establishments.
g) The scheme has been extended to private medical and educational institutions employing 20 or more persons in some states.

With effect from 1.5.2010 the Act covers all employees – manual, clerical, supervisory and technical getting upto Rs.15,000 per month. The provisions of the Act can be extended to any other agricultural or commercial establishment.

ADMINISTRATION

The administration of the ESI Scheme under the Act is entrusted to an autonomous body called the ESI *Corporation.* The Union Minister for Labour is the Chairman and the Secretary to Govt. of India Ministry of Labour is the Vice-Chairman of this corporation. It consists of members representing Central and State Governments, employers and employees' organizations, medical profession and Parliament. There is a Standing Committee, constituted from the members of the Corporation, which acts as an executive body for the administration of the Scheme. The chief executive officer of the Corporation is the Director General who is assisted by four Principal Officers – (1) Insurance Commissioner (2) Medical Commissioner (3) Financial Commissioner (4) Actuary. There is a Medical Benefit Council which is headed by the Director General of Health Services, Government of India who is assisted by the Medical Commissioner in all matters relating to medical relief. Besides the head office in New Delhi, the corporation has 23 regional offices and 26 sub-regional offices at 2 divisional offices and 624 branch offices, 197 cash offices and 406 inspection offices all over the country for the administration of the scheme.

Given the huge number of beneficiaries – about 720 lakhs by 31.3.13 – the corporation has set up a wide spread network of service outlets for prompt delivery of benefits in cash and kind that includes full medical care. ESI gives coverage to about 185 lakh family units of about 165 lakh employees including about 26.79 lakh females, as on 31.3.13.

Medical facilities are provided through a network of 1384 ESI dispensaries, over 2100 panel clinics, 307 diagnostic centres, besides 151 ESI hospitals and 42 hospital annexes with over 27,000 beds. For providing super-speciality medical care the corporation has tie up arrangements with advanced medical institutions in the country, both in public and private sector. The medical benefit is administered with the active co-operation of state governments.

The payment of cash benefits is made at the grass root level through as many as 624 branch offices, 197 cash offices that function under the direct control of the corporation.

There are 406 inspection offices throughout the country to inspect factories and for checking insurability of employees and correct payment of contributions *(41).*

FINANCE

The scheme is run by contributions by employees and employers and grants from Central and State Governments. The employer contributes 4.75 per cent of total wage bill; the employee contributes 1.75 per cent of wages (revised rates w.e.f. 1.1.97). Employees getting daily wages of below Rs.70 are exempted from payment of contribution. The State Government's share of expenditure on medical care is 1/8 of total cost of medical care; the ESI Corporation's share of expenditure on medical care is 7/8 of total cost of medical care.

BENEFITS TO EMPLOYEES

The Act has made provision for the following benefits to insured persons or , to other dependants as the case may be:

(1) Medical benefit
(2) Sickness benefit
(3) Maternity benefit
(4) Disablement benefit
(5) Dependant's benefit
(6) Funeral expenses
(7) Rehabilitation allowance.

1. Medical benefit

Medical benefit consists of "full medical care" including hospitalization, free of cost, to the insured persons in case of sickness, employment injury and maternity. The services comprise : (1) out-patient care (2) supply of drugs and dressings (3) specialist services in all branches of medicine (4) pathological and radiological investigations (5) domiciliary services (6) antenatal, natal and postnatal services (7) immunization services (8) family planning services (9) emergency services (10) ambulance services (11) health–education and (12) in-patient treatment. In complicated cases where specialized treatment is necessary, patients are sent for institutional treatment even outside their State at the expense of the ESI Corporation.

Medical care is provided either *directly* through the agency of ESI hospitals and dispensaries, or *indirectly* through a panel of private medical practitioners (panel system) appointed as "insurance medical practitioners". DIRECT PATTERN : (1) In areas having a concentration of 1,000 or more employees' family units, service dispensaries are established with full-time medical and para-medical personnel. On an average, a doctor will attend to about 80 cases in the out-patient department per day, and makes one home visit a day. (2) In areas where the employees are less than 750, part-time ESI dispensaries are established. (3) If the residential concentration of employees is scattered over a long distance, mobile dispensaries are established. INDIRECT PATTERN: This is known as "panel system". Registered medical practitioners designated as Insurance Medical Practitioners are appointed to provide medical care.

Medical care is also extended to families of workers where requisite arrangements could be made. A start has been made by providing "restricted medical care", i.e., only out-patient care. Where facilities are available "expanded medical care" i.e., full medical care short of hospitalization is given.

OTHER MEDICAL FACILITIES :(1) Dentures, spectacles and hearing aids are provided free to patients who are incapacitated due to employment injury (2) Artificial limbs are provided free to insured persons who lose their limbs in employment injury or otherwise (3) Special appliances such as hernia belts, walking callipers, surgical boots, spinal braces and jackets are provided as prescribed by specialists.

COST OF MEDICAL BENEFIT: The per capita cost of medical benefit under the ESI Scheme has been steadily increasing. It was Rs. 23.79 in 1961–62, Rs. 58.91 in 1969–70, Rs. 67.53 in 1973–74, Rs. 406.78 in 1992–93 and Rs. 905 in 2001–02, and has been rising further since then. Expenditure on medical benefit was Rs. 4058 crores in 2012–13.

2. Sickness benefit

It consists of periodical cash payment to an insured person in case of sickness, if his sickness is duly certified by an Insurance Medical Officer or Insurance Medical Practitioner. The benefit is payable for a maximum period of 91 days, in any continuous period of 365 days, the daily rate being about 50% of the average daily wages. A person receiving the sickness benefit is required to remain under medical treatment provided under the Act.

EXTENDED SICKNESS BENEFIT: In addition to 91 days of sickness benefit, insured persons suffering from certain long-term diseases are entitled to Extended Sickness Benefit as shown below, for a maximum period of two years.

34 diseases for which Extended Sickness Benefit with effect from 1.1.2000 is payable, in case where the insured person has been in continuous employment for 2 years :

I. Infectious Diseases
1. Tuberculosis.
2. Leprosy.
3. Chronic empyema.
4. AIDS.

II. Neoplasms
5. Malignant diseases.

III. Endocrine, Nutritional and Metabolic Disorders
6. Diabetes mellitus with proliferative retinopathy/ Diabetic foot/Nephropathy.

IV. Disorders of Nervous Systems
7. Monoplegia.
8. Hemiplegia.
9. Paraplegia.
10. Hemiparesis.
11. Intracranial space occupying lesion.
12. Spinal Cord compression.
13. Parkinson's disease.
14. Myasthenia Gravis/Neuromuscular dystrophy.
15. Immature cataract with vision 6/60 or less.
16. Detachment of retina.
17. Glaucoma.

V. Diseases of Cardiovascular System
18. Coronary Artery Disease
    a. Unstable angina.
    b. Myocardial infarction with ejection less than 45%.
19. Congestive Heart Failure – Left, Right.
20. Cardiac valvular diseases with failure/complications.
21. Cardiomyopathies.
22. Heart disease with surgical intervention alongwith complications.

VI. Chest Diseases
23. Bronchiectasis.
24. Interstitial Lung Disease.
25. Chronic Obstructive Lung Diseases (COPD) with congestive heart failure (Cor Pulmonale).

VII. Diseases of the Digestive System
26. Cirrhosis of liver with ascities/chronic active hepatitis.

VIII. Orthopaedic Diseases
27. Dislocation of vertebra/prolapse of intervertebral disc.
28. Non union or delayed union of fracture.
29. Post Traumatic Surgical amputation of lower extremity.
30. Compound fracture with chronic osteomyelitis.

IX. Psychosis
31. Sub-group under this head are listed for clarification
    a. Schizophrenia.
    b. Endogenous depression.
    c. Manic Depressive Psychosis (MDP).
    d. Dementia.

X. Others
32. More than 20% burns with infection/complication
33. Chronic renal failure.
34. Reynaud's disease/Burger's disease.

The insured person is protected from dismissal or discharge from service by the employer during the period of sickness.

Cash benefit is also payable to insured persons in the productive age group for undergoing sterilisation operation, viz. vasectomy/ tubectomy.

- Enhanced sickness benefit is payable to insured women for 14 days for tubectomy and for 7 days in case of vasectomy in respect of male IPs.
- The amount payable is double the standard sickness benefit rate, that is, equal to full wages.

3. Maternity benefit

The benefit is payable in cash to an insured woman for confinement/miscarriage or sickness arising out of pregnancy/confinement or premature birth of child or miscarriage. For confinement, the duration of benefit is 12 weeks (84 days), for miscarriage 6 weeks and for sickness arising out of confinement etc. 30 days. The benefit is allowed at about full wages. The rate of confinement expenses has been increased from Rs. 2,500 to Rs. 5,000 per confinement.

4. Disablement benefit

The Act provides for cash payment, besides free medical treatment, in the event of temporary or permanent disablement as a result of employment injury as well as

occupational diseases. The rate of temporary disablement benefit is about 90 per cent of the wages as long as the temporary disablement lasts. In case of total permanent disablement, the insured person is given life pension worked out on the basis of loss of earning capacity determined by a medical board, while in cases of partial permanent disablement a portion of it is granted as life pension.

5. Dependant's benefit

In case of death, as a result of employment injury, the dependants of an insured person are eligible for periodical payments. Pension at the rate of 90 per cent of the wages is payable, shared by dependants in a fixed ratio, on monthly basis in accordance with the prescribed share. An eligible son or daughter is entitled to dependant's benefit up to the age of 18; the benefit is withdrawn if the daughter marries earlier.

6. Funeral expenses

Funeral benefit is a cash payment payable on the death of an insured person towards the expenses on his funeral, the amount not exceeding Rs. 10,000/- w.e.f. 1.4.11.

7. Rehabilitation

On monthly payment of Rs 10, the insured person and his family members continue to get medical treatment after permanent disablement, or retirement.

The ESI Scheme has been implemented in 30 States/ Union territories. The Scheme, by 31.03.13, covered 165.04 lakh employees; including 26.79 lakhs women, and the total number of beneficiaries were around 720 lakhs *(40)*. Coverable employees in non-implemented areas were 13.89 lakhs.

Benefits to employers

(1) Exemption from the applicability of Workmen's Compensation Act 1923

(2) Exemption from Maternity Benefit Act 1961

(3) Exemption from payment of Medical allowance to employees and their dependants or arranging for their medical care

(4) Rebate under the Income Tax Act on contribution deposited in the ESI Account

(5) Healthy work-force.

As on 31.03.2013, about 6.66 lakhs employers were covered under the scheme *(41)*.

RAJIV GANDHI SHRAMIK KALYAN YOJNA *(41)*

The ESI Corporation has launched a new Yojna for the employees covered under the ESI scheme. This scheme provides an unemployment allowance for the employees covered under ESI scheme who are rendered unemployed involuntarily due to retrenchment/closure of factory etc. after fulfilling certain eligibility conditions. The scheme came into effect from 1st April, 2005.

As per this scheme, an insured person going out of insurable employment involuntarily, on account of closure of a factory or establishment, retrenchment, or permanent invalidity arising out of non-employment injury, after rendering insurable employment and having contributed under the scheme for five or more years, is entitled to claim unemployment allowance for maximum period of 6 months during his/her entire service.

The allowance can be availed in one spell or in different spells of not less than one month.

The daily rate of unemployment allowance is the "standard benefit rate" as specified in the table on standard benefit rates under rule-54 of ESI (Central) Rules, 1950 corresponding to the average daily wage drawn by the insured person.

During the period for which a person is entitled for unemployment allowance, he is also eligible for medical care for himself and his/her family from ESI dispensaries, ESI panel clinics and ESI hospitals to which he/she was attached prior to the date of loss of employment.

OCCUPATIONAL HEALTH IN INDIA

The trend in India is towards industrialization. As industries develop, both in size and complexity, occupational health will pose new and more difficult problems. The National Government have recognised the need for protecting the health of the workers. The Directive Principles of State Policy, in the Indian Constitution are important in this context. The relevant portions are :

(a) "The State shall, in particular, direct its policy towards securing that the health and strength of the workers, man, woman, and the tender age of the children are not abused, and that citizens are not forced by economic necessity to enter avocations unsuited to their strength.

(b) The State shall make provisions for securing just and humane conditions of work",

To assess the health conditions of the workers, a number of inquiries have been conducted and were submitted to the Government of India by many experts. The important reports in this connection are: Adarkar's Report of Health Insurance for Industrial Workers (1945); Report of the Health Survey and Development Committee (1946); Report of the Health of the Industrial Workers (Thomas Bedford, 1946) and Report on the Health of Workers in Plantation (Jones, 1947). The Government of India have given practical shape to some of the recommendations contained in these reports and have introduced certain legislative measures pertaining to both the curative and preventive aspects of occupational health. Most important among these measures are the Indian Factories Act 1948, the Coal Mines Labour Welfare Act (1947) and the Employees State Insurance Act (1948).

At present, there is no comprehensive occupational health service in India. However, there are various organizations active in the field of occupational health. The Organization of the Chief Adviser of Factories – now Directorate General, Factory Inspection and Advisory Service – was set up in 1945, to function as an integrated service to advise the Government, industries, and other interests concerned in matters relating to health, welfare and safety of industrial workers. The Organization deals with questions relating to the administration of the Factories Act and other Acts and the rules framed thereunder and the training of Factory Inspectors.

For scientific study of the various aspects of occupational health, particularly the "human factor" in industry, the Central Labour Institute was set up in Mumbai in 1960. Three Regional Labour Institutes at Kanpur, Kolkata and Chennai have also been set up. These institutes are dealing with a variety of activities important in the field of safety and

health. They have (a) a Museum of Industrial Health, Safety and Welfare (b) Industrial Hygiene Laboratory (c) Training section (d) Library cum Information Centre (e) Industrial psychology and (f) Occupational Physiology sections.

At the State level, the Departments of Health and Labour, through the Chief Inspector of Factories and Industrial Health Inspection Service are rendering assistance by making studies and undertaking surveys at the plant level and enforcing the legal standards laid down in the various Acts.

In addition to the above, the following Research Institutes are active in the field of occupational health : (1) The Central Mining and Research Station, Dhanbad under the Council of Scientific and Industrial Research (CSIR). (2) Industrial Toxicology Research Centre, Lucknow under the CSIR. (3) Occupational Health Research Institute, Ahmedabad under the Indian Council of Medical Research (4) National Environmental Engineering Research Institute at Nagpur (5) The All India Institute of Hygiene and Public Health, Kolkata. (6) Indian Institute of Technology, Kanpur. Besides these, the Indian Council of Medical Research has an occupational health division. The Indian Association of Occupational Health is playing an important role in the promotion of occupational health.

6 Genetics and health

"Human genetics is much more than the study of mere inborn abnormalities"

The basic principles of genetics were laid down by Mendel and Galton towards the close of the 19th century. But it is only during the past few years the science of genetics including human genetics has made rapid progress. The discovery of the biological role of nucleic acids, the uncovering of the structure of genetic information and its role in regulating life processes are discoveries, the importance of which can hardly be over estimated.

With increasing control of communicable diseases and infant mortality, inherited abnormalities are assuming a proportionately greater importance in medical practice. Over 2,300 hereditary diseases have been identified and more are added to the list every year. According to many authors, genetically conditioned diseases or diseases with a clear genetic component account for 25–40 per cent of all cases treated by the health services *(1)*.

Human genetics is much more than the study of mere hereditary diseases. It has emerged as a basic biological science for understanding the endogenous factors in health and disease and the complex interaction between nature and nurture. Owing to rapid specialization, several branches in genetics have come into being, e.g., cytogenetics, biochemical genetics, clinical genetics, pharmacogenetics, immunogenetics, microbial genetics, population genetics and so on. Achievements in these fields have created a basis for effective medical and preventive intervention in many diseases, and also possibly of "genetic engineering", i.e., of controlling the traits of an individual.

Cytologic facts

In 1956, Tjio and Levan surprised the scientific world by reporting that they could find only 46 chromosomes in the normal human karyotype. This was immediately confirmed by other workers. There is now universal agreement that the normal human body cell (except the sex cells) contains 46 chromosomes, i.e., 22 pairs of autosomes and a pair of sex chromosomes, XX in the female and XY in the male. The chromosomes vary in length, the longest being about 5 times as long as the smallest. Each pair of chromosomes is homologous. The autosomes are numbered according to their length, the first pair being the longest and the last pair the shortest. The sex chromosomes are not included in the numbering, but are merely termed X and Y. Barr and his group discovered that the normal female cell nucleus contains in addition a dark-staining area at the periphery of cell nucleus, called a Barr body or "sex chromatin" body which is not present in normal males.

The autosomes have been classified and divided on the basis of length and certain morphological similarities into 7 groups as follows :

Group A	.....	1 to 3	pairs
Group B	.....	4 and 5	pairs
Group C	.....	6 to 12	pairs
Group D	.....	13 to 15	pairs
Group E	.....	16 to 18	pairs
Group F	.....	19 and 20	pairs
Group G	.....	21 and 22	pairs

The X-chromosome is included in Group 'C' with chromosomes 6–12, and the Y-chromosome is included in Group G with chromosomes 21 and 22.

Mitosis

During ordinary cell division, each chromosome divides lengthwise into two sister chromosomes called *chromatids*. The chromatids are joined together for a short time at a point called *centromere*. Then the chromatids separate, one goes to one daughter cell, and one to the other daughter cell. In this manner, each daughter cell inherits the same number and kind of sister chromosomes. This process of nuclear division is called *mitosis*.

Meiosis

The reproductive cells (sperms and ova) are produced in a different manner. There are two nuclear divisions and only one chromosome division. This form of division is called 'reduction division' or *meiosis*. A detailed description of meiosis is unnecessary here. Broadly, the main events in meiosis are : (1) The homologous chromosomes first come together. This is called "pairing". (2) The chromosomes then replicate – each doubling into two chromatids which are held together at centromere. (3) At this stage there is "crossing over" and a redistribution of genetic material. (4) Then the homologous chromosomes separate – one goes to one pole of the nucleus and the other to the other pole. The chromosome number is thus reduced to half, i.e., 23. (5) The cell divides and the nucleus of each daughter cell contains 23 chromosomes. (6) The second meiotic division follows : the centromeres divide and the chromatids move apart. (7) The cell divides again so that the daughter cells each contain 23 chromosomes. During fertilization, the two half-sets come together and restore the full compliment of 46. The full compliment of 46 chromosomes is called the *diploid* number, and the half set of 23 is called the *haploid* number.

Chromosomes

Chromosomes are rod-like condensations of chromatin. They become visible in the nucleus only during cell division. They occur in pairs – one member of each pair comes from

the father, and other from the mother. The largest chromosome measures about 7 μ and is about five times the length of the shortest. Biochemically, the chromosomes are made up of deoxyribonucleic acid (DNA). Genetically, they consists of genes arranged like the beads of a necklace. The number of chromosomes in each species is fixed. All individuals of the same species have the same number of chromosomes (with exceptions). Thus the total number for man is 46, the fruit fly 8, garden peas 14 and potato 48.

Methods of Chromosomal Study : Buccal smears, peripheral blood, bone marrow, skin and in some instances testis tissue are used to study chromosomes. More information can be obtained by using cell cultures. Cells, which are usually peripheral white blood cells, are cultured in the proper medium and incubated for 3 days. Colchicine is then added to arrest cells in metaphase. After further incubation for 3 to 5 hours, the cells are placed in a hypotonic solution which causes them to swell and the chromosomes to disperse within the cell. The cells are fixed, stained and examined for chromosomes. A more recent discovery in cytogenetics is the fluorescent staining of chromosomes. It has been shown that human chromosomes treated with quinacrine hydrochloride (Atabrine) or quinacrine mustard exhibit distinct fluorescence *(2)*.

Genes

Genes are the units of heredity. They contain the hereditary information encoded in their chemical structure for transmission from generation to generation. They affect development and function, both normal and abnormal. Though genes are not seen with a microscope, much is known about them by indirect methods. It is said we inherit about 50,000 genes from the father and 50,000 from the mother. The genes occupy a specific position or *locus* on the chromosomes. For example, the locus for the ABO blood groups is in chromosome 9 and the *locus* for the major histocompatibility complex is in chromosome 6. The Y-chromosome contains genes that determine the normal development of testis. It is known that the human X-chromosome carries the genes governing a blood group haemophilia, red-green colour-blindness, glucose-6-phosphate dehydrogenase, muscular dystrophy, height and gonadal development *(3)*. Presumably, some thousands of loci are contained in chromosomes. More than 20 loci have been assigned to chromosome '1' including the Rh locus. More than 100 loci have been assigned to X-chromosome *(4)*.

Since genes are contained in the chromosomes, genes also occur in pairs. If the genes comprising a pair are alike (AA), the individual is described as *homozygous* for that gene, and if it is different (Aa) the individual is described as heterozygous.

A gene is said to be *dominant* when it manifests its effect both in the heterozygous and the homozygous state. A gene is said to be *recessive* when it manifests its effect only in the homozygous state. Genes whose combined action affects one particular character are known as *polygenes* or "multiple genes". In man three genes have been identified as being responsible for muscular dystrophy – one is a sex-linked recessive gene, the second is an autosomal recessive, and the third is an autosomal dominant gene. Many instances are known in which the same character is controlled by several genes – the colour of our skin, height and weight, life span, degree of resistance to disease, rate of heart beat, arterial blood pressure and many other inherited traits. These genes may occupy separate positions in the chromosomes; some may be widely distributed on several non-homologous chromosomes *(3)*. The extent to which a genetically determined condition is expressed in an individual is called *penetrance*. Lack of penetrance is one reason for skipped generations and unexpected pedigree patterns *(4)*.

Genes are usually stable, but sometimes normal genes may be converted into abnormal ones – this change is called mutation. Mutation is a regular phenomenon in nature. The natural mutation rate is increased by exposure to mutagens such as ultraviolet rays, radiation or chemical carcinogens *(5)*.

Genotype and phenotype

The term *genotype* refers to the total genetic constitution of an individual and the term *phenotype* to the outward expression of the genetic constitution. Taking the ABO blood group system, the possible genotypes are AA, AB, BB, AO, BO and OO but the phenotypes are A, B and O. The colour, form, size and stature of individuals are all phenotypical expression of a particular genetic constitution. Certain phenotype characteristics of an individual may change from infancy to adulthood such as height, weight, muscularity, body shape, but the genotype is relatively stable throughout the life of an individual. Thus there are two aspects of the genetic material – one fixed and the other plastic. The fixed characters are the genotype, and the plastic ones are the phenotype. These two types may best be compared to a given pellet of clay which may be moulded into any desired shape by an artist but the weight, volume, density and chemical constitution of the pellet will remain the same *(6)*. *Therefore,* it is said that medicine is the science of management of the human phenotype *(7)*.

Chromosomal abnormalities

Chromosomal abnormalities (numerical or structural alterations) occur from time to time in human beings. They arise in various ways : (1) *Non-disjunction :* By an error in nuclear division called "non-disjunction" a pair of chromosomes may fail to separate and both are carried to one pole. The resulting daughter cells contain an unequal number of chromosomes, 45 or 47. This numerical abnormality in which the chromosome number is not an exact multiple of the haploid number is called aneuploidy. If a particular pair of chromosomes has three chromosomes instead of two, it is called "trisomy"; if there is only one chromosome instead of two in any given pair of chromosomes, it is called "monosomy". Non-disjunction may occur during gametogenesis or during mitosis. (2) *Translocation :* Sometimes during nuclear division, a portion of one chromosome breaks away and becomes attached to another which is not homologous to the first. This is called translocation. (3) *Deletion :* A piece of a chromosome may become detached and lost from the karyo-type resulting in the loss of one or more genes. If the loss is severe, it may be incompatible with live birth. (4) *Duplication :* Some genes may appear twice in the same chromosome. This is called duplication. (5) *Inversion :* Sometimes a chromosomal segment becomes inverted and then the order of sequence of genes is altered. (6) *Isochromosomes :* These are a special class of structurally abnormal chromosomes, arising because of misdivision, i.e., transverse division instead of the normal longitudinal division. (7) *Mosaicism :* The cells of the body are compounded of cells of two or more genetically different

chromosomal types. This can result by mutation or non-disjunction either during embryo or later life.

Laws of inheritance

Mendel crossed two races of the common pea (Pisum sativum) a tall and a short. The first generation (F_1 generation) consisted entirely of tall offspring. But when the F_1 generation was inbred, they gave rise to a mixed generation of tall and short in the ratio of 3:1, i.e., three-fourths tall and one-fourth short. This generation is known as the F_2 generation or the second filial generation. All the short plants of the F_2 generation bred true, producing short plants only. But the tall plants of the F_2 generation gave rise to a mixture of tall and short offspring in the same ratio of 3:1. The F_2 generation is therefore 1:2:1, i.e., one-fourth pure talls, half mixed talls and one-fourth pure shorts. From the result of his experiments, Mendel formulated certain laws to explain the inheritance of characters : (1) *Law of unit characters :* All characters are units by themselves, and certain factors (now called genes) control the expression of these characters during the development of the organism. (2) *Law of dominance :* The factors or genes occur in pairs. One factor may mask the expression of the other. The character that expresses itself in the F_1 generation is said to be dominant, and the character that does not appear in the F_1 generation is said to be recessive. (3) *Law of segregation :* When germ cells are formed, Mendel supposed, that the opposed factors are separated or segregated so that each germ cell carries one or other of the two factors and not both. Mendel's work provided the basis of the study of inheritance.

Classification of genetic disorders

These may be classified as :

a. Chromosomal abnormalities
b. Unifactorial (single gene or Mendelian) diseases
c. Multifactorial disorders

CHROMOSOMAL DISORDERS

More than 300 numerical and structural types of chromosome aberrations have been described *(8)*. A significant portion of embryonic and foetal wastage is due to chromosomal anomalies. The incidence of chromosomal abnormalities is 5.6 per 1000 live births. Of these, 2 per 1000 live births represent sex aneuploidies, 1.7 per 1000 live births autosomal aneuploidies, and 1.9 per 1000 live births chromosomal translocations. For the most part, these disorders are not inherited *(4)*.

1. Relating to sex chromosomes

The following are some of the well-known syndromes associated with abnormalities of sex chromosomes :

(a) Klinefelter's syndrome : This is a common sex – chromosome aneuploidy. Persons suffering from this syndrome are abnormal males having two or more X-chromosomes in addition to one Y-chromosome (XXY, XXXY). They have a normal autosomal set of 22. The main features of this syndrome are that the affected persons are eunuchoid males with non-functional testis. Spermatozoa are absent in their ejaculations. The growth of hair on face, axillae and pubes is scanty. The condition is associated with gynaecomastia and mental retardation. The incidence of this syndrome is about 1 in 1000 among males at birth *(9)*.

(b) XYY syndrome : The male with an extra Y-chromosome has attracted much attention because of his reported tendency to anti-social, aggressive and often criminal behaviour. However, the relationship is not yet clear. The principal features of this syndrome appear to be exceptional height (usually six feet and over) and a serious personality disorder leading to behavioural disturbances *(10)*. The incidence of this syndrome is about '1' in 1000 males at birth *(9)*.

(c) Turner's syndrome : This anomaly is probably the most common chromosome disorder in humans, but about 98 per cent of the conceptuses abort spontaneously. The remaining 2 per cent that reach term, account for an incidence of 1 in 7,500 live born girls *(9)*. They have an increased risk of dying in the neonatal period. Persons suffering from this syndrome are apparent females with underdeveloped sex glands. They have 45 chromosomes instead of the normal complement of 46. Their sex chromosome constitution is XO instead of XX ('0' represents the missing chromosome). This abnormal condition is due to non-disjunction of the sex chromosomes. Clinically the patients are of short stature, infertile and have primary amenorrhoea. They often show other congenital defects such as coarctation of the aorta, pulmonary stenosis, renal malformations and mental retardation.

(d) "Super females" : Females with 3 to 5 X-chromosomes (XXX, XXXX, XXXXX) have been found. In general, the higher the number of X-chromosomes, the greater the degree of mental retardation and congenital abnormalities, e.g., underdeveloped external genitalia, uterus and vagina.

2. Relating to autosomes

There are many syndromes associated with abnormalities of autosomes. A full description of these conditions is beyond the scope of this book. A brief account of *mongolism* which is a public health problem in some countries is given here. *Mongolism* or Down's Syndrome was described by Langdon Down in 1866. Most cases of mongolism are caused by an extra chromosome which occurs on the 21st pair. The anomaly is therefore sometimes described as "Trisomy 21". The syndrome is easily recognized in the older child and adult by the short stature and small round head, narrow, tilted eye-slits, mal-formed ears, short broad hands, lax limbs, mental retardation and quite a few other abnormalities especially internal congenital defects such as cardiac defects and atresia of the alimentary tract. In communities of European origin the incidence of mongolism at birth is reported to be one in 900 births *(9)*.

One observation which is important is that the frequency of mongolism increases with rising maternal age but is un-affected by the age of the father. The risk for a woman of 20 is estimated at about 1 in 3,000 and that for a woman of 45, 1 in 50 *(11)*.

Autosomal monosomies are rare. Loss of an entire chromosome is very serious genetic defect; the fertilised ovum may not survive.

MENDELIAN DISEASES

Mendelian diseases are inherited according to the Mendelian Laws. These are the dominant, recessive and sex-linked diseases. (a) An individual with an autosomal dominant trait will produce two kinds of gametes with respect to the mutant gene – half with the mutant gene and half with the normal allele. The offspring of such an

individual has a 50:50 chance of being affected, provided the other parent is normal. The sexes are equally affected. (b) Abnormalities caused by recessive genes occur when both the parents are heterozygous. Each off-spring of such parents has a chance of 1:4 being affected. Autosomal recessive diseases occur sporadically in the children of outwardly normal parents. (c) In sex linked inheritance, a mutant gene on X-chromosome in males will express itself readily as there is no normal allele, while a mutant gene on X-chromosome in females will not express itself in the presence of the normal allele. This is the basis of sex-linked inheritance of which haemophilia is an outstanding example. If an affected male marries a normal female, the gene is transmitted to all the daughters, but the sons escape. But if a carrier female marries a normal male, 50 per cent of her daughters will be carriers and 50 per cent normal; 50 per cent of her sons will be affected and 50 per cent normal. Fig.1 shows the patterns of inheritance.

Mendelian diseases are individually rare since there is strong selection against them and gene mutations are rare events. Mutation usually occurs at random. If mutation is confined to a single gene it is called "point" mutation, which is responsible for many human diseases and defects.

It is estimated that the combined incidence in man of diseases and disabilities in this category is about 1 per cent of all live-born individuals *(12)*. Rare as these diseases are, as many as 793 autosomal dominant phenotypes, 629 autosomal recessive traits and 123 sex-linked diseases have been catalogued to date *(10)*. A short list of these abnormalities is given in Table 1.

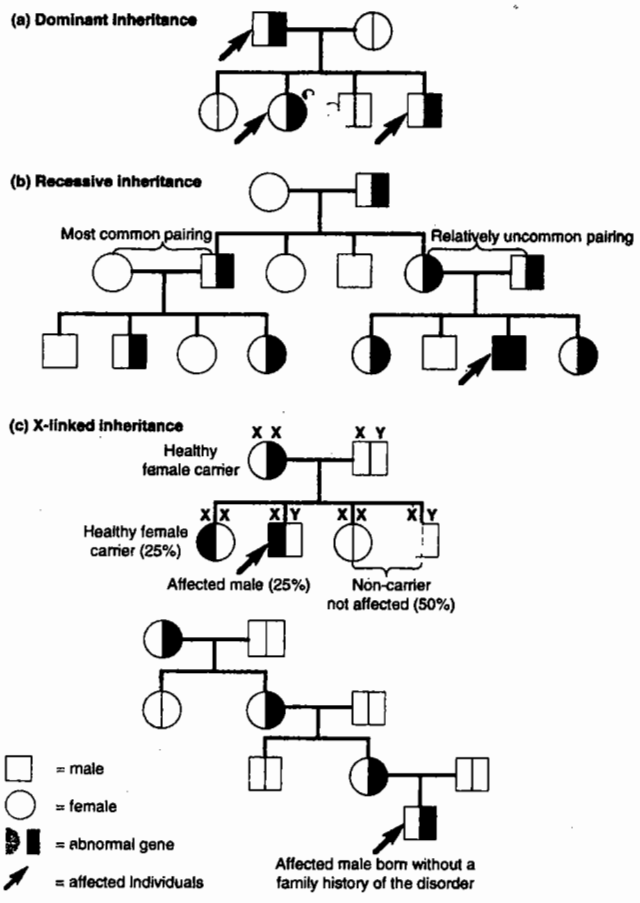

FIG. 1
Classical mendelian patterns of inheritance

Blood groups

Early genetic studies centred round blood groups in man. Blood groups are determined by genes. At present 14 blood group systems have been discovered in man; the well-known ones are the ABO and Rh blood groups.

ABO SYSTEM

The genotypes and phenotypes in the ABO system are shown in Table 2 :

TABLE 2

Genotypes and phenotypes in ABO system

Genotype	Phenotype (Blood Group)	Approximate frequency in Indian population
00	0	40 per cent
AA	A	22 per cent
AO	A	"
BB	B	33 per cent
BO	B	"
AB	AB	5 per cent

Source : *(13)*

Gene O is recessive; the red blood cells of a person whose blood group is O have no antigens. Genes A and B are co-dominant; when both are present, the red blood cells carry antigen-A and antigen-B. Blood groups provide valuable evidence in cases where there is a question of true parentage; they are also extensively used to determine whether the twins are identical or not.

RHESUS SYSTEM

The Rhesus system depends upon three genes which are designated by the letter C, D and E and their alleles by the small letters c, d and e. The Rh-antigens develop very early and have been demonstrated in a 38-day old foetus. It had been established that the Rh-antigens are present only on the surface of red cells *(14)*.

The possible genotypes in the rhesus system will be CDE, CDe, cDE, cdE, cDe and cde. The diploid individual inherits any two of these units, e.g., CDe/cde. Of the rhesus antigens, the most potent is the antigen D; so much so, the term "Rhesus-positive" has come to mean possessing this antigen and "Rhesus-negative" lacking it. In India, it is found that about 93 per cent of the population are Rhesus-positive as compared to 85 per cent in countries of Northern Europe and North America *(11)*. The importance of the rhesus system in preventive medicine is exemplified in the fatal disease in the newborn, Erythroblastosis foetalis.

Erythroblastosis foetalis

If the foetus is Rh-positive and the mother Rh-negative, certain consequences are likely. Some of the foetal red cells cross the placenta and enter the maternal circulation where they act as foreign antigen and the production of Rh antibodies.

The Rh antibodies are of two main types : (a) the "strong" or saline antibodies and (b) the "weak" or albumin antibodies. The latter are small 7S gammaglobulins which cross the placental barrier and pass back into the blood circulation of the foetus. When this happens, the RBC of the foetus are destroyed. If the damage is severe, the foetus is killed *in utero* and results in miscarriage; if the damage is less severe, the infant may be born with jaundice, anaemia and oedema. This symptom complex is known as Rh-haemolytic disease or erythroblastosis foetalis.

Blood groups and disease

During the past 10 years researchers have been trying to find out the association of certain diseases with particular blood groups. However, only two disease conditions have shown such association with the ABO groups. Duodenal ulcer and gastric ulcer are common in 'O' group and stomach cancer in 'A' group individuals. A number of other diseases appear to be associated with particular blood groups, especially carcinoma of the uterine cervix and pernicious anaemia with group 'A', and rheumatic heart disease with a lack of group 'O'. Haemolytic tendencies appear to be associated with group 'O', and thrombosis with group 'A'. An 'A' group woman taking an oral contraceptive is at greater risk of thrombotic episodes than an 'O' group woman *(15)*. The demonstration of associations between blood groups and certain diseases is an important contribution of human genetics.

Sickle cell anaemia

Sickle cell anaemia is an autosomal recessive disorder in which an abnormal haemoglobin leads to chronic haemolytic anaemia with a variety of severe clinical consequences. The disorder is a classic example of disease caused by a point mutation in DNA. Individuals with one gene of this disease are clinically healthy, but their RBC look abnormal under the microscope. Persons with 2 genes (homozygous) of this disease suffer from acute anaemia and in most cases die before puberty. The rate of sickling is influenced by a number of factors, most importantly by concentration of haemoglobin S in the individual red blood cell.

The disease is prevalent among blacks, specially in certain parts of Africa. It has been found that the areas where the disease is most prevalent also showed the higher frequencies of malaria. The haemoglobin S gene is carried in 8 per cent of American blacks, and one birth out of 400 in American blacks will produce a child with sickle cell anaemia. In India, it is an important disorder on account of its high incidence in certain regions.

The disorder has its onset during the first year of life, when haemoglobin F level falls. These patients are prone to delayed puberty. On examination, patients are often chronically ill and jaundiced. There is hepatomegaly, but the spleen is not palpable in adult life. The heart is enlarged, with hyperdynamic precardium and systolic murmurs. Non-healing ulcers may be present. Sickle cell anaemia becomes a chronic multisystem disease, with death from organ failure commonly occurring between ages 20 and 40 years.

No specific treatment is available for the primary disease. However, both longevity and quality of life may be improved by comprehensive medical management. Prenatal diagnosis is now available for couples at risk of producing a child with sickle cell anaemia. DNA from foetal cells can be directly examined, and the presence of the sickle cell mutation can be accurately diagnosed. Genetic counselling should be made available to such couples *(9)*.

Thalassaemias

The thalassaemias are hereditary disorders characterized by reduction in the synthesis of globin chain (alpha or beta). Reduced globin chain synthesis causes reduced haemoglobin synthesis and eventually produces a hypochromic microcytic anaemia because of defective haemoglobinization of red cells. Thalassaemias can be considered among hypo-proliferative anaemias, the haemolytic anaemias, and the anaemias related to abnormal haemoglobin, since all of these factors may play a role.

Alpha thalassaemia is primarily due to gene deletion directly causing reduced a – globin chain synthesis. Beta thalassaemia are usually caused by point mutations rather than large deletions. Signs of thalassaemia develop after 6 months of age, because this is the time when haemoglobin synthesis switches from haemoglobin F to haemoglobin A. Prenatal diagnosis is available for couples at risk of producing a child with one of the severe thalassaemia syndromes. Asian couples whose parents on both sides have alpha thalassaemia trait are at risk of producing an infant with hydrops foetalis. Mediterranean people with both parents heterozygous for beta thalassaemia, are at risk of producing homozygous child *(9)*.

Haemophilia *(16)*

Haemophilia is a hereditary bleeding disorder affecting 15-20 of every 100,000 males born, with equal incidence in all ethnic groups and geographical areas that have been surveyed. Prevalence, which depends on survival, varies according to available medical care. There are an estimated 420,000 people with haemophilia worldwide.

There are different forms of haemophilia. While the disorder affects males, it is carried by females, who are only occasionally affected, usually mildly. The disorder concerns the absence, decrease or deficient function of blood coagulating factor, leading to excessive, prolonged or

delayed bleeding. In severe cases it most commonly occurs in the large joints of the limbs. Unless such bleeding is controlled promptly by infusion of the deficient factor, there is progressive joint disease and muscle atrophy, leading to serious physical, psychological and social handicaps. Until recently, the foremost cause of death was haemorrhage, especially in the skull.

In countries with highly developed haemophilia care programmes, therapy with plasma derivatives has reduced mortality. In the past decade, the main causes of death have stemmed from infections as the side-effects of treatment, including AIDS and liver disease secondary to hepatitis. Survival in patients without these infections is almost the same as that of the general population.

Cystic fibrosis *(16)*

Cystic fibrosis is a genetic disease occurring worldwide, which affects the respiratory and gastrointestinal tracts and the sweat glands. Incidence ranges from 2.5 to 5 per 10,000 live births in most European populations. The condition is less common in blacks, and rare in orientals.

Until a few years ago, life expectancy of children with the disease was below 5 years of age. Now that it is recognized and treated earlier and more effectively, life expectancy in developed countries is about 30 years, and projections for young children alive with cystic fibrosis now suggest that they may live for 40 years or more, even without the development of new treatments. However, upto 95% of cases in Latin America are never diagnosed, and the life expectancy of those that are diagnosed is only about 10 years.

The gene defect in cystic fibrosis was identified in 1989, since then there has been unprecedented progress in understanding the disease, leading to new approaches to drug treatment and hopes for gene therapy. Such treatments are expected to be available within the lifetime of most current patients, with a corresponding anticipated improvement in outlook.

Phenylketonuria (PKU)

Phenylketonuria is an autosomal recessive disorder resulting in a deficiency of the liver enzyme phenylalanine hydroxylase which converts phenylalanine to tyrosine. The name PKU is derived from the build-up of phenylpyruvic acid in the urine, a characteristic of the disease. The frequency of the disease is about 1 in 10,000 births *(5)*.

Phenylalanine accumulates in the blood and tissues and has a toxic effect on the brain leading to mental retardation. Tests for elevated blood levels of phenylalanine are much more desirable than tests for urine phenylketone, since blood levels must be elevated before urine detection is possible. Testing of bottle-fed infants should be done no sooner than 48 hours after the first successful formula feeding. Breast-fed babies, however, are tested at 7 days, since breast milk often has little protein content before the 5th day *(17)*.

MULTIFACTORIAL DISORDERS

The frequency of multifactorial disorders is high compared with that of Mendelian and chromosomal disorders. There are indications that most of the common disorders of adult life such as essential hypertension, schizophrenia, mental retardation, duodenal ulcer, ischaemic heart disease of early onset, diabetes, congenital heart malformations are conditions with a multifactorial aetiology. A small minority of cancers (family cancer syndromes) are clearly inherited; these include familial polyposis coli, familial non-polyposis colon cancer and some thyroid cancers. Also known is a major genetic component in cancer of the colon and breast, although in these relatively common conditions it can be difficult to distinguish familial from non-familial cases.

In a disorder such as cancer or coronary heart disease, features that should arouse suspicion of an inherited predisposition include : early onset; similarly affected parents and/or siblings; when there is a difference in frequency between the sexes, occurrence in the less commonly affected sex (e.g., coronary heart disease in women); in ethnic groups in which there is a high incidence of a particular condition (e.g., spina bifida is 40 times more common in Caucasians – and even more frequent among the Irish – than in Asians.

The mode of inheritance of multifactorial disorders is complex because environmental factors are also involved, as for instance, the influence of smoking, diet, obesity and lack of exercise on ischaemic heart disease. Campbell (1965) stressed that environmental agents and genetic constitutions usually interact closely in producing abnormalities. He summarizes his conclusions in saying that some genetic factors are effective only under certain environmental conditions *(17)*. The relative contributions of genetic predisposition and environmental factors to the aetiology will vary greatly from patient to patient.

Role of genetic predisposition in common disorders *(16)*

Although the limits of intelligence, physical ability and longevity are genetically determined, external and environmental influences such as infections, malnutrition and war have long been the main determinants of health and survival. Now, with increased control of the environment, genetic make-up is becoming an ever-more important determinant of individual health. Genetic predisposition may lead to the premature onset of common diseases of adult life such as cancer, coronary heart disease, diabetes, hypertension and mental disorders.

Cancer : It is not yet certain whether most cancers are hereditary. But a genetic predisposition may be involved in as many as 10–25% of cases of cancer of the breast or colon. Numerous genes are being identified that may affect susceptibility to tumour development. This may lead to a general improvement in the diagnosis and treatment of cancer. For example, a DNA screening test for breast cancer could soon be available. Advice could be offered on the chemoprevention of cancers, tailored for families with different types of cancer risk.

Coronary heart disease : Until recently, it was generally believed that environmental factors alone cause coronary heart disease. But investigating family histories often uncover genetic risks. Mapping the human genome will make the genetic predisposition to CHD much easier. High blood pressure and high blood cholesterol levels, major risk factors in CHD, are also genetically influenced. A combination of risk detection and lifestyle counselling, with drug treatment, might cut the incidence of heart attacks to the low levels as two or three generations ago.

Diabetes : Evidence for a genetic element in insulin-dependent diabetes mellitus has emerged from studies

showing a higher concordance in identical twins (25–30%) than in non-identical twins (5–10%). About 85% of cases of diabetes in developed countries are of the non-insulin-dependent form of the disease, which has a particularly strong familial tendency. Diabetes of all types is an important candidate for future treatments such as gene therapy of pancreatic tissue transplantation.

Mental disorders : Evidence from family and twin studies demonstrate the existence of genetic predisposition to some common mental diseases. Alzheimer's disease, the most common form of senile dementia, has a strong familial tendency and is known to be caused by at least four different genes. Research may lead to the development of drugs useful in preventing or delaying the onset of the disease.

Enough is already known about the genetics of common diseases to introduce a family–oriented approach into basic as well as specialist medical practice. A major effort is being made to study the genetic factors involved, develop appropriate therapies, and determine how these approaches can best be applied in practice.

Advances in molecular genetics *(5)*

DNA technology depends on a number of basic tools that have been gradually developed over the past 20 years or so. A wide range of enzymes involved in DNA and RNA synthesis and repair have been identified and become available for laboratory use, nucleotide bases are available as laboratory reagents, and specific DNA sequences can be synthesized at will. DNA diagnostic methods have been greatly simplified over the past 10 years. DNA has many advantages for genetic diagnosis. It is easy to obtain, since every cell of an individual or foetus contains the full DNA complement of that individual. Genes can be studied whether they are actively producing their product or not. A definitive diagnosis can usually be made in all genetic conditions.

1. DNA technology (5)

Major new techniques that are contributing to the advances in medical genetics include the following :

- The synthesis of DNA probes with specific sequences that will bind to and identify any complementary DNA sequences that may be present. This allows genetic diagnosis and permits further analysis of DNA by the examination of unknown sequences adjacent to the known ones.
- DNA sequencing methods for the rapid analysis of unknown DNA and the identification of mutations that give rise to disease.
- New diagnostic techniques, such as the use of restriction enzymes that cut DNA consistently only at specific sequences, and the polymerase chain reaction (PCR) for amplifying known DNA sequences. Such methods allow simple and rapid diagnosis using extremely small tissue samples. It is even becoming possible to analyse the DNA contained in a single cell.
- Techniques for synthesis of DNA that allow the production of known sequences of increasing length. Coding sequences produced in this way can be used for the production of therapeutic agents such as insulin, erythropoietin and factor VIII. They may also be used in the creation of transgenic animals and in gene therapy.
- Positional cloning strategies using genetic markers, which are now defined along the entire human genome. These have greatly simplified the study of families. Even quite small kindreds can be examined using highly informative probes, and disease mutations can be rapidly assigned to their chromosomal position.
- *In vitro* methods for examining the protein product of gene sequences with unknown functions.
- New cytogenetic techniques such as fluorescence *in situ* hybridization (FISH), which permits direct visualization of the relationship of genes to one another in the nucleus of the living cell.
- Comparison between the DNA sequences of different genes and species. This helps elucidate the mechanisms of evolution.
- Insertion of coding DNA sequences into animal embryos to create transgenic animals, including animal models of human diseases. The availability of transgenic techniques and the use of experimental site-specific mutagenesis are particularly valuable for studying the roles of specific genes in multifactorial diseases, where combinations of different genotypes and environments can be examined.
- Insertion of missing DNA sequences into individuals with genetically determined disorders, or the excision of harmful sequences (gene therapy).

2. Gene therapy (5)

Gene therapy is the introduction of a gene sequence into a cell with the aim of modifying the cell's behaviour in a clinically relevant fashion. It may be used in several ways, e.g., to correct a genetic mutation (as for cystic fibrosis), to kill a cell (as for cancer) or to modify susceptibility (as for coronary artery disease).

The gene may be introduced using a virus (usually a retrovirus or adenovirus) or by means of lipid or receptor targeting. There is now almost universal agreement that gene delivery to somatic cell to treat disease is ethical, and that gene therapy should take its place alongside other forms of medical treatment.

3. The human genome project (5)

The human genome project is an attempt to systematize the research on mapping and isolating human genes that is already in progress in many countries, in order to create a single linear map of the human genome, with each coding gene defined and sequenced.

Agencies with a role in coordinating human genome data include UNESCO, the Genome Data Base, HUGO, the National Institute of Health/Department of Energy (USA), the Medical Research Council (UK), Genethon (France) and the European Union.

4. The human genome diversity project (5)

As part of the work of HUGO, the Human Genome Diversity Project is aimed at increasing understanding of human evolution. The major objective is to define the genetic relationships between human populations and interpret them in terms of natural selection, genetic drift, migration, etc. For example, the frequency and distribution of rare single-gene disorders are related to the history of human migration. Differences in distribution between

populations may often be accounted for by "founder effects". When a population expands from a relatively few founding members, some contribute more, and some less, to the genetic make-up of subsequent generations. If one prolific founder carries a genetic abnormality, this can lead to a localized cluster of affected individuals. Studies of isolated and aboriginal populations can be particularly informative.

Population genetics

Population genetics has been defined as the study of the precise genetic composition of population and various factors determining the incidence of inherited traits in them *(10)*.

Population genetics is founded on a principle enunciated independently by Hardy in England and Weinberg in Germany in 1908. Let us consider the results when a human population consisting of tall (TT), intermediate (Tt) and short (tt) individuals were allowed to mate at random. Even after several generations of interbreeding, it will be found that there will be some individuals who are tall (TT) some intermediate (Tt) and some short (tt). In other words, we cannot produce a race which is "pure" or uniform in height.

The Hardy-Weinberg law states that "the relative frequencies of each gene allele tends to remain constant from generation to generation" in the absence of forces that change the gene frequencies. Thus, the study of gene frequencies, and the influences which operate to alter the "gene pool" and their long-term consequences is the central theme in population genetics.

Factors which influence the gene frequencies

The Hardy-Weinberg law assumes that human population is static. But in reality, human population and consequently human gene pool is never static. There are several factors which influence the human gene pool. The following are some : *(a) Mutation :* Mutation implies a change in the genetic material of an organism which results in a new inherited variation. Mutation is a rather regular phenomenon in nature. It is now recognized that mutant genes are so wide-spread in their occurrence that every one of us might be harbouring a few or many of them. According to modern geneticists, the entire body structure of man and every other animal and plant cell have been built through hundreds of millions of years by means of a long succession of mutation *(7)*. The cause of spontaneous mutation is not yet known. But we know that certain external influences such as ionizing radiation and certain chemicals are capable of producing mutations experimentally and there is no reason to believe that man is an exception. Most mutant genes are believed to be harmful. But there are instances where a mutant gene could be beneficial, e.g., sickle cell anaemia. The heterozygotes of sickle cell trait were found to be resistant to falciparum malaria. Some mutant genes remain "neutral" in that they do not harm or impair the survival ability of the carriers. Such genes may persist indefinitely in the population for many generations. Specialists in population genetics are interested in mutation rates. It is said that each gene has its own characteristic mutation rate which is estimated anywhere from 10^4 to 10^6 per generation. During the past 30 years, mutation rates have probably risen owing to increased use of X-rays and chemical mutagens. *(b) Natural selection :* Darwin proposed the theory of natural selection or survival of the fittest to explain evolution. Natural selection is the process whereby harmful genes are eliminated from the gene pool and genes favourable to an individual tend to be preserved and passed on to the offspring. When DDT was first used, it was lethal to houseflies. Today, not many houseflies are killed by DDT. This is an example of natural selection in response of DDT; the resistant variety of houseflies has become the usual form. The forces which operate in the animal kingdom do not apply in human populations because man by his superior intelligence has interfered with natural selection in every conceivable way by changing the environmental conditions under which people live and by advances in technology, public health and medical care services. *(c) Population movements :* Because of industrialization, increased facilities for earning, ways of living and education, people are moving – sometimes on a large scale – from rural to urban areas. There is also a migration of people between countries. Such population movements will lead to changes in the distribution of genes, affecting both the areas of immigration and emigration. The intermixing of people makes new genetic combinations possible. *(d) Breeding structure :* If all marriages were to occur in a random fashion, the effect would be the attainment of a genetic equilibrium. In practice, however, matings tend to occur selectively within various subgroups based on religion, economic and educational status and family relationships. In open societies, there is more freedom in mating. For instance doctors tend to marry doctors or nurses; musicians tend to marry musicians. This type of mating is called "assortative mating", or birds of the same feather flocking together. The genetic consequences of assortative mating have not been adequately studied. *(e) Public health measures :* Advances in public health and medical care services do affect the genetic endowment of people as a whole. More lives are now being saved by advances in medical sciences than ever before. For instance, Ramstedt's operation which was introduced in 1912 has saved many children suffering from congenital pyloric stenosis. Individuals with genetically conditioned retinoblastoma may be saved by timely surgery. The provision of insulin has saved the lives of diabetics. The carriers of hereditary diseases, malformations and constitutional weaknesses are able to survive and pass their genes to their progeny. Public health measures are thus decreasing the selection rates and increasing the genetic burden. This has led some scientists to prophesy that "medicine will harm people in the long run by helping them in the short run" *(12)*.

PREVENTIVE AND SOCIAL MEASURES

1. Health promotional measures

(a) EUGENICS : Galton proposed the term eugenics for the science which aims to improve the genetic endowment of human population. Eugenics has both negative and positive aspects.

(i) Negative eugenics : Hitler sought to improve the German race by killing the weak and defective; this was negative eugenics. But nobody in the civilized world would approve of such a measure to improve the human race.

On the other hand, if people who are suffering from serious hereditary diseases are sterilized or otherwise debarred from producing children, there should be no

serious objection to marriage. The aim of negative eugenics is to reduce the frequency of hereditary disease and disability in the community to as low as possible. However, the question one would ask is how far negative eugenic measures would be helpful in eliminating genetic defects? The simple answer is that in spite of eugenic sterilization, new cases of hereditary diseases will continue to arise in the population partly because of fresh mutations, and partly because of marital alliances between hidden carriers (heterozygotes) of recessive defects. Nevertheless, it may be hoped that should eugenic measures be applied, hereditary diseases would become less frequent *(12)*.

(ii) Positive eugenics : This is a more ambitious programme than negative eugenics. It seeks to improve the genetic composition of the population by encouraging the carriers of desirable genotypes to assume the burden of parenthood. At present, positive eugenics has very little application. Its realization is difficult for 2 reasons (i) The majority of socially valuable traits – let us say – intelligence and positive character features, though partially determined biologically are not inherited in such a simple way as, say blood groups. These traits have a complex, multifactorial determination, both genetical and environmental. It would be difficult to expect, therefore, that positive eugenic measures will yield direct results (ii) Secondly, we cannot determine which gene we transmit to our children *(7)*.

(b) EUTHENICS : Mere improvement of the genotype is of no use unless the improved genotype is given access to a suitable environment, an environment which will enable the genes to express themselves readily. Throughout the course of history, man has been adapting environment to his genes more than adapting his genes to the environment. Studies with mentally retarded (mild) children indicated that exposure to environmental stimulation improved their IQ. Thus the solution of improving the human race does not lie in contrasting heredity and environment, but rather in the mutual interaction of heredity and environmental factors. This environmental manipulation is called euthenics and has considerable broader prospects for success.

(c) GENETIC COUNSELLING *(19)* : The most immediate and practical service that genetics can render in medicine and surgery is genetic counselling *(12)*. Genetic counselling may be prospective or retrospective *(8)*.

(i) Prospective genetic counselling : This allows for the true prevention of disease. This approach requires identifying heterozygous individuals for any particular defect by screening procedures and explaining to them the risk of their having affected children if they marry another heterozygote for the same gene. In other words, if heterozygous marriage can be prevented or reduced, the prospects of giving birth to affected children will diminish. The application in this field, for example, are sickle cell anaemia and thalassemia. It is possible that this kind of prevention may find wider application to cover a number of other recessive defects *(12)*.

(ii) Retrospective genetic counselling : Most genetic counselling is at present retrospective, i.e., the hereditary disorder has already occurred within the family. A survey carried out by the WHO showed that genetic advice was chiefly sought in connection with congenital abnormalities, mental retardation, psychiatric illness and inborn errors of metabolism and only a few sought premarital advice. The WHO recommends the establishment of genetic counselling centres in sufficient numbers in regions where infectious disease and nutritional disorders have been brought under control and in areas where genetic disorders have always constituted a serious public health problem (e.g., sickle cell anaemia and thalassaemia) *(12)*.

The methods which could be suggested under retrospective genetic counselling are : (i) contraception (ii) pregnancy termination and (iii) sterilization depending upon the attitudes and cultural environment of the couples involved *(8)*.

(d) OTHER GENETIC PREVENTIVE MEASURES : *(i) Consanguineous marriages :* When blood relatives marry each other there is an increased risk in the offspring of traits controlled by recessive genes, and those determined by polygenes. Examples are albinism, alkaptonuria, phenylketonuria and several others. An increased risk of premature death is also noted in such offspring. For instance, in a certain Japanese city, a death rate of 116 per 1,000 was found during the first 8 years of life amongst the offspring of first cousins, against 55 amongst the controls *(12)*. Therefore, a lowering of consanguineous marriages would be advantageous to the health of the community.

(ii) Late marriages : The pendulum is swinging in favour of early marriages. The discovery of "Trisomy 21" in mongols coupled with the knowledge that mongolism is more frequent in children born of elderly mothers, lends support to the view that early marriage of females is better than late marriage from the point of view of preventing mongolism. Its incidence in a mother at age 20 is only 1 : 3000; by the age 40, it is 1:40.

2. Specific protection

Increasing attention is now being paid to the protection of individuals and whole communities against mutagens such as X-rays and other ionizing radiations and also chemical mutagens. Patients undergoing X-ray examination should be protected against unnecessary exposure of the gonads to radiation. X-ray examination of the pregnant uterus to determine the presence of twins or the lie of the foetus is to be strongly deprecated. Rh haemolytic disease of the newborn which is a genetically determined immunological disorder is now preventable by immunization by anti-D globulin.

3. Early diagnosis and treatment

(a) Detection of genetic carriers : It is now possible to identify the healthy carriers of a number of genetic disorders, especially the inborn errors of metabolism. The female carriers of Duchenne type of muscular dystrophy, an X-linked disorder, can now be detected by elevated levels of serum creatine kinase in 80 per cent of carriers. In some conditions, carriers can be recognized with a high degree of certainty (e.g., acatalasia); in some only a proportion of carriers can be detected (e.g., haemophilia, PKU, galactosaemia); in other conditions, no method has yet been found which will distinguish carriers (e.g., alkaptonuria) *(20)*.

(b) Prenatal diagnosis : Amniocentesis in early pregnancy (about 14–16 weeks) has now made it possible for prenatal diagnosis of conditions associated with chromosomal anomalies (e.g., Down's Syndrome); many inborn errors of metabolism (e.g., Tay-Sach's disease, galactosaemia, Maple syrup urine disease, Alpha-thalassaemia and neural tube defects). The indications for prenatal diagnosis are listed in Table 3.

TABLE 3

Indications for prenatal diagnosis

Indications	Methods
a. Advanced maternal age, previous child with chromosome aberration, intrauterine growth delay	Cytogenetics (amniocentesis, chorionic villus sampling)
b. Biochemical disorders	Protein assay, DNA diagnosis
c. Congenital anomaly	Sonography, foetoscopy
d. Screening for neural tube defects and trisomy	Maternal serum alpha-fetoprotein and chorionic gonadotropin

Source : *(9)*

Amniocentesis : Examination of a sample of amniotic fluid makes possible the prenatal diagnosis of chromosomal anomalies and certain metabolic defects. The procedure can be used as early as 14th week of pregnancy when abortion of the affected fetus is still feasible. The diagnosis of chromosomal anomalies is made by culture and Kryotyping of fetal cells from the amniotic fluid, and of metabolic defects by biochemical analysis of the fluid.

Amniocentesis is called for in the following circumstances if the parents are prepared to consider abortion.

1. A mother aged 35 years or more (because of high risk of Down's syndrome with advanced maternal age).
2. Patients who have had a child with Down's syndrome or other chromosomal anomalies.
3. Parents who are known to have chromosomal translocation.
4. Parents who have had a child with a metabolic defect – detectable by amniocentesis. The most common are defects of the neural tube, anencephaly and spina bifida which can be detected by an elevation of alpha fetoprotein in the amniotic fluid.
5. When determination of the sex is warranted, given a family history of a sex-linked genetic disease e.g., certain muscular dystrophies.

For the detection of neural tube defects there is now the possibility of widespread screening by the determination of alpha-fetoprotein levels in the maternal serum. If the test is positive it can be confirmed by amniocentesis.

(c) Screening of newborn infants : We have today a long list of screening tests for the early diagnosis of genetic abnormalities – sex chromosome abnormalities, congenital dislocation of hip, PKU, congenital hypothyroidism, sickle cell disease, cystic fibrosis, Duchenne muscular dystrophy, congenital adrenal hyperplasia, G6PD deficiency etc.

Neonates should be routinely examined for congenital abnormalities, particularly dislocation of the hip, which can be simply corrected at this stage. Biochemical screening of newborn infants was first used for PKU in 1966. Heel-prick blood samples are usually collected at 5–10 days after birth. Several drops of blood are collected on filter paper (the Guthrie card), which is sent to screening laboratory. Screening of newborns for congenital hypothyroidism is carried out in most developed countries. Sickle-cell disease can be detected cheaply and reliably by haemoglobin electrophoresis using Guthrie blood spots. Neonatal screening for cystic fibrosis is based on the measurement of immunoreactive trypsin in Guthrie blood spots.

(d) Recognizing pre-clinical cases : We have today a pretty long list of screening tests for the early diagnosis of hereditary diseases. For example, heterozygotes for phenylketonuria can be detected by a phenylalanine tolerance test. A simple urine examination for sugar after morning breakfast is good enough to detect diabetics. Examination of sibs and close relatives of diabetics by a glucose tolerance test will often reveal preclinical cases of acholuric jaundice. A raised serum uric acid should arouse suspicion of gout. Sickle cell trait can be uncovered by subjecting the red cells to reduced oxygen tension. Thalassaemia minor can be detected by studying the blood picture.

Genetic counselling can have the greatest impact when individuals or couples at genetic risk are identified prospectively, i.e., before they have developed symptoms themselves or produced their first affected child. Prospective counselling is technically possible only when carriers can be accurately identified. To some extent, the established genetic population–screening services listed in Table 4 may serve as models for the development of future genetic screening programmes *(5)*.

Once diagnosed, some of the genetic conditions can be treated with complete or partial success by medical and surgical measures. For example, diets low in phenylalanine are now prescribed as treatment for PKU children. Persons suffering from haemophilia can be greatly helped by administering antihaemolytic globulin, which promotes the clotting of blood. Modern surgical techniques have brought great improvements in dealing with cases of spina bifida.

Rehabilitation

Finally, rehabilitation. With many genetic or partially genetic conditions causing physical or mental disability, much can be done for the patient and for his family in helping him to lead a better and more useful life.

TABLE 4

Established genetic population-screening services

Type of service	Conditions	Preventive or screening action
Primary prevention	Rhesus haemolytic disease	Postpartum use of Anti-D globulin
	Congenital rubella	Immunization of girls
	Congenital malformations	Addition of folic acid to the maternal diet (may prevent neural tube defects)
		Control of maternal diabetes;
		Avoidance of mutagens and teratogens such as alcohol, certain drugs and possibly tobacco
Antenatal screening	Congenital malformations	Ultrasound foetal anomaly scan, maternal serum alpha-fetoprotein estimation
	Chromosomal abnormalities	Noting maternal age and maternal serum factor levels
		Checking family history
	Inherited disease	Carrier screening for haemoglobinopathies, Tay-Sach's disease
Neonatal screening	Congenital malformations	Examination of the newborn for early treatment (e.g., of congenital dislocation of the hip)
	Phenylketonuria, congenital hypothyroidism, sickle-cell disease	Biochemical tests for early treatment

Mental Health

"A mentally healthy person feels right towards others"

Health is defined as a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity. A sound mind in a sound body has been recognised as a social ideal for many centuries. The Indian sages and seers had paid particular attention to the unconscious, wherein lay the suppressed unfulfilled desires and compulsions of several kinds which led the individual astray; by mastering their minds, they attained the highest level of emotional equilibrium. Mental health is thus the balanced development of the individual's personality and emotional attitudes which enable him to live harmoniously with his fellow-men. Mental health is not exclusively a matter of relation between persons; it is also a matter of relation of the individual towards the community he lives in, towards the society of which the community is a part, and towards the social institutions which for a large part guide his life, determine his way of living, working, leisure, and the way he earns and spends his money, the way he sees happiness, stability and security *(1)*.

In 1950, a WHO Expert Committee on mental health reviewed the various definitions of mental health and observed "Mental health, as the Committee understands it, is influenced by both biological and social factors. It is not a static condition but subject to variations and fluctuations of degree; the Committee's conception implies the capacity in an individual to form harmonious relations with others, and to participate in, or contribute constructively to, changes in his social and physical environment. It implies also his ability to achieve a harmonious and balanced satisfaction of his own potentially conflicting instinctive drives in that it reaches an integrated synthesis rather than the denial of satisfaction to certain instinctive tendencies as a means of avoiding the thwarting of others *(2)*.

Problem statement

WORLD: Mental disorders are not the exclusive preserve of any special group; they are truly universal. Mental and behavioural disorders are found in people of all regions, all countries and all societies. An analysis done by WHO shows that neuropsychiatric conditions, which included a selection of these disorders, had an aggregate point prevalence of about 10 per cent for adults. About 450 million people were estimated to be suffering from neuropsychiatric conditions.

INDIA : Surveys of mental morbidity carried out in various parts of the country suggest a morbidity rate of not less than 18–20 per 1,000, and the types of illness and their prevalence are very much the same as in other parts of the world. The number of specialized hospitals for mental disorder patients in the country are 47 with total number of beds about 10,329. The number of outdoor (old and new) mental disorder cases treated in these hospitals during 2004 were about 896,425 and 22,361 cases were treated in child guidance clinics. The total number of new outdoor cases during 2004 in specialized mental hospitals were 6,737 psychotic substance users, 55,869 schizophrenia, 31,555 mood disorder, 38,482 neurotic, stress related, 3,417 behavioural syndromes, 906 disorder of adult personality, 4,256 mental retardation, 885 disorder occurring in childhood, 1,151 psychological disorder, 4,577 organic disorder, and 2,904 unspecified mental disorders *(5)*.

The new cases treated in child guidance clinics during 2004 were 447 organic and symptomatic disorders, 317 psychoactive substance users, 2,588 schizophrenia, 1,118 mood disorders, 413 neurotic and stress related, 125 behavioural syndromes, 87 disorder of adult personality, 1,135 mental retardation, 85 psychological disorder, 190 disorders occuring in childhood, and 1,022 unspecified mental disorders *(5)*.

Characteristics of a mentally healthy person

Mental Health is not mere absence of mental illness. A mentally healthy person has three main characteristics: (1) He feels comfortable about himself, that is, he feels reasonably secure and adequate. He neither underestimates nor overestimates his own ability. He accepts his shortcomings. He has self-respect. (2) The mentally healthy person feels right towards others. This means that he is able to be interested in others and to love them. He has friendships that are satisfying and lasting. He is able to feel a part of a group without being submerged by it. He is able to like and trust others. He takes responsibility for his neighbours and his fellow-men. (3) The mentally healthy person is able to meet the demands of life. He does something about the problems as they arise. He is able to think for himself and to take his own decisions. He sets reasonable goals for himself. He shoulders his daily responsibilities. He is not bowled over by his own emotions of fear, anger, love or guilt *(6)*.

Warning signals of poor mental health

William C. Menninger, President of the Menninger Foundation, Topeka, Kansas, United States of America drew up the following questions to aid in taking one's own mental health pulse:

1. Are you *always* worrying ?
2. Are you *unable* to concentrate because of unrecognized reasons?
3. Are you *continually* unhappy without justified cause?
4. Do you lose your *temper easily* and *often*?

5. Are you troubled by *regular* insomnia?
6. Do you have wide fluctuations in your moods from depression to elation, back to depression, which *incapacitate* you?
7. Do you *continually* dislike to be with people?
8. Are you *upset* if the routine of your life is disturbed?
9. Do your children *consistently* get on your nerves ?
10. Are you "browned off" and *constantly* bitter?
11. Are you afraid *without* real cause?
12. Are you *always* right and the other person *always* wrong?
13. Do you have numerous aches and pains for which no doctor can find a physical cause?

The conditions chartered in these questions are the major warning signals of poor mental health in one degree or another. According to Dr. Menninger, help is necessary if the answer to any of these questions is definitely "yes".

Types of mental illness

Mental and behavioural disorders are understood as clinically significant conditions characterized by alteration in thinking, mood (emotions) or behaviour associated with personal distress and/or impaired functioning. Any classification of mental disorder classifies syndromes and conditions. Individuals may suffer from one or more disorders during one or more periods of their life. One incidence of abnormal behaviour or a short period of abnormal mood does not of itself, signify the presence of a mental or behavioural disorder.

The International Classification of Diseases (ICD–10) classifies the mental and behavioural disorders as *(3)*:

- *Organic, including symptomatic, mental disorders* – e.g., dementia in Alzheimer's disease, delirium.
- *Mental and behavioural disorders due to psychoactive substance use* – e.g., harmful use of alcohol, opioid dependence syndrome.
- *Schizophrenia, schizotypal and delusional disorders* – e.g., paranoid schizophrenia, delusional disorders, acute and transient psychotic disorders.
- *Mood (affective) disorders* – e.g., bipolar affective disorder, depressive episode.
- *Neurotic, stress-related and somatoform disorders* – e.g., generalized anxiety disorders, obsessive-compulsive disorders.
- *Behavioural syndromes associated with physiological disturbances and physical factors* – e.g., eating disorders, non-organic sleep disorders.
- *Disorders of adult personality and behaviour* – e.g., paranoid personality disorder, trans-sexualism.
- *Mental retardation.*
- *Disorders of psychological development* – e.g., specific reading disorders, childhood autism.
- *Behavioural and emotional disorders with onset usually occurring in childhood and adolescence* – e.g., hyperkinetic disorders, conduct disorders, tic disorders.
- *Unspecified mental disorder.*

Mental illness is a vast subject, broad in its limits and difficult to define precisely. There are major and minor illnesses. The major illnesses are called *psychoses*. Here, the person is "insane" and out of touch with reality. There are three major illnesses: (1) SCHIZOPHRENIA (split personality) in which the patient lives in a dream world of his own. (2) MANIC DEPRESSIVE PSYCHOSIS in which the symptoms vary from heights of excitement to depths of depression, and (3) PARANOIA which is associated with undue and extreme suspicion and a progressive tendency to regard the whole world in a framework of delusions. The minor illnesses are of two groups: (a) NEUROSIS OR PSYCHONEUROSIS: In this the patient is unable to react normally to life situations. He is not considered "insane" by his associates, but nevertheless exhibits certain peculiar symptoms such as morbid fears, compulsions and obsessions, (b) PERSONALITY AND CHARACTER DISORDERS: This group of disorders are the legacy of unfortunate childhood experiences and perceptions.

Causes of mental illhealth

Mental illness like physical illness is due to multiple causes. There are many known factors of agent, host and environment in the natural histories of mental disorders. Among the known factors are the following: (1) ORGANIC CONDITIONS: Mental illnesses may have their origin in organic conditions such as cerebral arteriosclerosis, neoplasms, metabolic diseases, neurological diseases, endocrine diseases and chronic diseases such as tuberculosis, leprosy, epilepsy, etc. (2) HEREDITY: Heredity may be an important factor in some cases. For example, the child of two schizophrenic parents is 40 times more likely to develop schizophrenia than is the child of healthy parents. (3) SOCIAL PATHOLOGICAL CAUSES: To produce any disease, there must be a combination of genetic and environmental factors. The social and environmental factors associated with mental illhealth comprise : worries, anxieties, emotional stress, tension, frustration, unhappy marriages, broken homes, poverty, industrialization, urbanization, changing family structure, population mobility, economic insecurity, cruelty, rejection, neglect and the like. The social environment not only determines the individual's attitudes but also provides the "framework" within which mental health is formulated.

Environmental factors other than psychosocial ones capable of producing abnormal human behaviour are: (1) *Toxic substances* – carbon disulfide, mercury, manganese, tin, lead compounds, etc. (2) *Psychotropic drugs* – barbiturates, alcohol, griseofulvin. (3) *Nutritional factors* – deficiency of thiamine, pyridoxine. (4) *Minerals* – deficiency of iodine. (5) *Infective agents* – infectious disease (e.g., measles, rubella) during the prenatal, perinatal and post-natal periods of life may have adverse effects on the brain's development and the integration of mental functions. (6) *Traumatic factors* – road and occupational accidents and (7) *Radiation* – nervous system is most sensitive to radiation during the period of neural development.

Crucial points in the lifecycle of human beings

There are certain key points in the development of the human being which are important from the point of view of mental health. These are : (1) *Prenatal period :* Pregnancy is a stressful period for some women. They need help not only for their physical but also emotional needs. (2) *First 5 years of life*: The roots of mental health are in early childhood. The infant and young child should experience a warm, intimate and continuous relationship with his mother and father. It is in this relationship where underlies the development of mental health. It follows that broken homes

are likely to produce behaviour disorders in children and this has been confirmed by several studies. (3) *School child :* Everything that happens in the school affects the mental health of the child. The programmes and practices of the school may satisfy or frustrate the emotional needs of the child. Children who have emotional problems may need child guidance clinic or psychiatric services. From the standpoint of the child's mental health and his effectiveness in learning, proper teacher-pupil relationship and climate of the class room are very important. (4) *Adolescence :* The transition from adolescence to manhood is often a stormy one and fraught with dangers to mental health, manifested in the form of mental illhealth among the young, and juvenile delinquents in particular. The basic needs of the adolescents are: (a) the need to be needed by others, (b) the need for increasing independence, (c) the need to achieve adequate adjustment to the opposite sex and (d) the need to rethink the cherished beliefs of one's elders. The failure to recognize and understand these basic needs may prevent sound mental development *(1).* (5) *Old age :* The mental health problems of the aged have received considerable attention in recent times in the developed countries. The causes of mental illness in the aged are organic conditions of the brain, economic insecurity, lack of a home, poor status and insecurity.

Thus throughout his life, the needs of man remain the same (1) the need for affection, (2) the need for belonging, (3) the need for independence, (4) the need for achievement, (5) the need for recognition or approval, (6) the need for a sense of personal worth and (7) the need for self-actualization. These needs only differ in degree and qualitative importance at various ages.

Preventive aspects

Three levels of prevention have been described *(7).*

(1) *Primary :* Primary prevention operates on a community basis. This consists of "improving the social environment", and promotion of the social, emotional and physical well-being of all people. It includes working for better living conditions and improved health and welfare resources in the community.

(2) *Secondary :* This consists of *early diagnosis* of mental illness and of social and emotional disturbances through screening programmes in schools, universities, industry, recreation centres, etc., and provision of treatment facilities and effective community resources. In this regard, "family-based" health services have much role to play. The family service agencies identify emotional problems and early symptoms of mental illness, help family members to cope with overwhelming stress, treat problems of individual and social maladjustment when required and prepare individual family members for psychiatric care. "Case work" or "counselling" is the method most commonly employed by the family service agencies. The agencies, main responsibility is to provide a counselling service and help to families with marital conflict, disturbed parent-child relationships and strained interpersonal relationships. Family counselling is one method of treatment intervention for helping the mentally ill. Family counsellors make an accurate psychosocial diagnosis.

(3) *Tertiary:* Tertiary prevention seeks to reduce the duration of mental illness and thus reduce the stresses they create for the family and the community. In short, the goal at this level is to prevent further break-down and disruption.

Mental health services

Mental health services in a community are concerned not only with early diagnosis and treatment, but also with the preservation and promotion of good mental health and prevention of mental illness. The mental health services comprise:

(1) Early diagnosis and treatment.
(2) Rehabilitation.
(3) Group and individual psychotherapy.
(4) Mental health education.
(5) Use of modern psychoactive drugs, and
(6) After-care services.

Comprehensive mental health programme

Since 95 per cent of psychiatric cases can be treated with or without hospitalization close to their homes, the current trend is full integration of psychiatric services with other health services. The Community Mental Health Programme includes all community facilities pertinent in any way to prevention, treatment and rehabilitation. The philosophy of Community Mental Health Programme consists of the following essential elements : (1) In-patient services (2) Out-patient services (3) Partial hospitalization (4) Emergency services (5) Diagnostic services (6) Pre-care and aftercare services including foster home placement and home visiting (7) Education services (8) Training, and (9) Research and evaluation.

ALCOHOLISM AND DRUG DEPENDENCE

Definition

The word "drug" is defined as "any substance that, when taken into the living organism, may modify one or more of its functions" (WHO). "Drug abuse" is defined as self-administration of a drug for non-medical reasons, in quantities and frequencies which may impair an individual's ability to function effectively, and which may result in social, physical, or emotional harm. "Drug dependence" is described as "a state, psychic and sometimes also physical, resulting from the interaction between a living organism and a drug, characterized by behavioural and other responses that always include a compulsion to take the drug on a continuous or periodic basis in order to experience its psychic effects, and sometimes to avoid the discomfort of its absence. A person may be dependent upon more than one drug *(8, 9).*

The problem

The non-medical use of alcohol and other psychoactive drugs has become a matter of serious concern in many countries. While alcohol abuse is a more or less universal problem, the incidence of drug abuse varies from place to place. An estimated 12–20 million people smoke marijuana in the US. 30–50 per cent of all high school students had made marijuana an accepted part of life *(10).* Experience in Sweden indicates that drug dependence reached a peak in the age-group 12–20 years and the problem is less among girls. The problem of drug dependence has reached epidemic proportions in many countries *(11).*

Agent factors

Dependence-producing drug

A dependence-producing drug is one that has the capacity to produce dependence, as described above. The specific characteristics of dependence varies with the type of

drug involved. ICD–10 recognizes the following psychoactive drugs, or drug classes, the self administration of which may produce mental and behavioural disorders, including dependence :

1. Alcohol
2. Opioids
3. Cannabinoids
4. Sedatives or hypnotics
5. Cocain
6. Other stimulants including caffeine
7. Hallucinogens
8. Tobacco
9. Volatile solvents
10. Other psychoactive substances, and drugs from different classes used in combination.

Although the dependence-producing properties and public health problems caused by tobacco were recognized since long, its acute effects on behaviour were minimal. The WHO Expert Committee on drug dependence at its meeting in Sept. 1992 felt that tobacco and other forms of nicotine use warranted their inclusion in the report. Furthermore, it recommended that WHO should consider expanding the Committee's term of reference to include substances such as anabolic steroids, which are used because of their performance-enhancing effects. Anabolic steroids are being abused by people who wish to increase muscle mass for cosmetic reasons or for greater strength. In addition to the medical problems, the practice is associated with significant mood swings, aggressiveness, and paranoid delusions. Alcohol and stimulant use is higher in these individuals. Withdrawal symptoms of steroid dependency include fatigue, depressed mood, restlessness, and insomnia *(12)*. This form of use is described in ICD–10 under the category F-55, "Abuse of non-dependence-producing substances". The development of other performance enhancing drugs may present new types of drug use problems in the future.

The drugs which are in common use today are *(13, 11, 14, 15, 16)* :

(1) AMPHETAMINES AND COCAINE : Amphetamines are synthetic drugs, structurally similar to adrenaline. In medical practice, they are used to treat obesity, mild depression, narcolepsy and certain behaviour disorders in children. The ordinary therapeutic dose is 10–30 mg a day. There are various brands of amphetamines: the common names are Benzedrine, Dexedrine, Methedrine, etc. These drugs act on the central nervous system. They produce mood elevation, elation, a feeling of well-being and increased alertness and a sense of heightened awareness. Because they give a tremendous boost to self-confidence and energy, while increasing endurance, they are called "superman" drugs. The use of these drugs results in psychic dependence. With large doses, such dependence, is often rapid and strong.

Cocaine is derived from the leaves of the coca plant. It was formerly used in medical practice as a potent local anaesthetic. Cocaine is a central nervous stimulant. It produces a sense of excitement, heightened and distorted awareness and hallucinations. Unlike amphetamines, it produces no tolerance. There is a 'no physical dependence; no withdrawal symptoms', *per se*. The chewing of coca leaves is a very common practice in Bolivia and Peru in South America.

(2) BARBITURATES: If amphetamines stimulate, barbiturates sedate. They are a major ingradient in sleeping pills. The drug-users generally prefer short-acting barbiturates such as pentobarbital and secobarbital to long acting ones. The addiction to barbiturates is one of the worst forms of suffering. It leads to craving, or both physical and psychic dependence.

(3) CANNABIS: Perhaps, the most widely used drug today is *Cannabis*, which is a very ancient drug obtained from the hemp plants – *Cannabis sativa, C.indica and C. americana.* The resinous exudate from the flowering tops of the female plant contains most of the active ingradients – called *hashish* or *charas.* The dried leaves and flowering shoots are called *bhang;* the resinous mass from the small leaves and brackets of inflorescence is called *ganja.* In USA, the term *marijuana* is used to refer to any part of the plant which induces somatic and psychic changes in man.

Most commonly the plant is cut, dried, chopped and incorporated into cigarettes. It is also taken with drinks or incorporated in foods like sweets and cakes. A marijuana cigarette will produce intoxication within minutes and lasts from 1 to 4 hours. The oral consumption results in a delayed onset of action and a prolonged effect lasting many hours.

The most common reaction is the development of a dreamy state of altered consciousness. Relaxation, euphoria, and an increased tendency to laugh, greater awareness of colours and sounds, interference with perception of both time and space, and paranoia are among the psychological effects reported by marijuana users. Human death appears to be a rare phenomenon. There is a psychic dependence.

(4) HEROIN: Heroin, morphine, codein, methadone, pethidine are narcotic analgesics. Addiction to heroin is perhaps the worst type of addiction because it produces craving. With narcotics generally psychic dependence is strong and tends to develop early. Tolerance to narcotics also occurs rapidly, making it necessary to take increasing doses of the drug to achieve the same effect.

(5) LSD: Lysergic acid diethylamide (LSD) was synthesized in 1938 by Hoffmann in the Sandoz Laboratories in Switzerland. Its psychic properties were noticed much later in 1943, when he accidentally sniffed a few micrograms of it.

LSD is a potent psychotogenic agent. Although amounts as low as 20–25 μg may produce subjective disturbances, oral doses in the range of 100–250 μg are usually required to effect intense depersonalization. The lethal dose in man is not known.

LSD alters the normal structuring of perception. The individual perceives the world in a different manner. There is intensification of colour perception and auditory acuity; body image distortions, visual illusions, fantasies pseudohallucinations are common. Colours are heard and music becomes palpable. Subjective time is deranged so that seconds seem to be minutes and minutes pass as slowly as hours.

Physical dependence does not develop with LSD; hence there is no addiction liability. No characteristic abstinence syndrome is manifest upon abrupt discontinuation of chronic use of the drug.

(6) ALCOHOL: By pharmacological definition, alcohol is a drug and may be classified as a sedative, tranquillizer, hypnotic or anaesthetic, depending upon the quantity consumed. Of all the drugs, alcohol is the only drug whose self-induced intoxication is socially acceptable.

Alcohol is rapidly absorbed from the stomach and small intestine. Within 2–3 minutes of consumption, it can be

detected in the blood – the maximum concentration is usually reached about one hour after consumption. The presence of food in the stomach inhibits the absorption of alcohol because of dilution.

Over the past 30–40 years, increasing percentages of young people have started to drink alcoholic beverages, their alcohol consumption has increased in quantity and frequency, and the age at which drinking starts has declined *(13)*. This situation is disturbing because the young people concerned may run a greater risk of alcoholic problems in later life and also, in the short term, because of increased rates of drunkenness and involvement in road accidents.

Worldwide, an estimatd 2.3 million people die from alcohol-related causes. This is 3.7 per cent of all deaths; 6.1 per cent among men and 1.1 per cent among women. Also, 64.9 million DALYs are lost due to alcohol related causes. WHO has estimated that there are about 2 billion people worldwide who consume alcoholic bevarages and 76.3 million with disorders arising out of harmful use of alcohol. Unintentional injuries and suicides account for large number of deaths due to alcohol *(19)*.

In India, survey showed that around 20–30 per cent of adult males and around 5 per cent of adult females use alcohol. While alcohol is used traditionally by men, its use by women is now on the increase. The proportion of dependent users is large. Issues of concern include pay-day drinking, violence including domestic violence, alcohol's contribution to poverty, illicit and home-brewed alcohol, and reduction in average age of initiation *(19)*. In a study in Bangalore, nearly 28 per cent of traffic injuries were found directly attributable to alcohol. Alcohol use is considered a risk factor for high risk sexual behaviour leading to sexually transmitted diseases including HIV/AIDS.

Alcohol has a marked effect on the central nervous system. It is not a "stimulant" as long believed, but a primary and continuous depressant. Alcohol produces psychic dependence of varying degrees from mild to strong. Physical dependence develops slowly.

According to current concepts, alcoholism is considered a disease and alcohol a "disease agent" which causes acute and chronic intoxication, cirrhosis of the liver, toxic psychosis, gastritis, pancreatitis, cardiomyopathy and peripheral neuropathy. Also, evidence is mounting that it is related to cancer of the mouth, pharynx, larynx and oesophagus. Further, alcohol is an important aetiologic factor in suicide, automobile and other accidents, and injuries and deaths due to violence. The health problems for which alcohol is responsible are only part of the total social damage which includes family disorganization, crime and loss of productivity.

(7) TOBACCO : Tobacco is in legal use everywhere in the world, yet it causes far more deaths than all other psychoactive substances combined. About 3 million premature deaths a year (6 per cent of the world total) are already attributed to tobacco smoking. Tobacco is responsible for about 30 per cent of all cancer deaths in developed countries. More people die from tobacco related diseases other than cancer such as stroke, myocardial infarction, aortic aneurysm and peptic ulcer. Young people who take up smoking have been shown to experience an early onset of cough, phlegm production, and shortness of breath on exertion. There is evidence that the earlier a person begins to smoke, the greater is the risk of life-threatening diseases such as chronic bronchitis, emphysema, cardiovascular disease, and lung cancer. Experimentation with smoking as a symbol of "adult" behaviour is common in adolescence. It is suggested that three factors are associated with young people smoking : peer pressure, following the example of siblings and parents, and employment outside the home. If a child's older sibling and both parents smoke, the child is four times as likely to smoke as one with no smoking model in the family *(13)*.

Women who smoke run even more risks than men. For example, the adverse effects of oral contraceptive use are markedly increased in women smokers. Osteoporosis is accelerated with tobacco use. Some evidence indicates that fertility is impaired with smoking. Tobacco use is also associated with a higher rate of spontaneous miscarriages. In pregnancy, smoking contributes to perinatal complications such as bleeding, which is dangerous for both mother and fetus, especially in poor countries where health facilities are inadequate. Intrauterine growth retardation and low-birth-weight babies are known out-comes of smoking during pregnancy *(17)*. The babies of mothers who smoke may weigh, on an average, 200 grams less at birth than those of non-smokers *(16)*. The harm from maternal smoking can extend beyond pregnancy, affecting the child's growth and development. This is often compounded by the child's exposure to second-hand smoke from parents and other adults.

Passive smoking

Second-hand tobacco smoke is the combination of smoke emitted from the burning end of a cigarette or other tobacco products and smoke exhaled by the smoker.

Smoking harms non-smokers too. The first conclusive evidence of the danger of passive smoking came from a study carried out by Takeshi Hirayama, in 1981, on lung cancer in non-smoking Japanese wives married to men who smoked. Surprising at the time, those women showed a significantly increased risk of dying from lung cancer, despite never having smoked a cigarette. Hirayama believed that passive smoking (i.e. breathing in the smoke from their husbands) caused these women's excess cancer risk. About 40 further studies have confirmed this link.

Today, research indicates that passive smoking can also give rise to other potentially fatal diseases such as heart disease and stroke, and new scientific evidence on the adverse effects of second-hand smoke continues to accumulate *(17)*.

Per capita consumption of tobacco is decreasing slowly in developed countries. By contrast, per capita tobacco consumption is rising in many developing countries among both men and women. Because of the long delay between the cause and full effect, people tend to misjudge the hazards of tobacco. When a generation of young adults begin to smoke, they do not witness the high morbidity and mortality associated with their behaviour until they reach middle age. The best documented example of this delay is that of men in the USA, among whom the main increase in smoking took place before 1945. In 1945 smoking was common but lung cancer was rare as in developing countries today. Over the next forty years (1945–1985) the smoking habit did not change greatly, but lung cancer in this population rose sharply – about twenty fold, whereas non-smokers lung cancer remained approximately constant at a low level during 1945–1985. About half of those killed by tobacco were still in middle age (35–69) and thereby lost almost twenty-five years of non-smoker life expectancy *(16)*.

Since the mechanization of cigarette manufacturing at the turn of the 20th century, global consumption of cigarettes has been rising steadily. Today, more people are smoking, and consuming more cigarettes per capita, than ever before. At present, about 1070 million males and 230 million females in the world smoke, generating an epidemic of global magnitude. In developed countries, the prevalence of smoking among adult males is decreasing, but the increasing number of adult male smokers in developing countries offsets this. Smoking is still rising among females in developed countries, with the exception of a few countries such as Australia, Canada, United Kingdom and the United States. With the expansion of the tobacco industry's marketing campaigns into the developing world, more and more people are taking up smoking in countries least able to deal with the grave public health consequences of tobacco use. China produces about a third of all the cigarettes in the world. It is also a major tobacco counsumer, since nearly 60% of adult Chinese males smoke, representing one-third of all smokers globally. Currently, it is estimated that one out of every three cigarettes in the world is smoked in China. According to Global Adult Tobacco Survey, India (2009–2010), the prevalence of overall tobacco use among males is 48 per cent and that among females is 20 per cent. Nearly 38 per cent adults in rural areas and 25 per cent in urban areas use tobacco in some form. Prevalence of smoking among males is 24 per cent whereas prevalence among females is 3 per cent. The extent of use of smokeless tobacco products among males is 33 per cent and in females 18 per cent *(18)*.

A variety of smokeless tobacco products are also consumed in South East Asia Region. Pan masala, gutkha (industrially manufactured chewing tobacco product), khaini (chewing of dry tobacco leaves and lime), and chewing tobacco with areca nuts are common in India, Bangladesh, Bhutan, Nepal and Myanmar. Smokeless tobacco use is more prevalent among men than among women in these countries excepting in Bangladesh, where smokeless tobacco use is more prevalent among women *(19)*.

The adverse health effects of smoking are as shown in Table 1.

The withdrawal symptoms include irritability, anxiety, craving, sleep problems, headache, tremors, and lethargy. Withdrawal symptoms may continue for 4-6 weeks, and craving may continue for many months.

(8) VOLATILE SOLVENTS : In a number of countries, the sniffing of substances such as glue, petrol, diethyl ether, chloroform, nitrous oxide, paint thinner, cleaning fluids, typewriter correction fluid etc., is causing increasing concern, as it can result in death, even on the first occasion. These substances are central nervous system depressants

TABLE 1

Adverse health effects of smoking

Body system or organ	Established or suspected adverse health effect of cigarette smoking
Lungs	– Lung cancer
	– Chronic obstructive pulmonary disease
	– Increased severity of asthma
	– Increased risk of developing various respiratory infections
Heart	– Coronary heart disease
	– Angina pectoris
	– Heart attack
	– Increased risk of repeat heart attack
	– Arrhythmia
	– Aortic aneurysm
	– Cardiomyopathy
Blood vessels	– Peripheral vascular disease
	– Thromboangiitis obliterans (Buerger's disease)
Skin	– Earlier wrinkling
	– Fingernail discoloration
	– Psoriasis
	– Palmoplantar pustulosis
Cancer	– Lung cancer
	– Esophageal cancer
	– Laryngeal cancer
	– Oral cancer
	– Bladder cancer
	– Kidney cancer
	– Stomach cancer
	– Pancreatic cancer
	– Vulvular cancer
	– Cervical cancer
	– Colorectal cancer
Bones	– Disc degeneration
	– Osteoporosis
	– Osteoarthritis
	– Less successful back surgery
	– Delayed fracture healing
	– Muscoloskeletal injury
Reproduction	– Infertility
	– Impotence
	– Decreased sperm motility and density
	– Miscarriage
	– Earlier menopause
The unborn child	– Fetal growth retardation
	– Prematurity
	– Stillbirth
	– Enhanced transmission of HIV to fetus
	– Birth defects
	– Intellectual impairment
	– Sudden infant death syndrome
Brain	– Transient ischaemic attack
	– Stroke
	– Worsened multiple sclerosis
Others	– Cataract
	– Macular degeneration
	– Snoring
	– Periodontal disease
	– Stomach and duodenal ulcers
	– Crohn disease
	– Impaired immunity

Source : *(17)*

and produce effects comparable to those produced by alcohol. There may be initial euphoria and exhilaration, followed by confusion, disorientation and ataxia. Some of the substances like petrol and toluene may also produce marked euphoria, grandiosity, recklessness, delusions and hallucinations and a substantial loss of self-control. With increasing doses, there may be convulsions, coma and death. In chronic abusers damage to the brain, peripheral nervous system, kidney, liver, heart or bone marrow may occur *(13)*. Lead encephalopathy can be associated with sniffing lead gasoline.

(9) CAFFEINE : Caffeine is one of the most commonly used drug worldwide. About 10 billion pounds of coffee are consumed yearly throughout the world. Tea, cocoa, and cola drinks also contribute to an intake of caffeine that is often very high in a large number of people. The approximate content of caffeine in a cup (180 ml) of beverage is as follows : brewed coffee 80–140 mg; instant coffee 60–100 mg; decaffeinated coffee 1–6 mg; black leaf tea 30–80 mg; tea bags 25–75 mg; instant tea 30–60 mg; cocoa 10–50 mg; and 12 oz cola drinks 30–65 mg. Symptoms of caffeinism (usually associated with ingestion of over 500 mg/day) include anxiety, agitation, restlessness, insomnia and somatic symptoms referable to the heart and gastrointestinal tract. Withdrawal from caffeine can produce headache, irritability, lethargy, and occasional nausea *(12)*.

Host factors

Many attempts have been made to define the host factors. Studies employing questionnaires or structured interviews report motives for drug dependence with descriptive words such as pleasure, desire to experiment, sense of adventure, wish for self-knowledge, and desire to escape. Increasingly, people are unwilling to accept even minor discomforts and are looking to drugs for solutions. Many of them have shown symptoms of social and psychological maladjustment resulting from personal handicaps of all sorts.

The average age of drug users has decreased considerably in recent years. Multiple drug-use has also become more common. Concern over drug-use by teenagers increased in the late 1960s, particularly in the developed countries. In countries with long experience of heavy drug use, there is a tendency to prefer a single drug, perhaps because a continuous supply is less problematic. Multiple drug use may be more common where drug abuse is a relatively recent occurrence.

Symptoms of drug addiction

1. Loss of interest in sports and daily routine ;
2. Loss of appetite and body weight ;
3. Unsteady gait, clumpsy movements, tremors ;
4. Reddening and puffiness of eyes, unclear vision ;
5. Slurring of speech ;
6. Fresh, numerous injection marks on body and blood stains on clothes ;
7. Nausea, vomiting and body pain ;
8. Drowsiness or sleeplessness, lethargy and passivity ;
9. Acute anxiety, depression, profuse sweating ;
10. Changing mood, temper, tantrums ;
11. Depersonalization and emotional detachment ;
12. Impaired memory and concentration; and
13. Presence of needles, syringes and strange packets at home.

Environmental factors

Among the environmental factors attributed to drug dependence are rapid technological developments with associated need for extended periods of education, along with the in-applicability of old solutions to novel problems. Television, world travel, affluence, freedom to speculate and experiment have encouraged youngsters to question and often reject the values and goals of their parents. Established social values are perceived as irrelevant, all to be stripped away, partly through the use of drugs in order to reveal the real person, the real humanity, and the real goals of mankind. Studies confirm that those who take drugs usually form part of a small antisocial and often criminal subculture.

The problem exists in virtually all societies and socio-economic groups. Some of the social and environmental factors associated with a high risk for drug abuse are listed in Table 2.

TABLE 2
Factors associated with a high risk for drug abuse

- unemployment
- living away from home
- migration to cities
- relaxed parental control
- alienation from family
- early exposure to drugs
- leaving school early
- broken homes; one parent families
- large urban environments
- areas where drugs are sold, traded, or produced
- certain occupations (tourism, drug production or sale)
- areas with high rates of crime or vice
- areas where there are drug - using gangs
- areas where delinquency is common

Source : *(13)*

Prevention

Approaches to prevention of drug dependence should have realistic aims. Over-ambitious hopes of *eradicating* a drug problem in a short time are likely to lead to policies that are unrealistic and self-discrediting. Changes in culture attitudes and alteration in relevant aspects of the environment can be brought about only slowly.

Legal approach : The legal control on the distribution of drugs, when effectively applied has been and remains an important approach in the prevention of drug abuse. Controls may be designed to impose partial restriction or to make a drug completely unavailable. Legislation may be directed at controlling the manufacture, distribution, prescription, price, time of sale, or consumption of a substance.

Legislation restricting or prohibiting advertisements that directly or indirectly promote use of tobacco and alcohol has been increasingly common in recent years. The antismoking measures suggested are : (a) prohibition of the sale of tobacco products to minors; (b) restriction on the sale of cigarettes from automatic vending machines; (c) prohibition of smoking in schools and other places frequented by young people; (d) prohibition of smoking in public; (e) prohibition of cigarette advertising at times, and in places and ways, calculated to ensure its maximum impact on adolescents; (f) establishment of mandatory public health education on health consequences of smoking; (g) insisting on the placing of mandatory health warning on cigarette packets.

The minimum age at which minors may legally have

access to alcoholic beverages, has been raised in some countries. There is also legislation controlling the distribution of alcohol in some countries. Mandatory jail sentences for drunken driving have not been very effective.

Educational approach : Educational approaches to the prevention of drug use and drug-related problems have been used in many countries. Common approaches have included educational programmes for school children and public information campaigns on electronic media. General principles of communication can be applied to increase the effectiveness of educational approach. The message should be clear and unambiguous to the intended audience, and come from credible source of information. The message should also provide specific advice, rather than general, and as far as possible the information should be new to the audience and should be capable of provoking discussion or action. Educational approach should not be planned and carried out as isolated activity. To be effective, such approaches should be regarded as a part of integrated plan of action involving other strategies.

Community approach : The non-medical use of the drugs individually as well as in its mass appearance involves a complex interaction of drug, man, and his environment, including social, economic, cultural, political and other elements of varying character and strength. The rapid changes taking place at the present time in relations between individuals, groups and nations are also reflected in a rapidly changing pattern of drug abuse in many parts of the world. There should be a strong emphasis on action at the community level to prevent drug abuse. Initiating preventive interventions in the community brings preventive action to the level of people's every day lives and actions, and contributes to emphasis on strengthening primary health care. Action at the community level is also important since communities often bear the main burden of dealing with the harmful use of drugs and drug related problems.

A popular approach to the prevention of drug abuse is provision of alternative activities which may help to prevent drug abuse – e.g., *teen centres* providing activities attractive to the adolescents who might otherwise drift in to drug taking subculture. Such activities include the establishment of groups or organizations interested in athletics, sports, music, public policy, religion, artistic activities of various kinds, and improvement of the environment through the prevention of pollution. Non-governmental organizations play a crucial role in the development of such activities and are likely to become important.

Treatment

Treatment cannot take place unless the individual attends for treatment. He must come to terms with the possibility of a life without drug taking. Unfortunately, drug takers, as a rule, have little or no motivation to undergo treatment. Alcoholics tend to deny that their consumption is abnormal; others openly defend their habits. Long term treatment is not only a medical problem, but needs the cooperation of psychologists and sociologists. There is a high relapse rate with all treatment methods *(16)*.

Though drug addiction may be considered as a social problem, the first step in its management is medical care, which includes :

- identification of drug addicts and their motivation for detoxication
- detoxication (requires hospitalization)
- post-detoxication counselling and follow-up (based on clinic and home visits), and
- rehabilitation.

Simultaneously with medical treatment, changes in environment (home, school, college, social circles) are important. The patient must effect a complete break with his group, otherwise the chances of relapse are 100 per cent. Psychotherapy has a valuable place in the management of the addict.

Rehabilitation *(8)*

The rehabilitation of former drug user, regardless of age, is in most cases a long and difficult process. Relapses are very frequent. Success of the treatment necessitates the adoption of mature and realistic attitude by the local community and the avoidance of panic, moral condemnation and discrimination. Facilities for vocational training and sometimes the provision of sheltered work opportunities are useful in rehabilitation and help to prevent relapse. Generally speaking, facilities for the registration, diagnosis, treatment, after-care, etc., of drug-dependent individuals and groups should be regarded as indispensable integrated parts of the health and social services structure of any community in which drug-dependence exists.

It is suggested that when there is evidence of significant "alienation" among a group, especially of younger persons, it should be regarded as indication of possible presence of actual or potential drug-takers, and should lead to an analysis of the situation and to such preventive or remedial action as may be indicated.

Health Information and Basic Medical Statistics

"As a general rule, the most successful man in life is the man who has the best information"

Health information is an integral part of the national health system. It is a basic tool of management and a key input for the progress of any society. A health information system is defined as :

> *"a mechanism for the collection, processing, analysis and transmission of information required for organizing and operating health services, and also for research and training" (1, 2).*

The primary objective of a health information system is to provide reliable, relevant, up-to-date, adequate, timely and reasonably complete information for health managers at all levels (i.e., central, intermediate and local), and at the sharing of technical and scientific (including bibliographical) information by all health personnel participating in the health services of a country; and also to provide at periodic intervals, data that will show the general performance of the health services and to assist planners in studying their current functioning and trends in demand and work load.

Unfortunately, it is still very difficult to get the information where it matters most – i.e., at the community level. It is conceded that no country at the present time has such a thoughtfully constructed system of health information in operation, but the concept is receiving much attention. The whole science of health statistics has undergone considerable changes in the past two decades *(3)*. In 1973, the World Health Assembly stressed the need for complete reconstruction of the health information system.

Distinction between data and information

There is more than a subtle semantic difference between "data", "information" and "intelligence". **Data** consists of discrete observations of attributes or events that carry little meaning when considered alone; data as collected from operating health care systems or institutions are inadequate for planning. Data need to be transformed into **information** by reducing them, summarizing them and adjusting them for variations, such as the age and sex composition of the population so that comparisons over time and place are possible. It is the transformation of information through integration and processing with experience and perceptions based on social and political values that produces **intelligence** *(4)*.

Data that are not transformed into *information,* and information that is not transformed into *intelligence* to guide decision-makers, policy-makers, planners, administrators and health care personnel themselves, are of little value.

Requirements to be satisfied by health information systems

A WHO Expert Committee *(5)* identified the following requirements to be satisfied by the health information systems :

(1) The system should be population-based
(2) The system should avoid the unnecessary agglomeration of data
(3) The system should be problem-oriented
(4) The system should employ functional and operational terms (e.g., episodes of illness, treatment regimens, laboratory tests)
(5) The system should express information briefly and imaginatively (e.g., tables, charts, percentages), and
(6) The system should make provision for the feed-back of data.

Components of a health information system

The health information system is composed of several related subsystems. A comprehensive health information system requires **information** and **indicators** on the following subjects *(6)* :

(1) demography and vital events
(2) environmental health statistics
(3) health status : mortality, morbidity, disability, and quality of life
(4) health resources : facilities, beds, manpower
(5) Utilization and non-utilization of health services : attendance, admissions, waiting lists
(6) indices of outcome of medical care, and
(7) financial statistics (cost, expenditure) related to the particular objective.

Uses of health information

The important uses to which health information may be applied are :

(1) to measure the health status of the people and to quantify their health problems and medical and health care needs
(2) for local, national and international comparisons of health status. For such comparisons the data need to be subjected to rigorous standardization and quality control
(3) for planning, administration and effective management of health services and programmes

(4) for assessing whether health services are accomplishing their objectives in terms of their effectiveness and efficiency
(5) for assessing the attitudes and degree of satisfaction of the beneficiaries with the health system, and
(6) for research into particular problems of health and disease.

Sources of health information

The lifeblood of a health information system is the routine health statistics. Information requirements will vary according to the administrative level at which planning is envisaged. For example, the information requirements of a public health administrator will be different from the information requirements of a hospital administrator. These different contexts require different sources of information. These are discussed in this section.

1. Census

The census is an important source of health information. It is taken in most countries of the world at regular intervals, usually of 10 years. A census is defined by the United Nations as "the total process of collecting, compiling and publishing demographic, economic and social data pertaining at a specified time or times, to *all* persons in a country or delimited territory" *(7)*. Census is a massive undertaking to contact every member of the population in a given time and collect a variety of information. It needs considerable organization, a vast preparation and several years to analyse the results. This is the main drawback of census as a data source – i.e., the full results are usually not available quickly.

The first regular census in India was taken in 1881, and others took place at 10-year intervals. The last census was held in March 2011. The census is usually conducted at the end of the first quarter of the first year in each decade, the reason being, most people are usually resident in their own homes during that period. The legal basis of the census is provided by the Census Act of 1948. The supreme officer who directs, guides and operates the census is the Census Commissioner for India.

Although the primary function of census is to provide demographic information such as total count of population and its breakdown into groups and subgroups such as age and sex distribution, it represents only a small part of the total information collected. The census contains a mine of information on subjects not only demographic, but also social and economic characteristics of the people, the conditions under which they live, how they work, their income and other basic information. These data provide a frame of reference and base line for planning, action and research not only in the field of medicine, human ecology and social sciences but in the entire governmental system. Population census provides basic data (such as population by age and sex) needed to compute vital statistical rates, and other health, demographic and socio-economic indicators. Without census data, it is not possible to obtain quantified health, demographic and socio-economic indicators.

2. Registration of vital events

Whereas census is an intermittent counting of population, registration of vital events (e.g., births, deaths) keeps a continuous check on demographic changes. If registration of vital events is complete and accurate, it can serve as a reliable source of health information. Much importance is therefore given to the registration of vital events in all countries. It is the precursor of health statistics. Over the years, it has dominated the health information system.

The United Nations defines a vital events registration system as including "legal registration, statistical recording and reporting of the occurrence of, and the collection, compilation, presentation, analysis and distribution of statistics pertaining to **vital events**, i.e., live births, deaths, foetal deaths, marriages, divorces, adoptions, legitimations, recognitions, annulments and legal separations" *(7)*. Registration of vital events has been the foundation of vital statistics.

India has a long tradition of registration of births and deaths. In 1873, the Govt. of India had passed the Births, Deaths and Marriages Registration Act, but the Act provided only for voluntary registration. Subsequently, individual States like Tamil Nadu, Karnataka and Assam passed their own Acts. However, the Registration system in India tended to be very unreliable, the data being grossly deficient in regard to accuracy, timeliness, completeness and coverage. This is because of illiteracy, ignorance, lack of concern and motivation. There are also other reasons such as lack of uniformity in the collection, compilation and transmission of data which is different for rural and urban areas, and multiple registration agencies (e.g., health agency, panchayat agency, police agency and revenue agency).

The Central Births and Deaths Registration Act, 1969

In an effort to improve the civil registration system, the Govt. of India promulgated the Central Births and Deaths Registration Act in 1969. The Act came into force on 1 April 1970. The Act provides for compulsory registration of births and deaths throughout the country, and compilation of vital statistics in the States so as to ensure uniformity and comparability of data. The implementation of the Act required adoption of rules for which also, model guidelines have been provided. The Act also fixes the responsibility for reporting births and deaths. While the public (e.g., parents, relatives) are to report events occurring in their households, the heads of hospitals, nursing homes, hotels, jails or dharmashalas are to report events occurring in such institutions to the concerning Registrar. The time limit for registering the event of births and that of deaths is 21 days uniformly all over India. In case of default a late fee can be imposed. The Act makes the beginning of a new era in the history of vital statistics registration in India.

Lay reporting

Because of slow progress in the development of a comprehensive vital registration system, some countries have attempted to employ first-line health workers (e.g., village health guides) to record births and deaths in the community. Indeed, one of the important functions of a primary health worker is to collect and record data on vital events and other health information in his or her community.

In order to obtain this information, a new approach has been developed in several countries. This approach is known as "lay reporting of health information" *(8)*. Lay reporting is defined as the collection of information, its use, and its transmission to other levels of the health system by non-professional health workers *(9)*.

In large majority of countries properly functioning vital events registers do not exist and it is necessary to resort to demographic surveys, etc. as an alternative source. The demographic survey, however, can never lead to the desired goal of complete recording of all vital events in a country.

Thus, where a vital events registration system is not functioning, the demographic survey should be regarded as a temporary substitute rather than a replacement *(7)*.

3. Sample Registration System (SRS)

Since civil registration is deficient in India, a Sample Registration System (SRS) was initiated in the mid-1960s to provide reliable estimates of birth and death rates at the National and State levels. The SRS is a dual-record system, consisting of continuous enumeration of births and deaths by an enumerator and an independent survey every 6 months by an investigator-supervisor. The half-yearly survey, in addition to serving as an independent check on the events recorded by the enumerator, produces the denominator required for computing rates.

The SRS now covers the entire country. It is a major source of health information. Since the introduction of this system, more reliable information on birth and death rates, age-specific fertility and mortality rates, infant, under-five and adult mortality, etc. have become available.

4. Notification of diseases

Historically notification of infectious diseases was the first health, information sub-system to be established. The primary purpose of notification is to effect prevention and/or control of the disease. Notification is also a valuable source of morbidity data i.e., the incidence and distribution of certain specified diseases which are notifiable.

Lists of notifiable diseases vary from country to country, and also within the same country between the States and between urban and rural areas. Usually diseases which are considered to be serious menaces to public health are included in the list of notifiable diseases. Notification system is usually operative through certain legal Acts (e.g., Madras Public Health Act, 1930). Some State Governments in India do not have any specific Act, except invoking the Epidemic Diseases Act of 1897, and extending the same from year to year. The notification system is linked up with the vital statistics machinery and the reporter is often the village chowkidar or headman. With the introduction of village Health Guides and multipurpose workers, the reporting responsibility is now shifted from the village chowkidar to the health workers. Since the legal provision is an essential pre-requisite for any notification system, the enactment of a uniform Act similar to the Registration of Births and Deaths Act, 1969 is deemed necessary for any improvement in the notification system in India.

At the international level, the following diseases are notifiable to WHO in Geneva under the International Health Regulations (IHR), viz. cholera, plague and yellow fever. A few others – louse–borne typhus, relapsing fever, polio, influenza, malaria, rabies and salmonellosis are subject to international surveillance. This information is published by WHO on a world-wide basis. The Expert Committee on Health Statistics in its third Report *(10)* recommended that yearly data of notification should be detailed by age and sex.

Although notification is an important source of health information, it is common knowledge that it suffers from serious limitations : (a) notification covers only a small part of the total sickness in the community (b) the system suffers from a good deal of under-reporting (c) many cases especially atypical and subclinical cases escape notification due to non-recognition, e.g., rubella, non-paralytic polio, etc. The accuracy of diagnosis and thereby of notification depends upon the availability of facilities for bacteriological, virological and serological examination. The lack of such facilities in the rural areas of India also works against the correct reporting of the causes of sickness.

Inspite of the above limitations, notification provides valuable information about fluctuations in disease frequency. It also provides early warning about new occurrences or outbreaks of disease. The concept of notification has been extended to many non-communicable diseases and conditions notably cancer, congenital malformations, mental illness, stroke and handicapped persons.

5. Hospital records

In a country like India, where registration of vital events is defective and notification of infectious diseases extremely inadequate, hospital data constitute a basic and primary source of information about diseases prevalent in the community. The eighth report of the WHO Expert Committee on Statistics *(11)* recommended that hospital statistics be regarded in all countries as an integral and basic part of the national statistical programme.

The main drawbacks of hospital data are : (a) they constitute only the "tip of the iceberg" – i.e., they provide information on only those patients who seek medical care, but not on a representative sample of the population. Mild cases may not attend hospitals; subclinical cases are always missed (b) the admission policy may vary from hospital to hospital; therefore hospital statistics tend to be highly selective (c) population served by a hospital (population at risk) cannot be defined. There are no precise boundaries to the catchment area of a hospital. In effect, hospital statistics provide only the **numerator** (i.e., the cases), not the denominator. Extrapolation of hospital data to an entire community is highly conjectural in estimating frequency rates of disease. Therefore, hospital statistics are considered a poor guide to the estimation of disease frequency in a community.

In spite of the above limitations, a lot of useful information about health care activities and utilization can be derived from hospital records. For example, hospital discharge sheets contain much useful information on diagnosis, medical and surgical procedures, complications, length of stay, laboratory data, etc. A study of hospital data provides information on the following aspects: (a) geographic sources of patients (b) age and sex distribution of different diseases and duration of hospital stay (c) distribution of diagnosis (d) association between different diseases (e) the period between disease and hospital admission (f) the distribution of patients according to different social and biological characteristics, and (g) the cost of hospital care. Such information may be of great value in the planning of health care services *(3, 12)*. Indices such as bed-occupancy rates, duration of stay, cost-effectiveness of treatment policies are useful in monitoring the use of hospital facilities. For the development of hospital statistics, the importance of establishing a medical record department in each hospital cannot be overemphasized. It is now felt that computerization of medical records will enable medical care to be more effectively rendered, better planned, and better evaluated.

6. Disease registers

The term "registration" implies something more than "notification". A register requires that a permanent record be established, that the cases be followed up, and that basic statistical tabulations be prepared both on frequency and on survival. In addition, the patients on a register should frequently be the subjects of special studies *(13)*.

Morbidity registers exist only for certain diseases and conditions such as stroke, myocardial infarction, cancer, blindness, congenital defects and congenital rubella. Tuberculosis and leprosy are also registered in many countries where they are common.

Morbidity registers are a valuable source of information as to the duration of illness, case fatality and survival. These registers allow follow-up of patients and provide a continuous account of the frequency of disease in the community. Even in the absence of a defined population base, useful information may be obtained from registers on the natural course of disease, especially chronic diseases in different parts of the world *(13)*. If the reporting system is effective and the coverage is on a national or representative basis, the register can provide useful data on morbidity from the particular diseases, treatment given and disease-specific mortality.

7. Record linkage

The term **record linkage** is used to describe the process of bringing together records relating to one individual (or to one family), the records originating in different times or places *(14)*. The term **medical record linkage** implies the assembly and maintenance for each individual in a population, of a file of the more important records relating to his health *(14)*. The events commonly recorded are birth, marriage, death, hospital admission and discharge. Other useful data might also be included such as sickness absence from work, prophylactic procedures, use of social services, etc. Record linkage is a particularly suitable method of studying associations between diseases; these associations may have aetiological significance *(13)*.

The main problem with record linkage is the volume of data that can accumulate. Therefore in practice record linkage has been applied only on a limited scale e.g., twin studies, measurement of morbidity, chronic disease epidemiology and family and genetic studies. At the moment, record linkage is beyond the reach of many developing countries.

8. Epidemiological surveillance

In many countries, where particular diseases are endemic, special control/eradication programmes have been instituted, as for example national disease control programmes against malaria, tuberculosis, leprosy, filariasis, etc. As part of these programmes, surveillance systems are often set up (e.g., malaria) to report on the occurrence of new cases and on efforts to control the diseases (e.g., immunizations performed). These programmes have yielded considerable morbidity and mortality data for the specific diseases.

9. Other health service records

A lot of information is also found in the records of hospital out-patient departments, primary health centres and subcentres, polyclinics, private practitioners, mother and child health centres, school health records, diabetic and hypertensive clinics, etc. For example, records in MCH centres provide information about birth weight, weight, height, arm-circumference, immunization, disease specific mortality and morbidity. However, the drawback with this kind of data is that it relates only to a certain segment of the general population. Further the data generated by these records are mostly kept for administrative purposes rather than for monitoring.

10. Environmental health data

Another area in which information is generally lacking is that relating to the environment. Health statistics are now sought to provide data on various aspects of air, water and noise pollution; harmful food additives; industrial toxicants, inadequate waste disposal and other aspects of the combination of population explosion with increased production and consumption of material goods. Environmental data can be helpful in the identification and quantification of factors causative of disease. Collection of environmental data remains a major problem for the future *(3)*.

11. Health manpower statistics

Information on health manpower is by no means least in importance. Such information relates to the number of physicians (by age, sex, speciality and place of work), dentists (classified in the same way), pharmacists, veterenarians, hospital nurses, medical technicians, etc. Their records are maintained by the State medical/dental/nursing councils and the Directorates of Medical Education. The census also provides information about occupation. The Institute of Applied Manpower Research attempts estimates of manpower, taking into account different sources of data, mortality and out-turn of qualified persons from the different institutions. The Planning Commission also gives estimates of active doctors for different States. Regarding medical education, statistics of numbers admitted, numbers qualified, are given every year in "Health Information of India", published by the Government of India, in the Ministry of Health & Family Welfare.

12. Population surveys

A health information system should be population-based. The routine statistics collected from the above sources do not provide all the information about health and disease in the community. This calls for population surveys to supplement the routinely collected statistics. The statistics available for cholera, malaria, plague, respiratory diseases, fevers and diarrhoea are of use for public health administration.

The term "health surveys" is used for surveys relating to any aspect of health – morbidity, mortality, nutritional status, etc. When the main variable to be studied is disease suffered by the people, the survey is referred to as "morbidity survey". Broadly, the following types of surveys would be covered under health survey *(15)* :

a. surveys for evaluating the health status of a population, that is community diagnosis of problems of health and disease. It is information about the distribution of these problems over time and space that provides the fundamental basis for planning and developing needed services *(16)*.

b. surveys for investigation of factors affecting health and disease, e.g., environment, occupation, income, circumstances associated with the onset of illness, etc. These surveys are helpful for studying the natural history of disease, and obtaining more information about disease aetiology and risk factors; and

c. surveys relating to administration of health services, e.g., use of health services, expenditure on health, evaluation of population health needs and unmet needs, evaluation of medical care, etc.

Population surveys can be conducted in almost any setting; sampling techniques have been developed so that estimates at any level of precision desired within the constraints of available resources can be achieved *(17)*. Health surveys may be cross-sectional or longitudinal; descriptive or analytic or both *(18)*. Health surveys on a permanent basis are in operation in only a few countries, viz. in Japan since 1953, USA since 1957 and UK since 1971. The first methodological general health survey was carried out in Singur Health Centre by Lal and Seal in 1944–46.

Survey methods

From the point of view of the method employed for data collection, health surveys can be broadly classified into 4 types :

a. Health interview (face-to-face) survey
b. Health examination survey
c. Health records survey
d. Mailed questionnaire survey

Each method has its advantages and disadvantages. When information about morbidity is needed, **Health examination surveys** generally provide more valid information than health interview surveys. The survey is carried out by teams consisting of doctors, technicians and interviewers. The main disadvantage of a health examination survey is that it is expensive and cannot be carried out on an extensive scale. The method also requires consideration of providing treatment to people found suffering from certain diseases. **The health interview (face-to-face) survey** is an invaluable method of measuring subjective phenomena such as perceived morbidity, disability and impairment; economic loss due to illness, expenditure incurred on medical care; opinions, beliefs and attitudes; and some behavioural characteristics. It has also the advantage of giving population-based data. **The National Sample Survey Organization** in India has been active in conducting interview surveys; these surveys have provided some country-wide data on general morbidity, family planning and vital events, but the morbidity data is not reliable because of the limitation of the interview method. This is why interviews are often combined with health examination surveys and/or laboratory measurements. An alternative method of measuring subjective phenomena is the self-administered **Questionnaire,** i.e., a questionnaire without an interviewer. The use of questionnaires is simpler and cheaper, and they may be sent, for example, by mail to persons sampled from a given target population. A certain level of education, and skill is expected from the respondents when a questionnaire is administered. There is usually a high rate of non-response. **Health records survey** involves collection of data from health service records. This is obviously the cheapest method of collecting data. This method has several disadvantages : (a) the estimates obtained from the records are not population–based (b) reliability of data is open to question, and (c) lack of uniform procedures and standardization in the recording of data.

Unless the aim of survey is to derive information from a special group (e.g., school children or a particular occupational group), the **household** is the most common sampling unit. It is one that allows for the collection of most social, economic and health information in a convenient way. National Family Health Survey and District Level Health Survey are some of the examples.

The size of the sample, necessary for a household survey, depends upon the measurement being taken and the degree of precision needed. Many national samples typically cover between 5,000 to 10,000 households. This is usually considered adequate for providing national estimates on such variables as health care status, anthropometric measurements, food consumption, income, expenditure, housing, literacy, etc. *(7)*.

Surveys carried out by either single or repeat visits provide direct estimates of vital events. A single survey obtains the necessary information retrospectively and is subject to problems of recall and omission. Follow-up surveys on the same households within short intervals (e.g., 6 months) appear to provide more accurate estimates of vital events, but may be too expensive for monitoring purposes *(7)*.

Data must be gathered under standardized conditions with quality control. The collection of data should be limited to those items for which there is a clearly defined use or need; the fact that data might be of interest or use to someone, someday, somewhere is not a valid reason for collecting them *(16)*. The data that is collected should be transformed into information by reducing them, summarizing them and adjusting them for variations in the age and sex composition of the population so that comparisons over time and place are possible.

13. Other routine statistics related to health

The following list, which is not comprehensive, merely serves to give examples of sources of data that have already been put to good use by epidemiologists :

(1) *Demographic :* In addition to routine census data, statistics on such other demographic phenomena as population density, movement and educational level.

(2) *Economic :* consumption of such consumer goods as tobacco, dietary fats and domestic coal; sales of drugs and remedies; information concerning per capita income; employment and unemployment data.

(3) *Social security schemes :* medical insurance schemes make it possible to study the occurrence of illnesses in the insured population. Other useful data comprise sickness absence, sickness and disability benefit rates.

14. Non-quantifiable information

Hitherto, the health information system concentrated mainly on quantifiable (statistical) data. Health planners and decision makers require a lot of non-quantifiable information, for instance, information on health policies, health legislation, public attitudes, programme costs, procedures and technology. In other words, a health information system has multi-disciplinary inputs. There should be proper **storage, processing** and **dissemination** of information.

ELEMENTARY STATISTICAL METHODS

In any field of inquiry or investigation, data is first obtained which is subsequently classified, analysed and tested for accuracy by statistical methods. Data that is obtained directly from an individual is called *primary data*. The census of 1991 is an example of collecting primary data relating to the population. The collection of data about the health and sickness of a population is primary data. Data that is obtained from outside source is called *secondary data*. If we are studying the hospital records and want to use

the census data, the census data becomes secondary data. Primary data gives the precise information wanted which the secondary data may not give.

Presentation of Statistical Data

Statistical data, once collected, must be arranged purposively, in order to bring out the important points clearly and strikingly. Therefore the manner in which statistical data is presented is of utmost importance. There are several methods of presenting data – tables, charts, diagrams, graphs, pictures and special curves. A brief description of these methods is given below :

TABULATION

Tables are devices for presenting data simply from masses of statistical data. Tabulation is the first step before the data is used for analysis or interpretation. A table can be simple or complex, depending upon the number or measurement of a single set or multiple sets of items. Whether simple or complex, there are certain general principles which should be borne in mind in designing tables : (a) The tables should be numbered e.g., Table 1, Table 2, etc. (b) A title must be given to each table. The title must be brief and self-explanatory, (c) The headings of columns or rows should be clear and concise, (d) The data must be presented according to size or importance; chronologically, alphabetically or geographically, (e) If percentages or averages are to be compared, they should be placed as close as possible, (f) No table should be too large, (g) Most people find a vertical arrangement better than a horizontal one because, it is easier to scan the data from top to bottom than from left to right, (h) Foot notes may be given, where necessary, providing explanatory notes or additional information. Some examples of tabulation are given below :

1. Simple tables

(a)

TABLE 1

Population of some states in India*

States	Population 1st March 2011
Andhra Pradesh	8,46,65,533
Bihar	10,38,04,637
Madhya Pradesh	7,25,97,565
Uttar Pradesh	19,95,81,477

*Source : Census of India, 2011

(b)

TABLE 2

Population of India*

Year	Population
1901	238,396,000
1921	251,321,000
1981	685,185,000
1991	843,930,000
2001	1027,015,247
2011	1210,193,422

* Source : Census of India, 2011

2. Frequency distribution table

In a frequency distribution table, the data is first split up into convenient groups (class intervals) and the number of items (frequency) which occur in each group is shown in the adjacent column.

Example : The following figures are the ages of patients admitted to a hospital with poliomyelitis. Construct a frequency distribution table.

8, 24, 18, 5, 6, 12, 4, 3, 3, 2, 3, 23, 9, 18, 16, 1, 2, 3, 5, 11, 13, 15, 9, 11, 11, 7, 10 6, 9, 5, 16, 20, 4, 3, 3, 3, 10, 3, 2, 1, 6, 9, 3, 7, 14, 8, 1, 4, 6, 4, 15, 22, 2, 1, 4, 7, 1, 12,3, 23, 4, 19, 6, 2, 2, 4, 14, 2, 2, 21, 3, 2, 9, 3, 2, 1, 7, 19

The data given above may be conveniently analyzed as shown below :

Age group		Frequency
0–4	𝍸 𝍸 𝍸 𝍸 𝍸 𝍸 𝍸	35
5–9	𝍸 𝍸 𝍸 ///	18
10–14	𝍸 𝍸 /	11
15–19	𝍸 ///	8
20–24	𝍸 /	6

The data, analysed above, is prepared in the form of a frequency table as shown below :

TABLE 3

Age distribution of polio patients

Age	Number of Patients
0–4	35
5–9	18
10–14	11
15–19	8
20–24	6

In the above example, the age is split into groups of five. These are known as *class intervals.* The number of observations in each group is called *frequency.* In constructing frequency distribution tables, the questions that arise are : Into how many groups the data should be split ? And what class intervals should be chosen ? As a practical rule, it might be stated that when there is large data, a maximum of 20 groups, and when there is not much data, a minimum of 5 groups, could be conveniently taken. As far as possible, the class intervals should be equal, so that observations could be compared. The merits of a frequency distribution table are, that it shows at a glance how many individual observations are in a group, and where the main concentration lies. It also shows the range, and the shape of distribution.

CHARTS AND DIAGRAMS

Charts and diagrams are useful methods of presenting simple statistical data. They have a powerful impact on the imagination of people. Therefore, they are a popular media of expressing statistical data, especially in newspapers and magazines. The impact of the picture depends on the way it is drawn. A few general remarks need be mentioned about charts and diagrams. Diagrams are better retained in the memory than statistical tables. The data that is to be presented by diagrams ought to be simple. Then there is no risk that the reader will misunderstand. However, simplicity may be obtained only at the expense of details and accuracy. That is, lot of details of the original data may be lost in the charts and diagrams. If we want the real study, we have to go back to the original data.

1. Bar charts

Bar charts are merely a way of presenting a set of numbers by the length of a bar – the length of the bar is proportional to the magnitude to be represented. Bar charts are a popular media of presenting statistical data because they are easy to prepare, and enable values to be compared visually. The following are some examples of bar charts.

(a) SIMPLE BAR CHART

Bars may be vertical or horizontal (Fig. 1 and Fig. 2). The bars are usually separated by appropriate spaces with an eye to neatness and clear presentation. A suitable scale must be chosen to present the length of the bars.

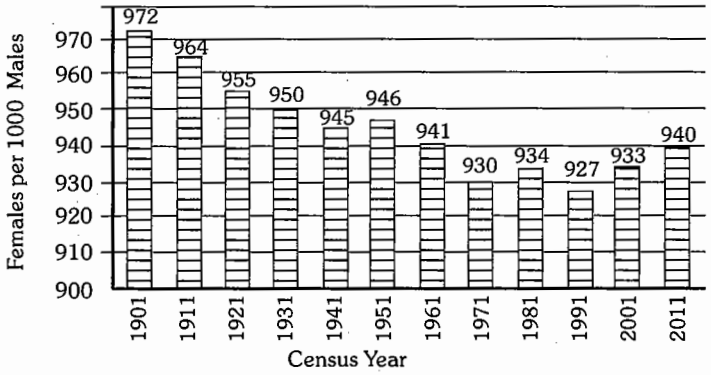

FIG. 1
India; Sex Ratio 1901-2001

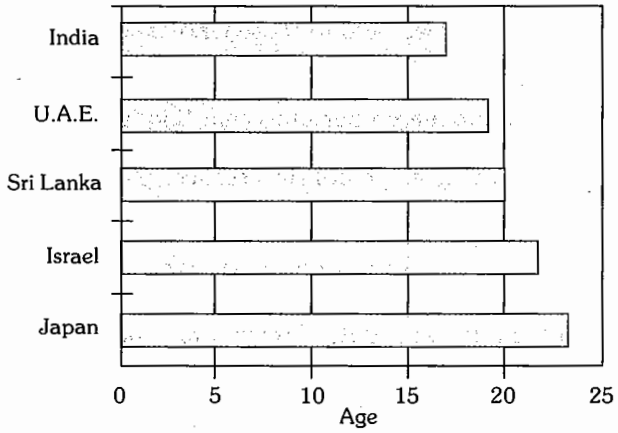

FIG. 2
Mean age at marriage (Females) in some countries

(b) MULTIPLE BAR CHART

Fig. 3 gives an example of a multiple bar chart or a compound bar chart. Two or more bars can be grouped together. In Fig. 3, population and land area by region are compared.

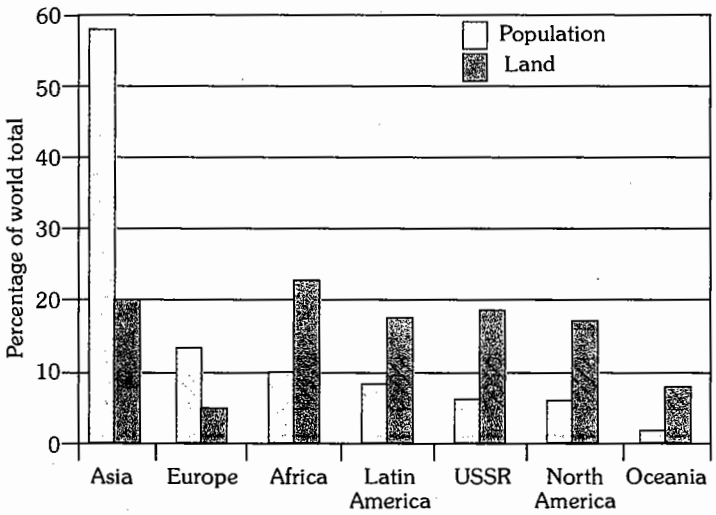

FIG. 3
Population and land area by Region,

(c) COMPONENT BAR CHART

The bars may be divided into two or more parts ... each part representing a certain item and proportional to the magnitude of that particular item (Fig. 4).

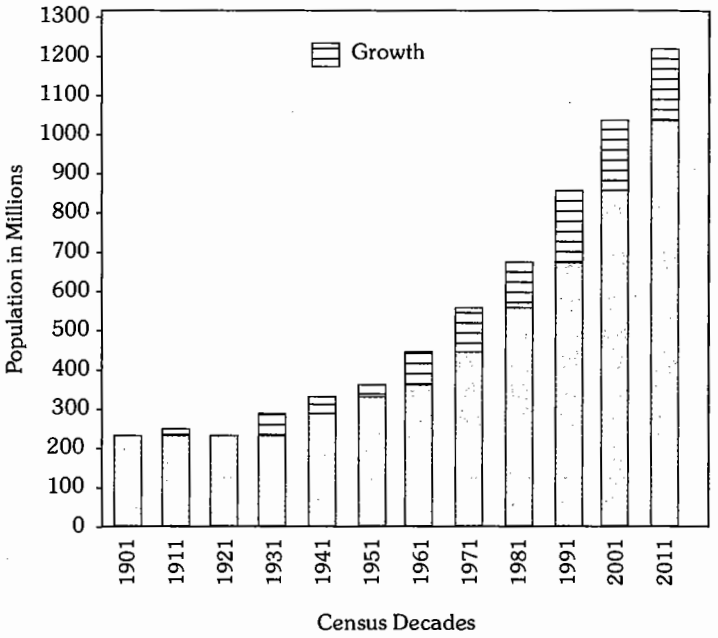

FIG. 4
India : Growth of population 1901 to 2011

2. Histogram

It is a pictorial diagram of frequency distribution. It consists of a series of blocks (Fig. 5). The class intervals are given along the horizontal axis and the frequencies along the vertical axis. The area of each block or rectangle is proportional to the frequency. Fig. 5 is the histogram of the frequency distribution of blood pressure in females 45–64 years.

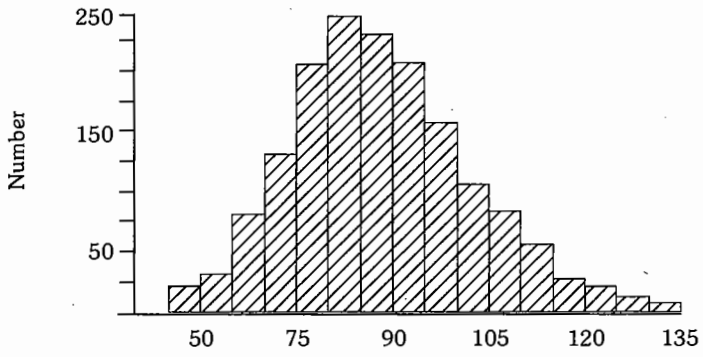

FIG. 5
Frequency distribution of diastolic blood pressure in females aged 45–64 years

FREQUENCY POLYGON

A frequency distribution may also be represented diagrammatically by the frequency polygon. It is obtained by joining the mid-points of the histogram blocks. Fig. 6 is the frequency polygon of the distribution of readings of systolic blood pressure in a community.

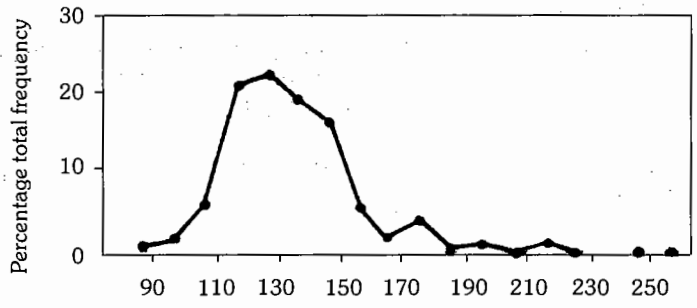

FIG.6
Frequency distribution of readings of systolic blood pressure

LINE DIAGRAM

Line diagrams are used to show the trend of events with the passage of time. The following is an example of a line diagram, (Fig. 7) showing the trend of malaria cases reported throughout the world (excluding the African Region) during 1972–78.

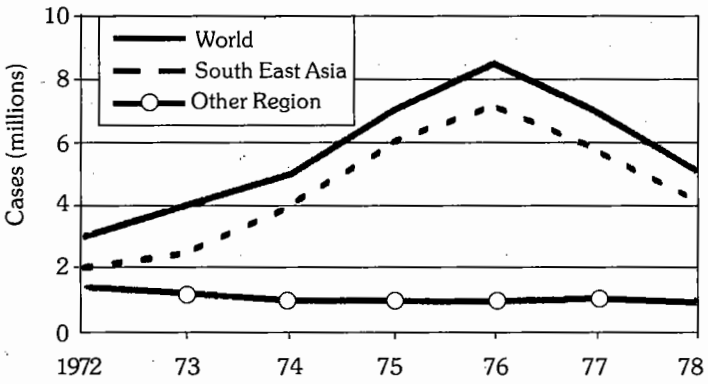

FIG. 7
Malaria cases reported, 1971-1978 (excluding African Region)

3. Pie charts

Instead of comparing the length of a bar, the areas of segments of a circle are compared. The area of each segment depends upon the angle. Pie charts are extremely popular with the laity, but not with statisticians who consider them inferior to bar charts. It is often necessary to indicate the percentages in the segments (Fig. 8) as it may not be sometimes very easy, virtually, to compare the areas of segments.

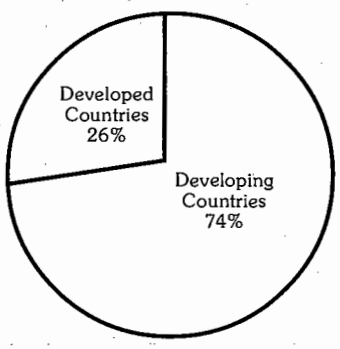

FIG. 8
World population

4. Pictogram

Pictograms are a popular method of presenting data to the "man in the street" and to those who cannot understand orthodox charts. Small pictures or symbols are used to present the data. For example, a picture of doctor to represent the population per physician (Fig. 9). Fractions of the picture can be used to represent numbers smaller than the value of a whole symbol. In essence, pictograms are a form of bar charts.

STATISTICAL MAPS

When statistical data refer to geographic or administrative areas, it is presented either as "Shaded Maps" or "Dot maps" according to suitability. The shaded maps are used to present data of varying size. The areas are shaded with different colours, or different intensities of the same colour, which is indicated in the key.

Scatter diagram shows the relationship between two variables, e.g., Fig. 10 shows a positive correlation between the intakes of fat and sugar in the average diets of 41 countries. Populations with more income are known to consume more protein, fat and also sugar (Source : Yudkin, J. (1964) : *Lancet*, 2, 5)

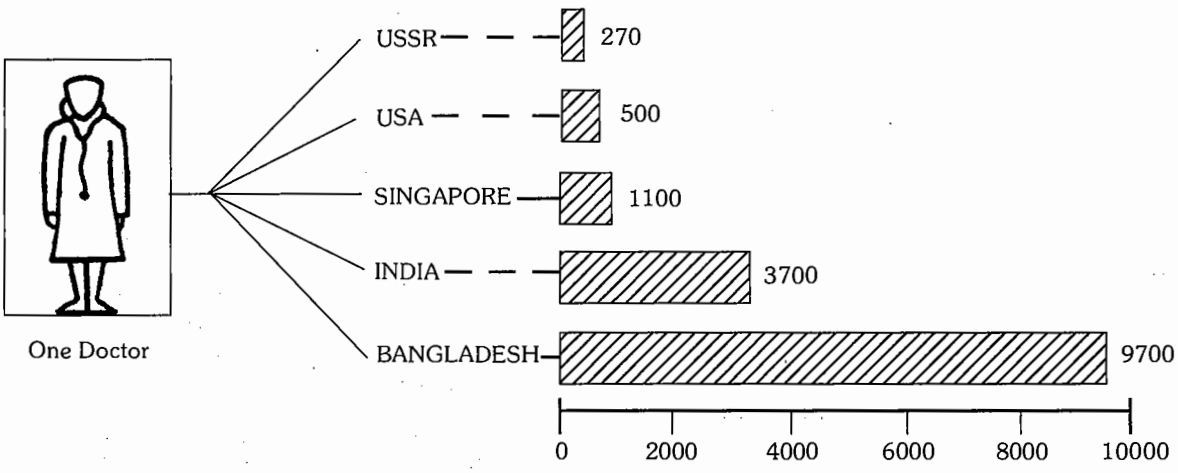

FIG. 9
Population per physician

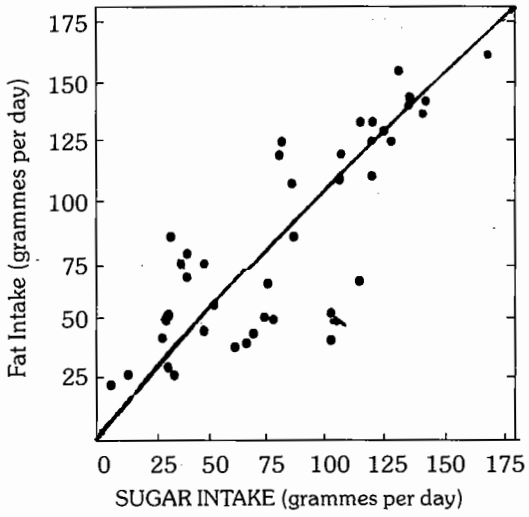

FIG. 10
Relation between average fat intake and sugar intake in 41 countries

If the dots cluster round a straight line, it shows evidence of a relationship of a linear nature. If there is no such cluster, it is probable that there is no relationship between the variables.

STATISTICAL AVERAGES

The word "average" implies a value in the distribution, around which the other values are distributed. It gives a mental picture of the central value. There are several kinds of averages, of which the commonly used are : – (1) The Arithmetic Mean, (2) Median, and (3) The Mode.

The Mean

The arithmetic mean is widely used in statistical calculation. It is sometimes simply called *Mean*. To obtain the mean, the individual observations are first added together, and then divided by the number of observations. The operation of adding together is called 'summation' and is denoted by the sign Σ or S. The individual observation is denoted by the sign η and the mean is denoted by the sign $\bar{x}$ (called "X bar").

The mean ($\bar{x}$) is calculated thus : the diastolic blood pressure of 10 individuals was 83, 75, 81, 79, 71, 95, 75, 77, 84, 90. The total was 810. The *mean* is 810 divided by 10 which is 81.0.

The advantages of the *mean* are that it is easy to calculate and understand. The disadvantages are that sometimes it may be unduly influenced by abnormal values in the distribution. Sometimes it may even look ridiculous; for instance, the average number of children born to a woman in a certain place was found to be 4.76, which never occurs in reality. Nevertheless, the arithmetic mean is by far the most useful of the statistical averages.

The Median

The *median* is an average of a different kind, which does not depend upon the total and number of items. To obtain the median, the data is first arranged in an ascending or descending order of magnitude, and then the value of the middle observation is located, which is called the *median*. For example, the diastolic blood pressure of 9 individuals was as follows : (Fig. 11).

The *median* is 79, which is the value of the middle observation (Fig. 12).

Diastolic Blood Pressure

79	Median
81	
83	
84	
95	

FIG. 12
Data arranged in order of magnitude

If there are 10 values instead of 9, the median is worked out by taking the average of the two middle values. That is, if the number of items or values is even, the practice is to take the average of the two middle values. For example, the diastolic blood pressure of 10 individuals was : Fig. 13.

In the *example* given, the median will be 79+81 divided by 2 which is 80 (Fig. 14).

81	
83	
84	$= 80$
90	
95	

FIG. 14
Data arranged in order of magnitude

The relative merits of median and mean may be examined from the following example : The income of 7 people per day in Rupees was as follows :

5, 5, 5, 7, 10, 20, 102 = (Total 154)

The mean is 154 divided by 7 which is 22; the median is 7 which is the value of the middle observation. In this example, the income of the seventh individual (102) has seriously affected the mean, whereas it has not affected the median. In an example of this kind median is more nearer the truth, and therefore more representative than the mean.

The Mode

The *mode* is the commonly occurring value in a distribution of data. It is the most frequent item or the most "fashionable" value in a series of observations. For example, the diastolic blood pressure of 20 individuals was :

85, 75, 81, 79, 71, 95, 75, 77, 75, 90,
71, 75, 79, 95, 75, 77, 84, 75, 81, 75

The mode or the most frequently occurring value is 75. The advantages of mode are that it is easy to understand, and is not affected by the extreme items. The disadvantages are that the exact location is often uncertain and is often not clearly defined. Therefore, mode is not often used in biological or medical statistics.

MEASURES OF DISPERSION

The daily calorie requirement of a normal adult doing sedentary work is laid down as 2,400 calories. This clearly is not universally true.

There must be individual variations. If we examine the data of blood pressure or heights or weights of a large group of individuals, we will find that the values vary from person to person. Even within the same subject, there may be variation from time. The questions that arise are : What is normal variation ? And how to measure the variation ?

There are several measures of variation (or "dispersion" as it is technically called) of which the following are widely known :

(a) The Range
(b) The Mean or Average Deviation
(c) The Standard Deviation

(a) The Range

The range is by far the simplest measure of dispersion. It is defined as the difference between the highest and lowest figures in a given sample. For example, from the following record of diastolic blood pressure of 10 individuals –

83, 75, 81, 79, 71, 90, 75, 95, 77, 94.

It can be seen that the highest value was 95 and the lowest 71. The range is expressed as 71 to 95 or by the actual difference *(24)*. If we have grouped data, the range is taken as the difference between the *mid-points* of the extreme categories. The range is not of much practical importance, because it indicates only the extreme values between the two values and nothing about the dispersion of values between the two extreme values.

(b) The Mean Deviation

It is the average of the deviations from the arithmetic mean. It is given by the formula :

$$\text{M.D.} = \frac{\Sigma (x - \bar{x})}{\eta}$$

Example : The diastolic blood pressure of 10 individuals was as follows : 83, 75, 81, 79, 71, 95, 75, 77, 84 and 90. Find the mean deviation.

Answer (Mean deviation)

Diastolic B.P. x	Arithmetic Mean $\bar{x}$	Deviation from the Mean $(x - \bar{x})$
83	81	2
75	81	–6
81	81	0
79	81	–2
71	81	–10
95	81	14
75	81	–6
77	81	–4
84	81	3
90	81	9
Total = 810		Total = 56(ignoring ± sign)

$$\text{Mean} = \frac{810}{10} = 81 \qquad \text{The Mean Deviation} = \frac{56}{10} = 5.6$$

(c) The Standard Deviation

The standard deviation is the most frequently used measure of deviation. In simple terms, it is defined as "Root – Means – Square – Deviation." It is denoted by the Greek letter sigma σ or by the initials S.D. The standard deviation is calculated from the basic formula :

$$\text{S.D.} = \sqrt{\frac{\Sigma (x - \bar{x})^2}{\eta}}$$

When the sample size is more than 30, the above basic formula may be used without modification. For smaller samples, the above formula tends to underestimate the standard deviation, and therefore needs correction, which is done by substituting the denominator $(\eta - 1)$ for η. The modified formula is as follows :

$$\text{S.D.} = \sqrt{\frac{\Sigma (x - \bar{x})^2}{\eta - 1}}$$

The steps involved in calculating the standard deviation are as follows :

(a) First of all, take the deviation of each value from the arithmetic mean,
$(x - \bar{x})$
(b) Then, square each deviation -
$(x - \bar{x})^2$
(c) Add up the squared deviations -
$\Sigma (x - \bar{x})^2$
(d) Divide the result by the number of observations η :
[or $(\eta - 1)$ in case the sample size is less than 30]
(e) Then take the square root, which gives the standard deviation.

Example : The diastolic blood pressure of 10 individuals was as follows : 83, 75, 81, 79, 71, 95, 75, 77, 84, 90. Calculate the standard deviation.

Answer

x	$(x - \bar{x})$	$(x - \bar{x})^2$
83	2	4
75	–6	36
81	0	–
79	–2	4
71	–10	100
95	14	196
75	–6	36
77	–4	16
84	3	9
90	9	81
$\bar{x} = 81$ $\eta = 10$		Total = 482

$$\text{S.D.} = \sqrt{\frac{\Sigma (x - \bar{x})^2}{\eta - 1}} = \sqrt{\frac{482}{10 - 1}} = \sqrt{\frac{482}{9}}$$

$$= \sqrt{53.55} = 7.31$$

The meaning of standard deviation can only be appreciated fully when we study it with reference to what is described as *normal curve*. For the present, we may contend

with the basic significance of standard deviation – that it is an abstract number; that it gives us an idea of the 'spread' of the dispersion; that the larger the standard deviation, the greater the dispersion of values about the mean.

NORMAL DISTRIBUTION

The normal distribution or 'normal curve' is an important concept in statistical theory. Let us suppose, we collect the haemoglobin values of a very large number of people and make a frequency distribution with narrow class intervals, we are likely to get a smooth, symmetrical curve. Such a curve is called a normal distribution or normal curve. The shape of the curve will depend upon the mean and standard deviation which in turn will depend upon the number and nature of observations. It follows, therefore, there will be an infinite number of normal curves.

It is useful to note at this stage that in a normal curve (Fig. 15) : (a) the area between one standard deviation on either side of the mean ($\bar{x} \pm 1\sigma$) will include approximately 68 per cent of the values in the distribution, (b) the area between two standard deviations on either side of the mean ($\bar{x} \pm 2\sigma$) will cover most of the values, i.e., approximately 95 per cent of the values, and (c) the area between ($\bar{x} \pm 3\sigma$) will include 99.7 per cent of the values. These limits on either side of the mean are called "confidence limits" and are as shown in Fig. 15.

Supposing we are considering the 95 per cent confidence limits ($\bar{x} \pm 2\sigma$). When we say this, we mean that 95 per cent of the *area* of the normal curve, and hence 95 per cent of the values in the distribution will be included between the limits $\bar{x} \pm 2\sigma$. Therefore, the probability of a reading falling outside the 95 per cent confidence limits is 1 in 20 (P = 0.05).

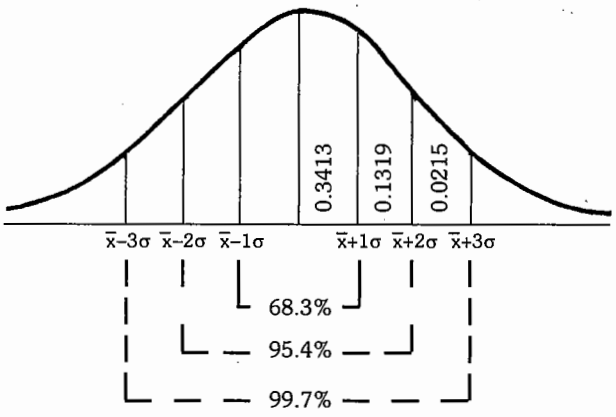

FIG. 15
Normal curve

Standard normal curve

Although there is an infinite number of normal curves depending upon the mean and standard deviation, there is only one **standardized** normal curve, which has been devised by statisticians to estimate easily the area under the normal curve, between any two ordinates. The standard normal curve is a smooth, bell-shaped, perfectly symmetrical curve, based on an infinitely large number of observations. The total area of the curve is 1; its mean is zero; and its standard deviation is 1. The mean, median and mode all coincide. The distance of a value (x) from the mean ($\bar{x}$) of the curve in units of standard deviation is called "relative deviate or standard normal variate" and is usually denoted by Z. The standard normal deviate or Z is given by the formula :

$$Z = \frac{(x - \bar{x})}{\sigma}$$

A random variable (x) is said to have been standardized when it has been adjusted so that its mean is zero and its standard deviation is 1. Standardization can be effected by subtracting the mean of x, from x and dividing the resulting difference by σ, the standard deviation of x. Thus $\frac{(x - \bar{x})}{\sigma}$ is a standardized variable. An important concept of mathematical statistics is that the new variate "Z" like the variate "x" also follows a normal distribution. The mean of the transformed distribution is zero (0), and the standard deviation (σ) is 1.

Areas under the standard normal curve are frequently needed. They have been computed for values of different relative deviate $\frac{(x - \bar{x})}{\sigma}$.

An extract of these values is given in Table 4.

TABLE 4

Areas of the standard normal curve with mean 0 and standard deviation 1

Relative deviate (z) $\frac{(x - \bar{x})}{\sigma}$	Proportion of area from middle of the curve of designated deviation
0.00	.0000
0.50	.1915
1.00	.3413
1.50	.4332
2.00	.4772
3.00	.4987
4.00	.49997
5.00	.4999998

Estimation of probability (Example)

Let us suppose, the pulse of a group of normal healthy males was 72, with a standard deviation of 2. What is the probability that a male chosen at random would be found to have a pulse of 80 or more ?

$$\text{The relative deviate (z)} = \frac{(x - \bar{x})}{\sigma}$$

$$= \frac{80 - 72}{2} = 4$$

The area of the normal curve corresponding to a deviate 4=0.49997 (Table 4). Since we are dealing with only half the total area (i.e., 0.5) the area beyond 0.49997 is equal to 0.5 – 0.49997 or 0.00003. Therefore, the probability is that only 3 out of 100,000 individuals would likely have a pulse rate of 80 or higher.

SAMPLING

When a large proportion of individuals or items or units have to be studied, we take a *sample*. It is easier and more economical to study the sample than the whole population or universe. Great care therefore is taken in obtaining a sample. It is important to ensure that the group of people or items included in the sample are representative of the whole population to be studied.

The Sampling frame

Once the *universe* has been defined, a sampling frame must be prepared. A sampling frame is a listing of the members of the universe from which the sample is to be drawn. The accuracy and completeness of the sampling frame influences the quality of the sample drawn from it.

Sampling Methods

The following three methods are most commonly used :

(1) *Simple random sample :* This is done by assigning a number to each of the units (the individuals or households) in the sampling frame. A table of random numbers is then used (see page 853) to determine which units are to be included in the sample. Random numbers are a haphazard collection of certain numbers, arranged in a cunning manner to eliminate personal selection of unconscious bias in taking out the sample. With this procedure, the sample is drawn in such a way that each unit has an equal chance of being drawn in the sample. This technique provides the greatest number of possible samples.

(2) *Systematic random sample :* This is done by picking every 5th or 10th unit at regular intervals. For example, to carry out a filaria survey in a town, we take 10 per cent sample. The houses are numbered first. Then a number is selected at random between 1 and 10 (say four). Then every 10th number is selected from that point on 4, 14, 24, 34, etc. By this method, each unit in the sampling frame would have the same chance of being selected, but the number of possible samples is greatly reduced.

(3) *Stratified random sample :* The sample is deliberately drawn in a systematic way so that each portion of the sample represents a corresponding strata of the universe. This method is particularly useful where one is interested in analysing the data by a certain characteristic of the population, viz. Hindus, Christians, Muslims, age-groups etc. – as we know these groups are not equally distributed in the population.

It is useful to note at this stage that Greek letters are usually used to refer to population characteristics : mean (μ), standard deviation (σ), and Roman letters to indicate sample characteristics : mean ($\bar{x}$), standard deviation (s).

Sampling Errors

If we take repeated samples from the same population or universe, the results obtained from one sample will differ to some extent from the results of another sample. This type of variation from one sample to another is called *sampling error.* It occurs because data were gathered from a sample rather than from the entire population of concern. Presuming that the sampling procedure is such that all the individuals in the population are favoured equally to come to the sample, the factors that influence the sampling error are : (a) the size of the sample and (b) the natural *variability* of the individual readings. As the size of the sample increases, sampling error will decrease. As the individual readings vary widely from one another, we get more variability from one sample to another.

Non-Sampling Errors

The sampling error is not the only error which arises in a sample survey. Errors may occur due to inadequately calibrated instruments, due to observer variation, as well as due to incomplete coverage achieved in examining the subjects selected and conceptual errors. These are often more important than the sampling errors.

Standard Error

If we take a random sample (η) from the population, and similar samples over and over again we will find that every sample will have a different mean ($\bar{x}$). If we make a frequency distribution of all the sample means drawn from the same population, we will find that the distribution of the mean is nearly a *normal* distribution and the mean of the sample means practically the same as the population mean (μ). This is a very important observation that the sample means are distributed *normally* about the population mean (μ). The standard deviation of the means is a measure of the sample error and is given by the formula $\sigma/\sqrt{\eta}$ which is called the standard error or the *standard error of the mean.* Since the distribution of the means follows the pattern of a normal distribution, it is not difficult to visualize that 95 per cent of the sample means will lie within limits of two standard error [$\mu \pm 2\ (\sigma/\sqrt{\eta})$] on either side of the true or population mean. Therefore standard error (S.E.) is a measure which enables us to judge whether the mean of a given sample is within the set confidence limits or not.

TESTS OF SIGNIFICANCE

We have observed till now that *standard error* indicates how reliable an estimate of the mean is likely to be. The concept of standard error is applied with appropriate formulae to all statistics, i.e., mean, standard deviation, etc. It is proposed to consider briefly the following :-

(a) Standard Error of the Mean

(b) Standard Error of Proportion

(c) Standard Error of Difference

(d) Standard Error of Difference between two Proportions.

(a) Standard Error of the Mean

We have already considered in some detail the meaning of the "standard *error* of the mean" which is also called simply the *standard error,* and the distribution of the sample means about the true mean of the universe. In actual practice, we don't take repeated samples usually from a population. We take only one sample from the universe and calculate the mean and standard deviation. The questions that arise are : How accurate is the mean of our sample ? What can be said about the true mean of the universe ? In order to answer these questions, we calculate the standard error of the mean and set up 'confidence limits' within which the mean (μ), of the population (of which we have only one sample) is likely to lie.

Example : Let us suppose, we obtained a random sample of 25 males, age 20–24 years whose mean temperature was 98.14 deg. F with a standard deviation of 0.6. What can we say of the true mean of the universe from which the sample was drawn ?

We use the *standard error* as the yard stick :

$$\text{S.E.}\,\bar{x} = S/\sqrt{(\eta)} = 0.6/\sqrt{(25)} = 0.12$$

We now set up confidence limits on the basis of the normal curve distribution. If the limits are set out at twice the standard error from the mean (95 per cent confidence limits) the range of the population mean would be $98.14 \pm (2 \times 0.12) = 97.90$ deg. F. to 98.38 deg. F. The chances will be only 1 in 20 ($P = 0.05$) that the population mean would be outside these limits.

Very often we come across in scientific terminology the word 'significant'. When we say that "this difference is

significant", we mean that it is unlikely to be merely due to chance. It has become customary to regard as significant, when P<0.05 (1 in 20) and more significant, when P < 0.01 (1 in 100).

(b) Standard Error of Proportion

Let us suppose, the proportion of males in a certain village was 52 per cent. A random sample of 100 people was taken, and the proportion of males was found to be only 40 per cent. What conclusions could be drawn from the sample ? What possible range of males could we expect in a sample of 100, within 95 per cent confidence limits ?

In an example of this kind, we are not dealing with means but with proportions in a sample and its universe. We may designate these proportions as p and q and proceed to calculate the standard deviation round that expected 52 per cent. This is called the *standard error of proportion* and is given by the formula :

$$\text{Standard Error of Proportion} = \sqrt{\frac{pq}{n}}$$

where p = proportion of males; q = proportion of females and n = size of the sample. Substituting the values, we get :

$$\text{S.E. (Proportion)} = \sqrt{\frac{52 \times 48}{100}} = 5.0$$

We take two standard errors on either side of 52 as our criterion. That is, If the sample is a truly representative one, we might get by chance a value in the range 52+2 (5) = 62 and 52 – 2 (5) = 42. In other words, the proportion of males in our sample could vary from 42 to 62. Since the observed proportion of males was only 40 per cent and well outside the confidence limits, we consider the difference between the observed and expected values "significant" and is not likely to have arisen by chance. The *relative deviate* in this particular case, in units of a standard error of 5, will be :-

$$\text{Relative deviate} = \frac{52 - 40}{5} = 2.4$$

Since the relative deviate exceeded 2, it is obvious in the present example, that the deviation was 'significant'. This significance test is applicable in situations where the population consists of only 2 classes or proportions, e.g., males and females, sick and healthy, successes and failures, etc.

(c) Standard Error of Difference Between two Means

Very often, in biological work the investigator is faced with the problem of comparing results between two groups. One may be the control group and the other experimental group. The question arises, whether the difference between the means of the two groups is significant to indicate that the samples represent two different universes. We proceed to tackle this problem by calculating the *standard error of difference* between the two means.

Let us suppose, we are testing the effect of a drug on mice. 24 mice, comparable in all respects, were randomly divided into 2 groups. Group A was the control group, i.e., no treatment. The other group, the experimental group was given a drug for a certain period of time. At the end of the experiment, the mice were sacrificed and the kidney of each animal was weighed in milligrams. The effects of the treatment on the kidney weights was as follows :

	Number	Mean	Standard Deviation
Control group	12	318	10.2
Experimental group	12	370	24.1

Let us determine whether the difference between the kidney weights of the two groups is significant.

We apply the formula for the *standard error of difference between the two means :*

$$\text{S.E. (d) between the means} = \sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}$$

$$= \sqrt{\frac{(10.2)^2}{12} + \frac{(24.1)^2}{12}}$$

$$= \sqrt{8.67 + 48.4}$$

$$= \sqrt{57.07}$$

$$= 7.5$$

The standard error of difference between the two means is 7.5. The actual difference between the two means is (370 – 318) = 52, which is more than twice the standard error of difference between the two means, and therefore "significant". We conclude that the treatment affected the kidney weights.

(d) Standard Error of Difference Between Proportions

Instead of means, sometimes we may have to test the significance of difference between two proportions or ratios to find out if the difference between the two proportions or ratios have occurred by chance. In this case, we calculate the *standard error of difference between two proportions.*

Confidence limits	Normal deviate (N.D.) $= \frac{x - \mu}{\sigma / \sqrt{n}}$	Significance
μ is outside the 95 per cent confidence limits	N.D. > 2	P < 0.05 Significant at 5 per cent level
μ is just within 95 per cent confidence limits	N.D. = 2	P = 0.05 Just significant at 5 per cent level
μ is within the 95 per cent confidence limits	N.D. < 2	P > 0.05 Not significant at 5 per cent level

Let us suppose, we are making a trial of 2 whooping cough vaccines. The results of the field trial were as follows :

Vaccine	No. Vaccinated	No. of Exposures	No. of cases	Attack Rate
A	2,400	90	22	24.4%
B	2,300	86	14	16.2%

From the above it appears that vaccine B is superior to vaccine A. Is there any significance ?

We calculate the standard error of difference between the two proportions :

$$\text{S.E. of Diff rence between two proportions} = \sqrt{\frac{p_1 q_1}{n_1} + \frac{p_2 q_2}{n_2}}$$

$$= \sqrt{\frac{24.4 \times 75.6}{90} + \frac{16.2 \times 83.8}{86}}$$

$$= \sqrt{20.49 + 15.78} = \sqrt{36.27} = 6.02$$

The standard error of difference is 6 whereas the observed difference (24.4 – 16.2) was 8.2. In other words, the observed difference between the two groups is less than twice the S.E. of difference, i.e., 2 × 6. We infer that there was no strong evidence of any difference between the efficacy of the two vaccines. Therefore, the observed difference might be easily due to chance.

Alternatively, we can use the CHI-SQUARE (χ^2) Test in an example of this kind.

CHI-SQUARE TEST

Chi-square (χ^2) Test offers an alternate method of testing the significance of difference between two proportions. It has the advantage that it can also be used when more than two groups are to be compared.

Let us consider the previous example : we were making a trial of 2 whooping cough vaccines. The results of the field trial were as below:

Vaccine	Attacked	Not Attacked	Total	Attack Rate
A	22	68	90	24.4%
B	14	72	86	16.2%
Total	36	140	176	–

Apparently, vaccine B was superior to vaccine A. The question that arises is whether the vaccine B was really superior to vaccine A, or whether the difference was merely due to chance.

(1) TEST THE 'NULL HYPOTHESIS'

First, we set up a hypothesis, called the *Null Hypothesis* that there was no difference between the effect of the two vaccines, and then proceed to test the hypothesis in quantitative terms. It is done in the following manner :

We first pool the results from the two vaccines. The proportion of people attacked will be 36/176 = 0.204. The proportion of people not attacked will be 140/176 = 0.795. From these proportions, we now calculate the *expected* number of attacks or cases, and those not attacked. The expected number of attacks by vaccine A will be 90 × 0.204 = 18.36; the expected number not attacked will be 90 × 0.795 = 71.55. Similarly, the expected number of attacks by vaccine B will be 86 × 0.204 = 17.544; the expected number not attacked will be 86 × 0.795 = 68.37. We shall now rewrite the previous table, showing the *observed* (O) and *expected* (E) values in each cell :

Vaccine	Attacked	Not Attacked
A	O = 22 E = 18.36 + 3.64	O = 68 E = 71.55 3.55
B	O = 14 E = 17.54 – 3.54	O = 72 E = 68.37 + 3.63

(2) APPLYING THE χ^2 TEST

$$\chi^2 = \frac{\Sigma (O - E)^2}{E}$$

$$\chi^2 = \frac{(3.64)^2}{18.36} + \frac{(3.55)^2}{71.55} + \frac{(3.54)^2}{17.54} + \frac{(3.63)^2}{68.37}$$

$$= 0.72 + 0.17 + 0.71 + 0.19 = 1.79$$

(3) FINDING THE DEGREE OF FREEDOM

The next step in the calculation is to find out what is known as the *degree of freedom* (d.f.). This depends upon the number of columns and rows in the original table, and given by the formula :

d.f. = (c – 1) (r – 1)
c = Number of columns
r = Number of rows

In our table (cited above), there are two rows (attacked and not attacked) and two columns (vaccine A and vaccine B). It is a 2 × 2 contingency table. The degree of freedom will be :

d.f. = (c – 1) (r – 1)
= (2 – 1) (2 – 1) = 1

(4) PROBABILITY TABLES

We next turn to the published probability tables given below. On referring to χ^2 Table, with 1 *degree of freedom,* the value of χ^2 for a probability of 0.05 is 3.84. Since the observed value (1.79) is much lower we conclude that the *null hypothesis* is true and that vaccine B is not superior to vaccine A. The test is valid only if the expected number in each cell is not less than two.

CORRELATION AND REGRESSION

Meaning of Correlation

Often we wish to know whether there is linear relation between two variables, e.g., height and weight, temperature and pulse, age and vital capacity, etc. In order to find out whether there is significant association or not between two variables (we may call them x and y), we calculate what is known as *Co-efficient of Correlation,* which is represented by the symbol "r".

Suppose, we have 2 variables x and y and we have n individuals who have each one reading of x and one reading of y. The correlation coefficient is given by the formula :

$$r = \frac{\Sigma (x - \bar{x})(y - \bar{y})}{\sqrt{\Sigma (x - \bar{x})^2 \; \Sigma (y - \bar{y})^2}}$$

TABLE OF χ^2
Probability (P)

D.F.	.50	.10	.05	.02	.01	.005	.001
1.	0.45	2.71	3.84	5.41	6.64	7.88	10.83

*Taken from Table XXXIII of : Fisher, R.A. & Yates, F. *Statistical tables for biological, agricultural and medical research,* 6th ed., Longman Group Ltd., London, 1974.

The correlation coefficient r tends to lie between – 1.0 and + 1.0. If r is near + 1, it indicates a strong positive association between x and y i.e., when one variable increases the other variable also increases. A value near – 1 indicates a strong negative association i.e. when one variable increases the other decreases. If r = 0, it indicates there is no association between x and y. There are also tests to show whether or not the correlation could be due to chance. However, it needs to be noted that correlation does not necessarily prove *causation.*

Meaning of Regression

If we wish to know in an individual case the value of one variable, knowing the value of the other, we calculate what is known as the *regression coefficient* of one measurement to the other. It is customary to denote the independent variate by x and the dependent variate by y. The formula for obtaining the regression coefficient is as follows :

$$y = \bar{y} + b\,(x - \bar{x})$$

where $\bar{y}$ = mean of $y_1, y_2, y_3 \ldots\ldots y_n$

$\bar{x}$ = mean of $x_1, x_2, x_3 \ldots\ldots x_n$

$$b = \frac{\Sigma\,(x-\bar{x})\,(y-\bar{y})}{\Sigma\,(x-\bar{x})^2}$$

The value of b is called the *regression coefficient* of y upon x. Similarly, we can obtain the regression of x upon y.

$$x = \bar{x} + b^1\,(y-\bar{y})$$

$$b^1 = \frac{\Sigma\,(x-\bar{x})\,(y-\bar{y})}{\Sigma\,(y-\bar{y})^2}$$

Where b^1 is the regression coefficient of x upon y. The function of regression is to provide a means of estimating the value of one variable from the value of another.

19 Communication for Health Education

"The only thing more expensive than education is ignorance"

Communication can be regarded as a two-way process of exchanging or shaping ideas, feelings and information. Broadly it refers "to the countless ways that humans have of keeping in touch with one another" *(1)*.

Communication is more than mere exchange of information. It is a process necessary to pave way for desired changes in human behaviour, and informed individual and community participation to achieve predetermined goals. Communication has, in recent years, developed into an interdisciplinary science drawing richly from social sciences. With the development of newer methods of communication and information explosion, the mental development of the humans has expanded considerably for clearer thinking, better social inter-sectoral coordination.

Communication and education are interwoven. Communication strategies can enhance learning. The ultimate goal of all communication is to bring about a change in the desired direction of the person who receives the communication. This may be at the **cognitive** level in terms of increase in knowledge; it may be **affective** in terms of changing existing patterns of behaviour and attitudes; and it may be **psychomotor** in terms of acquiring new skills. These are referred to as learning objectives *(2)*.

Communication is part of our normal relationship with other people. Our ability to influence others depends on our **communication skills**, e.g., speaking, writing, listening, reading and reasoning. These skills are much needed in health education. The developing countries are now beginning to exploit the current "communication revolution" to put today's health information at the disposal of families, to help people to achieve health by their own actions and efforts. It is said that without communication an individual could never become a human being; without mass communication, he could never become a part of modern society *(3)*.

THE COMMUNICATION PROCESS

Communication which is the basis of human interaction is a complex process. It has the following main components (Fig. 1) :

1. sender (source)
2. receiver (audience)
3. message (content)
4. channel(s) (medium)
5. feedback (effect)

1. Sender

The sender (communicator) is the originator of the message. To be an effective communicator, he must know:

- his objectives, clearly defined
- his audience : it's interests and needs
- his message
- channels of communication
- his professional abilities and limitations

The impact of the message will depend on his own social status (authority), knowledge and prestige in the community.

2. Receiver

All communications must have an audience, this may be a single person or a group of people. Without the audience, communication is nothing more than mere noise. It is this element of audience and their frame of mind (e.g., opinions, attitudes, prejudices) which lends meaning to all the different types of communication.

The audience may be of two types : the controlled and the uncontrolled. A controlled audience is one which is held together by a common interest. It is a homogeneous group. An uncontrolled or "free" audience is one which has

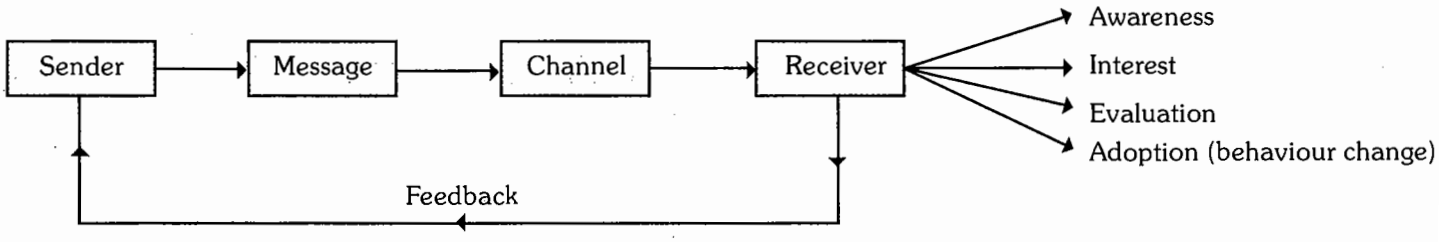

FIG. 1
Communication process

gathered together from motives of curiosity. This type of audience poses a challenge to the ability of the educator. The more homogeneous the audience is, the greater are the chances of an effective communication.

3. Message

A message is the information (or "technical know-how") which the communicator transmits to his audience to receive, understand, accept and act upon. It may be in the form of words, pictures or signs. Health communication may fail in many cases, if its message is not adequate.

A good message must be :

- in line with the objective (s)
- meaningful
- based on felt needs
- clear and understandable
- specific and accurate
- timely and adequate
- fitting the audience
- interesting
- culturally and socially appropriate

Transmitting the right message to the right people at the right time is a crucial factor in successful communication.

4. Channels of communication

By channel is implied the "physical bridges" or the media of communication between the sender and the receiver.

Media systems

The total communication effort is based on three media systems :

a. Interpersonal communication
b. Mass media
c. Traditional or folk media

a. Interpersonal communication

The most common channel of communication is the interpersonal or face-to-face communication. Being personal and direct it is more persuasive and effective than any other form of communication. Interpersonal communication is particularly important in influencing the decisions of the undecided persons. The superiority of interpersonal communication over mass media for creation of motivational effect has been well documented *(4)*.

When the message relayed *via* mass media gets diffused in the community, it is picked up by the interpersonal and informal networks. The message is then subject to debate and discussion by interpersonal communications. On the basis of this scrutiny a consensus is gradually built up in the community whether to accept or reject the message *(5)*.

b. *Mass media*

In mass communication, the channel is one or more of the following "mass media", viz TV, radio, printed media, etc. Mass media have the advantage of reaching a relatively larger population in a shorter time than is possible with other means. Being one-way channels of communication, mass media carry messages only from the centre to the periphery ; feedback mechanisms are poorly organized. Being impersonal media, they are usually not effective in changing established modes of behaviour.

c. *Folk media*

Every community has its own network of traditional or folk media such as folk dances, singing, dramas, *Nautanki* in Uttar Pradesh, *Burrakatha* in Andhra Pradesh and *Harikatha* in Western India besides informal group gatherings, caste or religious meetings. These are important channels of communication close to the cultural values of the rural population. They have been the principal instruments of preserving the cultural heritage. Health messages may be communicated through these traditional media.

Every channel of communication has its advantages and limitations. For instance, knowledge of surgery cannot be effectively transmitted by verbal communication, demonstrations are needed. The proper selection and use of channels results in successful communication. Since effective communication is seldom achieved through the use of one method alone, an attempt should be made to combine a variety of methods to accomplish the educational purpose. Health education uses a variety of methods to help people understand their own situations and choose actions that will improve their health.

5. Feedback

It is the flow of information from the audience to the sender. It is the reaction of the audience to the message. If the message is not clear or otherwise not acceptable the audience may reject it outright. The feedback thus provides an opportunity to the sender to modify his message and render it acceptable. In interpersonal communication the feedback is immediate. In mass communication it takes some time to get feedback. Feedback is generally obtained through opinion polls, attitude surveys and interviews. It can rectify transmission errors.

TYPES OF COMMUNICATION

1. One-way communication (Didactic Method)

The flow of communication is "one-way" from the communicator to the audience. The familiar example is the lecture method in class rooms. The drawbacks of the didactic method are :

- knowledge is imposed
- learning is authoritative
- little audience participation
- no feedback
- does not influence human behaviour

2. Two-way communication (Socratic method)

The Socratic method is a two-way method of communication in which both the communicator and the audience take part. The audience may raise questions, and add their own information, ideas and opinions to the subject. The process of learning is active and "democratic". It is more likely to influence behaviour than one-way communication.

3. Verbal communication

The traditional way of communication has been by word of mouth. The advent of written and printed matter are of comparatively recent origin. Direct verbal communication by word of mouth may be loaded with hidden meanings. It is persuasive. Non-direct or written communication may not be as persuasive as the spoken word.

4. Non-verbal communication

Communication can occur even without words. It includes a whole range of bodily movements, postures, gestures, facial expressions (e.g., smile, raised eye brows, frown, staring, gazing etc.). Silence is non-verbal communication. It can speak louder than words.

5. Formal and informal communication

Communication has been classified into formal (follows lines of authority) and informal (grape-vine) communication. Informal network (e.g., gossip circles) exists in all organizations. The informal channels may be more active, if the formal channels do not cater to the information needs.

6. Visual communication

The visual forms of communication comprise : charts and graphs, pictograms, tables, maps, posters etc.

7. Telecommunication and internet

Telecommunication is the process of communicating over distance using electromagnetic instruments designed for the purpose. Radio, TV and internet etc. are mass communication media, while telephone, and telegraph are known as point-to-point telecommunication systems. The point-to-point systems are closer to interpersonal communication. With the launching of satellites, a big explosion of electronic communication has taken place all over the world.

BARRIERS OF COMMUNICATION

Health education may often fail due to communication barriers between the educator and the community – these may be:

1. Physiological – difficulties in hearing, expression
2. Psychological – emotional disturbances, neurosis, levels of intelligence, language or comprehension difficulties.
3. Environmental – noise, invisibility, congestion
4. Cultural – illiteracy, levels of knowledge and understanding, customs, beliefs, religion, attitudes, economic and social class differences, language variations, cultural difficulties between foreigners and nationals, between urban education and the rural population.

Even when health services are readily available, the social and cultural barriers can present serious problems to the achievement of health behaviour change. These barriers should be identified and removed.

HEALTH COMMUNICATION

Health is the concern of everyone for everyone. Health communication is therefore an important area of communication. The term "health communication" is often used synonymously with health education, which itself suggests "outward and downward" communication of knowledge *(6)*. Health education is the foundation of a preventive health care system.

Functions of health communication

Health communication has to cater to the following needs:

1. Information
2. Education
3. Motivation
4. Persuasion
5. Counselling
6. Raising morals
7. Health development
8. Organization

1. Information

The primary function of health communication is to provide scientific knowledge or information to people about health problems and how to maintain and promote health. People rarely seek such information although they have a right to know the facts about health and disease.

Information should be easily accessible to the people. Exposure to the right kind of health information can

- eliminate social and psychological barriers of ignorance, prejudice and misconceptions people may have about health matters;
- increase awareness of the people to the point that they are able to perceive their health needs ; and
- influence people to the extent that unfelt needs become felt needs, and felt needs become demands.

The government, the media and health providers have an important social responsibility to provide factual and balanced health and health related information to the people and awaken their interest on the basis of which they can make informed decisions. But, the assumption that the acquisition of information will mean a change in an individual's behaviour and attitudes is fallacious. Most people make important decisions regarding their health only after much thought, perhaps over a period of time and after serval educational contacts. The cultural values, beliefs and norms of the people influence their acceptance of health information. Correct information is a basic part of health education.

2. Education

Education of the general public is an integral part of a prevention oriented approach to health and disease problems; and, the basis of all education is communication. Education can help to increase knowledge. It is often assumed that knowledge determines attitudes and attitudes determine behaviour *(7)*.

Health education can bring about changes in life styles and risk factors of disease. Most of the world's major health problems and premature deaths are preventable through changes in human behaviour at low cost *(8)*. But education *alone* is insufficient to achieve optimum health. The target population must have access to proven preventive measures or procedures.

3. Motivation

It is the power that drives a person from within to act. One of the goals of health communication is to motivate individuals to translate health information into personal behaviour and lifestyle for their own health. Motivation includes the stages of interest, evaluation and decision making. Health communication assists the individual in passing from the state of awareness and interest to the final stage of decision making and adoption of the new idea or programme. Motivation may not be long-lasting; it may

diminish with lapse of time. The best channels of success involve programmes directed at individuals who already have some strong motivation, in patients with chronic illness or a disability, those facing acute crisis such as surgery or childbirth. This suggests that probably the quickest pay off will come in the area of patient education.

4. Persuasion

Persuasion is the art of winning friends and influencing people. It is an art that does not employ force or deliberate manipulation. The sole purpose of communication is to influence. Persuasion is "a conscious attempt by one individual to change or influence the general beliefs, understanding, values and behaviour of another individual or group of individuals in some desired way". Persuasive communication is more effective than coercion or authoritative communication. Persuasion can change life style and modify the risk factors of disease.

When persuasive communication is deliberately employed to manipulate feelings, attitudes and beliefs, it becomes "propaganda" or "brain washing" *(1)*.

5. Counselling

Counselling is a process that can help people understand better and deal with their problems and communicate better with those with whom they are emotionally involved. It can improve and reinforce motivation to change behaviour. It can provide support at times of crisis. It helps them face up to their problems and to reduce or solve them.

Counselling is different from advising. It implies choice, not force. Advising amounts to directing people and cautioning them to some do's and dont's.

In different circumstances different people can undertake counselling. A counsellor should be able:

- to communicate information
- to gain the trust of the people
- to listen sympathetically to people who are anxious, distressed and possibly hostile.
- to understand other person's feelings and to respond to them in such a way that the other person can feel free to express his feelings
- to help people reduce or resolve their problems.

Thus counselling relies heavily on communication and relationship skills. Counselling is an important part of treatment, disease prevention and health promotion. It helps people to avoid illness and to improve their lives through their own efforts *(9)*. Counselling develops positive attitudes. It is an integral part of all health care programmes.

6. Raising morale

Morale is "the capacity of a group of people (or team) to pull together persistently or consistently. Communication – vertical and horizontal, internal and external is the first step in any attempt to raise morale of the health team or a group of people.

7. Health development

Communication can play a powerful role in health development by helping to diffuse knowledge in respect of the goals of development and preparing the people for the roles expected of them. But its own role is essentially, supportive *(5)*. Judicial use of communication media can contribute to health development *(10)*.

8. Health organization

Communication is the life and blood of an organization. There are two major directions in which communications within an organization flow. These are vertical and horizontal communications. Vertical communication can be downward or upward. Horizontal or cross communication takes place usually between equals at any level. The downward communication extends from top administrator down through the hierarchy of professionals and non-professionals to the beneficiaries or employees. The direction in which communication flows in an organization suggests the degree of freedom in the internal communication network *(1)*.

Communication is an important dimension of health organization. It is an important means of intra – and inter–sectoral coordination.

HEALTH EDUCATION

Health education is a term commonly used and referred to by health professionals.

Definitions

Health education is indispensable in achieving individual and community health. It can help to increase knowledge and to reinforce desired behaviour patterns. But there is no single acceptable definition of health education. A variety of definitions exist. Concepts of health education as a process or an activity for inducing behavioural changes are emphasized in the following definitions :

1. Health education is the translation of what is known about health, into desirable individual and community behaviour patterns by means of an educational process *(11)*.
2. The definition adopted by John M Last is "The process by which individuals and groups of people learn to behave in a manner conducive to the promotion, maintenance or restoration of health" *(12)*.
3. Any combination of learning opportunities and teaching activities designed to facilitate voluntary adaptations of behaviour that are conducive to health *(13)*.
4. The definition adopted by the National Conference on Preventive Medicine in USA is "Health education is a process that informs, motivates and helps people to adopt and maintain healthy practices and lifestyles, advocates environmental changes as needed to facilitate this goal and conducts professional training and research to the same end" *(14)*.
5. Health education is the part of health care that is concerned with promoting healthy behaviour *(9)*.

Alma-Ata Declaration

The Declaration of Alma-Ata (1978) by emphasizing the need for "individual and community participation" gave a new meaning and direction to the practice of health education. The dynamic definition of health education is now as follows :

> "a process aimed at encouraging people to want to be healthy, to know how to stay healthy, to do what they can individually and collectively to maintain health, and to seek help when needed" *(6)*.

The Alma-Ata Declaration has revolutionized the *concepts* and *aims* of health education :

The modern concept of health education emphasizes on health behaviour and related actions of people.

Health education and behaviour

The behaviours to be adopted or modified may be that of individuals, groups (such as families, health professionals, organizations or institutions) or entire community.

Strategies designed to influence the behaviour of individuals or groups will vary greatly depending upon the specific disease (or health problem) concerned and its distribution in the population as well as upon the characteristics and acceptability of available methods preventing or controlling that disease (or health problem).

Health education can help to increase knowledge and to reinforce desired behaviour patterns.

It is clear that education is necessary, but education *alone* is insufficient to achieve optimum health. The target population must have access to proven preventive measures or procedures.

Changing concepts

Historically health education has been committed to disseminating information and changing human behaviour. Following the Alma-Ata Declaration adopted in 1978, the emphasis has shifted from *(6)* :

- Prevention of disease to promotion of healthy lifestyles;
- the modification of individual behaviour to modification of "social environment" in which the individual lives ;
- community participation to community involvement; and
- promotion of individual and community "self-reliance".

Aims and objectives

The definition adopted by WHO in 1969 *(15)* and the Alma-Ata Declaration adopted in 1978 provide a useful basis for formulating the aims and objectives of health education, which may be stated as below :

1. to encourage people to adopt and sustain health promoting lifestyle and practices;
2. to promote the proper use of health services available to them;
3. to arouse interest, provide new knowledge, improve skills and change attitudes in making rational decisions to solve their own problems; and
4. to stimulate individual and community self-reliance and participation to achieve health development through individual and community involvement at every step from identifying problems to solving them.

The educational objectives are aimed at the group to be taught in the educational programme. The objectives flow from the health needs which have been discovered. They should be carefully unambiguously defined in terms of knowledge to be acquired, behaviour to be acquired or actions to be mastered. They must be pertinent if the programme is to be appropriate and successful.

The focus of health education is on people and on action *(15)*. Its goal is to make realistic improvements in the basic quality of life. Many health education programmes hope, in some way, to influence behaviour or attitudes. The implication of these new concepts is that health education is an integral part of the national health goals. The fact remains that effective health education has the potential for saving many more lives than has any one research discovery in the foreseeable future.

Role of health care providers

It is clear that education is necessary, but education alone is not sufficient to achieve optimum health. The role of health care providers in this regard comprise to *(6)*:

a. provide opportunities for people to learn how to identify and analyze health and health related problems, and how to set their own targets and priorities ;

b. make health and health related information easily accessible to the community;

c. indicate to the people alternative solutions for solving the health and health-related problems they have identified; and

d. people must have access to proven preventive measures.

APPROACH TO HEALTH EDUCATION

There are 4 well-known approaches to health education :

1. Regulatory approach (Managed prevention)

Regulation in the context of health education may be defined as any governmental intervention, direct or indirect, designed to alter human behaviour. Regulations may be promulgated by the State by a variety of administrative agencies. Regulations may take many forms ranging from prohibition to imprisonment.

The coercive or regulatory approach seeks change in health behaviour and improvement in health through a variety of external control or laws placed on people, as for example, The Child Marriage Restraint Act in India and the use of compulsory seat belts in the western countries. The legislative approach may seem to be simplest and quickest way to improve health or bring about desired changes in society, but there are also important failures of laws, e.g., prohibition of alcohol.

The reasons for the failure of the coercive approach are not far to seek; in the first place, the cause of disease (medical or social) cannot be eradicated by legislation, at the most the government can make laws to prevent a person spreading disease in his community, as for example vaccination in an emergency. Secondly in areas involving personal choice (e.g., diet, exercise, smoking) no government can pass legislation to force people to eat a balanced diet or not to smoke. It amounts to taking away some of the rights of the individual. The disastrous sterilization campaign of 1976 in India which led to the Congress defeat in the 1977 elections is a case in point. The lesson learnt is that it is difficult to enforce a law unless the majority of people are in favour of it and if it does not interfere with the rights of the individual.

However, laws may be useful in times of emergency or in limited situations such as control of an epidemic disease or management of fairs and festivals. Even in cases where it is the duty of the government to make laws to prevent the spread of disease (e.g., AIDS) it is difficult to enforce laws without a vast administrative infrastructure and considerable expenditure. To a degree, the people must be ready to accept a law. In short, the coercive approach runs counter to the basic tenet of health education, that is, in health education, we do not force people to change. In specific situations, legislation can be used to reinforce the pressure to change collective behaviour.

2. Service approach

This approach was tried by the Basic Health Services in 1960's. It aimed at providing all the health services needed by the people at their door steps on the assumption that people would use them to improve their own health. This approach proved a failure because it was not based on the felt-needs of the people. For example, when water-seal latrines were provided by the government, free of cost, many people in the rural areas did not make use of them because it was not their habit to use latrines. The lesson is simple – the people will not accept a programme or service, even if it is offered free of cost, unless it is based on their felt-needs.

3. Health education approach

There are many problems (e.g., cessation of smoking, use of safe water supply, fertility control) which can be solved only through health education. It is a general belief in western democracies that people will be better off if they have autonomy over their own lives, including health affairs on which an informed person should be able to make decisions to protect his own health. These are the higher goals of health education. However, if the necessary behaviour changes are to take place, people must be educated through planned learning experiences what to do, and be informed, educated and encouraged to make their own choice for a healthy life. This approach is consistent with democratic philosophy which does not "order" the individual. The results are slow, but enduring. The mass media and social organizations must be mobilized to help introduce new attitudes and new habits without conflicting with the masses and the collective reaction to particular change.

Since attitudes and behavioural patterns are formed early in life. We must move back in time and start health education with young population. The assumption is that behaviour is more easily controlled or developed in young population than adults *(16)*.

4. Primary health care approach

This is a radically new approach starting from the people with their full participation and active involvement in the planning and delivery of health services based on principals of primary health care, viz. community involvement and intersectoral coordination. The underlying objective is to help individuals to become self-reliant in matters of health. This, in turn, can be done if the people receive the necessary guidance from health care providers in identifying their health problems and finding workable solutions. This approach is a fundamental shift from the earlier approaches.

Health education versus propaganda

Health education is not health propaganda; it is more than mere information or propaganda. To *educate* means to cause or facilitate learning; propaganda means to spread particular systemized doctrine. The differences between health education and propaganda drawn up by the Central Health Education Bureau, Government of India are given in Table 1.

MODELS OF HEALTH EDUCATION

During the past few decades, a number of health education models have been developed *(6)*. They include the following :

1. Medical model

Most health education in the past has relied on knowledge transfer to achieve behaviour changes. The medical model is primarily interested in the recognition and treatment of disease (curing) and technological advances to facilitate the process. It is concerned with disease (as defined by the doctor) or opposed to illness (as defined by the client).

Originally health education developed along the lines of the bio-medical views of health and disease. The emphasis was on dissemination of health information based on scientific facts. The assumption was that people would act on the information supplied by health professionals to improve their health. In this model social, cultural and psychological factors were thought to be of little or no importance. The medical model did not bridge the gap between knowledge and behaviour.

2. Motivation model

When people did not act upon the information they received, health education started emphasizing "motivation" as the main force to translate health information into the desired health action. But the adoption of a new behaviour or idea is not a simple act, it is a process consisting of several stages through which an individual is likely to pass

TABLE 1

Health education and propaganda

	Education	*Propaganda or publicity*
1.	Knowledge and skills actively acquired	Knowledge instilled in the minds of people
2.	Makes people think for themselves	Prevents or discourages thinking by ready-made slogans
3.	Disciplines primitive desires	Arouses and stimulates primitive desires
4.	Develops reflective behaviour. Trains people to use judgement before acting	Develops reflexive behaviour; aims at impulsive actions
5.	Appeals to reason	Appeals to emotion
6.	Develops individuality, personality and self-expression	Develops a standard pattern of attitudes and behaviours according to the mould used
7.	Knowledge acquired through self-reliant activity	Knowledge is spoon-fed and passively received
8.	The process is behaviour centred – aims at developing favourable attitudes, habits and skills	The process is information centred – no change of attitude or behaviour designed.

before adoption. In this regard, sociologists have described 3 stages in the process of change in behaviour (Fig. 2).

1. Awareness	Interest
2. Motivation	Evaluation Decision-making
3. Action	Adoption or acceptance

FIG. 2
Adoption model

The individual first goes through AWARENESS or getting general information about the subject. In health education, we must first create awareness of health needs and problems through a programme of public information. Mere awareness is not of much value unless it leads to motivation. Motivation includes the stages of interest, evaluation and decision-making. The individual evinces interest in the subject; he may seek more detailed information about the usefulness, limitations or applicability of the new idea or practice. He then evaluates the various aspects (social, psychological, economic) of the information received, if necessary by consulting others. Such an evaluation is a mental exercise and results in decision-making. He finally decides whether to accept or reject the new idea, programme or proposal. At this stage, interpersonal communication (friends, kinship groups, technical persons) is vital to lend support to his decision. Conviction leads to action, adoption or acceptance of the new idea. The new idea or acquired behaviour becomes part of his own existing values. This is called **internalization**. Effective communication strategy should be evolved to help the individual in passing from one stage to another.

The above stages are not necessarily rigid; there may be skipping of stages. It is also found that in the same community, people may be in different stages of the adoption process. Adoptions are slow at first and increase as more and more people accept the practice.

3. Social intervention model

Soon, however, it was realized that the public health problems facing us today are so complex that the traditional motivation approach is insufficient to achieve behavioural change, as for example, reducing smoking, adoption of small family norm, raising the age of marriage, elimination of dowry, etc.

The motivation model ignored the fact that in a number of situations, it is not the individual who needs to be changed but the **social environment** which shapes the behaviour of individual and the community. It is often found that people will not readily accept and try something new or novel until it has been "legitimated" (or approved) by the group to which they belong. Most of us prefer to do only the things commonly done by our group. This highlights the importance of group support in helping reaching the decisions and taking action. Adoption of a new idea such as vasectomy or loop insertion is facilitated if there is a group support. This gave birth to the development of social intervention model of health education. An effective health education model is based on precise knowledge of human ecology and understanding of the interaction between the cultural, biological, physical and social environmental factors.

In sum, a coherent strategy needs to be developed involving *all the ways* to change behaviour and to recognize that the approach will differ for different behaviour one wants to change. The need is for a programme of pacts. Reliance on only one method is likely to lead to failures. A combination of approaches using all methods to change life-style and appropriate use of medical care will be necessary.

CONTENTS OF HEALTH EDUCATION

The scope of health education extends beyond the conventional health sector. It covers every aspect of family and community health. While no definite training curricula can be proposed, the content of health education may be divided into the following divisions for the sake of simplicity. Since health education has a limited impact when directed from general education, most of the needed information must be integrated into the educational system (by way of books, class-room material, etc.) and must have the young population as the principal target.

1. *Human biology*

Understanding health, demands an understanding of the human biology, i.e., the structure and functions of the body; how to keep physically fit – the need for exercise, rest and sleep; the effects of alcohol, smoking and drugs on the body; cultivation of healthy lifestyles, etc. Reproductive biology is another area of current interest. UNICEF's "State of the World's Children report 1989" has drawn up a basic list of health information which it believes, every family has a right to know. The list comprises of child spacing, breast-feeding, safe motherhood, immunization, weaning and child growth, diarrhoeal disease, respiratory infections, house hygiene – which could enable families to bring about significant improvements in their own and their children's health *(8)*.

The best place to teach human biology is the school. It is only the school, through its sequential health curriculum, which can provide continuous in-depth learning experiences for millions of students. The provision of information and advice on human biology and hygiene is vital for each new generation.

2. *Nutrition*

The aim of nutrition education is to guide people to choose optimum and balanced diets, remove prejudices and promote good dietary habits – not to teach the familiar jargon of calories and the biochemistry of nutrients. Nutritional problems such as ignorance about the value of breast feeding beyond the first year of life, misconceptions about proper weaning, ignorance of the appropriateness of certain diets for infants and pregnant women, traditional food allocation pattern within the families, etc. can be best solved by nutrition education. In recent years, the link between dietary habits and certain chronic diseases of middle age such as obesity, diabetes and cardio-vascular diseases has been established. Nutrition education is a major intervention for the prevention of malnutrition, promotion of health and improving the quality of life.

3. *Hygiene*

This has two aspects – personal and environmental. The aim of personal hygiene is to promote standards of personal cleanliness within the setting of the condition where people live. *Personal hygiene* includes bathing, clothing, washing hands after toilet; care of nails, feet and teeth; spitting, coughing, sneezing, personal appearance and inculcation of clean habits in the young. Training in personal hygiene should begin at a very early age and must be carried through school age. ENVIRONMENTAL HYGIENE has two aspects – domestic and community. Domestic hygiene

comprises that of the home, use of soap, need for fresh air, light and ventilation; hygienic storage of foods; hygienic disposal of wastes, need to avoid pests, rats, mice and insects. Improvement of environmental health is a major concern of many governments and related agencies throughout the world. In the developing countries, the emphasis is on the improvement of basic sanitary services consisting of water supply, disposal of human excreta, other solid and liquid wastes, vector control, food sanitation and housing which are fundamental to health. In many areas, poor sanitary practices among the people have their roots in centuries – old customs, styles of living and habits. These are not easily altered *(17)*.

An environmental sanitation programme should include health education. It is not enough to provide sanitary wells, latrines and waste collecting facilities. People will continue to suffer from the diseases caused by poor sanitation if they do not use the facilities. If a health education approach is taken the people will participate from the beginning in identifying their sanitation problems and will choose the solutions and facilities they want. They will then be more likely to use these facilities and improve their health.

4. *Family health*

The family is the first defence, as well as the chief reliance for the well-being of its members. Health largely depends on the family's social and physical environment and its lifestyle and behaviour. The role of the family in health promotion and in prevention of disease, early diagnosis and care of the sick is of crucial importance. One of the main tasks of health education is to promote the family's self-reliance, especially regarding the family's responsibilities in childbearing, child rearing, self-care and in influencing their children adopt a healthy lifestyle.

5. *Disease prevention and control*

Drugs alone will not solve health problems without health education, a person may fall sick again and again from the same disease. The experiences of western countries have shown the role of education in the eradication of cholera, typhoid, malaria and tuberculosis etc. Education of the people about the prevention and control of locally endemic diseases is the first of eight essential activities in primary health care. Several public health programmes are in operation on a national scale to eradicate diseases such as malaria, tuberculosis, leprosy, filaria, goitre, etc. The recent experience of malaria eradication has indicated that anti-malarial spray with insecticides cannot solve the problem without health education.

6. *Mental health*

Mental health problems occur everywhere. They become more prominent when major killer diseases are brought under control. There is a tendency to an increase in the prevalence of mental diseases when there is a change in the society from an agricultural to an industrial economy, and when people move from the warm intimacy of a village community to the isolation found in big cities. The aim of education in mental health is to help people to keep mentally healthy and to prevent a mental breakdown. People should enjoy their relationships with others and learn to live and work without mental breakdown. There are certain special situations when mental health is of great importance – mother after child birth; child at entry into school for the first time, school child entering the secondary school, decision about a future career, starting a new family and at the time of widowhood. These are critical periods of life when external pressure tends to breakdown mental health. Health workers should help people achieve mental health by showing sympathy, understanding and by social contact.

7. *Prevention of accidents*

Accidents are a feature of the complexity of modern life. In the developed countries, they are taking an increasing toll of life and limb. Accidents occur in three main areas : the home, road and the place of work. Safety education should be directed to these areas. It should be the concern of the engineering department and also the responsibility of the police department to enforce rules of road safety. Accidents occur in workshops, factories, railways and mines. Management must provide a safe environment and promote general order and cleanliness. There should be a place for everything, and everything should be in its place in the factory, in the home, and in the office. The predominant factor in accidents is carelessness and the problem can be tackled through health education.

8. *Use of health services*

Many people particularly in rural areas do not know what health services are available in their community, and many more do not know what signs to look for that indicate a visit to the doctor is necessary. Studies indicate that the public attitude towards health services is still apprehensive. There is a communication gap between the public and the state health administration in the form of "feedback" for further improvement of health services.

One of the declared aims of health education is to inform the people about the health services that are available in the community and how they can utilize them (e.g., screening programmes, immunization, family planning services etc.) and use the health care resources.

PRINCIPLES OF HEALTH EDUCATION

Before we come to the practice of health education, we must know the principles involved. Health education brings together the art and science of medicine, and the principles and practice of general education. The link is to be found in the social and behavioural sciences – sociology, psychology and social anthropology.

Health education cannot be "given" to one person by another. It involves, among other things, the teaching, learning and inculcation of habits concerned with the objective of healthful living. Psychologists have given a great deal of attention to the learning process. Every individual learns and through learning develops the modes of behaviour by which he lives. Learning and teaching is a two-way process of transactions in human relations, between the teacher and taught. The teacher cannot teach unless the pupil wants to learn. Learning takes place not only in the class room, but also outside in the wider world. There is internal learning by which a man grows into an adult individual. It is possible to abstract certain principles of learning and use them in health education. These include :

(1) *Credibility* : It is the degree to which the message to be communicated is perceived as trustworthy by the receiver. Good health education is based on facts – that means it must be consistent and compatible with scientific knowledge and also with the local culture, educational system and social goals. Unless the people have trust and confidence in the communicator, no desired action will ensue after receiving the message.

(2) *Interest :* It is a psychological principle that people are unlikely to listen to those things which are not to their interest. It is salutary to remind ourselves that health teaching should relate to the interests of the people. The public is not interested in health slogans such as "Take care of your health" or "be healthy". A health education programme of this kind would be as useless as asking people to "be healthy", as a nutrition programme asking people to "eat good food". Health educators must find out the real health needs of the people. Psychologists call them "felt-needs", that is needs the people feel about themselves. If a health programme is based on "felt needs" people will gladly participate in the programme; and only then it will be a people's programme. Very often, there are groups who may have health needs of which they are not aware. This is especially true in India where about 25 per cent of the people are illiterate. The health educator will have to bring about a recognition of the needs before he proceeds to tackle them.

(3) *Participation :* Participation is a key word in health education. It is based on the psychological principle of active learning. Health education should aim at encouraging people to work actively with health workers and others in identifying their own health problems and also in developing solutions and plans to work them out. Participation of family members in patient care will create opportunity for more effective, practically based health education. A high degree of participation tends to create a sense of involvement, personal acceptance and decision-making. It provides maximum feedback. The Alma-Ata Declaration states : "The people have a right and duty to participate individually and collectively in the planning and implementation of their health care" *(18)*. If community participation is not an integral part, health programmes are unlikely to succeed *(19)*.

(4) *Motivation :* In every person, there is a fundamental desire to learn. Awakening this desire is called motivation. There are two types of motives – primary and secondary. Primary motives (e.g. sex, hunger, survival) are driving forces initiating people into action; these motives are inborn desires. Secondary motives are based on desires created by outside forces or incentives. Some of the secondary motives are praise, love, rivalry, rewards and punishment, and recognition. In health education, motivation is an important factor; that is, the need for incentives is a first step in learning to change. The incentives may be positive (the carrot) or negative (the stick). To tell a lady, faced with the problem of overweight, to reduce her weight because she might develop cardiovascular disease or it might reduce her life span, may have little effect; but to tell her that by reducing her weight she might look more charming and beautiful, she might accept health advice. When a father promises his child a reward for getting up early everyday, he is motivating the child to inculcate a good habit. In health education, we make use of motivation to change behaviour. Motivation is contagious; one motivated person may spread motivation throughout a group. For example, men who have already had vasectomies are among the best advertisements for male sterilization.

(5) *Comprehension :* In health education we must know the level of understanding, education and literacy of people to whom the teaching is directed. One barrier to communication is using words which cannot be understood. A doctor asked the diabetic to cut down starchy foods; the patient had no idea of starchy foods. A doctor prescribed medicine in the familiar jargon "one teaspoonful three times a day"; the patient, a village woman, had never seen a teaspoon, and could not follow the doctor's directions. In health education, we should always communicate in the language people understand, and never use words which are strange and new to the people. Teaching should be within the mental capacity of the audience.

(6) *Reinforcement :* Few people can learn all that is new in a single period. Repetition at intervals is necessary. If there is no reinforcement, there is every possibility of the individual going back to the pre-awareness stage. If the message is repeated in different ways, people are more likely to remember it.

(7) *Learning by doing :* Learning is an action – process; not a "memorizing" one in the narrow sense. The Chinese proverb : "If I hear, I forget; if I see, I remember; if I do, I know" illustrates the importance of learning by doing.

(8) *Known to unknown :* In health education work, we must proceed "from the concrete to the abstract"; "from the particular to the general"; "from the simple to the more complicated;" "from the easy to more difficult"; and "from the known to the unknown". These are the rules in teaching. We start where the people are and with what they understand and then proceed to new knowledge. We use the existing knowledge of the people as pegs on which to hang new knowledge. In this way systematic knowledge is built up. New knowledge will bring about a new, enlarged understanding which can give rise to an insight into the problem. The way in which medicine has developed from religion to modern medicine serves us as an illustration, the growth of knowledge from the unknown to the known. It is a long process full of obstacles and resistance, and we must not expect quick results.

(9) *Setting an example :* The health educator should set a good example in the things he is teaching. If he is explaining the hazards of smoking, he will not be very successful if he himself smokes. If he is talking about the "small family norm", he will not get very far if his own family size is big.

(10) *Good human relations :* Sharing of information, ideas and feelings happen most easily between people who have a good relationship. Building good relationship with people goes hand in hand with developing communication skills.

(11) *Feedback :* Feedback is one of the key concepts of the systems approach. The health educator can modify the elements of the system (e.g., message, channels) in the light of feedback from his audience. For effective communication, feedback is of paramount importance.

(12) *Leaders :* Psychologists have shown and established that we learn best from people whom we respect and regard. In the work of health education, we try to penetrate the community through the local leaders – the village headman, the school teacher or the political worker. Leaders are agents of change and they can be made use of in health education work. If the leaders are convinced first about a given programme, the rest of the task of implementing the programme will be easy. The attributes of a leader are : he understands the needs and demands of the community; provides proper guidance, takes the initiative, is receptive to the views and suggestions of the people; identifies himself with the community; self-less, honest, impartial, considerate and sincere; easily accessible to the people; able to control and compromise the various factions in the community; possesses the requisite skill and knowledge of eliciting cooperation and achieving coordination of the various official and non-official organizations.

PRACTICE OF HEALTH EDUCATION

Educational material should be designed to focus attention to provide new knowledge, to facilitate interpersonal and group discussion and to reinforce or clarify prior knowledge and behaviour.

1. Audio-visual aids

No health education can be effective without audiovisual aids. They help to simplify unfamiliar concepts; bring about understanding where words fail; reinforce learning by appealing to more than one sense, and provide a dynamic way of avoiding monotony. Modern science has made available an endless array of audiovisual aids which can be classified into three groups *(20)*:

(1) AUDITORY AIDS

Radio, tape-recorder, microphones, amplifiers, earphones.

(2) VISUAL AIDS

(a) *Not requiring projection :* Chalk-board, leaflets, posters, charts, flannelgraph, exhibits, models, specimens, etc.

(b) *Requiring projection :* Slides, film strips.

(3) COMBINED A-V AIDS

Television, sound films (Cinema), slide–tape combination.

A knowledge of the advantages, disadvantages and limitations of each audio-visual aid is necessary in order to make proper use of them. Audio-visual aids are means to an end, not an end in themselves.

2. Methods in health communication

The methods in health communication may be grouped as in Fig. 3.

A rundown of the assets of mass media and personal communication methods is as shown in Table 2.

Any one or a combination of these methods can be used selectively at different times, depending upon the objectives to be achieved, the behaviour to be influenced and available funds.

1. Individual approach

There are plenty of opportunities for individual health education. It may be given in personal *interviews* in the consultation room of the doctor or in the health centre or in the homes of the people. The individual comes to the doctor or health centre because of illness. Opportunity is taken in educating him on matters of interest – diet, causation and nature of illness and its prevention, personal hygiene, environmental hygiene, etc. Topics for health counselling may be selected according to the relevance of the situation. By such individual health teaching, we will be equipping the individual and the family to deal more effectively with the health problems. The responsibility of the attending physician in this regard, is very great because he has the confidence of the patient. The patient will listen more readily to the physician's health counselling. A hint from the doctor may have a more lasting effect than volumes of printed word. The nursing staff have also ample opportunities for undertaking health education. Florence Nightingale said that the nurse can do more good in the home than in the hospital. Public health nurses, health visitors and health inspectors are visiting hundreds of homes, they have plenty of opportunities for individual health teaching. In working with individuals, the health educator must first create an atmosphere of friendship and allow the individual to talk as much as possible. The biggest advantage of individual health teaching is that we can discuss, argue and persuade the individual to change his behaviour. It provides opportunities to ask questions in terms of specific interests. The limitation of individual health teaching is that the numbers we reach are small, and health education is given only to those who come in contact with us.

2. Group approach

Our society contains groups of many kinds – school children, mothers, industrial workers, patients, etc. Group teaching is an effective way of educating the community. The choice of subject in group health teaching is very important; it must relate directly to the interest of the group. For example, we should not broach the subject of tuberculosis control to a mother who has come for delivery; we should talk to her about child-birth and baby care.

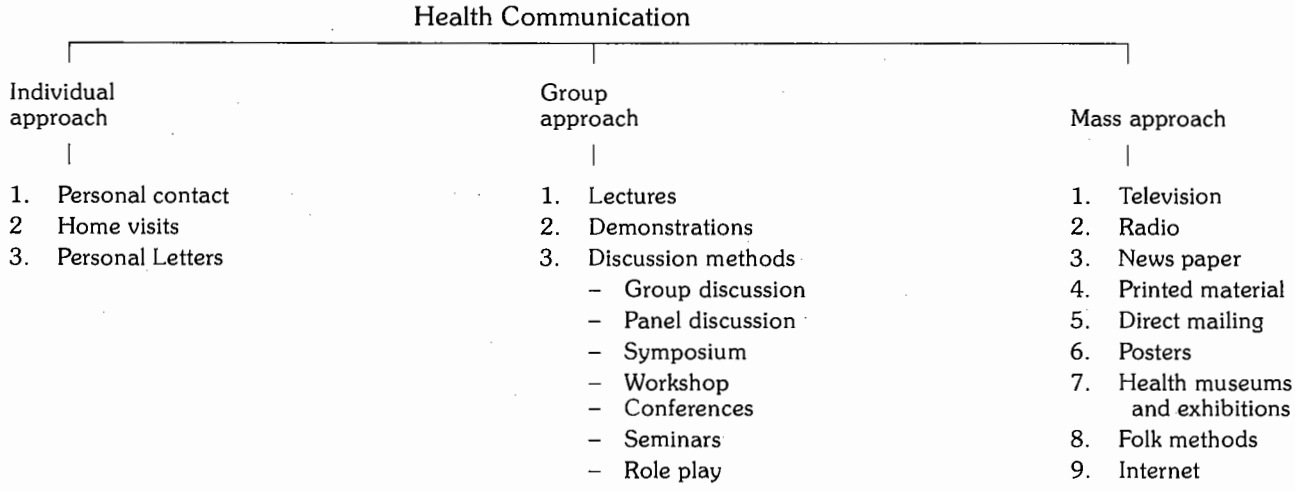

FIG. 3

Methods in health communication

TABLE 2

A rundown of assets of mass media and personal communication

Mass Media (TV, radio, newspaper)	Personal communication (Interpersonal and group methods)
1. Reaches the widest population	1. Capitalizes on warmth and understanding and knowledge of communication
2. Gets public attention	2. Provides the opportunity for involvement, for asking questions, expressing fears, and learning more
3. Gives greater support for concentrated programmes such as those for a week or month	3. Can get people to make changes in personal habits more readily, when discussion presents reasonable explanations for these changes.
4. More effective among those with above average educational level	4. More influential with average and below average educational level.

Similarly, school children may be taught about oral hygiene; tuberculosis patients about tuberculosis; and industrial workers about accidents. We have to select also the suitable method of health education including audio-visual aids for successful group health education. A brief account of the methods of group teaching is given below :

(1) Chalk and talk (Lecture)

A lecture may be defined as carefully prepared oral presentation of facts, organized thoughts and ideas by a qualified person. The "chalk" lends the visual component. The chalk and talk communication has still a very important place in small group education. Its effectiveness depends to a large extent on the speaker's ability to write legibly and to draw with chalk on a black board. The talk should be based on a topic of current interest or health needs of the group. The group should not be more than 30 and the talk should not exceed 15 to 20 minutes. If the talk is too long people may become bored and restless.

The lecture method can be made more effective by combining with suitable audio-visual aids such as : (a) *Flipcharts :* They consist of a series of charts (or posters), about 25 by 30 cms or more, each with an illustration pertaining to the talk to be given. They are meant to be shown one after another. Each chart is "flashed" or displayed before a group as the talk is being given. The message on the charts must be brief and to the point. These charts are primarily designed to hold attention of the group and help the lecture to proceed. (b) *Flannelgraph :* A piece of rough flannel or khadi fixed over a wooden board provides an excellent background for displaying cut-out pictures, graphs, drawings and other illustrations. The cut-out pictures and other illustrations are provided with a rough surface at the back by pasting pieces of sand paper, felt or rough cloth and they adhere at once when put on the flannel. Flannelgraph offers the advantage that pre-arranged sequence of pictures displayed one after another helps maintain continuity and adds much to the presentation. The other advantages are that the flannelgraph is a very cheap medium, easy to transport and promotes thought and criticism (c) *Exhibits :* Objects, models, specimens, etc. convey a specific message to the viewer. They are essentially mass media of communication, which can also be used in group teaching. (d) *Films and charts :* These are mass media of communication. If used with discrimination, they can be of value in educating small groups.

Lectures can be faulted on a number of grounds. Their disadvantages include the following : students are involved to a minimum extent; learning is passive; do not stimulate thinking or problem-solving capacity; the comprehension of a lecture varies with the student; and the health behaviour of the listeners is not necessarily affected.

(2) Demonstrations

A demonstration is a carefully prepared presentation to show how to perform a skill or procedure. Here a procedure (e.g. lumber puncture, disinfection of a well) is carried out step by step before an audience or the target group, the demonstrator ascertaining that the audience understands how to perform it. The demonstrator involves the audience in discussion.

Demonstration (a) dramatizes by arousing interest (b) persuades the onlookers to adopt recommended practices (c) upholds the principles of "seeing is believing" and "learning by doing", and (d) can bring desirable changes in the behaviour pertaining to the use of new practice.

Demonstration as a means of communication has been found to have a high educational value in programmes like environmental sanitation (e.g., installation of a hand-pump, construction of a sanitary latrine); mother and child health (e.g. demonstration of oral rehydration technique) and control of diseases (e.g., scabies). The clinical teaching in hospitals is based on demonstrations. This method has a high motivational value.

(3) Group discussion

A "group" is an "aggregation of people interacting in a face-to-face situation". This contrasts sharply to the group of students in a class room situation. Group discussion is considered a very effective method of health communication. It permits the individuals to learn by freely exchanging their knowledge, ideas and opinions. Group discussion provides a wider interaction among members than is possible with other methods. Where long term compliance is involved (e.g., cessation of smoking, obesity reduction) group discussion is considered valuable.

For effective group discussion, the group should comprise not less than 6 and not more than 12 members. The participants are all seated in a circle, so that each is fully visible to all the others (Fig. 4). There should be a group leader who initiates the subject, helps the discussion in the proper manner, prevents side-conversations, encourages everyone to participate and sums up the discussion in the end. If the discussion goes well, the group may arrive at decisions which no individual member would have been able to make alone. It is also desirable to have a person to

record whatever is discussed. The "recorder" prepares a report on the issues discussed and agreements reached. In a group discussion, the members should observe the following rules : (a) express ideas clearly and concisely (b) listen to what others say (c) do not interrupt when others are speaking (d) make only relevant remarks (e) accept criticism gracefully and (f) help to reach conclusions *(9)*. Group discussion is successful if the members know each other beforehand, when they can discuss freely.

A well conducted group discussion with adequate resources (Fig. 4) is very effective in reaching decisions, based on the ideas of ALL people. The decision taken by the group tends to be adopted more readily than in situations where the decision is a solitary one. Thus the group acceptance has a binding effect on the individual member to translate their acceptance into action. A well-conducted group discussion is effective for changing attitudes and the health behaviour of people.

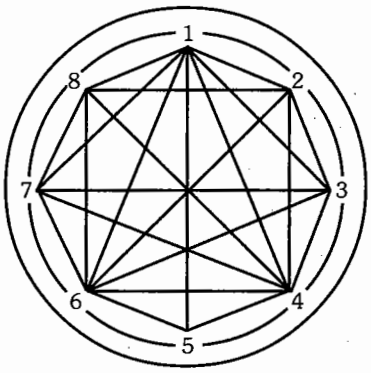

FIG. 4
A good group discussion

Limitations : Group discussion is not without limitations. Those who are shy may not take part in the discussions. Some may dominate the discussion (Fig. 5). Thus there may be unequal participation of members in a group discussion, unless properly guided. Some members may deviate from the subject and make the discussion irrelevant or unprofitable.

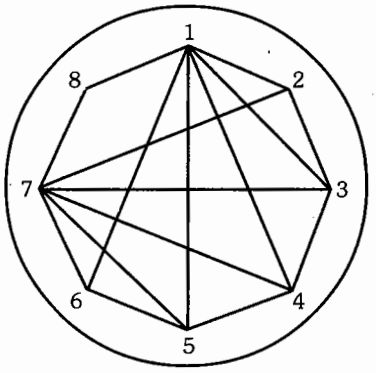

FIG. 5
A dominated group. No.1 and No.7 dominate the discussion

(4) Panel discussion

In a panel discussion, 4 to 8 persons who are qualified to talk about the topic sit and discuss a given problem, or the topic, in front of a large group or audience. The panel comprises, a chairman or moderator and from 4 to 8 speakers. The chairman opens the meeting, welcomes the group and introduces the panel speakers. He introduces the topic briefly and invites the panel speakers to present their points of view. There is no specific agenda, no order of speaking and no set speeches *(21)*. The success of the panel depends upon the chairman; he has to keep the discussion going and develop the train of thought. After the main aspects of the subject are explored by the panel speakers, the audience is invited to take part. The discussion should be spontaneous and natural. If members of the panel are unacquainted with this method, they may have a preliminary meeting, prepare the material on the subject and decide upon the method and plan of presentation. Panel discussion can be an extremely effective method of education, provided it is properly planned and guided.

(5) Symposium *(21,22)*

A symposium is a series of speeches on a selected subject. Each person or expert presents an aspect of the subject briefly. There is no discussion among the symposium members like in panel discussion. In the end, the audience may raise questions. The chairman makes a comprehensive summary at the end of the entire session.

(6) Workshop *(21, 22, 23)*

The workshop is the name given to a novel experiment in education. It consists of a series of meetings, usually four or more, with emphasis on individual work, within the group, with the help of consultants and resource personnel. The total workshop may be divided into small groups and each group will choose a chairman and a recorder. The individuals work, solve a part of the problem through their personal effort with the help of consultants, contribute to group work and group discussion and leave the workshop with a plan of action on the problem. Learning takes place in a friendly, happy and democratic atmosphere, under expert guidance. The workshop provides each participant opportunities to improve his effectiveness as a professional worker.

(7) Role playing *(21, 22)*

Role playing or socio-drama is based on the assumption that many values in a situation cannot be expressed in words, and the communication can be more effective if the situation is dramatised by the group. The group members who take part in the socio-drama enact their roles as they have observed or experienced them. The audience is not passive but actively concerned with the drama. They are supposed to pay sympathetic attention to what is going on, suggest alternative solutions at the request of the leader and if requested, come up and take an active part by demonstrating how they feel a particular role should be handled, or the like. The size of the group is thought to be best at about 25. Role playing is a useful technique to use in providing discussion of problems of human relationship. It is a particularly useful educational device for school children. Role playing is followed by a discussion of the problem.

(8) Conferences and seminars

This category contains a large component of commercialized continuing education. The programmes are usually held on a regional, state or national level. They range from once half-day to one week in length and may cover a single topic in depth or be broadly comprehensive. They usually use a variety of formats to aid the learning process from self instruction to multi-media.

3. Mass approach – Education of the general public

No health worker or health team can mount an effective health education programme for the whole community, except through **mass media** of communication. The evolution of the media has been rapid. Uptill the early 1920s, mass communication depended largely on what was printed – posters, pamphlets, books, periodicals and newspapers. Then came the radio and with it a new dimension of experience. TV went a gigantic step further and has become a very powerful weapon. The press caters primarily to the eye, the radio appeals to the ear, and TV to both eye and ear. A final word about radio and TV – they come close to the warmth and motivational effect of a person-to-person communication. They have become part of the fabric of modern civilization.

Mass media are a "one-way" communication. They are useful in transmitting messages to people even in the remotest places. The number of people who are reached usually count in millions. Their effectiveness can give high returns for the time and money involved.

Mass media alone are generally inadequate in changing human behaviour. For effective health communication, they should be used in combination with other methods. The power of mass media in creating a political will in favour of health, raising the health consciousness of the people, setting norms, delivering technical messages, popularising health knowledge and fostering community involvement are well recognized *(6)*. Public health methodologies should be culturally appropriate; they should be carefully thought-out before use. A brief account of the mass media is given below :

1. Television

Television has become the most popular of all media. It is effective in not only creating awareness, but also to an extent influencing public opinion and introducing new ways of life. It is raising levels of understanding and helping people familiarise with things they have not seen before, including crime and violence which are shown as part of feature programmes. TV is a one-way channel. It can only be an aid to teaching. It cannot cover all areas of learning. It has much potential for health communication.

2. Radio

Radio is found nearly in every home. In many developing countries the radio has a broader audience than TV. Both radio and TV can reach illiterate population not accessible through printed word. It is a purely didactic medium. It can be valuable aid in "putting across" useful health information, in the form of straight talks, plays, questions and answers and quiz programmes. Radio is much cheaper than TV. Doctors and health workers may speak out on radio. Local health issues may be identified and discussed leading to increased general awareness.

3. Internet

This new means of computer based communication system has opened vast capability of transfer of knowledge, and has made it possible to get into direct and instant communication across the world by means of e-mail and even a on-line chat. This is a fast growing communication media and holds very large potential to become a major health education tool. Already a fairly large number of persons in India are using this media, and the numbers are growing everyday. Vast amount of health related literature from WHO and other health agencies is available on line. The Health related information from the ministry of health and family welfare Govt. of India, is also available on their website.

4. Newspapers

Newspapers are the most widely disseminated of all forms of literature. News must be newsworthy before it is printed. Whereas many people turn to radio or TV for entertainment, newspaper readers are often seeking newspapers. Newspapers should, therefore provide more factual, detailed and even statistical material *(7)*. Unfortunately, health problems have little of value to newspapers. Newspapers have limitation of having low readership in rural areas because of illiteracy. They reach only a limited group, i.e. the literates in the community.

5. Printed material

Magazines, pamphlets, booklets and hand-outs have long been in use for health communication. They are aimed at those who can read. Their usefulness lies in the fact that they can convey detailed information. They can be produced in bulk for very little cost, and can be shared by others in the family and community.

6. Direct mailing

This is a new innovation in health communication in India. The intention is to reach the remote areas of the country with printed word (e.g., folders and newsletters and booklets on family planning, immunization and nutrition etc.). These are sent directly to village leaders, literate persons, panchayats and local bodies and others who are considered as opinion leaders. Direct mailing has been a successful mass media in creating public awareness. It is possibly the most personal of mass communication.

7. Posters, billboards and signs

These are intended to catch the eye and create awareness. Therefore, the message to be communicated must be simple, and artistic. Posters are not expensive when one considers they are seen by a large number of people. Motives such as humour and fear are introduced into posters in order to hold the attention of the public. In places where the exposure time is short (e.g., streets), the message of the poster should be short, simple, direct and one that can be taken at a glance and easy to understand immediately. In places where people have some time to spend (e.g., bus stops, railway stations, hospitals, health centres) the poster can present more information. The right amount of matter should be put up in the right place and at the right time. That is, when there is an epidemic of viral hepatitis, there should be posters displayed on viral jaundice, but not on cholera. The life of a poster is usually short; posters should be changed frequently, otherwise they will lose their effect. As a media of health education, posters have much less effect in changing behaviour than its enthusiastic users would hope. Indiscriminate use of posters by pasting them on walls serves no other useful purpose than covering the wall.

8. Health museums and exhibitions

If properly organized, health museums and exhibitions can attract large numbers of people. By presenting a variety of ideas, they do increase knowledge and awareness. Photographic panels attract more persons than graphic panels. This is because photos give a humanized touch to the communication. The three dimensional models with lighted visuals are even more effective than photos.

In exhibitions, there is a big element of personal communication through workers who explain each item on the exhibit. Printed literature explaining the exhibits is often freely distributed. Health exhibitions and museums thus offer a package of both personal and impersonal methods of communication.

9. Folk media

The term "mass communication" ought to refer to the totality of communication which takes within its compass not only the electronic media, but also folk (or indigenous) media such as keerthan, katha, folk songs, dances and dramas and puppet shows which have roots in our culture. The muslims have their own traditional folk forum like the ghazals, the kawali.

The mass media are only "instruments". As such they are neither good nor bad; what matters is the message they carry and the way the message is delivered *(6)*. There is no single way to do public education. Health education is still art rather than a science. Each community and country should develop techniques that meet its own needs.

PLANNING AND MANAGEMENT

Health education cannot be planned in a vacuum. It is planned in connection with a specific health programme or health service. Therefore, the specifics of a health education strategy in a local community have to be formulated in accordance with its socio-cultural, psycho-social, political, economic and situational characteristics. The planners should be fully conversant with the health education needs of the particular programme for which health education is to be planned.

Health education planning follows the main steps in scientific planning, which are :

1. Collecting information on specific problems as seen by the community
2. Identification of the problem
3. Deciding on priorities
4. Setting goals and measurable objectives
5. Assessment of resources
6. Consideration of possible solutions
7. Preparation of a plan of action :
   (i) What will be done ?
   (ii) When ?
   (iii) By whom ?
8. Implementing the plan
9. Monitoring and evaluating the degree to which stated objectives have been achieved
10. Reassessment of the process of planning. Planning and evaluation are essential for effective health education. The subject of planning is discussed more fully in chapter 20.

All health education work requires continuous evaluation to measure the effectiveness of health education activities in achieving stated objectives and to assess the importance on programme performance of such variables as knowledge, attitudes, behaviour change and consumer satisfaction.

ADMINISTRATION AND ORGANIZATION

Governments have a responsibility for assisting and guiding the health education of the general public. At the national level, the Government of India in 1956 established a Central Health Education Bureau in the Ministry of Health, New Delhi to promote and coordinate health education work in the country. Many state governments in India have now Health Education Bureaux in their Health Directorate.

There are also other official agencies in the country such as the Directorate of Advertising and Visual Publicity (DAVP), Press Information Bureau, Doordarshan and All India Radio which are active in health education work. Several voluntary agencies such as Indian Red Cross are also engaged in the health education work. At the international level, there is an International Union for Health Education with headquarters in Paris, whose main task is to promote the creation of national societies for health education. The South East Asia Regional Bureau (SEARB) of the International Union for Health Education was established in 1983 with headquarters at Bangalore.

A new division of Health Education and Health Promotion has been established by the WHO. The division will support regional offices of WHO in strengthening national capabilities in health education and promotion, and develop and test new ideas and tools. (The former Division of Public Information and Education for Health is now called Division of Public Information and Public Relations).

Health education is a complex activity in which different individuals and organizations play a part. Among them are parents, teachers, friends, physicians, nurses, health workers and various organizations, governmental and non-governmental. No country in the world, least of all a country with a large population and small resources such as India, can afford to employ institutionally trained health workers. Therefore, health education should be the concern of everybody engaged in any form of community welfare work.

20 Health Planning and Management

"Plan ahead - it was not raining when Noah built the ark"

Planning and management are relatively new subjects. Planning is for tomorrow, and management is for today. These subjects have acquired great importance during the past two decades. The purpose of planning is (1) to match the limited resources with many problems; (2) to eliminate wasteful expenditure or duplication of expenditure; and (3) to develop the best course of action to accomplish a defined objective. The increasing demand for medical and health care services, in the face of limited resources, has brought out the need for careful planning and management of health services. Planning and management are considered essential if higher standards of health and health care are to be achieved *(1)*.

Planning in its broadest sense includes three steps:

(a) Plan formulation
(b) Execution; and
(c) Evaluation

Planning is a matter of team work and consultation. The planning team consists of not only specialists within the field, but also specialized in other fields, viz. economics, statistics, sociology, management, etc.

DEVELOPMENT PLANNING

Every country has its own plan for national development. The purpose of national planning is to achieve a rapid, balanced, economic and social development of the country as a whole. The National Development Plan of a country is a combination of sectoral plans which comprise the following sectors, viz. food and agriculture, education, health and family planning, industry, transport and communications, housing, power, social welfare, etc. All these sectors compete for national resources *(2)*.

In this context, National Development Planning has been defined as "continuous, systematic, coordinated, planning for the investment of the resources of a country (men, money and materials) in programmes aimed at achieving the most rapid economic and social development possible *(3)*.

HEALTH PLANNING

Health planning is a concept of recent origin. It is part of national development planning. Health planning is necessary for the economic utilisation of material, man-power and financial resources. The purpose of health planning is to improve the health services.

In this context, National Health Planning has been defined as "the orderly process of defining community health problems, identifying unmet needs and surveying the resources to meet them, establishing priority goals that are realistic and feasible and projecting administrative action to accomplish the purpose of the proposed programme" *(3)*.

Health needs and demands

The purpose of health planning is to meet the health needs and demands of the people. Health needs have been defined as "deficiencies in health that call for preventive, curative, control or eradication measures" *(3)*; The need for medical care, safe water supply, adequate nutrition, immunization, family planning are all community health needs. It may be mentioned that the health needs as seen by the people are not exactly the same as seen by experts. Some needs may not be perceived at all; others vaguely perceived, and still others awaken only on contact with new ways of life. People's needs are conditioned by their aspirations. In a democratic society, people's needs may be presented as demands.

Resources

The term "resources" is widely used in health planning. It implies the manpower, money, materials, skills, knowledge, techniques and time needed or available for the performance or support of action directed towards specified objectives. The resources can be readily wasted if there is no proper planning and management.

Objectives, targets and goals

A number of words are used to describe the end–results of planning – objective, target, goal. These words are drawn from military and sports terminology. An important element of planning is the setting of clear-cut objectives, targets and goals. Let us consider the meaning of these words:

An OBJECTIVE (point) is precise – it is either achieved or not achieved. It is a planned end-point of all activities. A TARGET often refers to a discrete activity such as the number of blood films collected or vasectomies done; it permits the concept of degree of achievement. Targets are thus concerned with the factors involved in a problem, whereas objectives are concerned directly with the problem itself.

GOAL is defined as the ultimate desired state towards which objectives and resources are directed. Unlike objectives and targets, goals are not constrained by time or existing resources, nor are they necessarily attainable. Goals formulated at the highest level are generally broad. A goal is usually described in terms of (1) what is to be attained; (2) the extent to which it is to be attained; (3) the population or section of the environment involved; (4) the geographic area in which the proposed programme will operate; and (5) the length of time required for attaining the goal *(3)*.

Plan

Planning results in the formulation of a Plan. A "Plan" is a blue print for taking action. It consists of five major elements; objectives, policies, programmes, schedules and budget.

A "programme" is a sequence of activities designed to implement policies and accomplish objectives. A programme gives a step-by-step approach to guide the action necessary to reach a predetermined goal. Programmes must be closely integrated with objectives.

A "schedule" is a time sequence for the work to be done. "Procedures" are a set of rules for carrying out work which, when observed by all, help to ensure the maximum use of the resources and efforts. "Policies" are the guiding principles stated as an expectation, not as a commandment.

Pre-planning

Pre-planning is preparation for planning. The important preconditions are : *(a) Government interest :* Any plan for the health and welfare of a country must be based on a strong 'political will' as manifested by clear directives or policies given by the political authority. *(b) Legislation :* The social and health policies formulated may have to be translated into legislation. As an example may be cited the enactment of the Medical Termination of Pregnancy Act, 1971, by the Indian Parliament to protect the health of mothers. *(c) Organization for planning :* There should be an organizational structure for the preparation of the various parts of the plan. The Planning Commission in India serves this function. It is composed of full–time planners who are advised by representatives and technical experts in the field of social and economic development as well as political leaders. *(d) Administrative capacity :* One of the essential pre-conditions of planning is administrative capacity for proper coordination of activities and implementation of the plan at all levels. For the health plan, administrative capacity is vested in the Central and State Ministries of Health.

PLANNING CYCLE

Planning is the broad foundation on which much of the management is based. Planning may be defined as a process of analysing a system, or defining a problem, assessing the extent to which the problem exists as a need, formulating goals and objectives to alleviate or ameliorate those identified needs, examining and choosing from among alternative intervention strategies, initiating the necessary action for its implementation and monitoring the system to ensure proper implementation of the plan and evaluating the results of intervention in the light of stated objectives. Planning thus involves a succession of steps *(3, 4, 5)*. These are as shown in Fig. 1.

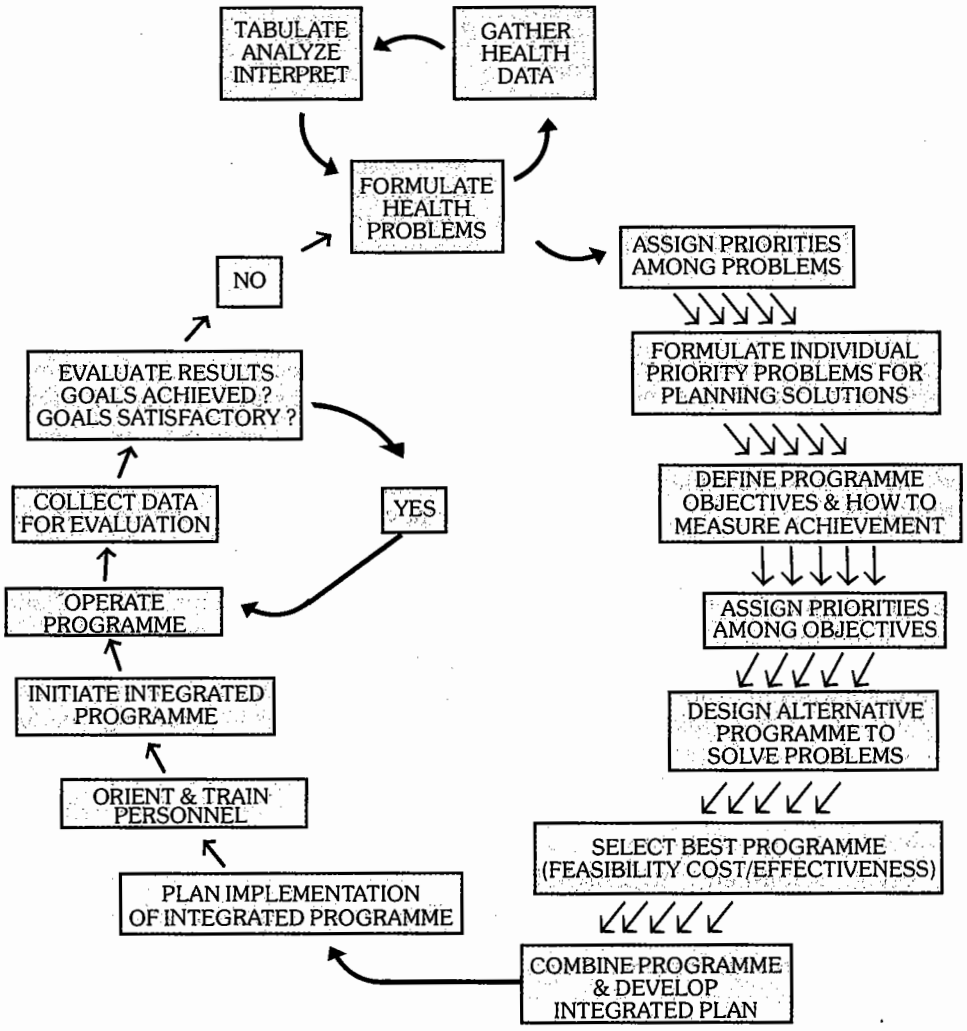

FIG. 1
The planning cycle

1. Analysis of the health situation

The first step in health planning is analysis of the health situation. It involves the collection, assessment and interpretation of information in such a way as to provide a clear picture of the health situation. The following items of data are the minimum essential requirements for health planning:

(a) The population, its age and sex structure
(b) Statistics of morbidity and mortality
(c) The epidemiology and geographical distribution of different diseases
(d) Medical care facilities such as hospitals, health centres, and other health agencies – both public and private
(e) The technical manpower of various categories
(f) Training facilities available
(g) Attitudes and beliefs of the population towards disease, its cure and prevention.

The analysis and interpretation of the above data brings out the health problems, the health needs and health demands of the population.

2. Establishment of objectives and goals

Objectives and goals are needed to guide efforts. Unless objectives are established, there is likely to be haphazard activity, un-economical use of funds and poor performance. Objectives must be established at all levels, down to the smallest organizational unit. At upper levels, objectives are general; at successively lower levels, they become more specified and detailed. The objectives may be short-term or long-term. In setting these objectives, time and resources are important factors. Objectives are not only a guide to action, but also a yard-stick to measure work after it is done. Modern management techniques such as "cost–benefit" analysis, and "input–output" study of health services are being used for defining goals, objectives and targets in more definite terms than hitherto.

3. Assessment of resources

The term resources implies the manpower, money, materials, skills, knowledge and techniques needed or available for the implementation of the health programmes. These resources are assessed and a balance is struck between what is required and what is available, or likely to be available in terms of resources.

4. Fixing priorities

Once the problems, resources and objectives have been determined, the next most important step in planning is establishment of priorities in order of importance or magnitude, since the resources always fall short of the total requirement. In fixing priorities, attention is paid to financial constraints, mortality and morbidity data, diseases which can be prevented at low cost, saving the lives of younger people in whom there has been considerable social investment; and also political and community interests and pressures.

Once priorities have been established, ALTERNATE PLANS for achieving them are also formulated and assessed in order to determine whether they are practicable and feasible. Alternate plans with greater effectiveness are chosen.

5. Write-up of formulated plan

The next major step in the planning process is the preparation of the detailed plan or plans. The plan must be complete in all respects for the execution of a project. For each proposed health programme, the resources (inputs) required are related to the results (outputs) expected. Each stage of the plan is defined and costed and the time needed to implement is specified. The plan must contain working guidance to all those responsible for execution. It must also contain a "built-in" system of evaluation. It will be left to the central planning authority and the government to consider modifications of the plan relating to allocation of resources.

6. Programming and implementation

Once the health plan has been selected and approved by the policy making authorities, programming and implementation are begun. Plan execution depends upon the existence of effective organization. The organizational structure must incorporate well–defined procedures to be followed and sufficient delegation of authority to and fixation of responsibility of different workers for achieving the predetermined objectives during the period prescribed. It is at the implementation stage that shortcomings often appear in practice. Many well considered plans have fallen down because of delays in critical supplies, inappropriate use of staff, and similar factors. The main considerations at the implementation stage include: (a) definition of roles and tasks (b) the selection, training, motivation and supervision of the manpower involved (c) organization and communication, and (d) the efficiency of individual institutions such as hospitals or health centres.

7. Monitoring

Monitoring is the day-to-day follow-up of activities during their implementation to ensure that they are proceeding as planned and are on schedule. It is a continuous process of observing, recording, and reporting on the activities of the organization or project. Monitoring, thus, consists of keeping track of the course of activities and identifying deviations and taking corrective action if excessive deviations occur.

8. Evaluation

The purpose of evaluation is to assess the achievement of the stated objectives of a programme, its adequacy, its efficiency and its acceptance by all parties involved. While monitoring is confined to day-to-day or ongoing operations, evaluation is mostly concerned with the final outcome and with factors associated with it. Good planning will have a built–in evaluation to measure the performance and effectiveness and for feed-back to correct deficiencies or fill up gaps discovered during implementation. In the words of the WHO Expert Committee on National Health Planning in Developing Countries, evaluation "measures the degree to which objectives and targets are fulfilled and the quality of the results obtained. It measures the productivity of available resources in achieving clearly defined objectives. It measures how much output or cost-effectiveness is achieved. It makes possible the reallocation of priorities and of resources on the basis of changing health needs" *(6)*.

MANAGEMENT *(7)*

The term "management" is used in many senses. It is sometimes confused with administration; sometimes with organization. Some equate the terms, management and administration. Others view it as a technique of leadership. The widely prevalent view is that administration broadly means "getting things done" and management as "the purposeful and effective use of resources – manpower,

materials and finances – for fulfilling a pre-determined objective". In theory, management consists of four basic activities :

(i) *planning*: determining what is to be done.
(ii) *organizing:* setting up the framework or apparatus and making it possible for groups to do the work.
(iii) *communicating*: motivating people to do the work.
(iv) *monitoring (controlling):* checking to make sure the work is progressing satisfactorily.

Management techniques are familiar in business, industry, defence and other fields. The current emphasis by WHO and many governments is on improving the efficiency of the health care delivery systems through the application of modern management methods and techniques.

MANAGEMENT METHODS AND TECHNIQUES *(1, 8, 9)*

Management techniques are many. They are based on principles of behavioural sciences as well as *quantitative* methods. These techniques have been developed by experts of management science to help the managers of any organization to achieve the stated goals more efficiently. Efforts are being made by the WHO for making these techniques more popular for application in the health field. A brief account of these techniques is given below :

Methods based on behavioural sciences

1. ORGANIZATIONAL DESIGN

Poor organization results in waste of resources. It is a theory of management that organization must be suited to its current situation and the needs to be serviced. The organization of health services should, therefore, be designed so as to meet the health needs and demands of the people. Further, the organizational design should be reviewed every few years because of changing concepts or purpose, changing problems and changing technology. Efficient delivery of health services depends upon the existence of an effective organization.

2. PERSONNEL MANAGEMENT

This is skilful use of human resources. Proper methods of selection, training and motivation; division of responsibility; distribution of roles; elimination of "square pegs in round holes" (i.e., professional staff not suited to administration, either through training, selection or natural inclination, should not be entrusted with administrative and management burdens); incentive for better work; opportunities for promotion and professional advancement; effective design of "health teams" are all fundamental techniques of personnel management which could contribute to the efficiency of health service delivery.

3. COMMUNICATION

Better communication contributes to effective functioning of an organization. Communication roadblocks exist at various levels: between the doctor and the patient; doctor and nurse; between the senior officials and juniors; between the directorate and the health ministry; between the health ministry and other ministries and rest of the government. Communication barriers are responsible for delays in regular reporting and notification; delays in the compilation of statistics; delays in the release of supplies and salaries; delays in the institution of prompt remedial measures. In fact, these are some of the major weaknesses in health ministries. One of the tasks of health management is to solve the communication problems by establishing suitable vertical and horizontal communication channels.

4. INFORMATION SYSTEMS

Information is needed for day-to-day management of the health system. Information comes from many sources – both formal and informal. The information system should be tailored according to the management needs of the individual health services. The functions of an information system consist of collection, classification, transmission, storage, retrieval, transformation and display of information. A good information system provides data for monitoring and evaluation of health programmes and gives the requisite feed–back to health administrators and planners at all levels. Computers can play a great role in improving the health information system.

5. MANAGEMENT BY OBJECTIVES (MBO)

Objectives are set forth for different units and subunits, each of which prepares its own plan of action – usually on a short-term basis. This helps in achieving the results more effectively and smoothly.

Quantitative methods

Quantitative methods are derived from the field of economics, operation research and budgeting. Some of these techniques have a great role in the management of health services :

1. COST-BENEFIT ANALYSIS

This is a management technique which has attracted the widest attention for application in the health field. The economic benefits of any programme are compared with the cost of that programme. The benefits are expressed in monetary terms to determine whether a given programme is economically sound, and to select the best out of several alternate programmes. The main drawback with this technique is that the benefits in the health field, as a result of a particular programme, cannot always be expressed in monetary terms. We generally express the benefit in terms of births or deaths prevented, or illness avoided or overcome. Hence the scope of applying this method is rather vague.

2. COST-EFFECTIVE ANALYSIS

This is a more promising tool for application in the health field than cost-benefit analysis. It is similar to cost-benefit analysis except that benefit, instead of being expressed in monetary terms is expressed in terms of results achieved, e.g., number of lives saved or the number of days free from disease. However, even cost-effective analysis is not possible in many cases.

3. COST-ACCOUNTING *(10)*

It provides basic data on cost structure of any programme. Financial records are kept in a manner permitting costs to be associated with the purpose for which they are incurred. Cost-accounting has three important purposes in health services : (a) cost control; (b) planning and allocation of people and financial resources; and (c) pricing of cost reimbursement.

4. INPUT-OUTPUT ANALYSIS

Input-output analysis is an economic technique. In the

health field, "input" refers to all health service activities which consume resources (manpower, money, materials and time); and "output" refers to such useful outcomes as cases treated, lives saved or inoculations performed. An input-output table shows how much of each "input" is needed to produce a unit amount of each "output". It enables calculations to be made of the effects of changing the inputs.

5. MODEL

The model is a basic concept of management science. It is an aid to understand how the factors in a situation affect one another. It is an abstraction of the reality, not the reality itself. The decision process includes the use of a model.

6. SYSTEMS ANALYSIS

The purpose of systems analysis is to help the decision maker to choose an appropriate course of action by investigating his problem, searching out objectives, finding out alternative solutions, evaluation of the alternatives in terms of cost-effectiveness, re-examination of the objectives if necessary and finding the most cost-effective alternative. Systems analysis is essentially finding the cost-effectiveness of the available alternatives. The system can be a hospital supply system, an information system, a total community health service system, an outpatient clinic or any other system with problems of management. A system may be made of independent subsystems.

7. NETWORK ANALYSIS

A network is a graphic plan of all events and activities to be completed in order to reach an end objective (Fig. 2). It brings greater discipline in planning. The two common types of network technique are (a) PERT and (b) CPM.

(a) PERT (Programme Evaluation and Review Technique) is a management technique which makes possible more detailed planning and more comprehensive supervision. Every housewife who plans a meal so that each part of the menu is completed at the same time is using the basic technique of PERT.

The essence of PERT is to construct an Arrow Diagram (Fig. 2). The diagram represents the logical sequence in which events must take place. It is possible with such a diagram to calculate the time by which each activity must be completed, and to identify those activities that are critical. This simple technique provides a basic discipline by which all concerned in a project can know what is expected of them and to minimise any delays or crises in the implementation of the plan.

PERT is a useful management technique which can be applied to a great variety of projects. It aids in planning, scheduling and monitoring the project; it allows better communication between the various levels of management; it identifies potential problems; it furnishes continuous, timely progress reports; it forms a solid foundation upon which to build an evaluation and checking system.

(b) CRITICAL PATH METHOD (CPM) : The longest path of the network (Fig. 2) is called "critical path". If any activity along the critical path is delayed, the entire project will be delayed *(11)*.

8. PLANNING–PROGRAMMING–BUDGETING SYSTEM (PPBS)

The Planning–Programming–Budgeting System (PPBS) is primarily a system to help decision makers to allocate resources so that the available resources of an organization are used in the most effective way in achieving its objectives. The PPBS does not call for changes in the existing organization. It calls for grouping of *activities* into *programmes* related to each *objective*. Another approach is known as the 'Zero Budget Approach", i.e., all budgets start at zero and no one gets any budget that he cannot specifically justify on a year–to–year basis.

9. WORK SAMPLING

It is systematic observation and recording of activities of one or more individuals, carried out at predetermined or random intervals. It provides quantitative measurement of the various activities. The major parameters that are analysed are the type of activities performed and the time needed to do specified jobs. Work sampling studies have been done on doctors, nurses, pharmacists and laboratory technicians. Work sampling permits judgments to the appropriateness of current staff, job description and training. It helps in standardising the methods of performing jobs and determining the manpower needs in any organization.

10. DECISION MAKING

Decision making is just like the basic discipline of differential diagnosis in medical practice. It is an adage that decisions should be made at the level where the best decisions can be made; it does not follow that the best decision is always made at the top of an organization. Decisions should not be made with incomplete data. In the health sector, decisions have to be made about development of resources, optimum work load for medical and paramedical workers, strategies for providing health care, etc.

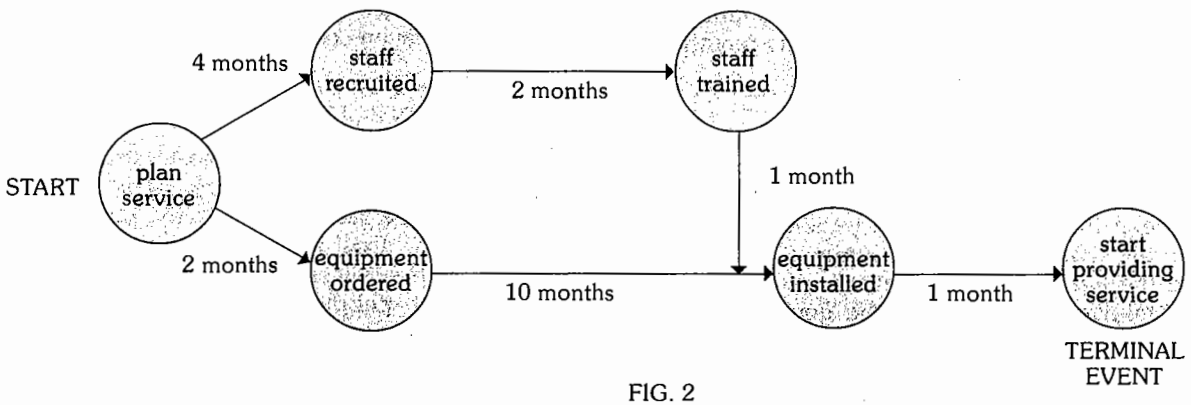

FIG. 2
Network analysis

NATIONAL HEALTH POLICY–2002 *(12)*

The Ministry of Health and Family Welfare, Govt. of India, evolved a National Health Policy in 1983 keeping in view the national commitment to attain the goal of Health for All by the year 2000. Since then there has been significant changes in the determinant factors relating to the health sector, necessitating revision of the policy, and a new National Health Policy–2002 was evolved.

The main objective of this policy is to achieve an acceptable standard of good health amongst the general population of the country. The approach would be to increase access to decentralized public health system by establishing new infrastructure in the existing institutions. Over-riding importance would be given to ensure a more equitable access to health services across the social and geographical expanse of the country. Primacy will be given to preventive and first line curative initiatives at the primary health level. The policy is focused on those diseases which are principally contributing to disease burden such as tuberculosis, malaria, blindness and HIV/AIDS. Emphasis will be laid on rational use of drugs within the allopathic system. To translate the above objectives into reality, the Health Policy has laid down specific goals to be achieved by year 2005, 2007, 2010 and 2015. These are as given in Table 1. Steps are already under way to implement the policy.

TABLE 1
National Health Policy – 2002
goals to be achieved by 2015

Eradicate Polio and Yaws	2005
Eliminate Leprosy	2005
Eliminate Kala-azar	2010
Eliminate Lymphatic Filariasis	2015
Achieve zero level growth of HIV / AIDS	2007
Reduce mortality by 50% on account of TB, Malaria and other vector and water borne diseases	2010
Reduce prevalence of blindness to 0.5%	2010
Reduce IMR to 30/1000 And MMR to 100/Lakh	2010
Increase utilization of public health facilities from current level of < 20% to > 75%	2010
Establish an integrated system of surveillance, National Health Accounts and Health Statistics.	2005
Increase health expenditure by Government as a % of GDP from the existing 0.9% to 2.0%	2010
Increase share of central grants to constitute at least 25% of total health spending	2010
Increase state sector health spending from 5.5% to 7% of the budget	2005
Further increase to 8% of the budget	2010

HEALTH PLANNING IN INDIA

Health planning in India is an integral part of national socio-economic planning *(2, 13)*. The guide-lines for national health planning were provided by a number of committees dating back to the Bhore committee in 1946. These committees were appointed by the Government of India from time to time to review the existing health situation and recommend measures for further action. A brief review of the recommendations of these committees, which are important landmarks in the history of public health in India, is given below.

The Alma-Ata Declaration on primary health care and the National Health Policy of the Government gave a new direction to health planning in India, making primary health care the central function and main focus of its national health system. The goal of national health planning in India was to attain Health for All by the year 2000.

1. Bhore committee, 1946 *(14)*

The Government of India in 1943 appointed the Health Survey and Development Committee with Sir Joseph Bhore as Chairman, to survey the then existing position regarding the health conditions and health organization in the country, and to make recommendations for the future development. The Committee which had among its members some of the pioneers of public health, met regularly for 2 years and submitted in 1946 its famous report which runs into 4 volumes. The Committee put forward, for the first time, comprehensive proposals for the development of a national programme of health services for the country. The Committee observed : "if the nation's health is to be built, the health programme should be developed on a foundation of preventive health work and that such activities should proceed side by side with those concerned with the treatment of patients." Some of the important recommendations of the Bhore Committee were :

(1) Integration of preventive and curative services at all administrative levels;

(2) The Committee visualised the development of primary health centres in 2 stages : (a) as a short-term measure, it was proposed that each primary health centre in the rural areas should cater to a population of 40,000 with a secondary health centre to serve as a supervisory, coordinating and referral institution. For each PHC, two medical officers, 4 public health nurses, one nurse, 4 midwives, 4 trained dais, 2 sanitary inspectors, 2 health assistants, one pharmacist, and 15 other class IV employees were recommended (b) a long-term programme (also called the 3 million plan) of setting up primary health units with 75–bedded hospitals for each 10,000 to 20,000 population and secondary units with 650–bedded hospitals, again regionalized around district hospitals with 2,500 beds; and

(3) Major changes in medical education which includes 3 month's training in preventive and social medicine to prepare "social physicians".

Although the Bhore Committee's recommendations did not form part of a comprehensive plan for national socio-economic development, the Committee's Report continues to be a major national document, and has provided guidelines for national health planning in India.

2. Mudaliar committee, 1962 *(15)*

By the close of the Second Five Year Plan (1956–61), a fresh look at the health needs and resources was called for to provide guidelines for national health planning in the context of the Five year Plans. In 1959, the Government of India appointed another Committee known as "Health Survey and Planning Committee", popularly known as the Mudaliar Committee (after the name of its Chairman, Dr. A.L. Mudaliar) to survey the progress made in the field of health since submission of the Bhore Committee's Report and to make recommendations for future development and expansion of health services.

The Mudaliar Committee found the quality of services provided by the primary health centres inadequate, and

advised strengthening of the existing primary health centres before new centres were established. It also advised strengthening of subdivisional and district hospitals so that they may effectively function as referral centres.

The main recommendations of the Mudaliar Committee were : (1) consolidation of advances made in the first two five year plans; (2) strengthening of the district hospital with specialist services to serve as central base of regional services; (3) regional organizations in each state between the headquarters organization and the district in charge of a Regional Deputy or Assistant Directors – each to supervise 2 or 3 district medical and health officers; (4) each primary health centre not to serve more than 40,000 population; (5) to improve the quality of health care provided by the primary health centres; (6) integration of medical and health services as recommended by the Bhore Committee; and (7) constitution of an All India Health Service on the pattern of Indian Administrative Service.

3. Chadah committee, 1963 *(16)*

In 1963, a Committee was appointed by the Government of India, under the Chairmanship of Dr. M.S. Chadah, the then Director General of health Services to study the arrangements necessary for the maintenance phase of the National Malaria Eradication Programme.

The Committee recommended that the "vigilance" operations in respect of the National Malaria Eradication Programme should be the responsibility of the general health services, i.e., primary health centres at the block level. The Committee also recommended that the vigilance operations through monthly home visits should be implemented through basic health workers. One basic health worker per 10,000 population was recommended. These workers were envisaged as "multipurpose" workers to look after additional duties of collection of vital statistics and family planning, in addition to malaria vigilance. The Family Planning Health Assistants were to supervise 3 or 4 of these basic health workers. At the district level, the general health services were to take the responsibility for the maintenance phase.

4. Mukerji committee, 1965

Within a couple of years of implementation of the Chadah Committee's recommendations by some states, it was realised that the basic health workers could not function effectively as multipurpose workers. As a result the malaria vigilance operations had suffered and also the work of the family planning programme could not be carried out satisfactorily. This subject came up for discussion at a meeting of the Central Health Council in 1965. A committee known as "Mukerji Committee, 1965" under the Chairmanship of Shri Mukerji, the then Secretary of Health to the Government of India, was appointed to review the strategy for the family planning programme. The Committee recommended separate staff for the family planning programme. The family planning assistants were to undertake family planning duties only. The basic health workers were to be utilized for purposes other than family planning. The Committee also recommended to delink the malaria activities from family planning so that the latter would receive undivided attention of its staff. The recommendations were accepted by the Government of India.

5. Mukerji committee, 1966 *(17)*

As the states were finding it difficult to take over the whole burden of the maintenance phase of malaria and other mass programmes like family planning, smallpox, leprosy, trachoma, etc. due to paucity of funds, the matter came up for discussion at a meeting of the Central Council of Health held in Bangalore in 1966. The Council recommended that these and related questions may be examined by a committee of Health Secretaries, under the Chairmanship of the Union Health Secretary, Shri Mukerji. The Committee worked out the details of the BASIC HEALTH SERVICE which should be provided at the block level, and some consequential strengthening required at higher levels of administration.

6. Jungalwalla committee, 1967 *(18)*

The Central Council of Health at its meeting held in Srinagar in 1964, taking note of the importance and urgency of integration of health services, and elimination of private practice by government doctors, appointed a Committee known as the "Committee on Integration of Health Services" under the Chairmanship of Dr. N. Jungalwalla, Director, National Institute of Health Administration and Education, New Delhi to examine the various problems including those of service conditions and submit a report to the Central Government in the light of these considerations. The report was submitted in 1967.

The Committee defined "integrated health services" as: (i) a service with a unified approach for all problems instead of a segmented approach for different problems; and (ii) medical care of the sick and conventional public health programmes functioning under a single administrator and operating in unified manner at all levels of hierarchy with due priority for each programme obtaining at a point of time.

The Committee recommended integration from the highest to the lowest level in the services, organization and personnel. The main steps recommended towards integration were: (a) unified cadre (b)common seniority (c) recognition of extra qualifications (d) equal pay for equal work (e) special pay for specialized work (f) no private practice, and good service conditions. The Committee while giving sufficient indication for action to be taken was careful neither to spell out steps and programmes nor to indicate an uniform integrated set-up but left the matter to the States to work out the set-up based on the experience of West Bengal, Punjab and Defence Forces. The Committee stated that "integration should be a process of logical evolution rather than revolution."

7. Kartar Singh committee, 1973 *(19)*

The Government of India constituted a Committee in 1972 known as "The Committee on Multipurpose Workers under Health and Family Planning" under the Chairmanship of Kartar Singh, Additional Secretary, Ministry of Health and Family Planning, Government of India. The terms of reference of the Committee were to study and make recommendation on : (a) the structure for integrated services at the peripheral and supervisory levels; (b) the feasibility of having multipurpose, bipurpose workers in the field: (c) the training requirements for such workers; and (d) the utilization of mobile service units set up under family planning programme for integrated medical, public health and family planning services operating in the field.

The Committee submitted its report in September 1973. Its main recommendations were: (a) That the present Auxiliary Nurse Midwives to be replaced by the newly designated "Female Health Workers", and the present–day Basic Health Workers, Malaria Surveillance Workers,

Vaccinators, Health Education Assistants (Trachoma) and the Family Planning Health Assistants to be replaced by "Male Health Workers". (b) The Programme for having multipurpose workers to be first introduced in areas where malaria is in maintenance phase and smallpox has been controlled, and later to other areas as malaria passes into maintenance phase or smallpox controlled. (c) For proper coverage, there should be one primary health centre for a population of 50,000; (d) Each primary health centre should be divided into 16 sub-centres each having a population of about 3,000 to 3,500 depending upon topography and means of communications; (e) Each sub-centre to be staffed by a team of one male and one female health worker (f) There should be a male health supervisor to supervise the work of 3 to 4 male health workers; and a female *health* supervisor to supervise the work of 4 female health workers (g) The present-day lady health visitors to be designated as female *health supervisors* and (h) The doctor in charge of a primary health centre should have the overall charge of all the *supervisors* and health workers in his area. The recommendations of the Kartar Singh Committee were accepted by the Government of India to be implemented in a phased manner during the Fifth Five year Plan.

8. Shrivastav committee, 1975 *(20, 21)*

The Government of India in the Ministry of Health and Family Planning had in November 1974 set up a 'Group on Medical Education and Support Manpower' popularly known as the Shrivastav Committee: (1) to devise a suitable curriculum for training a cadre of health assistants so that they can serve as a link between the qualified medical practitioners and the multipurpose workers, thus forming an effective team to deliver health care, family welfare and nutritional services to the people; (2) to suggest steps for improving the existing medical educational processes as to provide due emphasis on the problems particularly relevant to national requirements, and (3) to make any other suggestions to realise the above objectives and matters incidental thereto.

The Group submitted its report in April 1975. It recommended immediate action for : (1) creation of bands of para–professional and semi-professional health workers from within the community itself (e.g., school teachers, postmasters, gram sevaks) to provide simple, promotive, preventive and curative health services needed by the community; (2) establishment of 2 cadres of health workers, namely – multipurpose health workers and health assistants between the community level workers and doctors at the PHC; (3) development of a 'Referral Services Complex' by establishing proper linkages between the PHC and higher level referral and service centres, viz taluka/tehsil, district, regional and medical college hospitals, and (4) establishment of a Medical and Health Education Commission for planning and implementing the reforms needed in health and medical education on the lines of the University Grants Commission.

The committee felt that by the end of the sixth Plan, one male and one female health worker should be available for every 5,000 population. Also, there should be one male and female health assistant for 2 male and 2 female health workers respectively. The health assistants should be located at the sub-centre, and not at the PHC.

9. Rural health scheme, 1977

The most important recommendation of the Shrivastav Committee was that primary health care should be provided within the community itself through specially trained workers so that the health of the people is placed in the hands of the people themselves.

The basic recommendations of the Committee were accepted by the Government in 1977, which led to the launching of the Rural Health Scheme. The programme of training of community health workers was initiated during 1977–78. Steps were also initiated (a) for involvement of medical colleges in the total health care of selected PHCs with the objective of reorienting medical education to the needs of rural people; and (b) reorientation training of multipurpose workers engaged in the control of various communicable disease programmes into unipurpose workers. This "Plan of Action" was adopted by the Joint Meeting of the Central Council of Health and Central Family Planning Council held in New Delhi in April 1976 *(22)*.

10. Health for all by 2000 AD – Report of the working group, 1981 *(23, 24)*

A working group on Health was constituted by the Planning Commission in 1980 with the Secretary, Ministry of Health and Family Welfare, as its Chairman, to identify, in programme terms, the goal for Health for All by 2000 AD and to outline with that perspective, the specific programmes for the sixth Five Year Plan.

The Working Group, besides identifying and setting out the broad approach to health planning during the sixth Five Year Plan, had also evolved fairly specific indices and targets to be achieved in the country by 2000 AD.

PLANNING COMMISSION

The Government of India set up a Planning Commission in 1950 to make an assessment of the material, capital and human resources of the country, and to draft developmental plans for the most effective utilization of these resources. In 1957, the Planning Commission was provided with a Perspective Planning Division which makes projections into the future over a period of 20 to 25 years. The Planning Commission consists of a Chairman, Deputy Chairman and 5 members. The Planning Commission works through 3 major divisions – Programme Advisers, General Secretariat and Technical Divisions which are responsible for scrutinizing and analyzing various schemes and projects to be incorporated in the Five Year Plans. Over the years, the Planning Commission has been formulating successive Five Year Plans. By its terms of reference, the Planning Commission also reviews from time to time the progress made in various directions and to make recommendations to Government on problems and policies relevant to the pursuit of rapid and balanced economic development. The planning process was decentralised towards Decentralised District Planning by the year 2000.

NITI AAYOG

Government of India has established NITI Aayog (National Institution for Transforming India) to replace Planning Commission on 1st January 2015. It will seek to provide a critical directional and strategic input into the development process. NITI Aayog will emerge as a "think-tank" that will provide Governments at the central and state levels with relevant strategic and technical advice across the spectrum of key elements of policy. In addition, the NITI Aayog will monitor and evaluate the implementation of programmes, and focus on technology upgradation and capacity building.

HEALTH SECTOR PLANNING

Since "health" is an important contributory factor in the utilization of manpower, the Planning Commission gave considerable importance to health programmes in the Five Year Plans. For purposes of planning, the health sector has been divided into the following sub-sectors *(25)*.

(1) Water supply and sanitation
(2) Control of communicable diseases
(3) Medical education, training and research
(4) Medical care including hospitals, dispensaries and primary health centres
(5) Public health services
(6) Family planning; and
(7) Indigenous systems of medicine

All the above sub-sectors have received due consideration in the Five Year Plans. However, the emphasis has changed from Plan to Plan depending upon the felt–needs of the people and technical considerations. To give effect to a better coordination between the Centre and State Governments, a Bureau of Planning was constituted in 1965 in the Ministry of Health, Govt. of India. The main function of this Bureau is compilation of National Health Five Year Plans. The Health Plan is implemented at various levels, e.g., Centre, State, District, Block and Village.

FIVE YEAR PLANS *(26, 27, 28)*

The five year plans were conceived to re-build rural India, to lay the foundations of industrial progress and to secure the balanced development of all parts of the country. Recognising "health" as an important contributory factor in the utilisation of manpower and the uplifting of the economic condition of the country, the Planning Commission gave considerable importance to health programmes in the five year plans. The broad objectives of the health programmes during the five year plans have been :

(1) Control or eradication of major communicable diseases;
(2) Strengthening of the basic health services through the establishment of primary health centres and subcentres;
(3) population control; and
(4) development of health manpower resources.

Twelfth Five Year Plan (2012–2017)

The health of a nation is an essential component of development, vital to the nation's economic growth and internal stability. Assuring a minimal level of health care to the population is a critical constitutent of the development process.

Since independence, India has built up a vast health infrastructure and health personnel at primary, secondary and tertiary care in public, voluntary, and private sectors. For producing skilled human resources, a number of medical and paramedical institutions including Ayurveda, Yoga and Naturopathy, Unani, Siddha and Homeopathy (AYUSH) institutions have been set up.

Considerable achievements have been made over the last six decades in the efforts to improve health standards, such as life expectancy, child mortality, infant mortality, and maternal mortality. Smallpox, guineaworm, poliomyelitis have been eradicated. Nevertheless, problems abound. Malnutrition affects a large proportion of children. An unacceptably high proportion of the population continues to suffer and die from new diseases that are emerging; apart from continuing and new threats posed by the existing ones. Pregnancy and childbirth related complications also contribute to the suffering and mortality.

The strong link between poverty and ill-health needs to be recognized. The onset of a long and expensive illness can drive the non-poor into poverty. Ill health creates immense stress even among those who are financially secure. The country has to deal with rising costs of health care and growing expectations of the people. The challenge of quality health services in remote rural regions has to be urgently met. Given the magnitude of the problem, there is a need to transform public health care into an accountable, accessible, and affordable system of quality services during the Twelfth Five Year Plan.

The 12th Plan seeks to strengthen initiative taken in the 11th Plan to expand the reach of health care and work towards the long-term objective of establishing a system of Universal Health Coverage in the country. This means that each individual would have assured access to a defined essential range of medicines and treatment at an affordable price, which should be entirely free for a large percentage of the population. The High Level Expert Group (HLEG) has defined the Universal Health Coverage as "Ensuring equitable access for all Indian citizens in any part of the country, regardless of income level, social status, gender, caste or religion, to affordable, accountable and appropriate, assured quality health services (promotive, preventive, curative and rehabilitative) as well as services addressing wider determinants of health delivered to individuals and populations, with the government being the guarantor and enabler, although not necessarily the only provider of health and related services" *(29)*. This definition affirms that the system must be available for all who want it, though some, typically the upper income groups, may opt out.

In order to achieve health goals, the universal health coverage (UHC) must build on universal access to services that are determinants of health, such as safe drinking water and sanitation, wholesome nutrition, basic education, safe housing and hygienic environment. Therefore, it may be necessary to realise the goal of UHC in two parallel steps : (1) clinical services at different levels, defined in an Essential Health Package, which the government would finance and ensure provision through the public health system, supplemented by contracted-in private providers; (2) the universal provision of high impact, preventive and public health interventions which the government would universally provide within the 12th Five Year Period (as shown in Table 2). The UHC would take atleast two plan periods for realization.

Outcome Indicators for Twelfth Plan *(29)*

The Twelfth Plan will work towards national health outcome goals with following target health indicators :

1. *Reduction of Infant Mortality Rate (IMR) to 25 :* At the recent rate of decline of 5 per cent per year, India is projected to have an IMR of 36 by 2015 and 32 by 2017. An achievement of the MDG of reducing IMR to 27 by 2015 would require further acceleration of this historical rate of decline. If this accelerated rate is sustained, the country can achieve an IMR of 25 by 2017.

2. *Reduction of Maternal Mortality Ratio (MMR) to 100 :* At the recent rate of decline of 5.8 per cent per annum India is projected to have an MMR of 139 by 2015 and 123 by 2017. An achievement of the Millennium Development Goal (MDG) of reducing MMR to 109 by 2015 would require an accelerated rate of decline, the country can achieve an MMR of 100 by 2017.

TABLE 2

List of preventive and public health interventions funded and provided by government

1. Full immunization among children under three years of age, and pregnant women.
2. Full antenatal, natal and postnatal care.
3. Skilled birth attendance with a facility for meeting need for emergency obstetric care.
4. Iron and Folic acid supplementation for children, adolescent girls and pregnant women.
5. Regular treatment of intestinal worms, especially in children and reproductive age women.
6. Universal use of iodine and iron fortified salt.
7. Vitamin A supplementation for children aged 9 to 59 months.
8. Access to a basket of contraceptives, and safe abortion services.
9. Preventive and promotive health educational services, including information on hygiene, hand-washing, dental hygiene, use of potable drinking water, avoidance of tobacco, alcohol, high calorie diet and obesity, need for regular physical exercise, use of helmets on two-wheelers and seat belts; advice on initiation of breast-feeding within one hour of birth and exclusively upto six months of age, and complimentary feeding thereafter, adolescent sexual health, awareness about RTI/STI; need for screening for NCDs and common cancers for those at risk.
10. Home based newborn care, and encouragement for exclusive breast-feeding till six months of age.
11. Community based care for sick children, with referral of cases requiring higher levels of care.
12. HIV testing and counselling during antenatal care.
13. Free drugs to pregnant HIV positive mothers to prevent mother to child transmission of HIV.
14. Malaria prophylaxis, using Long Lasting Insecticide Treated Nets (LLIN), diagnosis using Rapid Diagnostic Kits (RDK), and appropriate treatment.
15. School check-up of health and wellness, followed by advice, and treatment if necessary.
16. Management of diarrhoea, especially in children, using Oral Rehydration Solution (ORS).
17. Diagnosis and treatment of Tuberculosis, Leprosy including Drug and Multi-Drug Resistant cases.
18. Vaccines for hepatitis B and C for high risk groups.
19. Patient transport systems including emergency response ambulance services of the 'dial 108' model.

3. *Reduction of Total Fertility Rate (TFR) to 2.1 :* India is on track for the achievement of a TFR target of 2.1 by 2017, which is necessary to achieve net replacement level of unity, and realise the long cherished goal of the National Health Policy, 1983 and National Population Policy of 2000.

4. *Prevention, and reduction of under-nutrition in children under 3 years to half of NFHS-3 (2005–06) levels :* Underweight children are at an increased risk of mortality and morbidity. At the current rate of decline, the prevalence of under-weight children is expected to be 29 per cent by 2015, and 27 per cent by 2017. An achievement of the MDG of reducing undernourished children under 3 years to 26 per cent by 2015 would require an acceleration of this historical rate of decline. The country needs to achieve a reduction in below 3 year child under-nutrition to half of 2005–06 (NFHS) levels by 2017. This particular health outcome has a very direct bearing on the broader commitment to security of life, as do MMR, IMR, anaemia and child sex ratio.

5. *Prevention and reduction of anaemia among women aged 15–19 years to 28 per cent :* Anaemia, an underlying determinant of material mortality and low birth weight, is preventable and treatable by a very simple intervention. The prevalence of anaemia needs to be steeply reduced to 28 per cent by the end of the twelfth plan.

6. *Raising child sex ratio in the 0–6 years age group from 914 to 950 :* Like anaemia, child sex ratio is another important indicator which has been showing a deteriorating trend, and needs to be targeted for priority attention.

7. *Prevention and reduction of burden of communicable and non-communicable diseases (including mental illnesses) and injuries :* State wise and national targets for each of these conditions will be set by the Ministry of Health and Family Welfare as robust systems are put in place to measure their burden. Broadly, the goals of communicable diseases shall be as indicated in Table 3.

8. *Reduction of poor household's out-of-pocket expenditure :* Out-of-pocket expenditure on health care is a burden on poor families, leads to impoverishment and is a regressive system of financing. Increase in public health spending to 1.87 per cent of GDP by the end of the twelfth plan, cost-free access to essential medicines in public facilities, regulatory measures proposed in the twelfth plan are likely to lead to increase in share of public spending. The twelfth plan measures will also aim to reduce out-of-pocket spending as a proportion of private spending on health.

TABLE 3

National health goals for communicable diseases

Disease	Twelfth plan goal
Tuberculosis	Reduce annual incidence and mortality by half
Leprosy	Reduce prevalence to <1/10,000 population and incidence to zero in all districts
Malaria	Annual malaria incidence of <1/1,000
Filariasis	<1 per cent microfilaria prevalence in all districts
Dengue	Sustaining case fatality rate of <1 per cent
Chikungunya	Containment of outbreaks
Japanese Encephalitis	Reduction in mortality by 30 per cent
Kala-azar	Elimination by 2015, that is, <1 case per 10,000 population in all blocks
HIV/AIDS	Reduce new infections to zero and provide comprehensive care and support to all persons living with HIV/AIDS and treatment services for all those who require it.

The achievements during the past 60 years of planned development are given in Table 4.

TABLE 4
Achievements during the plan periods

	1st Plan 1951–56	12th Plan 2012–2017
1. Primary Health Centres	725	25,020
2. Subcentres	NA	152,326
3. Community health centres	–	5,363
4. Total beds (2002)	125,000	914,543
5. Medical colleges	42	356
6. Annual admissions in medical colleges	3,500	41,569
7. Dental colleges	7	297
8. Allopathic doctors	65,000	918,303
9. Nurses	18,500	1,237,964
10. ANMs	12,780	602,919
11. Health visitors	578	52,653
12. Health Workers (F) (in position)	–	217,780
13. Health Workers (M) (in position)	–	55,445
14. Block Extension Educator	–	2,904
15. Health Assistant (M) (in position)	–	10,358
16. Health Assistant (F)/LHV (in position)	–	13,643
17. Village Health Guides	–	323,000

Table 5 shows the investments in health and Family Welfare Programmes during different plan periods.

HEALTH SYSTEM IN INDIA

India is a Union of 29 States and 7 Union territories. Under the Constitution of India, the States are largely independent in matters relating to the delivery of health care to the people. Each State, therefore, has developed its own system of health care delivery, independent of the Central Government. The Central responsibility consists mainly of policy making, planning, guiding, assisting, evaluating, and coordinating the work of the State Health Ministries, so that health services cover every part of the country, and no State lags behind for want of these services. The health system in India has 3 main links, i.e., Central, State and Local or peripheral.

I – AT THE CENTRE

The official "organs" of the health system at the national level consist of : (1) The Ministry of Health and Family Welfare; (2) The Directorate General of Health Services; and (3) The Central Council of Health and Family Welfare.

1. Union Ministry of Health and Family Welfare

(1) ORGANIZATION

The Union Ministry of Health and Family Welfare is headed by a Cabinet Minister, a Minister of State and a Deputy Health Minister. These are political appointments. Currently, the Union Health Ministry has the following departments: (1) Department of Health and (2) Department of Family Welfare. The Health Department is headed by a Secretary to the Government of India as its executive head, assisted by joint secretaries, deputy secretaries and a large administrative staff. The Department of Family Welfare was created in 1966 within the Ministry of Health and Family Welfare. The Secretary to the Govt. of India in the Ministry of Health and Family Welfare is in overall charge of the Department of Family Welfare. He is assisted by an Additional Secretary & Commissioner (Family Welfare), and one Joint Secretary.

(2) FUNCTIONS

The functions of the Union Health Ministry are set out in the seventh schedule of Article 246 of the Constitution of India under (a) the Union list and (b) the Concurrent list.

(a) Union list: The functions given in the Union list are: (1) International health relations and administration of port quarantine (2) Administration of central institutes such as the All India Institute of Hygiene and Public Health, Kolkata; National Institute for the Control of Communicable Diseases, Delhi, etc. (3) Promotion of research through research centres and other bodies (4) Regulation and development of medical, pharmaceutical, dental and nursing professions (5) Establishment and maintenance of drug standards (6) Census, and collection and publication of

TABLE 5
Investment in different plan periods (in Rs. Crores)

Period	Total plan Investment	Health	Family Welfare	Water supply & sanitation
I Plan (1951–56)	1960.00	65.20	0.1	NA
II Plan (1956–61)	4672.00	140.80	2.20	NA
III Plan (1961–66)	8576.00	225.00	24.90	10.70
Annual Plans (1966–69)	6625.40	140.20	70.50	102.70
IV Plan (1969–74)	15,778.80	335.50	284.40	458.90
V Plan (1974–79)	39,322.00	682.00	497.40	971.00
1979–80 Outlay	11,650.00	268.20	116.20	429.50
VI Plan (1980–85)	97,500.00	1,821.05	1,010.00	3,922.02
VII Plan (1985–90)	180,000.00	3,392.89	3,256.26	6,522.47
Annual Plan (1990–91)	61,518.10	960.90	784.90	1,876.80
Annual Plan (1991–92)	72,316.80	1,185.50	749.00	2,514.40
VIII Plan (1992–97)	798,000.00	7,575.92	6,500.00	16,711.03
IX Plan (1997–02)	859,200.00	10,818.40	15,120.20	–
X Plan (2002–07)	1,484,131.30	31,020.30	27,125.00	–

other statistical data (7) Immigration and emigration (8) Regulation of labour in the working of mines and oil fields and (9) Coordination with States and with other ministries for promotion of health.

(b) Concurrent list: The functions listed under the concurrent list are the responsibility of both the Union and State governments. The Centre and the States have simultaneous powers of legislation; the powers of the latter are restricted to the framework of such legislation as may be undertaken by the Centre. The concurrent list includes: (1) Prevention of extension of communicable diseases from one unit to another (2) Prevention of adulteration of foodstuffs (3) Control of drugs and poisons (4) Vital statistics (5) Labour welfare (6) Ports other than major (7) Economic and social planning, and (8) Population control and Family Planning.

2. Directorate General of Health Services

(a) ORGANIZATION : The Director General of Health Services is the principal adviser to the Union Government in both medical and public health matters. He is assisted by an additional Director General of Health Services, a team of deputies and a large administrative staff. The Directorate comprises of three main units, e.g., medical care and hospitals, public health and general administration.

(b) FUNCTIONS: The GENERAL functions are surveys, planning, coordination, programming and appraisal of all health matters in the country. The SPECIFIC functions are (1) International health relations and quarantine: All the major ports in the country (Kolkata, Visakhapatnam, Chennai, Cochin, Mumbai, Kandla) and international air ports (Mumbai–Santa Cruz, Kolkata–Dum Dum, Chennai–Meenambakkam, Tiruchirapalli, Delhi–Palam) are directly controlled by the Directorate General of Health Services. All matters relating to the obtaining of assistance from International agencies and the coordination of their activities in the country are undertaken by the Directorate General of Health Services. (2) Control of drug standards: The Drugs Control Organization is part of the Directorate General of Health Services, and is headed by the Drugs Controller. Its primary function is to lay down and enforce standards and control the manufacture and distribution of drugs through both Central and State Government Officers. The Drugs Act (1940) vests the Central Government with the powers to test the quality of imported drugs (3) Medical store depots: The Union Government runs medical store depots at Mumbai, Chennai, Kolkata, Karnal, Gauwahati and Hyderabad. These depots supply the civil medical requirements of the Central Government and of the various State Governments. These depots also handle supplies from foreign agencies. The Medical Stores Organization endeavours to ensure the highest quality, cheaper bargain and prompt supplies. (4) Post graduate training: The Directorate General of Health Services is responsible for the administration of national institutes, which also provide post–graduate training to different categories of health personnel. Some of these institutes are :– the All India Institute of Hygiene and Public Health at Kolkata, All India Institute of Mental Health at Bangalore, College of Nursing at Delhi, National Tuberculosis Institute at Bangalore, National Institute of Communicable Diseases at Delhi, Central Research Institute at Kasauli, National Institute of Health and Family Welfare at Delhi, etc. (5) Medical education: The Central Directorate is directly in charge of the following medical colleges in India: the Lady Hardinge, the Maulana Azad and the medical colleges at Puducherry, and Goa. Besides these, there are many medical colleges in the country which are guided and supported by the Centre. (6) Medical Research : Medical Research in the country is organised largely through the Indian Council of Medical Research, founded in 1911 in New Delhi. The Council plays a significant role in aiding, promoting and coordinating scientific research on human diseases, their causation, prevention and cure. The research work is done through the Council's several permanent research institutes, research units, field surveys and a large number of ad-hoc research enquiries financed by the Council. It maintains Cancer Research Centre, Tuberculosis Chemotherapy Centre at Chennai, Virus Research Centre at Poona, National Institute of Nutrition at Hyderabad and Blood Group Reference Centre at Mumbai. The funds of the Council are wholly derived from the budget of the Union Ministry of Health. (7) Central Govt. Health Scheme: (8) National Health Programmes: The various national health programmes for the eradication of malaria and for the control of tuberculosis, filaria, leprosy, AIDS and other communicable diseases involve expenditure of crores of rupees. Health programmes of this kind can hardly succeed without the help of the Central Government. The Central Directorate plays a very important part in planning, guiding and coordinating all the national health programmes in the country. (9) Central Health Education Bureau: An outstanding activity of this Bureau is the preparation of education material for creating health awareness among the people. The Bureau offers training courses in health education to different categories of health workers. (10) Health Intelligence: The Central Bureau of Health Intelligence was established in 1961 to centralise collection, compilation, analysis, evaluation and dissemination of all information on health statistics for the nation as a whole. It disseminates epidemic intelligence to States and international bodies. The Bureau has an Epidemiological Unit, a Health Economics Unit, a National Morbidity Survey Unit and a Manpower Cell. (11) National Medical Library: The Central Medical Library of the Directorate General Health Services was declared the National Medical Library in 1966. The aim is to help in the advancement of medical, health and related sciences by collection, dissemination and exchange of information.

3. Central Council of Health

A large number of health subjects fall in the Concurrent list which calls for continuous consultation, mutual understanding and cooperation between the Centre and the States. The Central Council of Health was set up by a Presidential Order on 9 August, 1952 under Article 263 of the Constitution of India for promoting coordinated and concerted action between the Centre and the States in the implementation of all the programmes and measures pertaining to the health of the nation. The Union Health Minister is the Chairman and the State Health Ministers are the members.

FUNCTIONS : The functions of the Central Council of Health are: (1) To consider and recommend broad outlines of policy in regard to matters concerning health in all its aspects such as the provision of remedial and preventive care, environmental hygiene, nutrition, health education and the promotion of facilities for training and research. (2) To make proposals for legislation in fields of activity relating to medical and public health matters and to lay down the pattern of development for the country as a whole. (3) To make recommendations to the Central Government

regarding distribution of available grants-in-aid for health purposes to the States and to review periodically the work accomplished in different areas through the utilisation of these grants-in-aid. (4) To establish any organisation or organisations invested with appropriate functions for promoting and maintaining cooperation between the Central and State Health administrations.

II – AT THE STATE LEVEL

Historically, the first milestone in State health administration was the year 1919, when the States (then known as provinces) obtained autonomy, under the Montague–Chelmsford reforms, from the Central Government, in matters of public health. By 1921–22, all the States had created some form of public health organization. The Government of India Act, 1935 gave further autonomy to the States. The health subjects were divided into three groups: federal, concurrent and state. The "state" list which became the responsibility of the State included provision of medical care, preventive health services and pilgrimages within the State. The position has largely remained the same, even after the new Constitution of India came into force in 1950. The State is the ultimate authority responsible for all the health services operating within its jurisdiction.

State health administration

At present there are 29 States in India, with each state having its own health administration. In all the States, the management sector comprises the State Ministry of Health and a Directorate of Health.

1. State Ministry of Health

The State Ministry of Health is headed by a Minister of Health and Family Welfare and a Deputy Minister of Health and Family Welfare. In some States, the Health Minister is also in charge of other portfolios. The Health Secretariat is the official organ of the State Ministry of Health and is headed by a Secretary who is assisted by Deputy Secretaries, Under Secretaries and a large administrative staff. The Secretary is a senior officer of the Indian Administrative Service. The Bhore Committee (1946) recommended that the Director of Health Services should also be Secretary to the State Government to facilitate administration, but this recommendation has not been implemented.

2. State Health Directorate

For a long time, two separate departments, medical and public health, were functioning in the States; the heads of these departments were known as Surgeon General and Inspector General of Civil Hospitals and Director of Public Health respectively. The Bhore Committee (1946) recommended that the medical and public health organizations should be integrated at all levels and therefore, should have a single administrative officer for the curative and preventive departments of health. West Bengal led the process of integrating health services at the State level by creating a post of the Director of Health Services in August 1947; the process was completed by Maharashtra in May 1970.

The Director of Health Services (known in some States as Director of Medical and Health Services) is the chief technical adviser to the State Government on all matters relating to medicine and public health. He is also responsible for the organization and direction of all health activities. With the advent of family planning as an important programme, the designation of Director of Health Services has been changed in some States and is now known as Director of Health and Family Welfare. A recent development in some States is the appointment of a *Director of Medical Education* in view of the increasing number of medical colleges. Some experts feel that there is no justification for the removal of medical education from general health services under the Director of Health Services. The health services and training institutions should develop into one logical whole designed to an end – the protection of the health of the people.

The Director of Health and Family Welfare is assisted by a suitable number of deputies and assistants. The Deputy and Assistant Directors of Health may be of two types – regional and functional. The Regional Directors inspect all the branches of public health within their jurisdiction, irrespective of their speciality. The Functional Directors are usually specialists in a particular branch of public health such as mother and child health, family planning, nutrition, tuberculosis, leprosy, health education etc. The Public Health Engineering Organization in most States is part of the Public Works Department of the State Government. It has been recommended by experts in the public health that the public health engineering organization in every State should be part of the State Health Department, and that the Chief Engineer of Public Health should have the status of an Additional Director of Health Services.

III – AT THE DISTRICT LEVEL

The District

The principal unit of administration in India is the district under a Collector. There are 614 (year 2007) districts in India. There is no "average" district, that is the districts vary widely in area and population. Within each district again, there are 6 types of administrative areas

1. Sub–divisions
2. Tahsils (Talukas)
3. Community Development Blocks
4. Municipalities and Corporations
5. Villages
6. Panchayats

Most districts in India are divided into two or more sub-divisions, each in charge of an Assistant Collector or sub-Collector. Each division is again divided into tahsils (taluks), in charge of a Tahsildar. A tahsil usually comprises between 200 to 600 villages. Since the launching of the Community Development Programme in India in 1952, the rural areas of the district have been organized into Blocks, known as Community development blocks, the area of which may or may not coincide with a tahsil. The block is a unit of rural planning and development, and comprises approximately 100 villages and about 80,000 to 1,20,000 population, in charge of a Block Development Officer. Finally there are the village panchayats, which are institutions of rural local self–government.

The urban areas of the district are organized into the following institutions of local self–government :

1. Town area committees – (in areas with population ranging between 5,000 and 10,000)
2. Municipal Boards – (in areas with population ranging between 10,000 and 2 lakhs)
3. Corporations – (with population above 2 lakhs)

The Town area committees are like panchayats. They provide sanitary services. The Municipal Boards are headed by a Chairman/President, elected usually by the members. The term of a Municipal Board ranges between 3–5 years. The functions of a municipal board are: construction and maintenance of roads, sanitation and drainage, street lighting, water supply, maintenance of hospitals and dispensaries, education, registration of births and deaths, etc. Corporations are headed by Mayors. The councillors are elected from different wards of the city. The executive agency includes the Commissioner, the Secretary, the Engineer and the Health Officer. The activities are similar to those of the municipalities, but on a much wider scale.

Health organization

The Bhore Committee (1946) recommended integrated preventive and curative services at all levels and the setting up of a unified health authority in each district. Subsequent expert committees, appointed by the Government of India have also recommended the same. Since "health" is a state subject, there is no uniform "model" of a district health organization in India, each State developed its own pattern to suit its policy and convenience.

Under the Multi–Purpose Workers Scheme, it has been suggested to the States to have an integrated set-up at the district level by having a Chief Medical Officer with three Deputy CMOs (existing Civil Surgeons, District Health Officers and District Family Welfare Officers) with each of the Dy. CMOs being incharge of one-third of the district for all the Health, Family Welfare and MCH programmes. The recent Working Group on Health for All by 2000 AD, appointed by the Planning Commission, recommended that the District Hospitals should be converted into District Health Centres, each centre monitoring all preventive, promotive and curative services of one million population. It has been recommended that the district set-up should be reorganized on the basis of the number of primary health centres it comprises *(23)*.

PANCHAYATI RAJ *(32, 33)*

The Panchayati Raj is a 3–tier structure of rural local self–government in India, linking the village to the district. The three institutions are:

(1) *Panchayat* – at the village level

(2) *Panchayat Samiti* – at the block level

(3) *Zilla Parishad* – at the district level

The Panchayati Raj institutions are accepted as agencies of public welfare. All development programmes are channelled through these bodies. The Panchayati Raj institutions strengthen democracy at its root, and ensure more effective and better participation of the people in the government.

1. At the Village level

The Panchayati Raj at the village level consists of:

(i) the Gram Sabha

(ii) the Gram Panchayat and

(iii) the Nyaya Panchayat

Gram Sabha : It is the assembly of all the adults of the village, which meets at least twice a year. The gram sabha considers proposals for taxation, discusses the annual programme and elects members of the gram panchayat.

Gram Panchayat : It is the executive organ of the gram sabha, and an agency for planning and development at the village level. Its strength varies from 15 to 30, and the population covered also varies widely from 5,000 to 15,000 or more. The members of the panchayat hold office for a period of 3 to 4 years. Every panchayat has an elected President (Sarpanch or Sabhapati or Mukhiya), a Vice–President and a Panchayat Secretary. The powers and functions of the Panchayat Secretary are very wide – they cover the entire field of civic administration, including sanitation and public health; and of social and economic development of the village.

2. At the Block level

The block consists of about 100 villages and a population of about 80,000 to 1,20,000. The Panchayati Raj agency at the block level is the Panchayat Samiti / Janpada Panchayat. The Panchayat Samiti consists of all Sarpanchas (heads) of the village panchayats in the Block; MLAs, MPs residing in the block area; representatives of women, scheduled castes, scheduled tribes and cooperative societies. The Block Development Officer (BDO) is the ex-officio secretary of the Panchayat Samiti. The prime function of the Panchayat Samiti is the execution of the community development programme in the block, The funds provided by the Government for Stage I and Stage II development are channelled through the Panchayat Samiti. The Block Development Officer and his staff give technical assistance and guidance to the village panchayats engaged in development work.

3. At the District level

The Zilla Parishad / Zilla Panchayat is the agency of rural local self-government at the district level. The members of the Zila Parishad include all heads of the Panchayat Samitis in the district; MPs, MLAs of the district; representatives of scheduled castes, scheduled tribes and women; and 2 persons of experience in administration, public life or rural development. The Collector of the district is a non-voting member. Thus, the membership of the Zilla Parishad is fairly large varying from 40 to 70.

The Zilla Parishad is primarily supervisory and coordinating body. Its functions and powers vary from state to state. In some states, the Zilla Parishads are vested with administrative functions. In Gujarat, the District Health Officer and the District Family Planning and MCH Officers are under the control of the Zilla Parishad.

RURAL DEVELOPMENT

Terms such as village improvement, rural upliftment, rural reconstruction and community development have been in vogue for many years to denote certain aspects of rural development. It is only during the last four decades that they have become comprehensive in content.

Community Development Programme

Community development was defined as "a process designed to create conditions of economic and social progress for the whole community with its active participation and the fullest possible reliance upon the community's initiative" *(34)*. The United Nations defined community development as "the process by which the efforts of the people themselves are united with those of governmental authorities to improve the economic, social and cultural conditions of communities, to integrate those

communities with the life of the nation and to enable them to contribute fully to national progress" *(33)*.

A beginning was made in India in 1952 during the First Five Year Plan to involve the rural population in the process of planning their own welfare measures. A Programme known as the Community Development Programme was launched on 2nd October 1952 for the all-round development of the rural areas, where nearly 72 per cent of India's population live. The programme was hailed as a programme "of the people, for the people, by the people" to exterminate the three ills of poverty, disease and illiteracy.

Under the Community Development Programme, the rural areas of the country have been organized into Community Development Blocks – each Block comprising approximately 100 villages and a population of one lakh. There are about 6,000 Community Development Blocks in the country, each Block is headed by a Block Development Officer. Over the years, the CD Block has emerged as a permanent unit of rural planning and development.

The Community Development Programme was envisaged as a multipurpose programme covering the following main activities – improvement of agriculture, improvement of communications, education, health and sanitation (through the establishment of primary health centres and sub-centres), improvement of housing through self-help, social welfare and training in rural arts, crafts and industries to local people.

Each Block passed through two stages of development – Stage I of 5 years intensive development followed by Stage II of another 5 years. The Central Government supported the programme substantially by providing funds to the tune of Rs.12 lakhs during Stage I and Rs.5 lakhs during Stage II phases of development. At the end of 10 years, the Blocks entered post–stage II phase and their financial arrangements became the responsibility of the State Governments. The Block continues to be the permanent infrastructure for rural planning and development.

Although the Community Development Programme has made its own contribution to rural development, it has not succeeded in bringing about an all–round improvement in rural areas and in eliminating rural poverty and unemployment. The hope that people would unite their efforts with those of the Government to build the village community on a pattern in which disparities in income and wealth would disappear was not realised. In fact, the benefits of the programme did not reach the weaker sections of the community.

Integrated Rural Development Programme (IRDP)

Another innovation in the continuous search for appropriate strategies to attack poverty is the IRDP. It was launched in April 1978 to eliminate rural poverty and improve the quality of life of the rural poor. The target families are generally agricultural labourers, small cultivators, village artisans and craftsmen. They are provided with resources and skills, bank loans and subsidies by the government. The IRDP is being implemented through District Rural Development Agency (DRDA).

During Ninth Five Year Plan it was implemented through an integrated approach under which the existing schemes of Training of Rural Youth for Self Employment (TRYSEM) and Supply of Improved Toolkits to Rural Artisans (SITRA), Development of Women and Children in Rural Areas (DWCRA) and Ganga Kalyan Yojana (GKY) were merged in to IRDP. There will be a strategic shift from an individual beneficiary approach to formation of Self-Help Groups. This approach will focus on the identification of few specified viable activities based on the local resources and occupational skills of the people of that area.

The Village Level Worker

The village level worker (gram sevak) is the key person responsible for transforming the economic and social life of the people. Each gram sevak is in charge of 10 villages and attends to 5 or 6 thousand people. He lives with the people and keeps in close touch with them and their families. He probes into their "felt-needs" and seeks to arouse in them interest in all-round family and village development. In short, he functions as a multi-purpose worker and a link between the people and governmental agencies.

EVALUATION OF HEALTH SERVICES

Health services have become complex. There has been a growing concern about their functioning both in the developed and developing countries. Questions are raised about the quality of medical care *(35)*, utilization and coverage of health services *(36)*, benefits to community health in terms of morbidity and mortality reduction *(37)* and improvement in the health status of the recipients of care. An evaluation study addresses itself to these issues.

General steps of evaluation

The basic steps involved are as follows :

1. Determine what is to be evaluated
2. Establish standards and criteria
3. Plan the methodology to be applied
4. Gather information
5. Analyze the results
6. Take action
7. Re-evaluate

1. Determine what is to be evaluated

Generally speaking, there are three types of evaluation : **(a) Evaluation of "structure":** This is evaluation of whether facilities, equipment, manpower and organization meet a standard accepted by experts as good. **(b) Evaluation of "process":** The process of medical care includes the problems of recognition, diagnostic procedures, treatment and clinical management, care and prevention. The way in which the various activities of the programme is carried out is evaluated by comparing with a predetermined standard. An objective and systematic way of evaluating the physician (or nurse) performance is known as "Medical (or nursing) Audit" *(38)*. **(c) Evaluation of "outcome":** This is concerned with the end results, that is, whether persons using health services experience measurable benefits such as improved survival or reduced disability. The traditional outcome components are the "5 Ds" of ill-health, viz. disease, discomfort, dissatisfaction, disability and death.

2. Establishment of standards and criteria

Standards and criteria must be established to determine how well the desired objectives have been attained. Naturally such standards are a prerequisite for evaluation. Standards and criteria must be developed in accordance with the focus of *evaluation–structural criteria* : e.g., physical facilities and equipment; process criteria: e.g., every prenatal

mother must receive 6 check-ups; every laboratory technician must examine 100 blood smears, etc; outcome criteria: e.g., alterations in patient health status (cured, death, disability); or behaviour resulting from health care (satisfaction, dissatisfaction); or the educational process (e.g., cessation of smoking, acceptance of a small family norm), etc.

3. Planning the methodology

A format in keeping with the purpose of evaluation must be prepared for gathering information desired. Standards and criteria must be included at the planning stage.

4. Gathering information

Evaluation requires collection of data or information. The type of information required may include political, cultural, economic, environmental and administrative factors influencing the health situation as well as mortality and morbidity statistics. It may also concern health and related socio-economic policies, plans and programmes as well as the extent, scope and use of health systems, services and institutions *(39)*. The amount of data required will depend on the purpose and use of the evaluation.

5. Analysis of results

The analysis and interpretation of data and feedback to all individuals concerned should take place within the shortest time feasible, once information has been gathered. In addition, opportunities should be provided for discussing the evaluation results.

6. Taking action

For evaluation to be truly productive, emphasis should be placed on actions – actions designed to support, strengthen or otherwise modify the services involved. This may also call for shifting priorities, revising objectives, or development of new programmes or services to meet previously unidentified needs.

7. Re-evaluation

Evaluation is an on-going process aimed mainly at rendering health activities more relevant, more efficient and more effective.

Elements of evaluation

Evaluation is perhaps the most difficult task in the whole area of health services. The components of the evaluation process are:

(a) Relevance: Relevance or requisiteness relates to the appropriateness of the service, whether it is needed at all *(40)*. If there is no need, the service can hardly be of any value. For example, vaccination against smallpox is now irrelevant because the disease no longer exists.

(b) Adequacy: It implies that sufficient attention has been paid to certain previously determined courses of action. For example, the staff allocated to a certain programme may be described as inadequate if sufficient attention was not paid to the quantum of work-load and targets to be achieved.

(c) Accessibility: It is the proportion of the given population that can be expected to use a specified facility, service, etc. The barriers to accessibility may be physical (e.g., distance, travel, time); economic (e.g., travel cost, fee charged); or social and cultural (e.g., caste or language barrier) *(41)*.

(d) Acceptability: The service provided may be accessible, but not acceptable to all, e.g., male sterilization, screening for rectal cancer *(42)*.

(e) Effectiveness: It is the extent to which the underlying problem is prevented or alleviated. Thus it measures the degree of attainment of the predetermined objectives and targets of the programme, service or institution – expressed, if possible, in terms of health benefits, problem reduction or an improvement of an unsatisfactory health situation. The ultimate measures of effectiveness will be the reduction in morbidity and mortality rates. *(45)*.

(f) Efficiency: It is a measure of how well resources (money, men, material and time) are utilized to achieve a given effectiveness. The following examples will illustrate: the number of immunizations provided in an year as compared with an accepted norm; the percentage of bed occupancy, cost per day in hospital, cost per patient treated, etc *(43, 44, 45)*.

(g) Impact: It is an expression of the overall effect of a programme, services or institution on health status and socio-economic development. For example, as a result of malaria control in India, not only the incidence of malaria dropped down, but all aspects of life–agricultural, industrial and social-showed an improvement. If the target of 100 per cent immunization has been reached, it must also lead to reduction in the incidence or elimination of vaccine–preventable diseases. If the target of village water supply has been reached, it must also lead to a reduction in the incidence of diarrhoeal diseases.

Planning and evaluating must be viewed as a continuous interactive process, leading to continual modification both of objectives and plans. Successful evaluation may also depend upon whether the means of evaluation were built into the design of the programme before it was implemented *(46)*.

HISTORY OF PUBLIC HEALTH IN INDIA

1. Early History

India has one of the most ancient civilizations in recorded history. Thousands of years before the Christian era, there existed a civilization in the Indus Valley, known as the Indus Valley Civilization. Excavations in the Indus Valley (e.g., Mohenjodaro and Harappa), showed relics of planned cities with drainage, houses and public baths built of baked bricks suggesting the practices of environmental sanitation, by ancient people as far back as 3,000 B.C. India was invaded by the Aryans around 1,400 B.C. It was probably during this period, the Ayurveda and the Siddha systems of medicine came into existence. Ayurveda or the Science of Life developed a comprehensive concept of health. The Manu Samhita prescribed rules and regulations for personal health, dietetics and hygienic ritual at the time of birth and death, and also emphasised the unity of the physical, mental and spiritual aspects of life *(47)*. Sarve Jana Sukhino Bhavatu (May all men be free from disease and may all be healthy) was an ancient saying of the Indian sages. This concept of happiness has its roots in the ancient Indian philosophy of life, which conceived the oneness and unity of all people, wherever they lived.

The Post-Vedic period (600 B.C.–600 A.D.) was dominated by the religious teachings of Buddhism and Jainism. Medical education was introduced in the ancient universities of Taxila and Nalanda, leading to the titles of

Pranacharya and Pranavishara *(47)*. A hospital system was developed during the reign of Rahula Sankirtyana (son of the Buddha) for men, women and animals and the system was continued and expanded by King Ashoka.

The next phase in Indian history (650–1850 A.D.) witnessed the rise and fall of the Moghul empire The Muslim rulers introduced into India around 1,000 A.D. the Arabic system of medicine, popularly known as the Unani system, the origin of which is traced to Greek medicine. The Unani system since then became part of Indian medicine. With changes in the political conditions in India, the torch which was lighted thousands of years ago by the ancient sages grew dim, medical education and medical services became static, and the ancient universities and hospitals disappeared.

2. Public Health in British India *(14, 15, 47, 48, 49)*

By the middle of the 18th Century, the British had established their rule in India which lasted till 1947. The significant events in the history of public health during this period are given below in chronological order :

1757 The British had established their rule in India. The civil and military services were established.

1825 The Quarantine Act was promulgated.

1859 A Royal Commission was appointed to investigate the causes of the extremely unsatisfactory condition of health in the British Army stationed in India. The Commission recommended the establishment of a 'Commission of Public Health' in each presidency and pointed out the need for the protection of water supplies, construction of drains and prevention of epidemics in the civil population for safeguarding the health of the British Army.

1864 Sanitary Commissioners were appointed in the three major provinces–Bombay, Madras and Bengal. The Civil Surgeons/District Medical Officers became ex-officio District Health Officers.

1869 A Public Health Commissioner and a Statistical Officer were appointed with the Government of India.

1873 A Birth and Death Registration Act was promulgated.

1880 The Vaccination Act was passed.

1881 The first Indian Factories Act was passed; the first all–India Census was taken.

1885 The Local Self–Government Act was passed; Local Bodies came into existence.

1888 The Government of India directed that sanitation should be looked after by the local bodies, but no local public health staff was created to look after sanitation.

1896 A severe epidemic of plague occurred in India which awakened the Government to the urgent need of improving public health. The Plague Commission was appointed.

1897 The Epidemic Diseases Act was promulgated.

1904 The Plague Commission in its report recommended the reorganisation and expansion of public health departments and establishment of laboratory facilities for research, and production of vaccines and sera.

1909 The Central Malaria Bureau was founded at Kasauli.

1911 The Indian Research Fund Association (now I.C.M.R.) was established for the promotion of research.

1912 The Government of India decided to help the local bodies with grants, and also sanctioned the appointment of Deputy Sanitary Commissioners and Health Officers.

1918 The Lady Reading Health School, Delhi was established. The Nutrition Research Laboratory was established at Coonoor.

1919 The Montague-Chelmsford Constitutional Reforms led to the transfer of public health, sanitation and vital statistics to the provinces under the control of an elected minister. This was the first step towards decentralisation of health administration in India.

1920–21 Municipality and Local Board Acts, containing legal provisions for the advancement of public health were passed in several provinces.

1930 The All India Institute of Hygiene and Public Health, Calcutta was established with aid from the Rockefeller Foundation. The Child Marriage Restraint Act (Sarda Act) came into effect fixing the minimum age of marriage at 14 for girls and 18 for boys.

1931 A Maternity and Child Welfare Bureau was established under the Indian Red Cross Society.

1935 The Government of India Act, 1935 revitalised the 1919 Act, giving greater autonomy to the provinces. All the health activities in the country were grouped in three lists–federal, concurrent and provincial under the control of Central, Central–cum–Provincial and Provincial Governments respectively.

1937 The Central Advisory Board of Health was set up with the Public Health Commissioner as Secretary and representatives from the provinces and Indian States as members, to coordinate the public health activities in the country.

1939 The Madras Public Health Act was passed, which was the first of its kind in India; the first Rural Health Training Centre was established at Singur, near Calcutta with aid from the Rockefeller Foundation; the Tuberculosis Association of India was established.

1940 The Drugs Act was passed, and drugs were brought under control for the first time.

1943 The Health Survey and Development Committee (Bhore Committee) was appointed by the Government of India to survey the existing position in regard to health conditions and health organization in the country, and to make recommendations for the future development.

1946 The Bhore Committee submitted its report. The health of the nation was reviewed under (1) Public Health (2) Medical Relief (3) Professional Education (4) Medical Research and (5) International health. The Committee recommended a short term and a long-term programme for the attainment of reasonable health services based on concept of modern health practice.

3. Public Health in the Post-independence era

India became independent in 1947. For the first time in India's long history, a democratic regime was set up with its

economy geared to a new concept, the establishment of a "Welfare State". The burden of improving the health of the people, and widening the scope of health measures fell upon the national government. The Bhore Committee's report and recommendations became the basis for most of the planning and measures adopted by the national government. The significant events in the history of public health since India became free are as follows:

1947 Ministries of Health were established at the Centre and States. The posts of Director General, Indian Medical Service, and of Public Health Commissioner with the Government of India were integrated in the post of Director General of Health Services, who is the principal adviser to the Union Government on both medical and public health matters. This example was followed by many States. The posts of Surgeon General, the Director of Public Health and Inspector General of Hospitals were integrated in many States in the post of Director of Health Services.

1948 (1) India joined the World Health Organization as a member state (2) The Employees State Insurance Act, 1948 was passed (3) The report of the Environmental Hygiene Committee was published.

1949 (1) The Constituent Assembly adopted the Constitution of India on 26 November, 1949. Article 246 of the Constitution of India covers all the health subjects; these have been enumerated in the seventh schedule under three lists – Union List, Concurrent List and State List. Article 47 of the Constitution under the Directive Principles of State Policy states; "That the State shall regard the raising of the level of nutrition and the standard of living of its people and the improvement of public health as among its primary duties". (2) The post of Registrar General of India was created in the Ministry of Home Affairs (3) The South East Asia Regional Office of the W.H.O. was established in New Delhi (4) The Indian Research Fund Association was reconstituted into Indian Council of Medical Research.

1950 The Constitution of India came into force in 1950 and India became a Republic. The Planning Commission was set up by the Government of India, which set to work immediately for drafting the first Five Year Plan.

1951 The beginning of the first Five Year Plan, with a total outlay of Rs.2,356 crores. A sum of Rs.140 crores (5.9 per cent) was allotted for health programmes. The B.C.G. vaccination programme was launched in the country.

1952 (1) The Community Development Programme was launched on 2 October, 1952 for the all-round development of the rural areas. Provision of medical relief and preventive health services were part of the programme (2) The Central Council of Health was constituted with the Union Health Minister as Chairman and the Health Ministers of the States as members to coordinate health policies between the Central and State Governments. Primary health centres set up *(3)*.

1953 (1) The National Malaria Control Programme was commenced as part of the first Five Year Plan (2) The National Extension Service Programme was started in various States as a permanent organization for rural development (3) A nation-wide family planning programme was started. (4) A committee was appointed to draft a Model Public Health Act for the country.

1954 (1) Contributory Health Service Scheme (Central Government Health Scheme) was started at Delhi (2) The Central Social Welfare Board was set up (3) The National Water Supply and Sanitation Programme was inaugurated (4) The National Leprosy Control Programme was started (5) VDRL antigen production was set up in Calcutta (6) The Prevention of Food Adulteration Act was passed by Parliament.

1955 (1) The National Filaria Control Programme was commenced as part of the first Five Year Plan (2) The Central Leprosy Teaching and Research Institute was established at Chingelput, Madras (3) A Filaria Training Centre was established at Ernakulam, Kerala. (4) The Hindu Marriage Act prescribed the minimum age for marriage – 18 for boys and 15 for girls. (5) National TB sample survey commenced.

1956 (1) The Second Five Year Plan (1956–61) was launched with an outlay of Rs.4,800 crores, out of which Rs.225 crores (5.0 per cent) were earmarked for health programmes. (2) The Model Public Health Act was published. (3) The Central Health Education Bureau was established in the Union Health Ministry. (4) Director, Family Planning was appointed in the Union Health Ministry (5) The Demographic Training and Research Centre was established in Bombay. (6) The Tuberculosis Chemotherapy Centre was established in Madras (7) The Immoral Traffic Act was passed by Parliament (8) The Trachoma Control Pilot Project was established (9) The R.C.A projects were established by the Union Health Ministry with aid from the Ford Foundation.

1957 (1) Influenza pandemic swept the country (2) The Demographic Research Centres were established in Calcutta, Delhi and Trivandrum.

1958 (1) The National Malaria Control Programme was converted into National Malaria Eradication programme (2) The Leprosy Advisory Committee of the Government of India was constituted (3) The National Development Council endorsed the recommendations made by the Balwantrai Mehta Committee on Panchayati Raj. A three-tier structure of local self-governing bodies from the village to the district was recommended for dispersal of power and responsibilities in the future (4) The National TB Survey was completed.

1959 (1) The Mudaliar Committee was appointed by the Government of India to survey the progress made in the field of health since submission of the Bhore Committee's Report, and to make recommendations for future development and expansion of health services (2) A Central Expert Committee was appointed under the ICMR to study the problems of cholera and smallpox in India, which recommended measures for their eradication. (3) Rajasthan was the first State to introduce Panchayati Raj (4) The National Tuberculosis Institute at Bangalore was established. (5) The Nutrition Research Laboratory at Coonoor was shifted to Hyderabad.

1960 (1) The School Health Committee was constituted

by the Union Health Ministry to assess the present standards of health and nutrition of school children and suggest ways and means to improve them (2) A National Nutrition Advisory Committee was constituted to tender advice regarding the nutritional policies to be adopted by the Government. (3) Pilot projects for the eradication of smallpox were initiated (4) Vital statistics were transferred to the Registrar General of India, Ministry of Home Affairs, from the Directorate General Health Services.

1961 (1) The Third Five Year Plan (1961–66) was launched with an outlay of Rs.7,500 crores out of which Rs.342 crores (4.3 per cent) were provided for health programmes. (2) The Report of the Mudaliar Committee was published. (3) The Central Bureau of Health Intelligence was established.

1962 (1) The Central Family Planning Institute was established in Delhi by amalgamating the Family Planning Training Centre and Family Planning Communications and Action Research Centre. (2) The National Smallpox Eradication Programme was launched (3) The School Health Programme was initiated (4) The National Goitre control programme was launched (5) The District Tuberculosis Programme was formulated.

1963 (1) The Applied Nutrition Programme was launched by the Government of India with aid from UNICEF, FAO and WHO. (2) The Defence Institute of Physiology and Allied Sciences was set up. (3) The National Institute of Communicable Diseases (formerly Malaria Institute of India) was inaugurated. (4) The National Trachoma Control Programme was launched. (5) The name "Contributory Health Service Scheme" was changed to "Central Government Health Scheme". (6) Extended Family Planning Programme was launched; emphasis in family planning was shifted from the clinic approach to "Extension approach". (7) The Chadha Committee established a norm of one Basic Health Worker for every 10,000 population. (8) A Drinking Water Board was set up.

1964 (1) The National Institute of Health Administration and Education was opened in collaboration with the Ford Foundation. (2) A Committee was set up by the Union Government under the chairmanship of Shantilal Shah, to study the question for legalising abortions.

1965 (1) Director, ICMR, recommended Lippes Loop as safe and effective for a mass programme (2) Reinforced Extended Family Planning was launched (3) 'Direct' BCG vaccination without prior tuberculin test, on a house to house basis, was introduced.

1966 (1) A Committee of Health Secretaries under the Chairmanship of Mukherjee, Secretary, Ministry of Health, Government of India was constituted to look into the minimum additional staff required for the primary health centres to take over the maintenance work of malaria and smallpox (2) The Minister of Health was also appointed Minister for Family Planning (3) A separate department of Family Planning was constituted in the Union Ministry of Health to coordinate family planning programme at the Centre and States, (4) The population Council started the International Postpartum Family Planning Programme in 25 hospitals in 15 countries. Two of these hospitals were located in India – Delhi and Trivandrum.

1967 (1) The Modhok Committee was constituted to review the working of the National Malaria Eradication Programme and recommended measures for improvement (2) A Small Family Norm Committee was set up to recommend suitable incentives to those accepting the small family norm and practising family planning. (3) The Central Council of Health recommended the levy of a health cess on patients attending hospitals: (i) a minimum charge of 10 Paise per patient and (ii) a minimum charge of 25 paise per day of hospital stay.

1968 (1) The Small Family Committee's Report was submitted. (2) A Bill of Registration of Births and Deaths was passed by the Parliament. (3) The Govt. of India appointed the Medical Education Committee to study all aspects of medical education in the light of national needs and resources.

1969 (1) The Fourth Five Year Plan (1969–74) was launched with an outlay of Rupees 16,774 crores, out of which Rs.840 crores were allocated to health and Rupees 315 crores to family planning. (2) The name of the Nutrition Research Laboratories was changed to National Institute of Nutrition. (3) Comprehensive legislation for control of river water pollution from domestic and industrial wastes was drafted to be introduced into Parliament. (4) The Central Births and Deaths Registration Act (1969) was promulgated. (5) The Report of the Medical Education Committee (1969) was submitted. The Committee recommended (i) that the total period for MBBS course should be 41/2 years and one year for internship, which should include posting in a rural centre for a period of at least 3 months and (ii) the medical teaching and training should be oriented to produce a basic doctor. i.e., a doctor conversant with the basic health problems of rural and urban communities and who is able to play an effective role in preventive and curative health services.

1970 (1) The Drugs (Price Control) Order, 1970 was promulgated (2) All India Hospital (Postpartum) Family Planning Programme was started (3) The Population Council of India was formed in April 1970 (4) Chittaranjan Mobile Hospitals (mobile training–cum–service unit) were installed on the birth centenary of Late C.R. Dass on 5 Nov. 1970. The scheme envisages attachment of a mobile hospital to a suitable medical college in each State. (5) The Registration of Births and Deaths Act, 1969 came into force from 1 April (6) The name of the Demographic Training and Research Centre, Bombay was changed into International Institute for Population Studies.

1971 (1) The Family Pension Scheme (FPS) for industrial workers came into force (2) The Medical Termination of Pregnancy Bill, 1969 was passed by Parliament (3) An expert committee was appointed by the Govt. of India to draft suitable legislation on air pollution.

1972 (1) The Medical Termination of Pregnancy Act came into force on April 1, 1972 (2) National Service Bill

passed. It authorises the Government to compel medical personnel below 30 years of age to take up work in the countryside. (3) The National Nutrition Monitoring Bureau was set up under the Indian Council of Medical Research, with headquarters at the National Institute of Nutrition, Hyderabad. Regional units have also been established in the States.

1973 (1) The National Programme of Minimum Needs was incorporated in the Fifth Five Year Plan. A provision of Rs. 2,803 crores was made for this programme, which covered elementary education, rural health, nutrition, rural roads and water supply, housing, slum improvement and rural electrification. (2) The Government envisaged a scheme for setting up 30–bedded rural hospitals; one such hospital for every 4 primary health centres. (3) The Kartar Singh Committee submitted its report recommending the formation of a new cadre of health workers designated "Multi-purpose Health Workers" for the delivery of health, family planning and nutrition services to the rural communities, who will replace in course of time the basic health workers, family planning health assistants, auxilliary – nurse–mid–wives. etc.

1974 (1) The Fifth Five Year Plan was launched on April 1, 1974 with a total out–lay of Rs.53,411 crores of which Rs.37,250 crores were in the public sector and Rs.16,161 crores in the private sector. A sum of Rs.796 crores were allotted to health, and Rs.516 crores to family planning. (2) Reports of the "Second Indepth Evaluation Committee" and the "Consultative Committee of experts" on the National Malaria Eradication Programme were submitted. Both the Committees suggested a "revised strategy" for malaria control (3) The United Nations designated 1974 as World Population Year. (4) Parliament enacted the Water (prevention and control of pollution) Act, 1974.

1975 (1) India became smallpox–free on 5 July, 1975 (2) The Government of India accepted the revised strategy for NMEP (3) The country embarked on a scheme of "Integrated Child Development" from October 2, 1975. A high powered National Children's Welfare Board was set up. (4) The ESI Act was amended. (5) The Cigarettes Regulation (of Production, Supply and Distribution) Act, 1975 was passed by Parliament. (6) The Group on Medical Education and Support Manpower (Shrivastav Committee) submitted its report.

1976 (1) Indian Factories Act of 1948 amended (2) The Prevention of Food Adulteration (Amendment) Act, 1975 came into force on 1 April, 1976 (3) The Equal Remuneration Act, 1975 was promulgated providing for equal wages for men and women for the same work of a similar nature (4) The Union Health Ministry announced a 'new population policy' (5) The Central Council of Health proposed a 3–tier plan for medical care in villages (6) The Indian Centre of Japan Leprosy Mission for Asia at Agra was handed over to the Indian authorities (7) National Programme for Prevention of Blindness was formulated.

1977 (1) Eradication of smallpox declared in April by the International Commission (2) National Institute of Health and Family Planning formed. (3) Rural Health Scheme was launched. Training of community health workers was taken up (4) Revised Modified Plan of malaria eradication was put into operation (5) The 42nd Amendment of the Constitution made "Population Control and Family Planning" a concurrent subject (6) WHO adopted the goal of Health for All by 2000 AD (7) ROME scheme was launched.

1978 (1) Bill on Air Pollution introduced in the Lok Sabha (2) Parliament approved the Child Marriage Restraint (Amendment) Bill, 1978 fixing the minimum age at marriage 21 years for boys and 18 years for girls. (3) EPI was launched (4) The Charter for Health Development in South East Asia was finalised and endorsed (5) Declaration of Alma Ata underlined the primary health care approach.

1979 (1) World Health Assembly endorsed the Declaration of Alma Ata on primary health care (2) The offices of family welfare and NMEP were merged and named as Regional Office for Health and Family Welfare.

1980 (1) On May 8, 1980, smallpox was officially declared eradicated from the entire world by World Health Assembly (2) Sixth Five Year Plan (1980–1985) was launched.

1981 (1) The 1981 census was taken (2) WHO and Member Countries adopted the Global strategy for Health for All (3) Report of the Working Group on Health for All, set up by the Planning Commission, was published (4) India is committed to the goal of providing safe drinking water and adequate sanitation for all by 1990, under the International Drinking water Supply and Sanitation Decade 1981–1990. (5) The Air (Prevention and Control of Pollution) Act of 1981 was enacted.

1982 (1) The New 20 Point Programme was announced. (2) The Govt. of India announced its National Health Policy.

1983 (1) India launched a National Plan of Action against avoidable disablement, known as "IMPACT India". (2) National Leprosy Control Programme to be called National Leprosy Eradication Programme. (3) Medical Education Review Committee submitted its report. (4) National Health Policy was approved by the Parliament (5) Guinea-worm eradication Programme was launched.

1984 (1) Bhopal gas tragedy, the worst ever industrial accident in history occurred on the night of Dec. 2/3 taking a toll of at least 3000 people and no fewer than 50,000 affected (2) The ESI (Amendment) Bill, 1984 was approved by Parliament (3) The Workmen's Compensation (Amendment) Act, 1984 came into force from July 1. (4) Juvenile Justice Act 1986 came into force.

1985 (1) Seventh Five Year Plan (1985–1990) was launched (2) Universal Immunization Programme was launched (3) The Lepers Act, 1898 was repealed by Parliament (4) A separate Department of Women and Child Development was set up under the newly created Ministry of Human Resource Development.

1986 (1) The Environment (Protection) Act 1986 promulgated (2) 20–point plan restructured (3) Parliament voted Mental Health Bill (4) Juvenile Justice Act 1986 came into force.

1987 (1) New 20 – point programme was launched (2) Indian Standards institution (ISI) renamed: Bureau of Indian Standards (3) A world-wide "safe motherhood" campaign was launched by World Bank. (4) National Diabetes Control Programme and National AIDS Control Programme initiated.

The Factories (Amendment) Act 1987 operated – with provisions to protect employees exposed to hazardous processes.

1989 Blood Safety Programme was launched

The ESI (Amendment) Act 1989 operated – Modifications in dependent, employee, family, factory and seasonal factory definitions and provisions in original Act.

1990 Control of Acute Respiratory Infection (ARI) Programme initiated as a pilot project in 14 districts

1991 India stages the last decadal Census of the Century

1992 (1) Eighth Five Year Plan (1992–97) was launched (2) Child Survival and Safe Motherhood Programme (CSSM) was launched on 20th August (3) The Infant Milk substitute, Feeding Bottles and Infant Foods (Regulation of Production, Supply and Distribution) Act 1992 came into force.

1993 (1) Revised National Tuberculosis Programme with DOTS introduced as Pilot Project in the country (2) National Nutrition Policy 1993 formulated.

1994 (1) Return of plague after 28 years of silence (2) The Panchayati Raj Act came into force with all States completing the process of legislation.

1995 (1) ICDS renamed as Integrated Mother and child Development Services (IMCD) (2) The legislation on Transplantation of Human Organs was enacted to regulate the removal, storage and transplantation of human organs for therapeutic purposes and for prevention of commercial dealings in human organs (3) Expert committee on Malaria submitted its report and recommended guidelines for Malaria Action Plan

1996 (1) Pulse Polio Immunization, the largest single day public health event took place on 9th December 1995 and 20th January 1996. The second phase of PPI was conducted on 7th December 1996 and 18th January 1997. (2) Family planning programme made target–free from 1st April 1996 (3) Prenatal Diagnostic Technique (Regulation and Prevention of Misuse) Act 1994 came into force from January 1996 (4) Yaws eradication programme launched.

1997 (1) Reproductive and Child Health Programme launched. (2) Ninth five Year Plan Launched

1998–99 (1) National Family Health Survey–II undertaken covering 90,000 women aged 15–49 years. (2) National Malaria Eradication Programme renamed as National Anti-Malaria Programme. (3) Phase II of National AIDS Control Programme became effective. (4) National Policy for older persons announced.

2000 (1) Government of India announced National Population Policy–2000. (2) Declared guinea-worm free country (3) Signatory to UN Millennium Declaration. (4) National Commission on Population constituted.

2001 (1) India stages first census of the century (2) National Policy for empowerment of women launched on 20th March 2001.

2002 (1) National Health Policy 2002 announced. (2) Government announces National AIDS Prevention and Control Policy 2002. (3) Tenth Five Year Plan launched 2003. Emergence of SARS.

2003 (1) Parliament approves the Cigarettes and other Tobacco Products (Prohibition, Regulation of Trade and Commerce, Production, Supply and Distribution) Act (2) National Vector Borne Disease Control Programme approved as umbrella programme for prevention of vector borne diseases viz. malaria, filaria, Kala-azar, dengue/DHF, and Japanese encephalitis.

2004 (1) Vandemataram Scheme launched (2) Revised Programme of Nutritional Support to Primary Education (Mid-day meal scheme) launched (3) Low osmolarity oral rehydration salt replaces the existing formula (4) Integrated Disease Surveillance Project launched (5) National Guidelines on Infant and Young Child Feeding formulated in Aug. 2004.

2005 (1) RCH II launched (2) Janani Suraksha Yojana launched (3) National Rural Health Mission launched (4) Indian Public Health Standards for Community health centres formulated (5) India achieved leprosy elimination target by end of 2005 (6) National Plan of Action for Children 2005 formulated.

2006 (1) WHO releases new paediatric growth chart based on breast-fed children (2) Ban on child labour as domestic servant (3) RNTCP covers whole country since March 2006 (4) National Family Health Survey-3 conducted (5) Ministry of Women and Child Development carved out of the Ministry of Human Resources and Development (6) IMNCI was launched in 16 states.

2007 (1) 11th Five Year Plan launched (2) NACP III launched (3) Indian Public Health Standards for PHC and sub-centres formulated (4) Maintenance and Welfare of Parents and Senior Citizens Bill 2007 passed.

2008 (1) Non-communicable Disease Programme as pilot project launched on 4th Jan.

2009 Pandemic Influenza A (H_1N_1) 2009 outbreak, New ICDS Mother and Child Protection Card came into use.

2010 ICMR announces nutrients requirements and recommended dietary allowances for Indians.

2011 India stages second census of the century.

2013 National Health Mission launched, RMNCH+A strategy launched.

2014 (1) India Newborn Action Plan launched on 27th March. (2) India declared polio free country. (3) Mission Indradhanush launched on 25th December.

2015 NITI Aayog replaces Yojana Aayog on 1st January 2015.

Health Care of the Community

"The needs of the many must prevail over those of the few"

Health has been declared a fundamental human right. This implies that the State has a responsibility for the health of its people. National governments all over the world are striving to expand and improve their health care services. The current criticism against health care services is that they are (a) predominantly urban-oriented (b) mostly curative in nature, and (c) accessible mainly to a small part of the population. The present concern in both developed and developing countries is not only to reach the whole population with adequate health care services, but also to secure an acceptable level of Health for All, through the application of primary health care programmes.

Concept of health care

Since health is influenced by a number of factors such as adequate food, housing, basic sanitation, healthy lifestyles, protection against environmental hazards and communicable diseases, the frontiers of health extend beyond the narrow limits of medical care. It is thus clear that "health care" implies more than "medical care". It embraces a multitude of "services provided to individuals or communities by agents of the health services or professions, for the purpose of promoting, maintaining, monitoring, or restoring health"*(1)*.

The term "medical care" is not synonymous with "health care". It refers chiefly to those personal services that are provided directly by physicians or rendered as the result of physicians's instructions. It ranges from domiciliary care to resident hospital care. Medical care is a subset of health care system.

Health care is a public right, and it is the responsibility of governments to provide this care to all people in equal measure. These principles have been recognized by nearly all governments of the world and enshrined in their respective constitutions. In India, health care is completely or largely a governmental function.

Health system

Health services are designed to meet the health needs of the community through the use of available knowledge and resources. It is not possible to define a fixed role for health services when the socio-economic pattern of one country differs so much from another. The health services are delivered by the "health system", which constitutes the management sector and involves organisational matters.

Two major themes have emerged in recent years in the delivery of health services : (a) First, that health services should be organised to meet the needs of entire populations and not merely selected groups. Health services should cover the full range of preventive, curative and rehabilitation services. Health services are now seen as part of the basic social services of a country *(2)*; (b) Secondly, it is now fully realised that the best way to provide health care to the vast majority of underserved rural people and urban poor is to develop effective "primary health care" services supported by an appropriate referral system. The social policy throughout the world was to build up health systems based on primary health care, towards the policy objective of Health for All by 2000 A.D.

Community participation is now recognized as a major component in the approach to the whole system of health care – treatment, promotion and prevention. The stress is on the provision of these services to the people – representing a shift from medical care to health care and from urban population to rural population.

Levels of health care

It is customary to describe health care service at 3 levels, viz. primary, secondary and tertiary care levels. These levels represent different types of care involving varying degrees of complexity.

1. Primary care level

It is the first level of contact of individuals, the family and community with the national health system, where "primary health care".("essential" health care) is provided. As a level of care, it is close to the people, where most of their health problems can be dealt with and resolved. It is at this level that health care will be most effective within the context of the area's needs and limitations *(3)*.

In the Indian context, primary health care is provided by the complex of primary health centres and their subcentres through the agency of multipurpose health workers, village health guides and trained dais. Besides providing primary health care, the village "health teams" bridge the cultural and communication gap between the rural people and organised health sector. Since India opted for "Health for All" by 2000 AD, the primary health care system has been reorganized and strengthened to make the primary health care delivery system more effective.

2. Secondary care level

The next higher level of care is the secondary (intermediate) health care level. At this level more complex problems are dealt with. In India, this kind of care is generally provided in district hospitals and community health centres which also serve as the first referral level*(4)*.

3. Tertiary care level

The tertiary level is a more specialized level than secondary care level and requires specific facilities and attention of highly specialized health workers *(5)*. This care is provided by the regional or central level institutions, e.g., Medical College Hospitals, All India Institutes, Regional Hospitals, Specialized Hospitals and other Apex Institutions.

A fundamental and necessary function of health care system is to provide a sound **referral system**. It must be a two-way exchange of information and returning patients to those who referred them for follow-up care *(6)*. It will ensure continuity of care and inspire confidence of the consumer in the system. For a large majority of developing countries (including India) this aspect of the health system remains very weak.

Changing concepts

With political independence, there was a national commitment to improve health in developing countries. Against this background different approaches to providing health care came into existence. These are :

1. Comprehensive health care

The term "comprehensive health care" was first used by the Bhore Committee in 1946. By comprehensive services, the Bhore committee meant provision of integrated preventive, curative and promotional health services from "womb to tomb" to every individual residing in a defined geographic area. The Bhore Committee defined comprehensive health care as having the following criteria :

(a) provide adequate preventive, curative and promotive health services,
(b) be as close to the beneficiaries as possible,
(c) has the widest cooperation between the people, the service and the profession,
(d) is available to all irrespective of their ability to pay,
(e) look after specifically the vulnerable and weaker sections of the community; and
(f) create and maintain a healthy environment both in homes as well as working places.

The Bhore Committee suggested that comprehensive health care should replace the policy of providing more medical care. This concept formed the basis of national health planning in India and led to the establishment of a network of primary health centres and subcentres.

The Government of India, during the successive 5 year plans has built up a vast infrastructure of rural health services based on primary health centres and subcentres. However, experience during the past 50 years has indicated that the primary health centres were not able to effectively cover the whole population under their jurisdiction, and their sphere of service did not extend beyond a 2–5 km radius. These facilities often did not enjoy the confidence of the people because they were understaffed and poorly supplied with medicines and equipment; as a result, there was growing dissatisfaction with the delivery of health services.

2. Basic health services

In 1965, the term "basic health services" was used by UNICEF/WHO in their joint health policy *(7)*. They defined the term as follows "A basic health service is understood to be a network of coordinated, peripheral and intermediate health units capable of performing effectively a selected group of functions essential to the health of an area and assuring the availability of competent professional and auxiliary personnel to perform these functions."

The change in terminology from comprehensive to basic health services did not affect materially the quality or content of health services. The handicaps or drawbacks of the basic health services are those shared by the comprehensive health care services, viz., lack of community participation, lack of intersectoral coordination and dissociation from the socio-economic aspects of health.

3. Primary health care

A new approach to health care came into existence in 1978, following an international conference at Alma-Ata (USSR). This is known as "primary health care". It has all the hallmarks of a primary health care delivery, first proposed by the Bhore Committee in 1946 and now espoused worldwide by international agencies and national governments *(8)*.

Before Alma-Ata, primary health care was regarded as synonymous with "basic health services", "first contact care", "easily accessible care", "services provided by generalists", etc. The Alma-Ata international conference gave primary health care a wider meaning. The Alma-Ata Conference defined primary health care as follows *(9)* :–

> *"Primary health care is essential health care made universally accessible to individuals and acceptable to them, through their full participation and at a cost the community and country can afford".*

The primary health care is equally valid for all countries from the most to the least developed, although it takes varying forms in each of them. The concept of primary health care has been accepted by all countries as the key to the attainment of Health for All by 2000 AD. It has also been accepted as an integral part of the country's health system.

Elements of primary health care

Although specific services provided will vary in different countries and communities, the Alma–Ata Declaration has outlined 8 essential components of primary health care *(9)*.

1. education concerning prevailing health problems and the methods of preventing and controlling them;
2. promotion of food supply and proper nutrition;
3. an adequate supply of safe water and basic sanitation;
4. maternal and child health care, including family planning;
5. immunization against major infectious diseases;
6. prevention and control of locally endemic diseases;
7. appropriate treatment of common diseases and injuries; and
8. provision of essential drugs.

Principles of primary health care

1. Equitable distribution

The first key principle in the primary health care strategy is equity or equitable distribution of health services, i.e., health services must be shared equally by all people irrespective of their ability to pay, and all (rich or poor, urban or rural) must have access to health services. At

present, health services are mainly concentrated in the major towns and cities resulting in inequality of care to the people in rural areas. The worst hit are the needy and vulnerable groups of the population in rural areas and urban slums. This has been termed as social injustice. The failure to reach the majority of the people is usually due to inaccessibility. Primary health care aims to redress this imbalance by shifting the centre of gravity of the health care system from cities (where three-quarters of the health budget is spent) to the rural areas (where three-quarters of the people live), and bring these services as near people's homes as possible.

2. Community participation

Notwithstanding the overall responsibility of the Central and State Governments, the involvement of individuals, families, and communities in promotion of their own health and welfare, is an essential ingredient of primary health care. Countries are now conscious of the fact that universal coverage by primary health care cannot be achieved without the involvement of the local community. There must be a continuing effort to secure meaningful involvement of the community in the planning, implementation and maintenance of health services, besides maximum reliance on local resources such as manpower, money and materials. In short, primary health care must be built on the principle of community participation (or involvement).

One approach that has been tried successfully in India is the use of village health guides and trained dais. They are selected by the local community and trained locally in the delivery of primary health care to the community they belong, free of charge. By overcoming cultural and communication barriers, they provide primary health care in ways that are acceptable to the community. It is now considered that "health guides" and trained dais are an essential feature of primary health care in India. These concepts are revolutionary. They have been greatly influenced by experience in China where community participation in the form of **bare-foot doctors** took place on an unprecedented scale.

3. Intersectoral coordination

There is an increasing realization of the fact that the components of primary health care cannot be provided by the health sector alone. The Declaration of Alma-Ata states that "primary health care involves in addition to the health sector, all related sectors and aspects of national and community development, in particular agriculture, animal husbandry, food, industry, education, housing, public works, communication and others sectors" *(9)*. To achieve such cooperation, countries may have to review their administrative system, reallocate their resources and introduce suitable legislation to ensure that coordination can take place. This requires strong political will to translate values into action. An important element of intersectoral approach is planning – planning with other sectors to avoid unnecessary duplication of activities.

4. Appropriate technology

Appropriate technology has been defined as "technology that is scientifically sound, adaptable to local needs, and acceptable to those who apply it and those for whom it is used, and that can be maintained by the people themselves in keeping with the principle of self reliance with the resources the community and country can afford" *(10)*. The term "appropriate" is emphasized because in some countries, large, luxurious hospitals that are totally inappropriate to the local needs, are built, which absorb a major part of the national health budget, effectively blocking any improvement in general health services. This also applies to using costly equipment, procedures and techniques when cheaper, scientifically valid and acceptable ones are available, viz, oral rehydration fluid, standpipes which are socially acceptable, and financially more feasible than house-to-house connections, etc.

It will be seen from the above discussion that primary care is qualitatively a different approach to deal with the health problems of a community. Unlike the previous approaches (e.g, basic health services, integrated health care, vertical health services) which depended upon taking health services to the doors of the people, primary health care approach starts with the people themselves. This approach signifies a new dynamism in health care and has been described as Health by the people, placing people's health in people's hands *(11)*. The ends of the primary health care approach are the same as those of earlier approaches (i.e., attainment of an acceptable level of health by every individual), but the means adopted are different *(12)*, that is, more equitable distribution and nation-wide coverage, more intersectoral coordination and more community involvement in health related matters. In short, primary health care goes beyond the conventional health services. It forms part of the larger concept of Human Resources and Development.

HEALTH FOR ALL

In 1977, it was decided in the World Health Assembly to launch a movement known as "Health for All by the year 2000". The fundamental principle of HFA strategy is equity, that is, an equal health status for people and countries, ensured by an equitable distribution of health resources. The Member countries of WHO at the 30th World Health Assembly defined Health for All as :

> *"attainment of a level of health that will enable every individual to lead a socially and economically productive life."*

In 1978, the Alma-Ata International conference on Primary Health Care reaffirmed Health for All as the major social goal of governments, and stated that the best approach to achieve the goal of HFA is by providing primary health care, especially to the vast majority of underserved rural people and urban poor. It was envisaged that by the year 2000, at least essential health care should be accessible to all individuals and families in an acceptable and affordable way, with their full participation.

The Alma-Ata Conference called on all governments to formulate national policies, strategies and plans of action to launch and sustain primary health care as part of a national health system. It is left to each country to develop its norms and indicators for providing primary health care according to its own circumstances.

In 1981, a global strategy for HFA was evolved by WHO *(13)*. The global strategy provides a global framework that is broad enough to apply to all Member States and flexible enough to be adapted to national and regional variations of conditions and requirements. This was followed by individual countries developing their own strategies for achieving HFA, and synthesis of national strategies for developing regional strategies.

The WHO has established 12 global indicators *(13)* as the

basic point of reference for assessing the progress towards HFA, as for example, a minimum life expectancy of 60 years and maximum IMR of 50 per 1000 live births.

National strategy for HFA/2000

As a signatory to the Alma-Ata Declaration in 1978, the Government of India was committed to taking steps to provide HFA to its citizens by 2000 AD. In pursuance of this objective various attempts were made to evolve suitable strategies and approaches. In this connection two important reports appeared : (i) Report of the Study Group on "Health for All – an alternative strategy", sponsored by ICSSR and ICMR, and (ii) Report of the Working Group on "Health for All by 2000 AD" sponsored by the Ministry of Health and Family Welfare, Government of India *(14, 15)*. Both the groups considered in great detail the various issues involved in providing primary health care in the Indian context. These reports formed the basis of the National Health Policy formulated by the Ministry of Health and Family Welfare, Government of India in 1983 *(16)* which commited the Government and people of India to the achievement of HFA.

The National Health Policy echoes the WHO call for HFA and the Alma-Ata Declaration. It had laid down specific goals in respect of the various health indicators by different dates such as 1990 and 2000 AD. Foremost among the goals to be achieved by 2000 AD were :

(1) Reduction of infant mortality from the level of 125 (1978) to below 60.

(2) To raise the expectation of life at birth from the level of 52 years to 64.

(3) To reduce the crude death rate from the level of 14 per 1000 population to 9 per 1000.

(4) To reduce the crude birth rate from the level of 33 per 1000 population to 21.

(5) To achieve a net reproduction rate of one.

(6) To provide potable water to the entire rural population.

THE MILLENNIUM DEVELOPMENT GOALS

During September 2000, representatives from 189 countries met at the Millennium Summit in New York, to adopt the United Nations Millennium Declaration. The goals in the area of development and poverty eradication are now widely referred to as **"Millennium Development Goals"** (MDGs). The MDGs place health at the heart of development and represent commitments by governments throughout the world to do more to reduce poverty and hunger and to tackle ill-health; gender inequality; lack of education; access to clean water; and environmental degradation. They are an integral part of the road map towards the implementation of the UN Millennium Declaration. Three of the 8 goals, 8 of the 18 targets required to achieve them, and 18 of the 48 indicators of progress, are health related. They assist in the development of national policies focussing on poor, and help track the performance of health programmes and systems. Although, the MDGs do not cover the whole range of public health domains, a broad interpretation of the goals provides an opportunity to tackle important cross cutting issues and key constraints to health and development. Governments have set a date of 2015 by which they would meet the MDGs, i.e. eradicate extreme poverty and hunger; achieve universal primary education; promote gender equality; improve maternal health; combat HIV/AIDS, malaria and other communicable diseases; ensure environmental sustainability; and develop a global partnership for development *(17,18,19)*.

More recently one of the major changes made to the MDG configurarion is the inclusion of a specific target on reproductive health : Millennium Development Goal 5, Target B, which seeks to "Achieve, by 2015, universal access to reproductive health." This new target falls within the goal's overarching objective of improving maternal health and complements its original target and associated indicators.

CONCEPTS AND DEFINITIONS OF MDG INDICATORS *(20)*

The concepts and definitions of MDGs are as follows (G,T and I written in parenthesis are pertaining to goal number, target no. and indicator no. of UN Declaration) *(20)*:

Prevalence of underweight children (under five years of age) (G1.T2.I4) : Proportion of children of under-five years with low weight-for-age, as measured by percentage of children in moderate and severe malnutrition–those falling below 80% of the median weight for reference value or below 2 standard deviations of national or international reference populations, such as growth charts of the US National Center for Health Statistics.

Proportion (%) of population below minimum level of dietary energy consumption (G1.T2.I5) : Since there is no specific data available, proxy indicator "Proportion of population undernourished" is used. It is the proportion in percentage of persons whose food intake falls below the minimum requirement or food intake that is insufficient to meet dietary energy requirements continuously.

Under-five mortality rate (G4.T5.I13) : Probability of dying between birth and exactly five years of age, expressed per 1,000 live births.

Infant mortality rate (G4.T5.I14) : Probability of dying between birth and exactly one year of age expressed per 1,000 live births.

Proportion (%) of 1 year old children immunized for measles (G4.T5.I15) : The percentage of infants reaching their first birthday fully immunized against measles (1 dose).

Maternal mortality ratio (G5.T6.I16) : Annual number of maternal deaths per 100,000 live-births. A maternal death is the death of a woman while pregnant or within 42 days of termination of pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes.

Proportion (%) of births attended by skilled health persons (G5.T6.I17).: The proportion in percentage of births attended by skilled personnel per 100 live-births. Skilled health personnel refer exclusively to those health personnel (for example, doctors, nurses, midwives) who have been trained to proficiency in the skills necessary to manage normal deliveries and diagnose or refer obstetric complications. Traditional birth attendants trained or untrained, are not included in this category.

HIV prevalence among young people (G6.T7.I18) : Since the relevant data is not available, the proxy indicator as proposed by UNAIDS/WHO is used. The proxy indicator is

"HIV prevalence among 15–24 years old by sex" which is the estimated number of young people (15–24 years old) living with HIV/AIDS as per proportion of the same population and sex. These country-specific estimates are expressed as a range generated by regional modelling. The other proxy indicator is "HIV prevalence rate among population 15–49 years of age".

Condom use in high-risk population (G6.T7.I19) : Since the data is not available, it has been proposed to use "condom-use among 15–24 years old by sex". This is the percentage of young men and women of age 15–24 years, who said that they used a condom the last time they had sex with a non-marital, non-cohabiting partner, of those who have had sex with such a partner in the last 12 months.

Ratio of children orphaned/non-orphaned in schools (G6.T7.I20) : Since the data is not available, the proxy indicator is used as "AIDS orphans currently living" which is the estimated number of children (0–14) in a given year, having lost their mother or both parents to AIDS.

Malaria death rate per 100,000 in children (0–4 years of age) (G6.T8.I21) : Proportion of children (0–4 years of age) died due to malaria in a given year.

Malaria death rate per 100,000 in all age groups (G6.T8.I21) : Proportion of people of all age groups died due to malaria in a given year. It is malaria crude death rate.

Malaria prevalence rate per 100,000 population (G6.T8.I21) : Proportion of notified or reported cases of malaria per 100,000 population in a given year. It is malaria crude prevalence rate.

Proportion (%) of population under-age 5 in malaria risk areas using insecticide treated bed nets (G6.T8.I22) : The percentage of children under-five years of age who are using insecticide-treated bed-nets among the same population living in malaria risk area, in a given year.

Proportion (%) of population under-age 5 with fever being treated with anti-malarial drugs (G6.T8.I22) : The percentage of children under-five years of age who are with fever being treated with anti-malarial drugs among the same population living in malaria risk area, in a given year.

Tuberculosis death rate per 100,000 (G6.T8.I23) : Proportion of people of all age groups died due to tuberculosis in a given year.

Tuberculosis prevalence rate per 100,000 (G6.T8.I23) : Proportion of tuberculosis cases of all age groups per 100,000 population in a given year.

Proportion (%) of smear-positive pulmonary tuberculosis cases detected and put under directly observed treatment short-course (DOTS) (G6.T8.I24) : Since the base line data is not available WHO proposed to use "DOTS detection rate".

Proportion (%) of smear-positive pulmonary tuberculosis cases detected cured under directly observed treatment short course (DOTS) (G6.T8.I24) : Since the baseline data is not available WHO proposed to use "DOTS cure rate" which implies treatment success rate that is treatment completion rate and cure rate.

Proportion (%) of population using biomass fuel (G7.T9.I29) : Biomass fuel is any material, derived from plants or animals, deliberately burnt by human, for example, wood, animal dung, crop residues and coal. Since the baseline data is not available the proxy indicator is proposed as "percentage of populations using solid fuels".

Proportion (%) of population with sustainable access to an improved water source, ***rural*** *(G7.T10.I30) :* Since the baseline data is not available, the proxy indicator "percentage of population with access to improved drinking water sources, rural" is used. "Improved" water sources means household connection, public standpipe, borehole, protected dug well, protected spring, rainwater collection. "Access" means the availability of at least 20 litres water per person per day from a source within one kilometre of the user's dwelling.

Proportion (%) of population with sustainable access to an improved water source, ***urban*** *(G7.T10.I30) :* Since the baseline data is not available, the proxy indicator "percentage of population with access to improved drinking water sources, urban" is used. "Improved" water sources mean household connection, public standpipe, borehole, protected dug well, protected spring, rainwater collection. "Access" means the availability of at least 20 litres water per person per day from a source within one kilometre of the user's dwelling.

Proportion (%) of urban population with access to improved sanitation (G7.T11.I31) : "Improved" sanitation means : connection to a public sewer, connection to septic system, pour–flush latrine, simple pit latrine, or ventilated improved pit latrine. The excreta disposal system is considered adequate if it is private or shared (but not public), and if hygienically, separates human excreta from human contact.

Proportion (%) of population with access to affordable essential drugs on a sustainable basis (G8.T17.I46) : Since the baseline data is not available, the proxy indicator "percentage of population with access to essential drugs", which WHO routinely reports for international comparison, is used. Every year, in order to estimate the level of access to essential drugs, WHO Global Action Programme on Essential Drugs interviews relevant experts in each country about the pharmaceutical situation. The interviewees could choose from four levels of access by the population to essential drugs : less than 50%; between 50–80%; 80–95%; and above 95%. They indicate which category is most appropriate for their country. Essential drugs are those drugs that satisfy the health care needs of the majority of the population.

The indicators selected to monitor progress towards MDG, 5 Target B are as follows :

Contraceptive prevalence rate : Percentage of women aged 15–49 in union currently using contraception.

Adolescent birth rate : Annual number of births to women aged 15–19 per 1,000 women in that age group. Alternatively, it is referred to as the age-specific fertility rate for women aged 15–18.

Antenatal care coverage : Percentage of women aged 15–49 attended at least once during pregnancy by skilled health personnel (doctors, nurses or midwives) and the percentage attended by any provider at least four times.

Unmet need for family planning : Refers to women who are fecund and sexually active but are not using any method of contraception and report not wanting any more children or wanting to delay the birth of the next child.

Table 1 shows the detailed information regarding the indicators of health related MDGs in India, i.e. the baseline (1990) and current level data *(20)*.

TABLE 1
Health-related Millennium Development Goals in India

Indicator	Year	India
Goal 1 : Eradicate extreme poverty and hunger		
Target 2 : Halve, between 1990 and 2015, the proportion of people who suffer from hunger		
G1.T2.I4 - Prevalence of underweight children (under-five years of age)	1990 2007–2011	53.4 43.0
G1.T2.I5 - Proportion (%) of population below minimum level of dietary energy consumption	1991 2004–06	25 15
Goal 4 : Reduce child mortality		
Target 5 : Reduce by two-thirds, between 1990 and 2015, the under-five mortality rate		
G4.T5.I13 - Under-five mortality rate (probability of dying between birth and age 5)	1990 2012	112.0 52.0
G4.T5.I14 - Infant mortality rate	1990 2012	80.0 42.0
G4.T5.I15 - Proportion (%) of 1 year-old children immunized for measles	1990 2012	32.7 74.0
Goal 5 : Improve maternal health		
Target 6 : Reduce by three-quarters, between 1990 and 2015, the maternal mortality ratio		
G5.T6.I16 - Maternal mortality ratio	1990 2010–12	420 178
G5.T6.I17 - Proportion (%) of births attended by skilled health personnel	1990 2008–12	89/36 57.0
Target B		
Contraceptive prevalence rate	1990 2007–12	NA 55
Adolescent birth rate	1990 2006–10	NA 57
Antenatal care coverage (3 or more)	1990 2006–13	NA 50
Unmet need for family planning	1990 2006–12	NA 21.0
Goal 6 : Combat HIV/AIDS, Malaria and other diseases		
Target 7 : Have halted by 2015, and begun to reverse, the spread of HIV/AIDS		
G6.T7.I18 - HIV prevalence among young people		
15-24 years age group %	1990 2012 (M) 2012 (F)	NA 0.1 0.1
15-49 years age group	2012	0.1
G6.T7.I19 - Condom use in high risk population	1990 2008–12 (M) 2008–12 (F)	NA 32 17
G6.T7.I20 - Ratio of children orphaned/non-orphaned in schools	1990 2008–12	NA 72
Target 8 : Have halted by 2015, and begun to reverse the incidence of malaria and other major diseases		
G6.T8.I21 - Malaria death rate per 100,000 in children (0-4 years of age)	1990 2006–2010	NA 8
G6.T8.I21 - Malaria death rate per 100,000 (all ages)	1990 2012	NA 2.3
G6.T8.I21 - Malaria incidence rate per 100,000	1990 2012	NA 1523
G6.T8.I22 - Proportion (%) of population in malaria risk areas using insecticide-treated bed nets	1990	NA NA
G6.T8.I22 - Proportion (%) of population under age 5 with fever being treated with anti-malarial drugs	1990 2006–2012	NA 8
G6.T8.I23 - Tuberculosis death rate per 100,000	1990 2003	NA 19
G6.T8.I23 - Tuberculosis prevalence rate per 100,000	1990 2003	NA 211
G6.T8.I24 - Proportion (%) of smear-positive pulmonary tuberculosis cases detected and put under directly observed treatment short course (DOTS)	1990 2012	NA 64
G6.T8.I24 - Proportion (%) of smear-positive pulmonary tuberculosis cases detected cured under directly observed treatment short course (DOTS)	1990 2012	NA 88
Goal 7 : Ensure environmental sustainability		
Target 9 : Integrate the principles of sustainable development into country policies and programmes and reverse the loss of environmental resources		
G7.T9.I29 - Proportion (%) of population using biomass fuels	1990 2012	NA 63
Target 10 : Halve, by 2015, the proportion of people without sustainable access to safe drinking water		
G7.T10.I30 - Proportion (%) of population with sustainable access to an improved water source, rural	1990 2011	61 87
G7.T10.I30 - Proportion (%) of population with sustainable access to an improved water source, urban	1990 2011	88 96
Target 11 : By 2020 to have achieved a significant improvement in the lives of at least 100 million slum dwellers		
G7.T11.I31 - Proportion (%) of urban population with access to improved sanitation	1990 2011	44 60
Goal 8 : Develop global partnership for development		
Target 17 : In cooperation with pharmaceutical companies, provide access to affordable, essential drugs in developing countries		
G8.T17.I46 - Proportion (%) of population with access to affordable essential drugs on a sustainable basis	1990 1997	NA 80

Goal (G), Target (T), Indicator (I),
(Goals 2 & 3 are not pertaining to health)

To help track the progress for the achievement of Millennium Development Goals and in order to have focused analysis of data at country level, Government of India has modified some indicators. The modifications and their justification are as shown in Table 2.

HEALTH CARE DELIVERY

The challenge that exists today in many countries is to reach the whole population with adequate health care services and to ensure their utilization. The "large hospital" which was chosen hitherto for the delivery of health services has failed in the sense that it serves only a small part of the population, that too, living within a small radius of the building and the services rendered are mostly curative in nature. Therefore, it has been aptly said that these large hospitals are more ivory towers of diseases than centres for the delivery of comprehensive health care services. Rising costs in the maintenance of these large hospitals and their failure to meet the total health needs of the community have led many countries to seek 'alternative' models of health care delivery with a view to provide health care services that are reasonably inexpensive, and have the basic essentials required by rural population.

THE MODEL

A number of models have been developed for the delivery of health care services *(22)*. One of the simplest models is shown in Fig. 1.

TABLE 2

Millennium Development Goals – modification of indicators relating to health in India

Goals and targets (From the Millennium Declaration)	Indicator for monitoring the progress under MDG	Comments of national health programmes on the indicators	Justification extended by national health programme where indicators replaced/deleted/added
Goal 6 Combat HIV/AIDS, malaria and other diseases			
Target 7 Have halted by 2015 and begun to reverse the spread of HIV/AIDS	**Indicator 18** HIV prevalence among pregnant women aged 15-24 years	**Accepted** Also add the following: HIV prevalence among pregnant women aged 25-49 years	Additional age group to include the whole of "reproductive age group" (15-49 yrs) is considered appropriate
	Indicator 19 (a) Condom use at last high risk sex	**Replace by** Condom use rate among non-regular sex partners	This indicator has more relevance to HIV/AIDS
	Indicator 19(b) Percentage of population aged 15-24 years with comprehensive correct knowledge of HIV/AIDS	**Replace by** Percentage of population aged 15-49 years with comprehensive correct knowledge of HIV/AIDS	15-24 age group substituted by the whole reproductive age group 15-49 yrs in India
	Indicator 19(c) Contraceptive prevalence rate	**May be deleted** from purview of NACO*	Already explained by indicators 19a & 19b
	Indicator 20 Ratio of school attendance of orphans to school attendance of non orphans aged 10-14 years	**May be deleted** from purview of NACO*	Not suitable for capturing related information in context of HIV/AIDS
Target 8 Have halted by 2015 and begun to reverse the incidence of malaria and other major diseases.	**Indicator 21** Prevalence and death rates associated with malaria	**Replace by** * Annual Parasite Incidence (API) (Annual number of positive cases per thousand population), and *Actual number of confirmed deaths due to malaria per 1 lakh population	Under the national program 10% of population is screened annually for malaria surveillance through blood slides examination. The annual parasite incidence also reflects the status & trend of disease in an area
	Indicator 22 Proportion of population in malaria risk areas using effective malaria prevention and treatment measures	**Replace by** * Number and percentage of people with fever given presumptive treatment (malaria) * Number and percentage of malaria positive cases given radical treatment (malaria) * Percentage of villages with functioning Drug Distribution Centre (DDC) and Fever Treatment Depot (FTD) in the country. * Percentage of targeted population in high risk areas covered with Insecticide Residual Spray (IRS) * Percentage of Insecticide treated bednets distributed against targeted population	These indicators more aptly reflect the malaria prevention and control in the country
	Indicator 23 Prevalence and death rates associated with tuberculosis	**Replace by** Incidence and death rates associated with T.B.	Estimation of prevalence of TB is technically difficult and no standardized methodology available for carrying out such estimations, however, death rate associated with TB could be estimated. A nation-wide study to estimate incidence of TB has recently been completed and these estimates of incidence are acknowledged to be robust
	Indicator 24 Proportion of TB cases detected and cured under DOTS	**Accepted**	
Goal 7 Ensure environmental sustainability			
Target 17 In co-operation with pharmaceutical companies, provide access to affordable essential drugs in developing countries	**Indicator 46** Proportion of population with access to affordable essential drugs on a sustainable basis	**May be modified as -** Proportion of population with access to affordable essential drugs on sustainable basis through the Govt. health facilities	Since Deptt. of FW/GOI is covering free supply of essential drugs to sub-centres, primary health centres, and community health centres; it was considered appropriate that Deptt. of Family Welfare may cover this indicator while also taking into account the free drugs supplies made under other National Health Programs like NLEP, RNTCP and NVBDCP through Govt. health facilities

Source : *(21)*

In actual practice the model is more detailed and complex. The INPUTS are the health status or health problems of the community; they represent the health needs and health demands of the community. Since resources are always limited to meet the many health needs, priorities have to be set. This envisages proper planning so that resources are not wasted. An account of the health planning has already been given in the preceding chapter. The HEALTH CARE SERVICES are designed to meet the health needs of the community through the use of available knowledge and resources. The services provided should be comprehensive and community-based. The resources must be distributed according to the needs of the community. The HEALTH CARE SYSTEM is intended to deliver the health care services; in other words, it constitutes the management sector, and involves organisational matters. The final outcome or the OUTPUT is the changed health status or improved health status of the community which is expressed in terms of lives saved, deaths averted, diseases prevented, cases treated, expectation of life prolonged, etc. Models such as these are being employed for improving health care services. A discussion of the application of the model (Fig. 1) in the Indian context is given in the following pages.

HEALTH STATUS AND HEALTH PROBLEMS

An assesment of the health status and health problems is the first requisite for any planned effort to develop health care services. This is also known as Community Diagnosis. The data required for analyzing the health situation and for defining the health problems comprise the following :

1. Morbidity and mortality statistics.
2. Demographic conditions of the population.
3. Environmental conditions which have a bearing on health.
4. Socio-economic factors which have a direct effect on health.
5. Cultural background, attitudes, beliefs, and practices which affect health.
6. Medical and health services available.
7. Other services available.

An analysis of the health situation in the light of the above data will bring out the health problems and health needs of the community. These problems are then ranked according to priority or urgency for allocation of resources. A brief description of current demographic and mortality profile and the health problems of India is given in the following pages.

1. Demographic profile

A major concern today is population explosion. The demographic profile is characterised by:

a. large population base
b. high fertility both in terms of birth rate and family size
c. low or declining mortality
d. "young" population (about 35.35 per cent of the population) is below the age of 15 years
e. the proportion of illiterate population is close to 34.62 per cent: this explains why the decline in birth rate has been so slow
f. dependency ratio of 62 per 100; that is, every economically productive member has to support almost one dependant

Table 3 summarizes the most recent demographic information available.

TABLE 3

India: Demographic profile

Total population (2014)	1364 million
Crude birth rate (2012)	21.6
Crude death rate (2012)	7.0
Annual growth rate % (2011)	1.6
Population doubling time (at current growth rate)	30 years
Population rural % (2011)	68.84
Adult literacy rate % (2011)	74.04
Density of population per sq.km (2014)	394
Sex ratio female per 1000 male (2011)	940
Population below 15 years % (2012)	30.0
Population above 60 years % (2012)	8.39
Average family size (2012)	2.5
Age at marriage, female (2012)	21.2 years
Annual per capita GNP (at current prices 2011–12)	Rs. 60,603

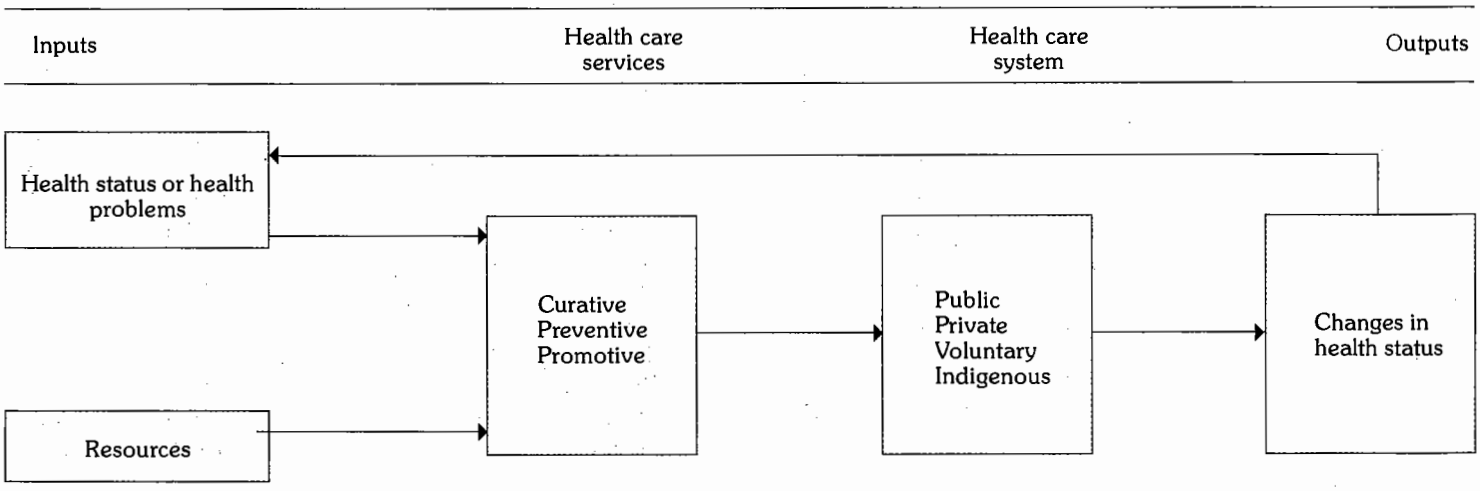

FIG. 1

Model of health care system

2. Mortality profile

During the last few decades, there has been a notable improvement in the health status of the population. The death rate has steadily declined from 21 (1965) to 7.0 (2012). The life expectancy at birth has gone up considerably since 1951, recording an estimated 66 years during 2012. The mortality rates for a number of infectious and communicable diseases have also registered a decline (e.g., cholera, tuberculosis, malaria).

However, a deeper study reveals distressing situation. India's health standards are still low compared to those in developed countries. While in the world as a whole, the IMR for the year 2012 is about 35 per 1000 live births, and in the developed countries as low as 5, in India it is as high as 42. Our life expectancy of about 66 years lags behind by almost 12–15 years compared to that in developed countries where it is currently between 71 and 80 years.

The mortality profile in terms of age-sex and urban-rural distribution is presented in Table 4 and 5. It shows wide variations in crude death rate between rural and urban areas. The current urban death rate (during 2012) was 5.6 and the rural death rate 7.6 per 1000 of population. There were also considerable interstate variations in death rate, as for example, during 2012 the death rate in Odisha was highest about 8.5 as compared to the national average of 7.0 and 4.2 in Delhi. Among the states, Kerala had the lowest IMR of 12 per 1000 live births and Madhya Pradesh had the highest IMR of 56 per 1000 live births *(24)*.

Table 4 shows that the death rate is the highest in the age group 0–4 years. This is as a result of malnutrition and infection. 15 to 25 per cent of total deaths are attributed to infectious and parasitic diseases.

TABLE 5

Child (Aged 0-4 years) and infant mortality indicators, India 2012

Indicators	Total	Rural	Urban
Child mortality rate	52	58	32
Infant mortality rate	42	46	28
Neo-natal mortality rate	29	33	16
Early neo-natal mortality rate	23	25	12
Late neo-natal mortality rate	6	7	4
Post neo-natal mortality rate	13	14	12
Peri-natal mortality rate	28	31	17
Still birth rate	5	5	5

Health problems

The HEALTH PROBLEMS of India may be conveniently grouped under the following heads :

1. Communicable disease problems
2. Non-communicable disease problems
3. Nutritional problems
4. Environmental sanitation problems
5. Medical care problems
6. Population problems.

1. Communicable disease problems

Communicable diseases continue to be a major problem in India. Diseases considered to be of great importance today are : (a) **Malaria :** Malaria continues to be a major health problem in India. Although total malaria cases has declined compared to previous years, the proportion of *P. falciparum* has increased. Malaria cases have increased in

TABLE 4

Age-specific crude death rate by sex and residence, India 2012

Age group	Total			Rural			Urban		
	Total	Male	Female	Total	Male	Female	Total	Male	Female
Below 1	42.7	42.0	43.5	46.5	45.9	47.0	28.6	27.3	30.0
1–4	2.6	2.1	3.2	3.0	2.3	3.8	1.2	1.2	1.2
0–4	11.5	10.9	12.1	12.8	12.1	13.5	7.0	6.7	7.2

North-East states, Madhya Pradesh, Chhattisgarh, Jharkhand, Orissa, Andhra Pradesh, Maharashtra etc. During 2013 there were 0.8 million cases of malaria (which included 0.44 million cases of *Pf* malaria) and 379 deaths. (b) **Tuberculosis :** Tuberculosis remains a public health problem, with India accounting for one-fifth of the world incidence. Every year about 2.6 million persons develop tuberculosis, of which about 0.62 million are new smear positive highly infectious cases and about 0.24 million people die of TB every year. The emergence of HIV-TB co-infection and multidrug resistant TB has increased the severity and magnitude of the disease. In March 2006 RNTCP has achieved nation-wide coverage. (c) **Diarrhoeal diseases :** Diarrhoeal diseases constitute one of the major causes of morbidity and mortality, specially in children below 5 years of age. They are responsible for about 10.76 million cases of diarrhoea each year. Outbreaks of diarrhoeal diseases (including cholera) continue to occur in India due to poor environmental conditions. (d) **ARI :** Acute repiratory diseases are one of the major causes of mortality and morbidity in children below 5 years of age. During 2013, 31.7 million episodes of ARI were reported with 3,278 deaths. (e) **Leprosy :** Leprosy is another important public health problem in India. During the year 2013–2014, total of 1.27 lakh new cases were detected, out of which child cases were 9.49% and deformity grade II and above was 4.14%. 51.48 per cent of these cases are estimated to be multibacillary. All the States and Union Territories report cases of leprosy. However, there are considerable variations not only between one State and another, but also between one district and another. With the prevalence rate of about 0.68 per 10,000 population, India has achieved the goal of leprosy elimination at national level. (f) **Filaria :** The problem of filaria remains endemic in about 250 districts in 20 States and UTs. The population at risk is over 600 million. To achieve elimination of LF, the Govt. of India has launched nationwide Annual Mass Drug Administration (MDA) with annual single recommended dose of diethylcar-bamazine citrate tablets in addition to scaling up home based foot care and hydrocele operations. In 2012, 250 endemic districts implemented MDA targeting a population of about 554 million with a coverage rate of 87 per cent. (g) **AIDS :** The problem of AIDS is stable. It is estimated that by the end of year 2012 there were about 2.08 million HIV positive cases in the country. (h) **Others :** Kala-azar, meningitis, viral hepatitis, Japanese encephalitis, dengue fever, enteric fever and helminthic infestations are among the other important communicable disease problems in India. The tragedy is that most of these diseases can be either easily prevented or treated with minimum input of resources. In fact most of the developed countries of the world have overcome many of these problems by such measures as manipulation of environment, practice of preventive medicine and improvement of standards of living.

2. Non-communicable diseases (NCDs)

India is experiencing a rapid epidemiological transition with a large and rising burden of chronic diseases, which were estimated to account for 53 per cent of all deaths and 44 per cent of Disability Adjusted Life Years lost in 2005. NCDs, especially diabetes mellitus, CVDs, cancer, stroke, and chronic lung diseases have emerged as major public health problems due to an ageing population and environmentally-driven changes in behaviour.

Cancer has become an important public health problem in India with an estimated 7 to 9 lakh cases occurring every year. At any point of time, it is estimated that there are nearly 25 lakh cases in the country. In India, tobacco related cancers account for about half the total cancers among men and 20% among women. About one million tobacco related deaths occur each year, making tobacco related health issues a major public health concern. In India, more then 12 million people are blind. Cataract (62.6 per cent) is the main cause of blindness followed by Refractive Error (19.70 per cent). There has been a significant increase in proportion of cataract surgeries with Intra Ocular Lens (IOL) implantation from <5 per cent in 1994 to 95 per cent in 2011–12. Oral Health Care has not been given sufficient importance in our country. Most of the district hospitals have a post of dental surgeon but they lack equipment, machinery, and material. Even where the equipment exists, the maintenance is poor, hence service delivery is affected.

3. Nutritional problems

From the nutritional point of view, the Indian society is a dual society, consisting of a small group of well fed and a very large group of undernourished. The high income groups are showing diseases of affluence which one finds in developed countries.

The specific nutritional problems in the country are : (a) **Protein-energy malnutrition :** Insufficiency of food – the so-called "food gap"– appears to be the chief cause of PEM, which is a major health problem particularly in the first years of life. The great majority of cases of PEM, nearly 80 per cent are mild and moderate cases. The incidence of severe cases is 1 to 2 per cent in preschool age children. The problem exists in all the States and the nutritional marasmus is more frequent than kwashiorkor. (b) **Nutritional anaemia :** India has probably the highest prevalence of nutritional anaemia in women and children. About one-half of non-pregnant women and young children are estimated to suffer from anaemia. 60 to 80 per cent of pregnant women are anaemic. 19 per cent of maternal deaths are attributed to anaemia. According to NFHS-3, about 57.9 per cent women are anaemic of which 54.6 per cent are in urban areas and 59 per cent in rural areas. The survey also shows that the incidence of anaemia in children aged 6-35 months is 79.2 per cent with 72.7 per cent in urban areas and 81.2 per cent in rural areas. By far the most frequent cause of anaemia is iron deficiency, and less frequently folate and vitamin B_{12} deficiency. (c) **Low birth weight :** This is a major public health problem in many developing countries. About 28 per cent of babies born are of low birth weight (less than 2.5 kg), as compared to about 4 per cent in some developed countries. Maternal malnutrition and anaemia are mainly responsible for this condition. (d) **Xerophthalmia (nutritional blindness) :** About 0.04 per cent of total blindness in India is attributed to nutritional deficiency of vitamin A. Keratomalacia has been the major cause of nutritional blindness in children usually between 1–3 years of age. Subclinical deficiency of vitamin A is also widespread and is associated with increased morbidity and mortality from respiratory and gastro-intestinal infections. (e) **Iodine deficiency disorders :** Goitre and other iodine deficiency disorders (IDD) have been known to be highly endemic in sub-Himalayan regions. Reassessment of the magnitude of the problem by the Indian Council of Medical Research showed that the problem is not restricted to the "goitre belt" as was thought earlier, but is extremely prevalent in other parts of India as well. It has been found that out of 324 districts surveyed in 29 states and all UTs, 263 districts

are endemic i.e. where the prevalence of IDD is more than 10 per cent. It is also estimated that more than 71 million people are suffering from goitre and other IDD. *(27)*.
(f) **Others :** Other nutritional problems of importance are lathyrism and endemic fluorosis in certain parts of the country. To these must be added the widespread adulteration of foodstuffs.

4. Environmental sanitation

The most difficult problem to tackle in this country is perhaps the environmental sanitation problem, which is multifaceted and multifactorial. The great sanitary awakening which took place in England in 1840's is yet to be born. The twin problems of environmental sanitation are lack of safe water in many areas of the country and primitive methods of excreta disposal. Besides these, there has been a growing concern about the impact of "new" problems resulting from population explosion, urbanization and industrialization leading to hazards to human health in the air, in water and in the food chain. At the United Nations Water Conference in Argentina, in 1977, it was recommended that the priority should be given to the provision of safe water supply and sanitation services for all. As of year 2012 safe water is available to 96 per cent of the urban and 87 per cent of the rural population; and adequate facilities for waste disposal to 54 per cent of the urban and 21 per cent of the rural population. The problem is gigantic.

5. Medical care problems

India has a national health policy. It does not have a national health service. The financial resources are considered inadequate to furnish the costs of running such a service. The existing hospital-based, disease-oriented health care model has provided health benefits mainly to the urban elite. Approximately 80 per cent of health facilities are concentrated in urban areas. Even in urban areas, there is an uneven distribution of doctors. With large migrations occurring from rural to urban areas, urban health problems have been aggravated and include overcrowding in hospitals, inadequate staffing and scarcity of certain essential drugs and medicines. The rural areas where nearly 72 per cent of the population live, do not enjoy the benefits of the modern curative and preventive health services. Many villages rely on indigenous systems of medicine. Thus the major medical care problem in India is inequable distribution of available health resources between urban and rural areas, and lack of penetration of health services to the social periphery. The HFA/2000 movement and the primary health care approach which lays stress on equity, intersectoral coordination and community participation seek to redress these imbalances.

6. Population problem

The population problem is one of the biggest problems facing the country, with its inevitable consequences on all aspects of development, especially employment, education, housing, health care, sanitation and environment. The country's population has already reached one billion mark by the turn of the century.

The Government has set a goal of 1 per cent population growth rate by the year 2000 (which was not attained); currently, the country's growth rate is 1.8 per cent. This calls for the "two child family norm". The population size and structure represent the most important single factor in health and manpower planning in India today where the law of diminishing returns, among other factors, plays an important role in the economic development of the country.

RESOURCES

Resources are needed to meet the vast health needs of a community. No nation, however rich, has enough resources to meet all the needs for all health care. Therefore an assessment of the available resources, their proper allocation and efficient utilization are important considerations for providing efficient health care services. The basic resources for providing health care are :

(i) Health manpower
(ii) Money and material; and
(iii) Time

Health manpower

The term "health manpower" includes both professional and auxiliary health personnel who are needed to provide the health care. An auxiliary is defined by WHO as "technical worker in a certain field with less than full professional training". Health manpower requirements of a country are based on (i) health needs and demands of the population; and (ii) desired outputs. The health needs in turn are based on the health situation and health problems and aspirations of the people.

Health manpower planning is an important aspect of community health planning. It is based on a series of accepted ratios such as doctor-population ratio, nurse-population ratio, bed-population ratio, etc. They are given in Table 6. The country is producing annually, on an average 31,298 allopathic doctors; 9,865 Ayurvedic graduates; 1525 Unani graduates; 320 Siddha graduates and 12785 Homoeopathic graduates *(26)*.

TABLE 6

Suggested norms for health personnel

Category of personnel	Norms suggested
1. Nurses	1 per 5,000 population
2. Health worker female and male	1 per 5,000 population in plain area and 3,000 population in tribal and hilly areas.
3. Trained dai	One for each village
4. Health assistant (male and female)	1 per 30,000 population in plain area and 20,000 population in tribal and hilly areas. Provides supportive supervision to 6 health workers (male / female).
5. Pharmacists	1 per 10,000 population
6. Lab. technicians	1 per 10,000 population
7. ASHA	1 per 1,000 population

Source : *(27)*

Although the averages are satisfactory on a national basis, they vary widely within the country. There is also maldistribution of health manpower between rural and urban areas. Studies in India have shown that there is a concentration of doctors (upto 73.6 per cent) in urban areas where only 26.4 per cent of population live. This maldistribution is attributed to absence of amenities in rural areas, lack of job satisfaction, professional isolation, lack of rural experience and inability to adjust to rural life.

The national averages of doctor-population ratio, population-bed ratio and nurse to doctor ratio in some countries are shown in Table 7.

TABLE 7

Health manpower in some countries 2005–2011

Country	Doctors per 10000 population	Beds per 10000 population	Nurses and Midwives per 10000 population
India	6.5	9.0	10.0
Bangladesh	3.0	3.0	2.7
Sri Lanka	4.9	29.0	19.3
Thailand	21.0	21.0	53.0
Myanmar	4.6	6.0	8.0

Source : *(25)*

Health manpower requirements are subject to change, both qualitatively and quantitatively, as new programmes, projects and philosophies are introduced into the health care system. For example, there has been a change from unipurpose to multipurpose strategy. Then came the goal of Health for All. In addition, national health programmes such as tuberculosis control, leprosy eradication and control of blindness needed more trained workers and technicians. Thus during the past decade many new categories of health manpower have been introduced. They include village health guides, multipurpose workers, technicians, ophthalmic assistants, etc. Table 8 gives the total health manpower current stock under the "rural health scheme".

TABLE 8

Health man-power in rural India as on March 2014

	Category	In position
1.	ANM at sub-centre and PHC	217,780
2.	MPW (Male)	55,445
3.	Health Assistant (Female)/ LHV	13,643
4.	Health Assistant (Male)	10,358

	(b) Gynaecologist and Obstetrician	1,263
	(c) Physician	931
	(d) Paediatrician	961
	Total Specialists at CHC	11,798
7.	Radiographer	2,189
8.	Pharmacist	22,689
9.	Lab. Technician	16,679
10.	Nurse Midwife	63,938
11.	BEE	2,904

Source : *(29)*

Money and material

Money is an important resource for providing health services. Scarcity of money affects all parts of the health delivery system. In most developed countries, average government expenditure for health is about 18 per cent of GNP. In developing countries it is less than 1 per cent of the GNP and it seldom exceeds 2 per cent of the GNP. This translates into an average of a few dollars per person per year in the underdeveloped countries as compared to several hundred dollars in developed ones. To make matters worse, much of the spending is for services that reach only a small fraction of the population.

To achieve Health for All, WHO has set as a goal the expenditure of 5 per cent of each country's GNP on health care. At present India is spending about 3 per cent of GNP on health and family welfare development.

Since money and material are always scarce resources they must be put to the most effective use, with an eye on maximum output of results for investment. Since deaths from preventable diseases such as whooping cough, measles, tuberculosis, tetanus, diphtheria, malnutrition frequently occur in developing countries, the case is strong for investing resources on preventing these diseases rather than spending money on multiplying prestigious medical institutions and other establishments which absorb a large portion of the national health budget *(30)*. Management techniques such as cost-effectiveness and cost-benefit analysis are now being used for allocation of resources in the field of community health.

Time

"Time is money", someone said. It is an important dimension of health care services. Administrative delays in sanctioning health projects imply loss of time. Proper use of man-hours is also an important time factor. For example, a survey by WHO has shown that an Auxiliary Nurse Midwife spends 45 per cent of her time in giving medical care; 40 per cent in travelling; 5 per cent on paper work; and only 10 per cent in performing duties for which she has been trained *(31)*. Such studies may be extended to other categories of health personnel with a view to promote better utilization of the time resource.

To summarize, resources are needed to meet the many health needs of a community. But resources are desperately short in the health sector in all poor countries. What is important is to employ suitable strategies to get the best out of limited resources.

HEALTH CARE SERVICES

The purpose of health care services is to improve the health status of the population. The goals to be achieved have been fixed in terms of mortality and morbidity reduction, increase in expectation of life, decrease in population growth rate, improvements in nutritional status, provision of basic sanitation, health manpower requirements and resources development and certain other parameters such as food production, literacy rate, reduced levels of poverty, etc.

The scope of health services varies widely from country to country and influenced by general and ever changing national, state and local health problems, needs and attitudes as well as the available resources to provide these services. A comprehensive list of health services may be found in the Report of the WHO Expert Committee (1961) on "Planning of Public Health Services" *(32)*.

There is now broad agreement that health services should be (a) comprehensive (b) accessible (c) acceptable (d) provide scope for community participation, and (e) available at a cost the community and country can afford. These are the essential ingredients of primary health care which forms an integral part of the country's health system, of which it is the central function and main agent for delivering health care *(9)*.

HEALTH CARE SYSTEMS

The health care system is intended to deliver the health care services. It constitutes the management sector and involves organisational matters. It operates in the context of

the socioeconomic and political framework of the country. In India, it is represented by five major sectors or agencies which differ from each other by the health technology applied and by the source of funds for operation. These are :

1. PUBLIC HEALTH SECTOR
   - (a) Primary Health Care
     - Primary health centres
     - Sub- centres
   - (b) Hospitals/Health Centres
     - Community health centres
     - Rural hospitals
     - District hospital/health centre
     - Specialist hospitals
     - Teaching hospitals
   - (c) Health Insurance Schemes
     - Employees State Insurance
     - Central Government Health Scheme
   - (d) Other agencies
     - Defence services
     - Railways
2. PRIVATE SECTOR
   - (a) Private hospitals, polyclinics, Nursing homes, and dispensaries
   - (b) General practitioners and clinics
3. INDIGENOUS SYSTEMS OF MEDICINE
   - Ayurveda and Siddha
   - Unani and Tibbi
   - Homoeopathy
   - Unregistered practitioners
4. VOLUNTARY HEALTH AGENCIES
5. NATIONAL HEALTH PROGRAMMES

PRIMARY HEALTH CARE IN INDIA

In 1977, the Government of India launched a Rural Health Scheme, based on the principle of "placing people's health in people's hands". It is a three tier system of health care delivery in rural areas based on the recommendation of the Shrivastav Committee in 1975. Close on the heels of these recommendations an International conference at Alma-Ata in 1978, set the goal of an acceptable level of Health for All the people of the world by the year 2000 through primary health care approach. As a signatory to the Alma-Ata Declaration, the Government of India was committed to achieving the goal of Health for All through primary health care approach which seeks to provide universal comprehensive health care at a cost which is affordable.

Keeping in view the WHO goal of "Health for All" by 2000 AD, the Government of India evolved a National Health Policy based on primary health care approach. It was approved by Parliament in 1983. The National Health Policy laid down a plan of action for reorienting and shaping the existing rural health infrastructure with specific goals to be achieved by 1985, 1990 and 1995 within the framework of the Sixth (1980-85) and Seventh (1985-90) Five Year Plans and the new 20 point Programme. Steps were taken to implement the National Health Policy objectives towards achieving Health for All by the year 2000. During the last decade further development of rural health infrastructure took place in view to implement National Health Policy 2000, National Population Policy 2002 and more recently National Rural Health Mission with formulation of Indian Public Health Standards.

1. Village level

One of the basic tenets of primary health care is universal coverage and equitable distribution of health resources. That is, health care must penetrate into the farthest reaches of rural areas, and that everyone should have access to it. To implement this policy at the village level, the following schemes are in operation :

a. Village Health Guides Scheme
b. Training of Local Dais
c. ICDS Scheme
d. ASHA Scheme

a. Village Health Guides

A Village Health Guide is a person with an aptitude for social service and is not a full time government functionary. The Village Health Guides Scheme was introduced on 2nd October 1977 with the idea of securing people's participation in the care of their own health. The scheme was launched in all States except Kerala, Karnataka, Tamil Nadu, Arunachal Pradesh and Jammu and Kashmir which had alternative systems (e.g., Mini-health Centres in Tamil Nadu) of providing health services at the village level.

The Health Guides are now mostly women. A circular was issued by Government of India in May 1986 that male Health Guides would be replaced by female Health Guides *(33)*. The Health Guides come from and are chosen by the community in which they work. They serve as links between the community and the governmental infrastructure. They provide the first contact between the individual and the health system. The guidelines for their selection are *(34)* :

(a) they should be permanent residents of the local community, preferably women
(b) they should be able to read and write, having minimum formal education at least up to the VI standard
(c) they should be acceptable to all sections of the community and
(d) they should be able to spare at least 2 to 3 hours every day for community health work.

After selection, the Health Guides undergo a short training in primary health care. The training is arranged in the nearest primary health centre, subcentre or any other suitable place for the duration of 200 hours, spread over a period of 3 months. During the training period they receive a stipend of Rs. 200 per month.

On completion of training, they receive a working manual and a kit of simple medicines belonging to the modern and traditional systems of medicine in vogue in that part of the country to which they belong. Broadly the duties assigned to health guides include treatment of simple ailments and activities in first aid, mother and child health including family planning, health education and sanitation. The manual or guidebook gives them detailed information about medical care of common illnesses – of what they can and cannot do. In practical terms, they know exactly what should be done when confronted with a situation, when they can begin treatment by themselves and when they should refer the patient immediately to the nearest health centre.

The Health Guides are free to attend to their normal vocation. They are expected to do community health work in their spare time of about 2 to 3 hours daily for which they are paid an honorarium of Rs. 50 per month and drugs worth Rs. 600 per annum. As the training involves expenditure, the Government will not train another Health

Guide from the same village before three years. As of date, there are 3.23 lakh village Health Guides functioning in the country *(35)*. The national target is to achieve one Health Guide for each village or 1000 rural population.

b. Local dais *(36)*

Most deliveries in rural areas are still handled by untrained dais who are often the only people immediately available to women during the perinatal period. An extensive programme has been undertaken, under the Rural Health Scheme, to train all categories of local dais (traditional birth attendants) in the country to improve their knowledge in the elementary concepts of maternal and child health and sterilization, besides obstetric skills. The training is for 30 working days. Each dai is paid a stipend of Rs. 300 during her training period. Training is given at the PHC, subcentre or MCH centre for 2 days in a week, and on the remaining four days of the week they accompany the Health worker (Female) to the villages preferably in the dai's own area. During her training each dai is required to conduct at least 2 deliveries under the guidance and supervision of the HW (F), ANM or HA (F). The emphasis during training is on asepsis so that home deliveries are conducted under safe hygienic conditions thereby reducing the maternal and infant mortality.

After successful completion of training, each dai is provided with a delivery kit and a certificate. These dais are also expected to play a vital role in propagating small-family norm since they are more acceptable to the community. The national target is to train one local dai in each village.

c. Anganwadi worker

Angan literally means a courtyard. Under the ICDS (Integrated Child Development Services) Scheme, there is an anganwadi worker for a population of 400–800. There are about 100 such workers in each ICDS Project. As of date over 6,719 ICDS blocks are functioning in the country. The anganwadi worker is selected from the community she is expected to serve. She undergoes training in various aspects of health, nutrition, and child development for 4 months. She is a part-time worker and is paid an honorarium of Rs. 1500 per month for the services rendered, which include health check-up including maintenance of growth chart, immunization, supplementary nutrition, health education, non-formal pre-school education and referral services. The beneficiaries are especially nursing mothers, pregnant women, other women (15–45 years), children below the age of 6 years and adolescent girls *(37)*. Along with Village Health Guides, the anganwadi workers are the community's primary link with the health services and all other services for young children.

d. ASHA

Please refer to page 449 for details.

2. Sub-centre level

The sub-centre is the peripheral outpost of the existing health delivery system in rural areas. They are being established on the basis of one sub-centre for every 5000 population in general and one for every 3000 population in hilly, tribal and backward areas. As of March 2014, 152,326 sub-centres were established in the country.

A sub-centre provides interface with the community at the grass-root level, providing all the primary health care services. Of particular importance are the packages of services such as immunization, antenatal, natal and postnatal care, prevention of malnutrition and common childhood diseases, family planning services and counselling. They also provide elementary drugs for minor ailments such as ARI, diarrhoea, fever, worm infestation etc. and carryout community needs assessment. Besides the above, the government implements several national health and family welfare programmes through these frontline workers.

Currently, a sub-centre is staffed by one Female Health Worker known as Auxiliary Nurse Midwife (ANM) and one Male Health Worker known as Multi Purpose Worker (Male). One Health Assistant (Female) known as Lady Health Visitor (LHV) and one Health Assistant (Male) located at the PHC level are entrusted with the task of supervision of six sub-centres under a PHC. The Ministry of Health and Family Welfare, Govt. of India provides assistance to all the sub-centres in the country since April 2002 in the form of salary of ANMs and LHVs, rent (if located in a rented building) and contingency, in addition to drugs and equipment kits. The salary of Male Health Worker is borne by the State Governments. In addition, a voluntary worker is provided at the sub-centre level as a helper to ANM, as and when needed. The ANM pays to the voluntary worker from her contingency fund.

Indian Public Health Standards for sub-centres *(38)*

In order to provide quality care in these sub–centres, Indian Public Health Standards (IPHS) are being prescribed to provide basic promotive, preventive and few curative primary health care services to the community and achieve and maintain an acceptable standard of quality of care. These standards would help monitor and improve functioning of the sub-centres. These services are called assured services and are as follows *(38)*.

1. Maternal health care :

Antenatal care : (a) Early registration of pregnancy (ideally before 12 weeks of pregnancy). Minimum three antenatal check-ups. Recording of general check–up, weight, blood pressure, abdominal examination, haemoglobin, routine urine examination and blood group (at first visit if not done previously); (b) Folic acid supplementation from first trimester and folic acid and iron supplementation from 12 weeks onwards; (c) Tetanus toxoid immunization; (d) Identification of high-risk pregnancy and referral; (e) Counselling on diet, pre-birth preparedness and rest.

Intranatal care : (a) Promotion of institutional deliveries; (b) Skilled attendance at home deliveries; and (c) Appropriate and prompt referral in case of complications. *Post-natal care :* (a) Minimum of 2 post-partum home visits, first within 48 hours and 2nd within 7 days of delivery; (b) Initiation of breast feeding within 1/2 hour of delivery; (c) Counselling on diet, hygiene and contraception; and (d) Provision of facilities of Janani Suraksha Yojana.

2. Child health care : (a) Essential new born care as per guidelines; (b) promotion of exclusive breast feeding for 6 months; (c) Full immunization of all infants and children against vaccine preventable diseases; (d) Vitamin A prophylaxis; and (e) Prevention and control of childhood diseases like malnutrition, ARI, diarrhoea etc.

3. Family Planning and Contraception : (a) Education, motivation and counselling to adopt appropriate family planning method; (b) Provision of contraceptives such as

condoms, oral pills, emergency contraceptives and IUD insertion (wherever ANM is trained for IUD insertion); and (c) Follow up services to the eligible couples adopting permanent methods of tubectomy and vasectomy.

4. Counselling and appropriate referral for safe abortion service (MTP).

5. Adolescent health care : Education, counselling and referral.

6. Assistance to school health services.

7. Water quality monitoring.

8. Promotion of sanitation including use of toilet and appropriate garbage disposal.

9. Field visits by appropriate health workers for disease surveillance, family welfare services including STI, RTI awareness.

10. Community need assessment.

11. Curative services for minor ailments including fever, diarrhoea, worm infestation and first–aid, appropriate and prompt referral if needed. To organize Health Day at anganwadi centres at least once in a month. To provide AYUSH treatment.

12. Training of Traditional Birth Attendants and ASHA/ community health volunteers.

13. Co-ordinate services of anganwadi workers, ASHA, village health and sanitation committee etc.

14. National health programmes.

National AIDS Control Programme (NACP) : (a) IEC activities to enhance awareness and preventive measures about STIs and HIV/AIDs, PPTCT services and HIV/TB coordination; (b) counselling and referral of persons practicing high risk behaviour in relation to HIV/AIDS and STD; (c) linkage with microscopy centre for HIV-TB coordination; (d) condom promotion and distribution of condoms to the high risk groups; and (e) help and guide patients with HIV/AIDS receiving ART with focus on adherence.

National Vector Borne Disease Control Programme (NVBDCP) : Prevention of breeding places of vectors through IEC, community mobilization, collection of blood smears from all fever cases, supply of anti-malarial drugs and follow-up of patients on treatment are the activities that are required at the sub-centre level. Rapid test kits for malaria may be used in sub-centre wherever such provision has been made. Assistance to integrated vector control activities in relation to Malaria, Filaria, JE, Dengue, Kala-Azar etc. as prevalent in specific areas and record keeping and reporting of the same. Where filarial is endemic, identification of cases of lymphoedema / elephantitis and hydrocele and their referrals to PHC/CHC for appropriate management. The disease specific guidelines issued by NVBDC are to be followed.

National Leprosy Eradication Programme (NLEP) : Refer the suspect cases of leprosy (patients with skin patches with loss of sensation) to PHC, provision of MDT to diagnosed patients of leprosy at sub-centre, follow-up and defaulter retrieval. Educating public about sign, symptoms and complication of leprosy and availability of MDT at government health institutions.

Integrated Disease Surveillance Projects (IDSP) : (a) Surveillance about any abnormal increase in cases of diarrhoea/dysentry, fever with rigors, fever with rash, fever with jaundice or fever with unconsciousness and early reporting to concerned PHC; (b) Weekly reporting of information for syndromic surveillance in prescribed format to primary health centres on every monday.

Revised National Tuberculosis Control Programme (RNTCP) : Referral of suspected symptomatic cases to the PHC/Microscopy centre; and provision of DOTS at sub-centre and proper documentation and follow-up.

National Blindness Control Programme (NBCP) : IEC is the major activity to help identify cases of blindness and refer suspected cataract cases to the PHC/CHC.

Non-communicable Disease (NCD) and cancer control programmes : IEC to sensitise the community about prevention of cancers and other NCDs, early detection through awareness regarding warning signs and appropriate and prompt referral of suspect cases.

Promotion of medicinal herbs : Locally available medicinal herbs/plants should be grown around the sub-centre.

Record of vital events : Recording and reporting of vital events including births and deaths, particularly of mothers and infants to the health authorities; maintenance of all the relevant records concerning mother, child and eligible couples in the area.

Manpower requirement

In order to provide above services, each sub-centre should have the following personnel :

Manpower	Existing	Proposed
Health worker (female)	1	2
Health worker (male)	1	1 (funded and appointment by the state government)
Voluntary worker to keep the sub–centre clean and assist ANM. She is paid by the ANM from her contingency fund @ Rs. 100/pm *	1 (optional)	1 (optional)
Total	2/3	3/4

* The voluntary worker at the sub–centre level should preferably be a Trained Birth Attendant (TBA) and be paid Rs. 200/- at least (with equal contribution by the Government of India and the concerned State).

3. Primary health centre level

The concept of primary health centre is not new to India. The Bhore committee in 1946 gave the concept of a primary health centre as a basic health unit, to provide, as close to the people as possible, an integrated curative and preventive health care to the rural population with emphasis on preventive and promotive aspects of health care. The Bhore Committee aimed at having a health centre to serve a population of 10,000 to 20,000 with 6 medical officers, 6 public health nurses and other supporting staff. But in view of the limited resources, the Bhore Committee's recommendations could not be fully implemented, even after a lapse of 60 years.

The health planners in India have visualized the primary health centre and its sub-centres as the proper infrastructure to provide health services to the rural population. The Central Council of Health at its first meeting held in January 1953 had recommended the establishment of primary health centres in community development blocks to provide comprehensive health care to the rural population. The number of primary health centres established since then had increased from 725 during the First Five Year Plan to 5484

by the end of the Fifth Plan (1975–1980) – each PHC covering a population of 100,000 or more spread over some 100 villages in each community development block. These centres were functioning as peripheral health service institutions with little or no community involvement. Increasingly, these centres came under criticism as they were not able to provide adequate health coverage, partly because they were poorly staffed and equipped,and partly because they had to cover a large population of one lakh or more. The Mudaliar Committee in 1962 had recommended that the existing primary health centres should be strengthened and the population to be served by them to be scaled down to 40,000.

The Declaration of Alma-Ata Conference in 1978 setting the goal of Health for All by 2000 AD has ushered in a new philosophy of equity, and a new approach, the primary health care approach. The National Health Plan (1983) proposed reorganization of primary health centres on the basis of one PHC for every 30,000 rural population in the plains, and one PHC for every 20,000 population in hilly, tribal and backward areas for more effective coverage. As on March 2014, 25,020 primary health centres have been established in the country.

Functions of the PHC

The functions of the primary health center in India cover all the 8 "essential" elements of primary health care as outlined in the Alma-Ata Declaration. They are :

1. Medical care
2. MCH including family planning
3. Safe water supply and basic sanitation
4. Prevention and control of locally endemic diseases
5. Collection and reporting of vital statistics
6. Education about health
7. National Health Programmes - as relevant
8. Referral services
9. Training of health guides, health workers, local dais and health assistants
10. Basic laboratory services

It is proposed to equip the primary health centres with facilities for selected surgical procedures (e.g., vasectomy, tubectomy, MTP and minor surgical procedures) and for paediatric care. In order to reorient medical education (ROME Programme) towards the needs of the country and community care, three primary health centres have been attached to each of the 148 medical colleges.

Indian Public Health Standards for PHCs *(39)*

The IPHS for primary Health Centres has been prepared keeping in view the resources available with respect to functional requirement for PHCs with minimum standards such as building, manpower, instruments and equipments, drugs and other facilities etc. The standards prescribed are for a PHC covering 20,000–30,000 population with six beds, as all the block level PHCs are ultimately going to be upgraded as CHC with 30 beds of providing specialized services.

The objectives of IPHS for PHCs are :

i. To provide comprehensive primary health care to the community through the Primary Health Centres.
ii. To achieve and maintain an acceptable standard of quality of care.
iii. To make the services more responsive and sensitive to the needs of the community.

Minimum requirements at primary health centre for meeting the IPHS

The assured services cover all the essential elements of preventive, promotive, curative and rehabilitative primary health care. This implies a wide range of services that include :

1. MEDICAL CARE : (a) OPD services : 4 hours in the morning and 2 hours in the afternoon/evening. Time schedule will vary from state to state. Minimum OPD attendance should be 40 patients per doctor per day; (b) 24 hours emergency services : appropriate management of injuries and accident, First-aid, stabilization of the condition of patient before referral, dog bite/snake bite/ scorpion bite cases, and other emergency conditions; (c) Referral services; and (d) In-patient services (6 beds).

2. MATERNAL AND CHILD HEALTH CARE : *Antenatal care :* (a) Early registration of pregnancy and minimum 3 antenatal check-ups; (b) Minimum laboratory investigations such as haemoglobin, urine albumin and sugar and RPR test for syphilis; (c) Nutrition and health counselling; (d) Supplementation of folic acid and iron tablets and tetanus toxoid immunization; (e) Identification of high risk pregnancies and appropriate management; (f) Referral to First Referral Unit or other hospital in case of high risk pregnancy beyond the management capability of medical officer in PHC.

Intranatal care : (a) 24 hours services for normal delivery; (b) Promotion of institutional delivery; (c) Conducting assisted deliveries including forceps and vacuum delivery whenever required; (d) Manual removal of placenta; and (e) Appropriate and prompt referral for cases needing specialist care.

Postnatal care : (a) A minimum of 2 post-partum home visits, first within 48 hours of delivery and 2nd within 7 days through sub-centre staff; (b) Initiation of breast-feeding within half-hour of delivery; (c) Education on nutrition, hygiene and contraception; and (d) Provision of facilities under Janani Suraksha Yojana.

New born care : (a) Essential new born care; (b) Facilities and care for neonatal resuscitation; and (c) Management of neonatal hypothermia and jaundice.

Care of the child : (a) Emergency care of sick child including Integrated Management of Neonatal and Childhood Illness (IMNCI); (b) Care of routine childhood illness; (c) Promotion of breast-feeding for 6 months; (d) Full immunization of all infants and children against vaccine preventable diseases as per guidelines; and (e) Vitamin A prophylaxis.

3. Full range of family planning services including counselling and appropriate referral for couples having infertility.

4. Medical termination of pregnancy using manual vacuum aspiration technique, wherever trained personnel and facility exists.

5. Health education for prevention and management of RTI/STI.

6. Nutrition Services : Diagnosis and management of malnutrition, anaemia and vitamin A deficiency and coordination with ICDS.

7. School health services.

8. Adolescent health care.

9. Disease surveillance and control of epidemics.

10. Collection and reporting of vital events.

11. Promotion of sanitation including use of toilet and appropriate garbage disposal.

12. Testing of water quality and disinfection of water sources.

13. National health programmes.

Revised National Tuberculosis Control Programme (RNTCP) : All PHCs to function as DOTS Centres to deliver treatment as per RNTCP treatment guidelines through DOTS providers and treatment of common complications of TB and side effects of drugs, record and report on RNTCP activities as per guidelines.

National Programme for Control of Blindness : (a) Basic services : Diagnosis and treatment of common eye diseases; (b) Refraction services; and (c) Detection of cataract cases and referral for cataract surgery.

National Vector Borne Disease Control Programme : (a) Diagnosis of malaria cases, microscopic confirmation and treatment; (b) Cases of suspected JE and dengue to be provided symptomatic treatment, hospitalization and case management as per the protocols. (c) Complete treatment to Kala–azar cases in Kala–azar endemic areas as per national policy. (d) Complete treatment of microfilaria positive cases with DEC and participation and arrangement of Mass Drug Administration (MDA) along with management of side reactions, if any. Morbidity management of lymphoedema cases.

National AIDS Control Programme : (a) IEC activities to enhance awareness and preventive measures about STIs and HIV/AIDS, Prevention of Parents to Child Transmission (PPTCT) services. (b) Organizing school health education programme. (c) Screening of persons practicing high-risk behaviour with one rapid test to be conducted at the PHC level and development of referral linkages with the nearest VCTC at the district hospital level for confirmation of HIV status of those found positive at one test stage in the high prevalence states. (d) Risk screening of antenatal mothers with one rapid test for HIV and to establish referral linkages with CHC or district hospital for PPTCT services in the six high HIV prevalence states of Tamil Nadu, Andhra Pradesh, Maharashtra, Karnataka, Manipur and Nagaland. (e) Linkage with microscopy centre for HIV-TB coordination. (f) Condom promotion and distribution of condoms to the high risk groups. (g) Help and guide patients with HIV/AIDS receiving ART with focus on adherence. (h) Pre and post-test counselling of AIDS patients by PHC staff in high prevalence states.

14. Appropriate and prompt referral of cases needing special care and providing transport facilities either by PHC vehicle or other available referral transport. The funds should be made available for referral transport as per the provision under NRHM/RCH-II programme.

15. Record of vital events, reporting of births and deaths, and maintenance of all relevant records concerning services provided in PHC.

16. Training :

(i) Health workers and traditional birth attendants.
(ii) Initial and periodic training of paramedics in treatment of minor ailments.
(iii) Training of ASHAs.
(iv) Periodic training of doctors through continuing medical education, conferences, skill development training, etc. on emergency obstetric care.
(v) Training of ANM and LHV in antenatal care and skilled birth attendance.
(vi) Training under Integrated Management of Neonatal and Childhood Illness (IMNCI).
(vii) Training of pharmacist on AYUSH component with standard modules.
(viii) Training of AYUSH doctor in imparting health services related to National Health and Family Welfare programme.

17. Basic laboratory services

(i) Routine urine, stool and blood tests.
(ii) Bleeding time, clotting time.
(iii) Diagnosis of RTI/STDs with wet mounting, Grams stain, etc.
(iv) Sputum testing for tuberculosis (if designated as a microscopy center under RNTCP).
(v) Blood smear examination for malarial parasite.
(vi) Rapid tests for pregnancy.
(vii) RPR test for Syphilis/YAWS surveillance.
(viii) Rapid diagnostic tests for typhoid (Tyhpi Dot) and malaria.
(ix) Rapid test kit for faecal contamination of water.
(x) Estimation of chlorine level of water using ortho-toludine reagent.

18. Monitoring and supervision :

(i) Monitoring and supervision of activities of sub–centres through regular meetings/periodic visits, etc.
(ii) Monitoring of all National Health Programmes.
(iii) Monitoring activities of ASHAs.
(iv) Medical officer should visit all sub-centres at least once in a month.
(v) Health assistants male and LHV should visit sub-centres once a week.

19. Selected surgical procedures

The vasectomy, tubectomy (including laparoscopic tubectomy), MTP, hydrocelectomy and cataract surgeries as a camp/fixed day approach have to be carried out in a PHC having facilities of O.T.

20. Mainstreaming of AYUSH

STAFFING PATTERN

The manpower that should be available in the PHC is as follows :

Staff	Existing	Recommended
Medical Officer	1	3 (At least 1 female)
AYUSH practitioner	Nil	1 (AYUSH or any ISM system prevalent locally)
Account Manager	Nil	1
Pharmacist	1	2
Nurse-midwife (Staff) (Nurse)	1	5
Health workers (F)	1	1
Health Educator	1	1
Health Asstt. (Male & Female)	2	2
Clerks	2	2
Laboratory Technician	1	2
Driver	1	Optional/vehicles may be out–sourced.
Class IV	4	4
Total	15	24/25

Source : *(39)*

4. Community Health Centres

As on 31st March 2014, 5,363 community health centres were established by upgrading the primary health centres, each community health centre covering a population of 80,000 to 1.20 lakh (one in each community development block) with 30 beds and specialists in surgery, medicine, obstetrics and gynaecology, and paediatrics with X-ray and laboratory facilities. For strengthening preventive and promotive aspects of health care, a new non-medical post called community health officer has been created at each community health centre. The community health officer is selected from amongst the supervisory category of staff at the PHC and district level with minimum of 7 years experience in rural health programmes. Some states have not accepted this scheme and have opted for a second medical officer *(27)*.

The specialists at the community health centre may refer a patient directly to the State level hospital or the nearest/ appropriate Medical College Hospital, as may be necessary, without the patient having to go first to the sub-divisional or District Hospital.

Indian Public Health Standards for community health centres

In order to provide quality care in CHCs, Indian Public Health Standards (IPHS) are being prescribed to provide optimal expert care to the community and achieve and maintain an acceptable standard of quality of care. These standards would help monitor and improve the functioning of the CHCs.

Every CHC has to provide following services which are known as the assured services *(39)* :

1. Care of routine and emergency cases in surgery:
   a. This includes incision and drainage, and surgery for hernia, hydrocele, appendicitis, haemorrhoids, fistula, etc.
   b. Handling of emergencies like intestinal obstruction, haemorrhage, etc.
2. Care of routine and emergency cases in medicine: Specific mention is being made of handling of all emergencies in relation to the national health programmes as per guidelines like dengue/DHF, cerebral malaria, etc. Appropriate guidelines are already available under each programme, which should be compiled in a single manual.
3. 24-hour delivery services, including normal and assisted deliveries.
4. Essential and emergency obstetric care including surgical interventions like caesarean sections and other medical interventions.
5. Full range of family planning services including laproscopic services.
6. Safe abortion services.
7. Newborn care.
8. Routine and emergency care of sick children.
9. Other management, including nasal packing, tracheostomy, foreign body removal etc.
10. All the national health programmes (NHP) should be delivered through the CHCs. Integration with the existing programmes like blindness control, Integrated Disease Surveillance Project, is vital to provide comprehensive services.
    a. RNTCP : CHCs are expected to provide diagnostic services through the microscopy centres which are already established in the CHCs, and treatment services as per the technical guidelines and operational guidelines for tuberculosis control.
    b. HIV/AIDS Control Programme services will be provided.
    c. National Vector-Borne Disease Control Programme: The CHCs are to provide diagnostic and treatment facilities for routine and complicated cases of malaria, filaria, dengue, Japanese Encephalitis and Kala-azar in the respective endemic zones.
    d. National Leprosy Eradication Programme: The minimum services that are to be available at the CHCs are for diagnosis and treatment of cases and reactions of leprosy along with advice to patient on prevention of deformity.
    e. National Programme for Control of Blindness: The eye care services that should be available at the CHC are diagnosis and treatment of common eye diseases, refraction services and surgical services including cataract by IOL implantation at selected CHCs optionally. 1 eye surgeon is being envisaged for every 5 lakh population.
    f. Under Integrated Disease Surveillance Project, the related services include services for diagnosis for malaria, tuberculosis, typhoid and tests for detection of faecal contamination of water and chlorination level. CHC will function as peripheral surveillance unit and collate, analyze and report information to District Surveillance Unit. In outbreak situations, appropriate action will be initiated.
11. Others:
    a. Blood storage facility
    b. Essential laboratory services
    c. Referral (transport) services

Manpower for community health centres

The existing staff for CHC is as follows :

Existing clinical manpower	
1. General Surgeon	1
2. Physician	1
3. Obstetrician / Gynaecologist	1
4. Paediatrician	1
Existing support manpower	
Nurse - midwife *	7+2
Dresser (certified by Red Cross/St. Johns ambulance)	1
Pharmacist / compounder	1
Lab. technician	1
Radiographer	1
Ophthalmic assistant **	0-1
Ward boy / nursing orderly	2
Sweepers	3
Chowkidar	
OPD attendant	
Statistical assistant / Data entry operator	5***
OT attendant	
Registration clerk	
Total essential	21-22+2

* 1 ANM and 1 PHN for family welfare will be appointed under the ASHA scheme.

** Ophthalmic assistant may be placed wherever it does not exist through redeployment or contract basis.

*** Flexibility may rest with the state for recruitment of personnel as per requirements.

In order to provide round the clock clinical services, the revised IPHS staff pattern is as follows *(40)* :

Personnel	Strength	Desirable Qualifications
Block Health Officer	-	Senior most specialists among the below mentioned speciality (Physician/General surgeon/Paed./Obs & Gyne Anaesthesia/Public Health/ Ophthalmology)
General Surgeon	1	MS/DNB, (General Surgery)
Physician	1	MD/DNB, (General Medicine)
Obstetrician & Gynaecologist	1	MD/DNB/DGO (OBG)
Paediatrics	1	MD (Paediatrics)/DNB/DCH
Anaesthetist	1	MD (Anaesthesia)/DNB/DA/ Certificate course in Anaesthesia for one year
Public Health Manager	1	MD (PSM)/MD (CHA)/MD Community Medicine or Post Graduation Degree with MBA
Eye surgeon	1 (1 for every five CHCs)	MD/MS/DOMS/DNB/ (Ophthal)
Dental Surgeon	1	BDS
General Duty Medical Officer	6 (at least 2 female doctors)	MBBS
Specialist of AYUSH	1	Post Graduate in AYUSH
General Duty Medical Offier of AYUSH	1	Graduate in AYUSH
Total	15/16	

Support manpower :

Personnel	Strength
Staff Nurse	19**
Public Health Nurse (PHN)	1*
ANM	1*
Pharmacist/compounder	3
Pharmacist-AYUSH	1
Lab. Technician	3
Radiographer	2
Ophthalmic Assistant	1
Dresser (certified by Red Cross/St. Johns Ambulance)	2
Ward Boys/Nursing Orderly	5
Sweepers	5
Chowkidar	5
Dhobi	1
Mali	1
Aya	5
Peon	2
OPD Attendant	1
Registration Clerk	2
Statistical Assistant/Data Entry Operator	2
Accountant/Admin. Assistant	1
OT Technician	1
Total	64

* Will be appointed under the ASHA scheme.

** For providing round the clock service at OT, labour room, casualty, male ward and female ward along with provision of leave reserve.

JOB DESCRIPTION OF MEMBERS OF THE HEALTH TEAM

1. Medical Officer, PHC

1. He is the captain of the health team at the primary health centre. He devotes the morning hours attending to patients in the out-door; in the afternoon he supervises the field work.
2. His tour programme is so designed as to cover all the basic health services including family planning.
3. He will plan and implement UIP as per guidelines and ensure maximum possible coverage of the population in the PHC. He will ensure proper storage of vaccine and maintenance of cold chain equipment. He will ensure adequate supplies of vaccine and miscellaneous items required for the effective implementation of UIP.
4. He will ensure proper implementation of IMNCI as per guidelines.
5. He will visit schools in the PHC area at regular intervals and arrange for medical check up and immunization.
6. He will organize and conduct tubectomy and vasectomy camps.
7. Organize training of all health personnel like ASHA, anganwadi worker, Dais etc.
8. He ensures that national health programmes are being implemented in his area properly.
9. He visits each subcentre regularly on fixed days and hours and provides guidance, supervision and leadership to the health team.
10. He spends one day in each month organising staff meetings at the primary health centre to discuss the problems and review the progress of health activities.
11. The success of a primary health centre depends largely on the team leadership which the medical officer is able to provide. The medical officer must be the planner, the promoter, the director, the supervisor, the coordinator as well as the evaluator.

Second Medical Officer

The second medical officer performs identical duties.

2. Health worker Male and Female

Under The Multipurpose Worker Scheme, one health worker female and one health worker male are posted at each sub-centre and are expected to cover a population of 5000 (3000 in tribal and hilly areas). However, health worker female limits her activities among 350-500 families.

A. HEALTH WORKER FEMALE (HWF)

She will carry out the following functions :

1. Maternal and Child Health
   - 1.1 Register and provide care to pregnant women throughout the period of pregnancy.
   - 1.2 Ensure that every pregnant woman makes at least 3 (three) visits for antenatal check-up.
   - 1.3 Test urine of pregnant women for albumin and sugar. Estimate haemoglobin level.
   - 1.4 Refer all pregnant women to PHC for RPR test for syphilis.
   - 1.5 Refer cases of abnormal pregnancy and cases with medical and gynaecological problems to Health Assistant Female (LHV) or the Primary Health Centre.

1.6 Conduct deliveries in her area when called for.
1.7 Supervise deliveries conducted by Dais and assist them whenever called in.
1.8 Refer cases of difficult labour and newborns with abnormalities, help them to get institutional care and provide follow-up to the patients referred to or discharged from hospital.
1.9 ANM will identify the beneficiaries, complete necessary formalities and obtain necessary approvals of the competent authority before disbursement to the beneficiaries under Janani Suraksha Yojana (JSY), and by 7th of each month will submit accounts of the previous month in the prescribed format to be designed by the State. ANM will prepare a monthly work schedule in the meeting of all accredited workers to be held on every 3rd Friday of every month, which is mandatory. The guideline under JSY is to be followed.
1.10 Make at least two post-natal visits for each delivery happened in her areas and render advice regarding care of the mother and care, feed of the newborn.
1.11 Assess the growth and development of the infant and take necessary action required to rectify the defect.
1.12 Educate mothers individually and in groups in better family health including maternal and child health, family planning, nutrition, immunization, control of communicable diseases, personal and environmental hygiene.
1.13 Assist Medical Officer and Health Assistant (Female) in conducting antenatal and postnatal clinics at the sub-centre.

2. Family Planning :
2.1 Utilize the information from the eligible couple and child register for the Family Planning programme. She will be responsible for maintaining eligible couple registers and updating at all times.
2.2 Spread the message of family planning to the couples and motivate them for family planning individually and in groups.
2.3 Distribute conventional contraceptives and oral contraceptives to the couples, provide facilities and to help prospective acceptors in getting family planning services, if necessary, by accompanying them or arranging for the Dai/ ASHA to accompany them to hospital.
2.4 Provide follow-up services to female family planning acceptors, identify side effects, give treatment on the spot for side effects and minor complaints and refer those cases that need attention by the physician to the PHC/Hospital.
2.5 Establish female depot holders, and provide a continuous supply of conventional contraceptives to the depot holders.
2.6 Build rapport with acceptors, village leaders, ASHA, Dais and others and utilize them for promoting Family Welfare Programme.
2.7 Identify women leaders and help the Health Assistant (Female) to train them.
2.8 Participate in Mahila Mandal meetings and utilize such gatherings for educating women in Family Welfare Programme.

3. Medical Termination of Pregnancy :
3.1 Identify the women requiring help for medical termination of pregnancy and refer them to nearest approved institution.
3.2 Educate the community of the consequences of septic abortion and inform them about the availability of services for medical termination of pregnancy.

4. Nutrition :
4.1 Identify cases of malnutrition among infants and young children (birth to five years), give the necessary treatment and advice and refer serious cases to the Primary Health Centre.
4.2 Distribute Iron and Folic Acid tablets as prescribed to pregnant women, nursing mothers, and young children (up to five years) as per the guidelines.
4.3 Administer Vitamin A solution to children as per the guidelines.
4.4 Educate the community about nutritious diet for mothers and children.
4.5 Coordinate with Anganwadi Workers.

5. Universal Programme on Immunization (UIP) :
5.1 Immunize pregnant women with tetanus toxoid.
5.2 Administer DPT vaccine, oral poliomyelitis vaccine, measles vaccine, hepatitis B vaccine and BCG vaccine to all infants and children, as per immunization schedule.
5.3 Ensure injection safety.

6. Dai Training :
6.1 List Dais in her area and involve them in promoting Family Welfare.
6.2 Help the Health Assistant (Female) / LHV in the training programme of Dais.

7. Communicable Diseases :
7.1 Notify the M.O. PHC immediately about any abnormal increase in cases of diarrhoea/ dysentry, fever with rigors, fever with rash, fever with jaundice or fever with unconsciousness which she comes across during her home visits, take the necessary measures to prevent their spread, and inform the Health Worker (male) to enable him to take further action.
7.2 If she comes across a case of fever during her home visits, she will take blood smear, administer presumptive treatment for malaria and inform Health Worker (male) for further action.
7.3 Identify cases of skin patches, especially if accompanied by loss of sensation, which she comes across during her home visits and bring them to the notice of the Health Worker (male)/ MO (PHC).
7.4 Assist the Health Worker (male) in maintaining a record of cases in her area, who are under treatment for malaria, tuberculosis and leprosy, and check whether they are taking regular treatment, motivate defaulters to take regular treatment and bring these cases to the notice of the Health Worker (male) or Health Assistant (male).
7.5 Give oral rehydration solution to all cases of diarrhoea/dysentry/vomiting.
Identify and refer all cases of blindness including suspected cases of cataract to M.O., PHC.
7.6 Education, counselling, referral, follow-up of cases STI/RTI, HIV/AIDS.

7.7 Where Filaria is endemic :
- Identification of cases of lymphoedema/ elephantiasis and hydrocele and their referrals to PHC/CHC for appropriate management.
- Training of patients with lymphoedema/ elephantiasis about care of feet and home based management remedies.
- Identification and training of drug distributors for mass drug distribution of DEC on National Filaria Day.

8. Vital Events
8.1 Record and report to the health authority of vital events including births and deaths, particularly of mothers and infants to the health authorities in her area.
8.2 Maintenance of all the relevant records concerning mothers, children and eligible couples in the area.

9. Record Keeping
9.1 Register (a) pregnant women from three months of pregnancy onward (b) infants zero to one year of age; and (c) women aged 15 to 44 years.
9.2 Maintain the prenatal and maternity records and child care records.
9.3 Prepare the eligible couple and child register and maintaining it up-to-date.
9.4 Maintain the records as regards contraceptive distribution, IUD insertion, couples sterilized, clinics held at the sub-centre and supplies received and issued.
9.5 Prepare and submit the prescribed weekly/ monthly reports in time to the Health Assistant (Female).
9.6 While maintaining passive surveillance register for malaria cases, she will record :
- No. of fever cases.
- No. of blood slides prepared.
- No. of malaria positive cases reported.
- No. of cases given radical treatment.

10. Treatment of minor ailments
10.1 Provide treatment for minor ailments, provide first-aid for accidents and emergencies and refer cases beyond her competence to the Primary Health Centre/Community Health Centre or nearest hospital.
10.2 Provide treatment as per Indian System of Medicine (ISM), as needed, at the local level.

11. Team Activities
11.1 Attend and participate in staff meetings at Primary Health Centre/Community Development Block or both.
11.2 Coordinate her activities with the Health Worker (male) and other health workers including the Health volunteers/ASHA and Dais.
11.3 Coordinate with the PRI and Village Health and Sanitation Committee.
11.4 Meet the Health Assistant (Female) each week and seek her advice and guidance whenever necessary.
11.5 Maintain the cleanliness of the sub-centre.
11.6 Dispose medical waste as per the guidelines.
11.7 Participate as a member of the team in camps and campaigns.

B. HEALTH WORKER MALE (HWM) *(38)*

I. Record-keeping

He will;

1. Survey all the families in his area and collect general information about each village/locality in his area.
2. Prepare, maintain and utilize family records and village registers containing columns for recording particulrs concerning FP, immunizations, vital events, environmental sanitation, other local health programmes, educational activities, services rendered and achievements, etc.

I. National health programmes

His duties pertaining to different national health programmes are as follows:

A. National vector borne disease control programme

I. Malaria

1. From each family, he shall enquire about
   a) Presence of any fever cases
   b) Whether there was any fever case in the family in between his fortnightly visits
   c) Whether any guest had come to the family and had fever
   d) Whether any member of the family who had fever in between his fortnightly visit had left the village.
2. He shall collect thick and thin blood smears on one glass slide from case having fever or giving history of fever and enter details in Malaria Form–2 (MF-2) and put appropriate serial number on the slide.
3. He shall contact the ASHAs (Accredited Social Health Activist under NRHM) and other FTDs, if any, during their fortnightly visit to the village and (i) collect blood smears already taken by the ASHA, FTD (ii) also collect details of each case in MF-2 (iii) replenish both drugs and glass-slides and Rapid Diagnostic Kits (RDKs) and look into the account of consumption of Anti malarial drugs and use of RDKs.
4. He shall dispatch blood smears along with MF-2 collected from the ASHA, FTD, multipurpose health worker (female), collected during their visit in his area, to the PHC Laboratory twice a week, or as instructed by the Medical Officer PHC.
5. He shall see the results obtained by the use of RDKs and verify the radical treatment administered by the ASHA, FTD, if any, during his visit.
6. He shall administer radical treatment to the positive cases as per drug schedule prescribed, and as per instructions issued by the Medical Officer PHC, and take laid down action if toxic manifestations are observed in a patient receiving radical treatment with primaquine.
7. He shall contact the ASHA and FTD and inform the spray dates, and make request to motivate the community and prepare them for accepting the spray operations.
8. Assist the Health Supervisor (Male)/ Health Assistant (Male) in supervising spraying operations and training of field spraying staff.

II. Kala-azar endemic areas

1. From each family, he will enquire about presence of any fever case of more than 15 days duration; whether any guest of the house had fever/Kala-azar; or any family member of the house/guest who had fever of more than 15 days duration left the village.

2. He will guide the suspected cases to the nearest PHC/ CHC for diagnosis and treatment. He will keep a record of such cases and make sure that they take complete treatment.
3. Health education about Kala-azar disease.

III. Japanese encephalitis (JE) endemic areas

1. From each family he will enquire about any fever case with symptoms of encephalitis and guide the suspected cases to the nearest PHC/CHC for diagnosis and treatment by the medical officer.
2. He will keep the record of all the cases of JE in his area for follow-up.
3. Health education activities about the JE disease.

IV. Filaria endemic areas

1. Identification of cases of lymphoedema/elephantiasis and hydrocele and their referrals to PHC/CHC for appropriate management.
2. Training of patients with lymphoedema/elephantiasis about care of feet and home based management remedies.
3. Identification and training of drug distributors for mass drug distribution of DEC on National Filaria Day.

B. Leprosy eradication programme

1. Identify cases of skin patches, especially if accompanied by loss of sensation and refer these cases to M.O., PHC for further investigations diagnosis.
2. Check whether all cases of leprosy are taking regular treatment. Motivate defaulter to take regular treatment.
3. Maintain patient records.

C. Revised national tuberculosis control programme

1. Identify persons especially 15 years and above, with prolonged cough or spitting of blood, and take sputum smears from these individuals. Refer cases to the M.O.PHC for further investigations.
2. Check whether all cases of tuberculosis are taking regular treatment. Motivate defaulters to take regular treatment.
3. Educate the community on various health education aspect of tuberculosis programme.
4. Assist the village Health Guide/ASHA and similar village health volunteers to carry-out DOTS activities, and to motivate the TB patients in taking regular treatment.

D. National blindness control programme

Identify and refer all cases of blindness including suspected cases of cataract to M.O., PHC.

E. Expanded programme on immunization

1. Administer DPT vaccine, oral poliomyelitis vaccine, measles vaccine and BCG vaccine to all infants and children in his area in collaboration with health worker (female).
2. Assist the Health Worker Female in administering tetanus toxoid to all pregnant women.
3. Assist the Health Assistant Male in the school immunization programme.
4. Educate the people in the community about the importance of immunization against various communicable diseases.

F. Reproductive and child health programme (RCH)

1. Utilize the information from the eligible couple and child register for the family planning Programme.
2. Spread the message of family planning to the couples and motivate them for family planning individually and in groups.
3. Distribute conventional contraceptives and oral contraceptives to the couples.
4. Help prospective acceptors of sterilization in obtaining the services, if necessary, by accompanying them or arranging for the ASHA/dai to accompany them to the PHC/Hospital.
5. Provide follow-up services to male family Planning acceptors, and refer those cases that need attention by the physician to PHC/Hospital.
6. Build rapport with satisfied acceptors, village leaders, ASHA, Dais and others and utilize them for promoting family welfare Programme.
7. Identify the male community leaders in each village of his area.
8. Assist the health supervisor male in training the leaders in the community and in educating and involving the community in Family Welfare Programme.
9. Identify the women requiring help for medical termination of pregnancy, refer them to the nearest approved institution and inform the health worker (female).
10. Educate the community on the availability of service for Medical Termination of Pregnancy.
11. Educate community on home management of diarrhoea and ORS.
12. Report any outbreak of diarrhoea disease.
13. Measures such as chlorination of drinking water to be carried out.
14. Proper sanitation to be maintained.
15. Encourage use of latrines.
16. Identify and refer cases of genital sore or urethral discharge or non-itchy rash over the body to medical officer.

II. Communicable diseases

1. Identify cases of diarrhoea/dysentery, fever with rash jaundice, encephalitis, diphtheria, whooping cough, tetanus, and acute eye infections and notify the Health Assistant Male and M.O. PHC immediately about these cases.
2. Carry out control measures until the arrival of the Health Assistant Male and assist him in carrying out these measures.
3. Give Oral Rehydration solution to all cases of diarrhoea/ dysentery/vomiting.
4. Educate the community about the importance of control and preventive measures against communicable diseases and about the importance of taking regular and complete treatment.

III. Environmental sanitation

1. Chlorinate public water sources including wells at regular intervals.
2. Educate community on (a) the method of disposal of liquid wastes; (b) the method of disposal of solid wastes; (c) home sanitation, (d) advantage and use of sanitary type of latrines; (e) construction and use of smokeless chulhas.
3. Coordination with Village Health and Sanitation Committee.

IV. Primary medical care

Provide treatment for minor ailments, first-aid for accidents and emergencies and refer cases beyond his competence to the nearest hospital or PHC/CHC.

V. Health education

Educate the community, about the availability of maternal and child health services and encourage them to utilize the facilities.

VI. Nutrition

1. Identify cases of malnutrition among infants and young children (0–5 years) in his area, give the necessary treatment and advice or refer them to the anganwadi for supplementary feeding and refer serious cases to the PHC.
2. Educate the community about the nutritious diet for mothers and children from locally available food.

VII. Vital events

1. Enquire about births and deaths occurring in his area, record them in the births and deaths register, sharing the information with ANM and report them to the Health Supervisor (Male)/Health Supervisor (Female).
2. Educate the community on the importance of registration of births and deaths.

VIII. Record Keeping

1. Survey all the facilities in his area and prepare/maintain maps and charts for the village.
2. Prepare, maintain and utilize family and village records.
3. Assist the Health Worker (Female)/ANM to prepare and maintain the eligible couple as well as maternal & child health register.
4. Maintain a record of cases in his area, who are under treatment for tuberculosis and leprosy.
5. Prepare and submit the prescribed monthly reports in time to the Health Supervisor (Male).
6. While maintaining passive surveillance register for malaria cases, he will record:
   a. No. of fever cases.
   b. No. of blood slides prepared.
   c. No. of malaria positive cases reported.
   d. No. of cases given radical treatment.

3A. Job responsibilities of Health Assistant (Female)

Note : Under the multipurpose workers scheme, a health assistant (female) is expected to cover a population of 30,000 (20,000 in tribal and hilly areas) in which there are six sub-centres, each with one health worker (female).

The health assistant (female) will carry out the following functions :

1. Supervision and guidance
   1.1 Supervise and guide the health worker (female) in the delivery of health care services to the community.
   1.2 Strengthen the knowledge and skills of the health worker (female).
   1.3 Help the health worker (female) in improving her skills in working in the community.
   1.4 Help and guide the health worker (female) in planning and organizing her programme of activities.
   1.5 Visit each sub-centre at least once a week on a fixed day to observe and guide the health worker (female) in her day-to-day activities.
   1.6 Assess periodically the progress of work of the health worker (female), and submit an assessment report to the medical officer of the primary health centre.
   1.7 Carry out supervisory home visits in the area of the health worker (female).
2. Team work
   2.1 Help the health worker to work as part of the health team.
   2.2 Co-ordinate her activities with those of the health assistant (male) and other health personnel including the *dais*.
   2.3 Co-ordinate the health activities in her area with the activities of workers of other departments and agencies, and attend meetings at block level.
   2.4 Conduct regular staff meetings with the health workers in coordination with the health assistant (male).
   2.5 Attend staff meetings at the primary health centre.
   2.6 Assist the medical officers of the primary health centre in the organization of the different health services in the area.
   2.7 Participate as a member of the health team in mass camps and campaigns in health programmes.
3. Supplies, equipment and maintenance of sub-centre
   3.1 In collaboration with the health assistant (male), check at regular intervals the stores available at the sub-centre and help in the procurement of supplies and equipment.
   3.2 Check that the drugs at the sub-centre are properly stored and that the equipment is well maintained.
   3.3 Ensure that the health worker (female) maintains her general kit and midwifery kit in the proper way.
   3.4. Ensure that the sub-centre is kept clean and is properly maintained.
4. Records and reports
   4.1 Scrutinize the maintenance of records by the health worker (female) and guide her in their proper maintenance.
   4.2 Maintain the prescribed records and prepare the necessary reports.
   4.3 Review reports received from the health workers (female), consolidate them, and submit periodical reports to the medical officer of the primary health centre.
5. Where Kala-azar is endemic, her additional duties are:
   1. She should check minimum of 10% of the house in a village to verify that the health worker (female) really visited those houses and carried her job of identifying suspected Kala-azar cases and ensuring complete treatment has been done properly.
   2. She will carry with her the proper record forms, diary and guidelines for identifying suspected Kala-azar cases; and she will be responsible along with Health Assistant (Male) for ensuring complete treatment of Kala-azar patients in her area.
   3. She will be responsible along with health assistant (male) for ensuring complete coverage during the spray activities and search operation.

4. She will also undertake health education activities particularly through interpersonal communication, arrange group meetings with leaders and organizing and conducting training of community leaders with the assistance of health team.

6. Where lymphatic filariasis is endemic, her specific duties are:
   1. She should check minimum of 10% of the houses in a village to verify that the health worker (female) really visited those houses and carried her job properly.
   2. She will be responsible along with Health Assistant (male) for ensuring compliance of drug more than 80% during mass drug administration.
   3. She will also undertake health education activities particularly through interpersonal communication, arrange group meetings with leaders and organizing and conducting training of community leaders with the assistance of health team.

7. Where Japanese Encephalitis is endemic, her specific duties are:
   1. She should check along with minimum of 10% of the houses in a village to verify that the health worker (female) really visited those houses and carried her job properly. Her job of identifying suspected JE cases and ensuring complete treatment has been done properly.
   2. She will carry with her proper record form and guidelines for identifying suspected JE cases.
   3. She will be responsible for ensuring complete treatment of JE patients in her area.
   4. She will be responsible for ensuring complete coverage during the spray activities and search operation.
   5. She will undertake health education activities about the disease.

8. Training

   Organize and conduct training for *dais*/ASHA with the assistance of the health worker (female).

9. Maternal and child health
   1. Conduct weekly MCH clinics at each sub-centre with the assistance of the health worker (female).
   2. Respond to calls from the health worker (female) and trained *dais*, and from the health worker (male) and render necessary help.
   3. Conduct deliveries when required at PHC level and provide domiciliary and midwifery services.

10. Family welfare and medical termination of pregnancy
    1. Conduct weekly family welfare clinics (alongwith the MCH clinics) at each sub-centre with the assistance of the health worker (female).
    2. Personally motivate resistant cases for family planning.
    3. Provide information on the availability of services for medical termination of pregnancy and refer suitable cases to the approved institutions.
    4. Guide the health worker (female) in establishing female depot holders for the distribution of conventional contraceptives and train the depot holders with the assistance of the health worker (female).
    5. Through spot checking, she will ensure that health worker (female) maintains up-to-date eligible couple register.
    6. Provide IUD services and their follow-up.
    7. Assist medical officer PHC in organizing family planning camps.

11. Nutrition
    1. Identify cases of malnutrition among infants and young children (zero to five years), give the necessary treatment and advice and refer serious cases to the primary health centre/community health centre.
    2. Ensure that iron and folic acid tablets; and vitamin A solution are distributed to the beneficiaries.
    3. Educate the expectant mother regarding breast feeding.

12. Immunization
    1. Supervise the immunization of all pregnant women and children (0–5) years.
    2. She will guide the health worker (female) to procure supplies, organize immunization camps, provide guidance for maintaining cold chain, storage of vaccine and health education about immunization programme.

13. Acute respiratory infection
    1. Ensure early diagnosis of pneumonia cases.
    2. Provide suitable treatment to mild/moderate cases of ARI.
    3. Ensure early referral in doubtful/severe cases.

14. School health

    Help medical officer in school health services.

15. Primary medical care
    1. Provide treatment for minor ailments, provide first-aid for accidents and emergencies, and refer cases beyond her competence to the primary health centre or nearest hospital.
    2. Attend to cases referred by the health workers and refer cases beyond her competence to the primary health centre or nearest hospital.

16. Health education
    1. Carry out educational activities for MCH, family planning, nutrition and immunization with the assistance of the health worker (female).
    2. Arrange group meetings with leaders and involve them in spreading the message for various health programmes.
    3. Organize and conduct training of woman leaders with the assistance of health worker (female).
    4. Organize and utilize *mahila mandals*, teachers and other women in the community in the family welfare programmes.

3B. Specific Job functions of Health Assistant (Male) *(39)*

I. Malaria

1. Supervise the work of Health Worker Male during concurrent visits.
2. Check minimum of 10% of the houses in a village.
3. Collect thick and thin smears from any fever case he come across and will administer presumptive treatment of prescribed dosage of anti-malarial drugs.

4. Administer radical treatment to positive cases in his area.
5. Supervise the spraying of insecticides during local spraying along with the Health Worker (Male).

II. Communicable diseases

1. Be alert to the sudden outbreak of epidemics of diseases such as diarrhoea/dysentery, fever with rash, jaundice, enecephalitis, diphtheria, whooping cough or tetanus, acute eye infections and take all possible remedial measures.
2. Take the necessary control measures when any notifiable disease is reported to him. Carry out the destruction of stray dogs with the help of the Health Worker Male.

III. Leprosy

1. Ensure that all cases of Leprosy take regular and complete treatment and inform the Medical Officer PHC about any defaulters to treatment.

IV. Tuberculosis

Ensure that all cases of tuberculosis take regular and complete treatment and inform the M.O. PHC about any defaulters to treatment.

V. Environmental sanitation

Help the community in the construction of :
(a) safe water source (b) soakage pits (c) kitchen garden (d) manure pits (e) compost pits (f) Sanitary latrines (g) smokeless chulhas and supervise their construction. Supervise the chlorination of water source including wells.

VI. Expanded programme on Immunization

1. Conduct immunization of all school going children with the help of the Health Worker Male.
2. Supervise the immunization of all children from one to five years.

VII. Family planning

1. Personally motivate resistant cases for family planning.
2. Guide the Health Worker Male in establishing male depot holders with the assistance of the Health Worker Male and supervise the functioning.
3. Assist M.O.PHC in organization of Family Planning camps and drives.
4. Provide information on the availability of services for medical termination of pregnancy and refer suitable cases to the approved institutions.
5. Ensure follow-up of all cases of vasectomy, tubectomy, IUD and other Family Planning acceptors.

VIII. Nutrition

1. Ensure that all cases of malnutrition among infants and young children (0-5 years) are given the necessary treatment and advice and refer serious cases to the PHC.
2. Ensure that Iron and Folic Acid and Vitamin A are distributed to the beneficiaries as prescribed.

IX. Control of blindness

All cases of blindness including suspected cases of cataract be referred to Medical Officer of Primary Health Centre.

4. Accredited Social Health Activist (ASHA)

The job responsibility of ASHA, and the integration of her role with anganwadi and ANM are described in detail on page 449.

HOSPITALS

Apart from the primary health centres, the present organization of health services of the Government sector consists of rural hospitals, sub-divisional/tahsil/taluka hospitals, district hospitals, specialist hospitals and teaching institutions.

(a) *Rural hospitals :* It is now proposed to upgrade the rural dispensaries (allopathic/traditional system of medicine) to primary health centres. At present a good number of PHCs are located at tahsil/Sub-divisional/taluka headquarters which also have hospitals. Such PHCs may be shifted to the interior rural areas. It is proposed to convert the Sub-divisional hospitals into Sub-divisional health centers so as to cover a population of 5 lakhs *(15)*. These centres will have an epidemiological wing attached to them.

(b) *District hospitals :* There are proposals to convert the district hospital into District Health Centre *(15)*. A hospital differs from a health centre in the following respects : (a) in a hospital, services provided are mostly curative; in a health centre, the services are preventive, promotive and curative – all integrated; (b) a hospital has no catchment area, i.e., it has no definite area of responsibility. Patients may be drawn from any part of the country. A health centre, on the other hand, is responsible for a definite area and population; (c) the health team in a health centre is a optimum "mix" of medical and paramedical workers; in a hospital, the team consists of only the curative staff, i.e., doctors, compounders, nurses, etc. Today, the role of the hospital in the community is being debated. The current opinion is that the hospital should not remain "an ivory tower of disease" in the community, but should take an active part in providing health services to the community. Experience has shown that the health of the community cannot be improved by multiplying hospitals alone.

Under the Multipurpose Workers Scheme, it has been suggested to the States to have an integrated set-up at the district level by having a Chief Medical Officer of the district with 3 Deputy CMO's (drawn from the cadre of existing Civil Surgeons, District Health Officers and District Family Welfare Officers) with each of the Deputy CMO being in charge of one-third of the district for all the health, Family Welfare and MCH programmes. It has been suggested that the district pattern should be based on the number of PHCs.

HEALTH INSURANCE

There is no universal health insurance in India. Health insurance is at present limited to industrial workers and their families. The Central Government employees are also covered by the health insurance, under the banner "Central Govt. Health Scheme".

Employees State Insurance Scheme

The ESI scheme, introduced by an Act of Parliament in 1948, is a unique piece of social legislation in India. It has introduced for the first time in India the principle of contribution by the employer and employee. The Act provides for medical care in cash and kind, benefits in the contingency of sickness, maternity, employment injury, and pension for dependents on the death of worker because of employment injury. The Act covers employees drawing wages not exceeding Rs. 15,000 per month (see page 815 for details).

Central Government Health Scheme

The Central Government Health Scheme (previously

known as Contributory Health Service Scheme) for the Central Government employees was first introduced in New Delhi in 1954 to provide comprehensive medical care to Central Government employees. The scheme is based on the principle of cooperative effort by the employee and the employer, to the mutual advantage of both.

The facilities under the scheme include (a) out-patient care through a network of dispensaries (b) supply of necessary drugs (c) laboratory and X-ray investigations (d) domiciliary visits (e) hospitalization facilities at Government as well as private hospitals recognized for the purpose (f) specialist consultation (g) paediatric services including immunization (h) antenatal, natal and postnatal services (i) emergency treatment (j) supply of optical and dental aids at reasonable rate, and (k) family welfare services.

The scope of the scheme has been gradually extended over the years to cover cities outside Delhi as well as other sectors of population such as the employees of the autonomous organizations, retired Central Govt. servants, widows receiving family pension, Members of Parliament, Ex-Governors and retired Judges. The Scheme now covers besides Delhi, the cities of Mumbai, Allahabad, Meerut, Kanpur, Patna, Kolkata, Nagpur, Chennai, Hyderabad, Bangalore, Jaipur, Pune, Lucknow, Ahmedabad, Bhubaneshwar, and Jabalpur.

The scheme which started with 16 allopathic dispensaries in 1954 covering 2.3 lakh beneficiaries has now 320 dispensaries/hospitals in various systems of medicine and provides service to about 42.76 lakh beneficiaries. There is also a yoga centre under the scheme in Delhi.

The Employees State Insurance Scheme and the Central Government Health Scheme cover two large groups of wage -earners in the country. They are well-organized health insurance schemes, and are providing reasonable medical care plus some essential preventive and promotive health services. Experience in other countries has shown that health insurance is a logical step towards nationalization of health services.

OTHER AGENCIES

Defence Medical Services

Defence services have their own organization for medical care to defence personnel under the banner "Armed Forces Medical Services". The services provided are integrated and comprehensive embracing preventive, promotive and curative services.

Health Care of Railway Employees

The Railways provide comprehensive health care services through the agency of Railway Hospitals, Health Units and clinics. Environmental sanitation is taken care of by Health Inspectors in big stations. A chief Health Inspector supervises the division's work. Heath check-up of employees is provided at the time of entry into service, and thereafter at yearly intervals. There are lady medical officers, health visitors and midwives who look after the MCH and School Health Services. Specialists' services are also available at the Divisional Hospitals.

PRIVATE AGENCIES

In a mixed economy such as India's, private practice of medicine provides a large share of the health services available. There has been a rapid expansion in the number of qualified allopathic physicians from about 50,000 at the time of Independence to about 7.67 lakhs in 2005 and the doctor-population ratio for the country as a whole is 1 : 1428. The general practitioners constitute 70 per cent of the medical profession. Most of them tend to congregate in urban areas. They provide mainly curative services. Their services are available to those who can pay. The private sector of the health care services is not organized. Some statutory bodies like the Medical Council of India and the Indian Medical Association regulate some of the functions and activities of the large body of private registered medical practitioners.

INDIGENOUS SYSTEMS OF MEDICINE

The practitioners of indigenous systems of medicine (e.g., Ayurveda, Siddha, Homoeopathy, etc.) provide the bulk of medical care to the rural people. Ayurvedic physicians alone are estimated to be about 4.38 lakhs *(21)*. Studies indicate that nearly 90 per cent of Ayurvedic physicians serve the rural areas. Most of them are local residents and remain very close to the people socially and culturally. In recent years there has been considerable state patronage to foster these systems of medicine. Many ayurvedic dispensaries are state-run. The Govt. of India has established a National Institute of Ayurveda in Jaipur and a National Institute of Homoeopathy in Kolkata. A Central Council of Indian Medicine was established in 1971 to prescribe minimum standards of education in Indian medicine. The Govt. of India is studying the question of how indigenous systems of medicine could best be utilized for more effective or total health coverage.

VOLUNTARY HEALTH AGENCIES

The voluntary health agencies occupy an important place in community health programmes. "A voluntary health agency may be defined as an organisation that is administered by an autonomous board which holds meetings, collects funds for its support chiefly from private sources and expends money, whether with or without paid workers, in conducting a programme directed primarily to furthering the public health by providing health services or health education, or by advancing research or legislation for health, or by a combination of these activities" *(42)*. The one country where voluntary health agencies have developed and flourished to an enormous extent is the United States. Even in 1945, it was estimated that there were more than 20,000 voluntary agencies in the United States. The voluntary health agencies have been compared to "motor trucks" which can penetrate the by-ways, and the official agencies to "Railway Trunk Lines" which must run on tracks established by law *(43)*.

FUNCTIONS

The types of service rendered by voluntary health agencies have been classified as : (a) SUPPLEMENTING THE WORK OF GOVERNMENT AGENCIES : It is well known that government agencies cannot provide complete service because they operate under financial and statutory restrictions. The voluntary health agencies can help strengthen the work of government agencies by lending personnel, or by contributing funds for special equipment, supplies or services. (b) PIONEERING : The voluntary health agencies are in a position to explore ways and means of doing new things. Research is one form of pioneering. When the efforts succeed and bear fruit, the government agencies can step in and take over the project for the benefit of the

larger numbers. The family planning programme in India is an example of pioneering by the voluntary agencies which first spearheaded the movement, in the face of much opposition. When the importance of family planning was realised, the government accepted family planning as a national policy. (c) EDUCATION : There is unlimited scope for health education in India. The government agencies cannot cope with the problem, unless it is supplemented by voluntary effort on the part of the people. (d) DEMONSTRATION : By putting up demonstrations and experimental projects, the voluntary health agencies have advanced the cause of public health. The demonstration of bore hole latrines by the Rockefeller Foundation to solve the problem of hookworm in India is a case in point. The bore-hole latrine and its modifications have since become an essential part of the environmental sanitation programme in India. (e) GUARDING THE WORK OF GOVERNMENT AGENCIES : By setting a good example the voluntary health agencies can always guide and criticise the work of government agencies. (f) ADVANCING HEALTH LEGISLATION : The voluntary agencies can also mobilise public opinion and advance legislation on health matters for the benefit of the whole community.

VOLUNTARY HEALTH AGENCIES IN INDIA *(44)*

1. INDIAN RED CROSS SOCIETY : The Indian Red Cross Society was established in 1920. It has a network of over 400 branches all over India. It has been executing programmes for the promotion of health, prevention of disease and mitigation of suffering among the people. Its activities are : (a) RELIEF WORK : When disaster strikes any part of the country in the shape of earth-quakes, floods, drought, epidemics, etc., the Red Cross Society immediately mobilises all its resources and goes to the rescue of the affected people. (b) MILK AND MEDICAL SUPPLIES : A number of hospitals, dispensaries, maternity and child welfare centres, schools and orphanges receive assistance from the society every year. The assistance given consists mainly of milk powder, medicines, vitamins and other supplies. (c) ARMED FORCES : The care of the sick and the wounded among the members of the forces is one of the primary obligations of the Red Cross. The Society runs a well-equipped hospital, 'the Red Cross Home' in Bangalore – the only one of its kind in India and the Far East – for permanently disabled ex-servicemen. (d) MATERNAL AND CHILD WELFARE SERVICES : There are a large number of maternity and child welfare centres all over India, either directly administered by or are affiliated to the Red Cross. There is a bureau of Maternity and Child Welfare, which provides technical advice and financial aid to schemes for establishing model maternity and child welfare centres. (e) FAMILY PLANNING : Several States in India are running family planning clinics under the auspices of the Indian Red Cross. (f) BLOOD BANK AND FIRST AID : Some of the State branches have started blood banks. The St. John Ambulance Association in India which is part of the Red Cross has trained several lakh men and women in first aid, home nursing and allied subjects.

2. HIND KUSHT NIVARAN SANGH : The Hind Kusht Nivaran Sangh was founded in 1950 with its headquarters in New Delhi. Its precursor was the Indian Council of the British Empire Leprosy Relief Association (B.E.L.R.A.) which was renamed as LEPRA in 1950. The programme of work of the Sangh includes rendering of financial assistance to various leprosy homes and clinics, health education through publications and posters, training of medical workers and physiotherapists, conducting research and field investigations, organising All-India Leprosy Workers Conferences and publication of 'Leprosy in India', a quarterly journal. The Sangh has branches all over India and works in close cooperation with the Government and other voluntary agencies.

3. INDIAN COUNCIL FOR CHILD WELFARE : Indian Council for Child Welfare was established in 1952. It is affiliated with the International Union for Child Welfare. Since its formation, the I.C.C.W. has built up a network of State Councils and district councils all over the country. The services of I.C.C.W. are devoted to secure for India's children those "opportunities and facilities, by law and other means" which are necessary to enable them to develop physically, mentally, morally, spiritually and socially in a healthy and normal manner and in conditions of freedom and dignity.

4. TUBERCULOSIS ASSOCIATION OF INDIA : The Tuberculosis Association of India was formed in 1939. It has branches in all the States in India. The activities of this Association comprise organising a T.B. Seal campaign every year to raise funds, training of doctors, health visitors and social workers in antituberculosis work, promotion of health education and promotion of consultations and conferences. The following institutions are under the management of the Association : The New Delhi Tuberculosis Centre, the Lady Linlithgow Sanatorium at Kasauli, the King Edward VII Sanatorium at Dharampur and the Tuberculosis Hospital at Mehrauli.

5. BHARAT SEVAK SAMAJ : The Bharat Sevak Samaj which is a non-political and non-official organization was formed in 1952. One of the prime objectives of the Bharat Sevak Samaj (B.S.S.) is to help people to achieve health by their own actions and efforts. The B.S.S. has branches in all the States and in nearly all the districts. Improvement of sanitation in villages is one of the important activities of the B.S.S.

6. CENTRAL SOCIAL WELFARE BOARD : The Central Social Welfare Board is an autonomous organization under the general administrative control of the Ministry of Education. It was set up by the Government of India in August 1953. The functions of the Board are :– (1) surveying the needs and requirements of voluntary welfare organizations in the country (2) promoting and setting up of social welfare organizations on a voluntary basis (3) rendering of financial aid to deserving existing organizations and institutions. The Board initiated, in 1968, "Family and Child Welfare Services" in rural areas for the welfare of women and children. The activities of these projects comprise teaching of craft, social education, literacy classes, maternity aid for women, distribution of milk, balwadis, and organisation of play centres for children. The Board has also started a scheme of Industrial Cooperatives to help the lower-middle class women in urban areas supplement their family income by doing paid work.

7. THE KASTURBA MEMORIAL FUND : Created in commemoration of Kasturba Gandhi, after her death in 1944, the Fund was raised with the main object of improving the lot of women, especially in the villages, through gram-sevikas. The trust has nearly a crore of rupees and is actively engaged in various welfare projects in the country.

8. FAMILY PLANNING ASSOCIATION OF INDIA : The Family Planning Association was formed in 1949 with its

headquarters at Mumbai. It has done pioneering work in propagating family planning in India. The Association has branches all over the country. These branches are running family planning clinics with grants-in-aid from the Government. The Association has trained several hundred doctors, health visitors and social workers. One of the activities of the Headquarters is to answer enquiries on family planning by correspondence or by personal interviews.

9. ALL INDIA WOMEN'S CONFERENCE : It is the only women's voluntary welfare organisation in the country. Established in 1926, it has now branches all over the country. Most of the branches are running M.C.H. Clinics, Medical centres, and adult education centres, milk centres and family planning clinics.

10. THE ALL-INDIA BLIND RELIEF SOCIETY : The All-India Blind Relief Society was established in 1946 with a view to coordinate different institutions working for the blind. It organises eye relief camps and other measures for the relief of the blind.

11. PROFESSIONAL BODIES : The Indian Medical Association, All India Licentiates Association, All India Dental Association, The Trained Nurses Association of India are all voluntary agencies of men and women who are qualified in their respective specialities and possess registerable qualifications. These professional bodies conduct annual conferences, publish journals, arrange scientific sessions and exhibitions, foster research, set up standards of professional education and organise relief camps during periods of natural calamities.

12. INTERNATIONAL AGENCIES : The Rockefeller Foundation, Ford Foundation, and CARE (Cooperative for Assistance & Relief Everywhere) are examples of voluntary international health agencies.

HEALTH PROGRAMMES IN INDIA

Since India became free, several measures have been undertaken by the National Government to improve the health of the people. Prominent among these measures are the NATIONAL HEALTH PROGRAMMES, which have been launched by the Central Government for the control/ eradication of communicable diseases, improvement of environmental sanitation, nutrition, control of population and rural health. Various international agencies like WHO, UNICEF, UNFPA, World Bank, as also a number of foreign agencies like SIDA, DANIDA, NORAD and USAID have been providing technical and material assistance in the implementation of these programmes. A brief account of these programmes which are currently in operation is given in chapter 7.

22 International Health

"Medicine is one of the pillars of peace"

"Nothing on earth is more international than disease", said Paul Russel. Health and disease have no political or geographical boundaries. Disease in any part of the world is a constant threat to other parts. History is replete with examples of the spread of pestilences – particularly of plague and cholera, along trade routes. In order to protect against the spread of disease from one country to another, many attempts were made in the past by individual rulers and States to place barriers against infection by detection and isolation of incoming travellers. In the 14th century, a procedure known as "quarantine" was introduced in Europe to protect against the importation of plague. Ships, crews, travellers and cargoes, suspected of harbouring infection, were detained for a 40–day period. The underlying idea was that the passage of time would give dormant disease to manifest itself or die out. Quarantine soon became an established practice in many countries, and different countries adopted different quarantine procedures. This was the origin of international health work.

Quarantine failed in its objective because of the lack of scientific knowledge regarding the causation and mode of spread of disease. Opposition to quarantine came from several quarters because the 40–day detention obstructed and caused serious inconveniences to international trade and travel. It became necessary for international agreement and cooperation on quarantine matters to control communicable diseases. International conferences were held and organizations set up for discussion, agreement and cooperation on matters of international health. A brief account of these endeavours and of the early health organizations which preceded the World Health Organization is given below.

First International Sanitary Conference (1851)

The origin of international health cooperation dates back to 1851, when an international sanitary conference – the first of its kind – was convened in Paris. The Conference was attended mainly by European countries – Austria, France, Great Britain, Greece, Portugal, Russia, Spain and four Sovereign States (Sardinia, the two Sicilies, the Papal States, Tuscany) that were later to form a united Italy *(1)*. Turkey also participated in this Conference. The objective of this Conference was very limited i.e., to introduce some order and uniformity into quarantine measures which varied from country to country. The conference lasted six months with no lasting results. Some members opposed quarantine, and some took an intermediate position. Despite the many difficulties involved, an international sanitary code was prepared, comprising 137 articles dealing with cholera, plague and yellow fever *(2)*. But, the sanitary code never came into force as it was ratified by only three countries – France, Portugal and Sardinia of which Portugal and Sardinia withdrew in 1865. Thus the conference was generally regarded as having ended in failure. The 1851 conference was followed in rapid succession by further conferences – no less than 10 conferences took place between 1851 and 1902, but they were equally unable to reach an agreement on quarantine measures *(2)*.

Pan American Sanitary Bureau (1902)

The next important milestone in international health work was the establishment of Pan American Sanitary Bureau (PASB) in 1902 in the Americas. It was primarily intended to coordinate quarantine procedures in the American States. In 1924 an important document was signed by the American Republic namely "The Pan American Sanitary Code" which is still in force between the States. In 1947, the Bureau was reorganized and the organization was called the Pan American Sanitary Organization (PASO). In 1949, an agreement was reached whereby the PASO would serve as the WHO Regional Office for the Americas. In 1958, the name was changed to Pan American Health Organization (PAHO) *(3)*. Over the years, PAHO has grown from a small information centre to a major health agency with its headquarters in Washington, D.C. The Pan American Sanitary Bureau was the World's first international health agency *(4)*.

Office International D'Hygiene Publique (1907)

At the 1903 International Sanitary Conference, a step of fundamental importance was taken, that is, to establish a permanent International Health Bureau *(1)*. This decision was probably influenced by the fact that the American republics had already established a similar bureau, the Pan American Sanitary Bureau in 1902. Accordingly in 1907, the "Office International d'Hygiene Publique" (OIHP), generally known as the "Paris Office" was created to disseminate information on communicable diseases and to supervise international quarantine measures. At its inception, the OIHP was predominantly European, but later on a considerable degree of cooperation grew up between OIHP and PASB. Sixty other countries, including British India, joined the OIHP, giving the Office an international character *(5)*.

Although the OIHP had no field staff to undertake investigation of epidemics it did remarkable work in disseminating knowledge of communicable diseases and their control, and also information on a variety of health problems of world-wide interest. The OIHP continued to exist until 1950, by which time its responsibilities had been taken over by the WHO.

The Health Organization of the League of Nations (1923)

After the first World War (1914–18), the League of Nations was established to build a better world. It included a 'Health Organization' to "take steps in matters of international concern for the prevention and control of disease". Although the League of Nations was a failure on the political side, its Health Organization, which was established in 1923, did creditable work. Not confining itself to quarantine regulations and epidemiological information or even larger problems of epidemic diseases, the Health Organization of the League branched out into such matters as nutrition, housing and rural hygiene, the training of public health workers and the standardization of certain biological preparations. The League analysed epidemiological information received, and started the series of periodical epidemiological reports now issued by the WHO. It also established the Far Eastern Bureau at Singapore. It laid down lines for technical studies (including the use of expert committees) which are substantially followed by the WHO. The WHO owes much to the work done and methods devised by the Health Organization of the League. It may be mentioned that efforts to amalgamate the OIHP, PASB and the Health Organization of the League of Nations proved a failure, and all the three organizations were co-existing during the years between the two World Wars. In 1939, the League of Nations was dissolved but its Health Organization in Geneva continued to deal as best it could with requests for information and the publication of the Weekly Epidemiological Records was never suspended.

The United Nations Relief and Rehabilitation Administration (1943)

The United Nations Relief and Rehabilitation Administration (UNRRA) was set up in 1943 with the general purpose of organizing recovery from the effects of the Second World War. The UNRRA had a health division to care for the health of the millions of displaced persons, to restore and help services and to revive the machinery for international interchange of information on epidemic diseases.

UNRRA did outstanding work of preventing the spread of typhus and other diseases, so that they never reached serious epidemic levels anywhere. Similarly, UNRRA'S assistance to malaria control in such countries as Greece and Italy, where war had disrupted peace–time anti-malaria services, was on an immense scale. The world renowned campaign for the eradication of malaria from Sardinia was begun as a joint effort of UNRRA, the Rockefeller Foundation and the Italian Government *(5)*.

At the end of 1946, UNRRA terminated its official existence and its health activities and financial assets were taken over by the Interim Commission on the WHO.

Birth of the WHO

The WHO has its origin in April 1945, during the conference held at San Francisco to set up the United Nations. The representatives of Brazil and China proposed that an international health organization should be established and that a conference to frame its constitution should be convened. The constitution was drawn up at an international health conference in New York in 1946. The same conference set up an "Interim Commission" to prepare the ground for the new organization and to carry out urgent tasks until the WHO constitution had been accepted by the required number of UN Member States. The ratifications were secured by 7 April 1948; the formal existence of the WHO as a specialised agency began on that date. The formation of WHO represents the culmination of efforts to establish a single worldwide inter–governmental health agency.

WORLD HEALTH ORGANIZATION

The World Health Organization is a specialized, non-political, health agency of the United Nations, with headquarters at Geneva. In 1946, the Constitution was drafted by the "Technical Preparatory Committee" under the chairmanship of Rene Sand, and was approved in the same year by an International Health Conference of 51 nations in New York. The constitution came into force on 7th April, 1948 which is celebrated every year as "World Health Day". A World Health day theme is chosen each year to focus attention on a specific aspect of public health.

Objective

The objective of the WHO is "the attainment by all people's of the highest level of health" which is set out in the preamble of the Constitution. The current objective of WHO is the attainment by all people of the world a level of health that will permit them to lead a socially and economically productive life. The preamble of the Constitution states :

> "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.
>
> The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being without distinction of race, religion, political belief, economic and social condition.
>
> The health of all peoples is fundamental to the attainment of peace and security and is dependent upon the fullest cooperation of individuals and States.
>
> The achievement of any State in the promotion and protection of health is of value to all.
>
> Unequal development in different countries in the promotion of health and control of disease, especially communicable disease, is a common danger.
>
> Healthy development of the child is of basic importance; the ability to live harmoniously in a changing total environment is essential to such development.
>
> The extension to all people of the benefits of medical, psychological and related knowledge is essential to the fullest attainment of health.
>
> Informed opinion and active cooperation on the part of the public are of the utmost importance in the improvement of the health of the people.
>
> Governments have a responsibility for the health of their peoples which can be fulfilled only by the provision of adequate health and social measures".

The WHO is unique among the UN Specialized Agencies in that it has its own constitution, own governing bodies, own membership and own budget. It is part of, but not subordinate to, the United Nations.

Two major policy developments have influenced the WHO. First, the Alma-Ata Conference in 1978 on primary health care which provided both WHO and UNICEF with a common charter for health, and secondly, the Global Strategy for Health for All by 2000, and more recently Millennium Development Goals.

Membership

Membership in WHO is open to all countries. While most countries are members of both the UN and of WHO, there are some differences. For example, Switzerland is a member of WHO, but not of the United Nations. Territories which are not responsible for the conduct of their international relations may be admitted as associate members. Associate members participate without vote in the deliberations of the WHO. Each member state contributes yearly to the budget and each is entitled to the services and aid the organization can provide. In 1948, the WHO had 56 Members. WHO now has 194 member states and two associate members.

Work of WHO

WHO's first Constitutional function is to act as the directing and coordinating authority on all international health work. This function permits WHO's Member States to identify collectively priority health problems throughout the world, to define collectively health policies and targets to cope with them, to devise collectively strategies, principles and programmes to give effect to these policies and to attain the targets. The WHO also has specific responsibilities for establishing and promoting international standards in the field of health, which comprise the following broad areas :

1. PREVENTION AND CONTROL OF SPECIFIC DISEASES

Almost all communicable diseases are or have been at sometime the subject of WHO activities. The global eradication of smallpox is an outstanding example of international health cooperation. With the same energy and commitment with which WHO eradicated smallpox, it is now directing the global battle against poliomyelitis.

An important activity of WHO is epidemiological surveillance of communicable diseases. The WHO collects and disseminates epidemiological information on diseases subject to International Health Regulations and occasionally other communicable diseases of international importance through an Automatic Telex Reply Service (ATRS) and the "Weekly Epidemiological Record" (WER). The latter contains more complete details and brief reviews of communicable diseases of international importance *(7)*. Member States can also make use of the "WHO Emergency Scheme for Epidemics" whenever necessary *(8)*. The aim of International Health Regulations is to ensure maximum security against international spread of diseases with the minimum interference with world traffic.

The WHO has also paid attention in its programme of work to non-communicable disease problems such as cancer, cardiovascular diseases, genetic disorders, diabetes, blindness, mental disorders, drug addiction and dental diseases.

The activities of WHO have also branched out into the fields of vector biology and control, immunology, quality control of drugs and biological products, drug evaluation and monitoring and health laboratory technology as these activities are relevant to the control of both communicable and non-communicable diseases. Immunization against common diseases of childhood (Expanded Programme on Immunization) is now a priority programme of the WHO.

2. DEVELOPMENT OF COMPREHENSIVE HEALTH SERVICES

WHO's most important single function is to promote and support national health policy development and the development of comprehensive national health programmes. This broad field of endeavour encompasses a wide variety of activities such as organizing health systems based on primary health care, the development of health manpower and utilization, building of long-term national capability, particularly in the areas of health infrastructure development, and managerial capabilities (including monitoring and evaluation) and health services research. Appropriate Technology for Health (ATH) is another new programme launched by the WHO to encourage self-sufficiency in solving health problems. The new programme is part of WHO's efforts to build up primary health care.

3. FAMILY HEALTH

Family health is one of the major programme activities of WHO since 1970, and is broadly subdivided into maternal and child health care, human reproduction, nutrition and health education. The chief concern is improvement of the quality of life of the family as a unit.

4. ENVIRONMENTAL HEALTH

Promotion of environmental health has always been an important activity of WHO. WHO advises governments on national programmes for the provision of basic sanitary services. The activities are directed to protection of the quality of air, water and food; health conditions of work, radiation protection and early identification of new hazards originating from new technological developments. A number of programmes have been developed such as the 'WHO Environmental Health Criteria Programme' and 'WHO Environmental Health Monitoring Programme' towards improving environmental health.

5. HEALTH STATISTICS

From its earliest days in 1947, WHO has been concerned with the dissemination of a wide variety of morbidity and mortality statistics relating to health problems. The data is published in the (a) Weekly Epidemiological Record (b) World Health Statistics Quarterly and (c) World Health Statistics Annual. Readers interested in current data may obtain it from the Chief Statistician, Dissemination of Statistical Information, WHO, Geneva. In order that statistics from different countries may be comparable, WHO publishes 'International Classification of Diseases' which is updated every 10th year. The Tenth Revision of ICD came into effect from 1st January 1993. Assistance is also given to countries in the improvement of their medical records, and in the planning and operating national health information systems.

6. BIOMEDICAL RESEARCH

The WHO does not itself do research, but stimulates and coordinates research work. It has established a world-wide network of WHO collaborating centres, besides awarding grants to research workers and research institutions for promoting research. There are Regional Advisory Committees on health research which define regional health research priorities and a Global Advisory Committee, which in close collaboration with the regional committee deals with policy issues of global import. Six tropical diseases (malaria, schistosomiasis, trypanosomiasis, filariasis, leishmaniasis and leprosy) are the target of the WHO Special Programme for Research and Training in Tropical Diseases to develop new tools, strengthen research institutions and training workers in the countries affected.

7. HEALTH LITERATURE AND INFORMATION

WHO acts as a clearing house for information on health problems. Its publications comprise hundreds of titles on a wide variety of health subjects. The WHO library is one of the satellite centres of the Medical Literature Analysis and Retrieval System (MEDLARS) of the U.S. National Library of Medicine. MEDLARS is fully computerised indexing system covering the whole of medicine on an international basis. The WHO has also a public information service both at headquarters and each of the six regional offices.

8. COOPERATION WITH OTHER ORGANIZATIONS

WHO collaborates with the UN and with the other specialized agencies, and maintains various degrees of working relationships. Besides, WHO has also established relations with a number of international governmental organizations.

Structure

The WHO consists of three principal organs : the World Health Assembly, the Executive Board and the Secretariat.

(a) THE WORLD HEALTH ASSEMBLY : This is the "Health Parliament" of Nations and the supreme governing body of the organization. It meets annually, usually in May, and generally at the headquarters in Geneva, but from time to time in other countries. The Assembly is composed of delegates representing Member States, each of which has one vote. The main functions of the Health Assembly are : (i) to determine international health policy and programmes (ii) to review the work of the past year (iii) to approve the budget needed for the following year and (iv) to elect Member States to designate a person to serve for three years on the Executive Board, and to replace the retiring members. The Health Assembly also appoints the Director General on the nomination of the Executive Board. It is now the practice to organize on the occasion of each Health Assembly, "technical discussions" on some subjects of world interest.

(b) THE EXECUTIVE BOARD : The Board had originally 18 members, each designated by a Member State. Subsequently, the number was raised to 24 and 30. The Health Assembly (1976) increased the membership from 30 to 31, providing that no fewer than three are to be elected from each of the WHO regions *(11)*. The board now has 34 members. The members of the Board are to be "technically qualified in the field of health"; they are designated by, but do not represent their governments. One–third of the membership is renewed every year. The Executive Board meets at least twice a year, generally in January and shortly after the meeting of the World Health Assembly in May. The main work of the Board is to give effect to the decisions and policies of the Assembly. The Board also has power to take action itself in an emergency, such as epidemics, earthquakes and floods where immediate action is needed.

(c) THE SECRETARIAT : The secretariat is headed by the Director General who is the chief technical and administrative officer of the Organization. The primary function of the WHO secretariat is to provide Member States with technical and managerial support for their national health development programmes. While in 1948, WHO staff counted 250 persons, the Organization in 1985 counted 4475 international public servants. The secretariat, by 2010, is staffed by about 8000 health and other experts and support staff. At WHO headquarters in Geneva, there are 5 Assistant Director Generals each of whom is responsible for the work of such divisions as may from time to time be assigned to him by the Director General. On 31st December, 1985, the WHO Secretariat comprised of the following divisions.

1. Division of epidemiological surveillance and health situation and trend assessment.
2. Division of communicable diseases.
3. Division of vector biology and control.
4. Division of environmental health.
5. Division of public information and education for health.
6. Division of mental health.
7. Division of diagnostic, therapeutic and rehabilitative technology.
8. Division of strengthening of health services.
9. Division of family health.
10. Division of non-communicable diseases.
11. Division of health manpower development.
12. Division of information systems support.
13. Division of personnel and general services.
14. Division of budget and finance.

Regions

In order to meet the special health needs of different areas, WHO has established six regional organizations. (Table 1).

TABLE 1

WHO Regional Organizations

Region	Headquarters
1. South East Asia	New Delhi (India)
2. Africa	Brazzaville Congo
3. The Americas	Washington D.C. (U.S.A.)
4. Europe	Copenhagen (Denmark)
5. Eastern Mediterranean	Alexandria (Egypt)
6. Western Pacific	Manila (Philippines)

The regional organizations are an integral part of the WHO and have under the constitution an important part in implementing the policies and programmes of the WHO. The regional office is headed by the Regional Director, who is assisted by technical and administrative officers, and members of the secretariat. There is a regional committee composed of representatives of the Member States in the region. Regional Committees meet once a year to review health work in the region and plan its continuation and development. Regional plans are amalgamated into overall plans for the Organization by the Director General at WHO's headquarters in Geneva.

The South East Asia Region

The headquarters of the South East Asia Regional Office (SEARO) is in New Delhi, the official address being World Health House, Indraprastha Estate, New Delhi. The Region has now 11 members (Table 2).

TABLE 2

WHO: SEARO Member countries

Year of joining	Member country SEARO	Population 2010 (million)
1972	Bangladesh	148.69
1982	Bhutan	0.726
1948	India	1224.6
1950	Indonesia	239.8
1973	Korea (Dem.People's Rep.)	24.3
1965	Maldives Islands	0.316
1948	Myanmar	47.96
1953	Nepal	29.9
1948	Sri Lanka	20.86
1947	Thailand	69.12
2002	Timor-Leste	1.12

The WHO activities in South East Asia Region cover a wide range of subjects such as malaria eradication, tuberculosis control, control of other communicable diseases, health laboratory services and production of vaccines, health statistics, public health administration and rural health services, maternal and child health, nursing, environmental health and water supply, health education, nutrition, mental health, dental health, medical rehabilitation, quality control of drugs and medical education.

OTHER UNITED NATIONS AGENCIES

UNICEF

UNICEF (United Nations International Children's Emergency Fund) is one of the specialized agencies of the United Nations. It was established in 1946 by the United Nations General Assembly to deal with rehabilitation of children in war ravaged countries. In 1953, when the emergency functions were over, the General Assembly gave it a new name "U.N. Children's Fund" but retained the initials, UNICEF. UNICEF's regional office is in New Delhi; the region is known as the South Central Asian Region which covers Afghanistan, Sri Lanka, India, the Maldives, Mongolia and Nepal. UNICEF is governed by a thirty six nation Executive Board as in 2010. The headquarters of the UNICEF is at United Nations, New York.

UNICEF works in close collaboration with WHO, and the other specialized agencies of the United Nations like UNDP, FAO and UNESCO. In the early years, UNICEF and WHO worked together on urgent problems such as malaria, tuberculosis and venereal diseases. Later, its assistance to countries covered such fields as maternal and child health, nutrition, environmental sanitation (especially the provision of water supplies to rural communities), health centres and health education and programmes which would directly or indirectly, benefit child health.

More recently, the tendency has been for UNICEF to turn away from campaigns for the eradication of specific diseases unless they are of direct benefit to mothers and children. Greater attention is being given to the concept of the "whole child" meaning that assistance should hence forward be geared not only to health and nutrition, as before, which are of immediate benefit to children, but also to their long-term personnel development and to the development of the countries in which they live. This approach is also known as 'country health programming' in which UNICEF is currently interested so as to meet the needs of children as an integral part of the country's development effort.

Content of services *(12)*

(a) Child health : UNICEF has provided substantial aid for the production of vaccines and sera in many countries. UNICEF has supported India's BCG vaccination programme from its inception. It has also assisted in the erection of a penicillin plant, near Pune; donated a DDT plant; two plants for the manufacture of triple vaccine and iodized salt. UNICEF has also assisted environmental sanitation programmes emphasizing safe and sufficient water for drinking and household use in rural areas. The purpose is not only to reduce child illness and death, but to improve the quality of life in the villages. Currently, UNICEF is focusing attention on providing primary health care to mothers and children. Emphasis is placed on immunization; infant and young child care; family planning aspects of family health; safe water and adequate sanitation. The services contemplated are intended to be so organized that the local community can participate in planning personnel and material support. The services will be delivered economically at the village level through resident volunteers or part-time primary health workers selected for the purpose with the agreement of the local community.

(b) Child nutrition : UNICEF gives high priority to improving child nutrition. Its aid for child nutrition, which first took the form of supplementing child feeding began to expand in mid–1950s with the development of low–cost protein–rich food mixtures. In collaboration with FAO, UNICEF also began aiding "applied nutrition" programmes through such channels as community development, agricultural extension, schools and health services so as to stimulate and help the rural population to grow and eat the foods it required for better child nutrition. The UNICEF has supplied equipment for modern dairy plants in various parts of India, viz. Maharashtra, Gujarat, Karnataka, Uttar Pradesh, West Bengal, Andhra Pradesh. Specific aid is also given for intervention against nutritional deficiency diseases, viz. provision of large doses of vitamin A in areas where xerophthalmia is prevalent; enrichment of salt with iodine in areas of endemic goitre; provision of iron and folate supplements to combat anaemias and enrichment of foods. More recently, FAO, UNICEF and WHO have been encouraging the development of national food and nutrition policies that make provision for child nutrition.

(c) Family and child welfare : The purpose is to improve the care of children, both within and outside their homes through such means as parent education, day–care centres, child welfare and youth agencies and women's clubs. These services are carried out not as separate projects but as part of health, nutrition and education or home economics extension programmes.

(d) Education – formal and non-formal : In collaboration with UNESCO, UNICEF is assisting India in the expansion and improvement of teaching science in India. Science laboratories' equipment, workshop tools, library books, audiovisual aids are being made available to educational institutions. Emphasis is placed on the kind of schooling relevant to the environment and future life of the children.

Currently, UNICEF is promoting a campaign known as GOBI campaign to encourage 4 strategies for a "child health revolution"

- G for growth charts to better monitor child development
- O for oral rehydration to treat all mild and moderate dehydration

- B for breast feeding, and
- I for immunization against measles, diphtheria, polio, pertussis, tetanus and tuberculosis.

Since 1976, UNICEF has been participating in Urban Basic Services (UBS). The aim of the UBS projects is to upgrade basic services (e.g., health, nutrition, water supply, sanitation and education) – especially for children and women – in selected cities and towns. The overall objective is to improve the degree and quality of survival and development of the children of urban low-income families.

In short, UNICEF activities cover programmes assisting in child survival, protection and development; interventions like immunization, improved infant feeding practices; child growth monitoring, homebased diarrhoea management, drinking water, environmental sanitation, birth spacing, education of girls and income–generating activities for women.

As full partners in primary health care, UNICEF and WHO have been developing joint strategies in support of its implementation at country level.

UNDP

The United Nations Development Programme (UNDP) was established in 1966. It is the main source of funds for technical assistance. The member countries – rich and poor – of the United Nations meet annually and pledge contributions to the UNDP.

The basic objective of the UNDP is to help poorer nations develop their human and natural resources more fully. The UNDP projects cover virtually every economic and social sector – agriculture, industry, education and science, health, social welfare, etc.

UN Fund for Population Activities

The United Nations Fund for Population Activities (UNFPA) has been providing assistance to India since 1974. In addition to funding national level schemes, Area Projects for intensive development of health and family welfare infrastructure and improvement in the availability of services in the rural areas have been under implementation in eleven districts of Bihar and 4 districts of Rajasthan.

The UNFPA inputs are designed to develop national capability for the manufacture of contraceptives, to develop population education programmes, to undertake organized sector projects, to strengthen programme management as well as to improve output of grass–root level health workers and introduction of innovative approaches to family planning and MCH care *(16)*.

FAO

The Food and Agriculture Organization (FAO) was formed in 1945 with headquarters in Rome. It was the first United Nations Organization specialized agency created to look after several areas of world cooperation. The chief aims of FAO are : (1) to help nations raise living standards (2) to improve nutrition of the people of all countries (3) to increase the efficiency of farming, forestry and fisheries (4) to better the condition of rural people and, through all these means, to widen the opportunity of all people for productive work. FAO's prime concern is the increased production of food to keep pace with the ever–growing world population. The most important aspect of FAO's work is towards ensuring that the food is consumed by the people who need it, in sufficient quantities and in right proportions, to develop and maintain a better state of nutrition throughout the world *(13)*. In this context, the FAO has organized a world Freedom from Hunger Campaign (FFHC) in 1960. The main object of the Campaign is to combat malnutrition and to disseminate information and education. The FAO is also collaborating with other international agencies in the Applied Nutrition Programmes. The joint WHO/FAO expert committees have provided the basis for many cooperative activities – nutritional surveys, training courses, seminars and the coordination of research programmes on brucellosis and other zoonoses *(4)*.

ILO

Soon after the First World War, it was recognized that problems of industry, like disease, know no frontiers. In 1919, the International Labour Organization (I.L.O.) was established as an affiliate of the League of Nations to improve the working and living conditions of the working population all over the world. The purposes of ILO are : (1) to contribute to the establishment of lasting peace by promoting social justice (2) to improve, through international action, labour conditions, and living standards and (3) to promote economic and social stability. The International Labour Code is a collection of international minimum standards related to health, welfare, living and working conditions of workers all over the world. The ILO also provides assistance to organizations interested in the betterment of living and employment standards. There is a close collaboration between ILO and WHO in the field of health and labour. The headquarters of ILO is in Geneva, Switzerland.

WORLD BANK

World Bank is a specialized agency of the United Nations. It was established with the purpose of helping less developed countries raise their living standards. The powers of the Bank are vested in a Board of Governors. The Bank gives loans for projects that will lead to economic growth (e.g., India's Population Projects). The projects are usually concerned with electric power, roads, railways, agriculture, water supply, education, family planning, etc. Health and environmental components have been added to many projects. Cooperative programmes exist between WHO and the Bank, e.g., projects for water supply, World Food Programme, Population Control, and the control of onchocerciasis programme in West Africa *(14)*.

HEALTH WORK OF BILATERAL AGENCIES

USAID

The US Government presently extends aid to India through three agencies : (1) United States Agency for International Development (USAID); (2) The Public Law 480 (Food for Peace) Programme and (3) The US Export–Import Bank. The USAID was created in 1961; it is in charge of activities previously administered by the Technical Cooperation Mission (TCM). A USAID mission functions in New Delhi. Both grants and loans are extended by the Agency.

The US has been assisting in a number of projects designed to improve the health of India's people. These are : (1) malaria eradication (2) medical education (3) nursing education (4) health education (5) water supply and sanitation (6) control of communicable diseases (7) nutrition and (8) family planning *(15)*. The recent trend in assistance

from the USA is increasingly in the support of agricultural and family planning programmes, with some reduction in aid in the general public health field *(5)*.

THE COLOMBO PLAN

At a meeting of the commonwealth Foreign Ministers at Colombo in January 1950, a programme was drawn up for cooperative economic development in South and South East Asia. Membership comprises 20 developing countries within the region and 6 non–regional members – Australia, Canada, Japan, New Zealand, UK and USA. The bulk of Colombo Plan assistance goes into industrial and agricultural development, but some support has also been given to health promotion, mostly through fellowships. The All India Institute of Medical Sciences at New Delhi was established with financial assistance from New Zealand. The Plan provides for visits to countries by experts who can offer advice on local problems and train the local people. The contribution of Canada in supplying Cobalt Therapy Units to medical institutions in India was an important item of aid under the Colombo plan *(5)*. Colombo plan seeks to improve living standards of the people of the area by reviewing developmental plans and coordinating development assistance.

SIDA

The Swedish International Development Agency is assisting the National Tuberculosis Control Programme since 1979. The SIDA assistance is usually spent on procurement of supplies like X–ray unit, microscopes and anti–tuberculosis drugs. SIDA authorities are also supporting the Short Course Chemotherapy Drug Regimens under pilot study, which were introduced in 18 districts of the country during 1983–84, and pilot phase–I of the Revised strategy of NTP in 5 sites namely Delhi, Bangalore, Mumbai, Kolkata and Mehsana (Gujarat) since 1993.

DANIDA

The Government of Denmark is providing assistance for the development of services under National Blindness Control Programme since 1978.

NON-GOVERNMENTAL AND OTHER AGENCIES

Rockefeller Foundation

The Rockefeller Foundation is a philanthropic organization chartered in 1913 and endowed by Mr. John D. Rockefeller. Its purpose is to promote the well-being of mankind throughout the world. In its early years, the Foundation was active chiefly in public health and medical education. Subsequently, its interest was expanded to include the advancement of life sciences, the social sciences, the humanities and the agricultural sciences *(13)*.

The work of the Rockefeller Foundation in India began in 1920 with a scheme for the control of hookworm disease in the then Madras Presidency. Since then, the Foundation has been associated with several medical and public health programmes in India. The establishment of the All India Institute of Hygiene and Public Health at Kolkata was in a large measure due to the cooperation of the Rockefeller Foundation. The Foundation's programme included the training of competent teachers and research workers; training abroad of candidates from India through fellowships and travel grants; the sponsoring of visits of a large number of medical specialists from the USA; providing grants-in-aid to selected institutions: development of medical college libraries; population studies; assistance to research projects and institutions (e.g., National Institute of Virology at Pune and more recently the setting up of a field demonstration area (Ballabhgarh) in connection with a department of preventive and social medicine, as well as to the All India Institute of Medical Sciences. At present the Foundation is directing its support to the improvement of agriculture, family planning and rural training centres as well as to medical education *(5)*.

Ford Foundation

Whereas the Rockefeller Foundation earlier concentrated most of its assistance on universities and post–graduate institutions, on professional education and on research, the Ford Foundation has been active in the development of rural health services and family planning *(5)*. The Ford Foundation has helped India in the following projects : (1) Orientation training centres : The orientation training centres at Singur, Poonamalle and Najafgarh were set up with help from the Ford Foundation. The centres provide training courses in public health for medical and paramedical personnel from all over India. (2) Research–cum–action projects : These projects were aimed at solving some of the basic problems in environmental sanitation, e.g., designing and construction of hand-flushed acceptable sanitary latrines in rural areas (3) Pilot project in rural health services, Gandhigram (Tamil Nadu) : Among a rural population of 100,000 people, an attempt was made to develop and operate a coordinated type of health service which will provide a useful model for health administrators in the country. (4) Establishment of NIHAE: In the last few years, the Ford Foundation has supported the establishment of the National Institute of Health Administration and Education at Delhi. The Institute provides a senior staff-college type training for health administrators. (5) Calcutta water supply and drainage scheme : The Foundation has helped in the preparation of a master plan for water supply, sewerage and drainage for the city of Calcutta in collaboration with other international agencies. (6) Family planning programme : The Foundation is supporting research in reproductive biology and in the family planning fellowship programmes.

CARE

CARE (Cooperative for Assistance and Relief Everywhere) was founded in North America in the wake of the Second World War in the year 1945. It is one of the world's largest independent, non–profit, non–sectarian international relief and development organization. CARE provides emergency aid and long term development assistance.

CARE began its operation in India in 1950. Till the end of 1980s, the primary objective of CARE – India was to provide food for children in the age group of 6–11 years. From mid 1980s, CARE–India focused its food support in the ICDS programme and in development of programmes in the areas of health and income supplementation. It is helping in the following projects : Integrated Nutrition and Health Project; Better Health and Nutrition Project; Anaemia Control Project; Improving Women's Health Project; Improved Health Care for Adolescent Girl's Project; Child Survival Project; Improving Women's Reproductive Health and Family Spacing Project; Konkan Integrated Development Project etc.

CARE–India works in partnership with the Government of India, State Governments, NGOs etc. Currently it has projects in Andhra Pradesh, Bihar, Madhya Pradesh, Maharashtra, Orissa, Rajasthan, Uttar Pradesh and West Bengal.

International Red Cross

The Red Cross is a non–political non–official international humanitarian organization devoted to the service of mankind in peace and war. It was founded by Henry Dunant, a young Swiss businessman, who when travelling through North Italy in 1859 happened to be on the scene of one of the most savage battles of history, the battle of Solferino. Appalled by the neglect of thousands of the wounded and dying soldiers, Dunant recruited volunteers from nearby villages to help relieve their suffering. Later, in his book "Un Souvenir de Solferine" and in countless interviews with eminent persons, throughout Europe, Dunant urged that voluntary national societies be founded "which in time of war would render aid to the wounded without distinction of nationality". He proposed further that these societies should have a protective emblem and trained workers and their services to the wounded should be protected by international treaty.

Dunant's plea met with success. The First Geneva Convention took place in 1864 and a treaty was signed for the relief of the wounded and the sick of the armies in the field. Thus came into being the International Committee of the Red Cross (ICRC), an independent, neutral institution, the founder organization of the Red Cross. It has since grown into a mighty mission with branches all over the world symbolising the spirit of compassion and universal brotherhood. In 1919, the League of the Red Cross Society was created with headquarters in Geneva to coordinate the work of the national societies, which now number more than 90.

Role of Red Cross

In the beginning, the role of the Red Cross, as conceived by Dunant, was largely confined to humanitarian service on behalf of the victims of war. Soon thereafter, it was realised that natural disasters too bring in their wake great human suffering and that on such occasions there is equally great need for help among nations "as good neighbours". Later on the work of the Red Cross was extended to other programmes which would prevent human suffering. These comprise service to armed forces, service to war veterans, disaster service, first aid and nursing, health education and maternity and child welfare services.

Indian Red Cross

The Red Cross Society of India was established by an Act of the Indian Legislature in 1920 with the three objectives of the improvement of health, prevention of disease and mitigation of suffering. In peacetime, the Society provides military hospitals with such amenities as newspapers, periodicals, musical instruments and other comfort goods. The Red Cross Home at Bangalore for disabled ex–servicemen is one of the pioneer institutions of its kind in Asia. Disaster services comprise distribution of milk, medicines, Vitamin tablets, codliver oil and hundred other items to the famine stricken people and to those who have been hit by the floods. In the development of maternity and child welfare services, the Society has done pioneering work and has functioned as an auxiliary of the country's health services.

The JUNIOR RED CROSS is one of the most active sections of the Society. It gives an opportunity to lakhs of boys and girls all over India to be associated with activities like the village uplift, first aid, antiepidemic work and building up of an international fraternity of youth, thus promoting international friendliness, understanding and cooperation.

There are numerous other non–governmental organizations (NGO's). Some of these are: Oxfam, Save-the-Children Fund, International Planned Parenthood Federation, The Population Council, Voluntary Health Association of India, All India Women's Conference, India Medical Association, Trained Nurses Association of India, International Agency for the Prevention of Blindness, World Federation of the Deaf, International Leprosy Association, World Federation of Medical Education, International Union against Cancer, and so on. Non-governmental organizations constitute a valuable resource in promoting health care.

ABBREVIATIONS

ABER	Annual blood examination rate
ACD	Active case detection
ACT	Artemisinin-based combined therapy
ADB	Asian Development Bank
ADLA	Acute dermatolymphangioadenitis
AEFI	Adverse events following immunization
AES	Acute encephalitis syndrome
AFB	Acid fast bacillus
AFP	Acute flaccid paralysis
AIDS	Acquired immunodeficiency syndrome
AIMS	All India Institute of Medical Sciences
ALRI	Acute lower respiratory tract infections
ANC	Antenatal care
ANCDR	Annual new case detection rate
ANM	Auxiliary Nurse Midwife
API	Annual parasite incidence
AR	Attributable risk
ARC	AIDS-related complex
ARI	Acute respiratory infections
ART	Anti-retroviral therapy
ART	Antiretroviral treatment
ASFR	Age-specific fertility rate
ASHA	Accredited social health activist
ASMFR	Age-specific marital fertility rate
AURI	Acute upper respiratory tract infection
AUWSP	Accelerated Urban Water Supply Programme
AWC	Anganwadi centre
AWW	Anganwadi worker
AYUSH	Ayurvedic, unani, siddha & homeopathic, system of medicine
BCC	Behaviour change communication
β-cells	Bone-marrow derived lymphocytes
BCG	Bacillus calmette guarine
BDO	Block development officer
BEE	Block extension officer
BEE	Block extension educator
BFHI	Baby friendly hospital initiatives
BLAC	Block leprosy awareness campaign
BMI	Body mass index
BPL	Below poverty line
CABG	Coronary artery bypass grafting
CARE	Cooperative assistance and relief everywhere
CBR	Crude birth rate
CDPO	Child development project officer
CDSCO	Central Drug Standard Control Organization
CGHS	Central Government Health Scheme
CHC	Community health centre
CHW	Community health worker
CMO	Chief Medical Officer
CNS	Central nervous system
COPD	Chronic obstructive pulmonary disease
CPCB	Central Pollution Control Board
CPM	Critical path method
CPR	Couple protection rate
CRY	Child Relief and You
CSF	Cerebrospinal fluid
CSSM	Child survival and safe motherhood
CVD	Cardiovascular diseases
DALY	Disability adjusted life year
DANIDA	Danish International Development Agency
DBCS	District blindness control society
DDC	Drug distribution center in malaria control
DEC	Diethylcarbamazine
DES	Diethylstilbestrol
DFWO	District family welfare officer
DGHS	Director General of Health Services
DHF	Dengue haemorrhagic fever
DHO/DMO	District health/medical officer
DHS	Directorate of health services
DM	Diabetes mellitus
DMC	Designated microscopy centre
DOTS	Directly observed therapy short-course
DPT	Diphtheria, pertussis, and tetanus vaccine
DSS	Dengue shock syndrome
DT	Diphtheria-Tetanus toxoid
dta	Diphtheria-tetanus adult type
DTC	District tuberculosis centre
DTP	District tuberculosis programme
DTPa	Diphtheria, tetanus, acellular pertussis
DTPw	Diphtheria, tetanus, whole-cell-pertussis
% E	Percentage of total energy
EAA	Essential amino acids
EAG	Empowered action group
EFA	Essential fatty acids
ELF	Elimination of lymphatic filariasis
EPI	Expanded programme on immunization
EQA	External quality assessment
ESI	Employees state insurance scheme
ETEC	Enterotoxin Escherichia coli
FAO	Food and Agriculture Organization
F-IMNCI	Facility based IMNCI
FLEP	Focused leprosy elimination plan
FRUs	First referral units
FSW	Female sex worker
FTD	Fever treatment depot
GDP	Gross domestic product
GFR	General fertility rate
GMFR	General marital fertility rate
GNI	Gross national income
GNP	Gross net product
HAV	Hepatitis A virus
HBIG	Hepatitis B immunoglobulin
HBNC	Home based newborn care
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HDL	High density lipoproteins
HDV	Hepatitis D virus
HEV	Hepatitis E virus
HFA	Health for all
Hib Vaccine	Haemophilus influenzae type B vaccine
HIV	Human immunodeficiency virus
HPS	High performing states
HPV	Human papilloma virus
HRD	Human resource development
HW (F)	Health worker female
HW (M)	Health worker male
ICDS	Integrated child development service
ICMR	Indian Council of Medical Research
ICTC	Integrated counselling and testing centre
IDD	Iodine deficiency disorder
IDDM	Insuline dependent diabetes mellitus
IDSP	Integrated disease surveillance project
IDUS	Intravenous drug users
IEC	Information, education & communication
IEC	Information Education Commission
IFA	Iron & folic acid
IHD	Ischaemic heart disease
IHR	International Health Regulations
ILO	International labour organization
IMCI	Integrated management of childhood illness
IMR	Infant mortality rate
INH	Isoniazid
IMNCI	Integrated management of neonatal & childhood illness
IOL	Intraocular lens
IPHS	Indian public health standards
IPPI	Intensified pulse polio immunization
IPV	Inactivated polio vaccine
IRC	International red cross
IRLs	Intermediate Reference Laboratories
IRS	Indoor residual spray
ISM	Indian system of medicine
ITN	Insecticide treated bed nets
IUCD	Intrauterine contraceptive device
IUD	Intrauterine device
JE	Japanese encephalitis
JSSK	Janani shishu suraksha karyakram
JSY	Janani suraksha yojana
KFD	Kyasanur forest disease
LBW	Low birth weight
LDL	Low density lipoproteins
LECs	Leprosy elimination campaigns
LEM	Leprosy elimination monitoring

LHV	Lady health visitor
LLIN	Long lasting insecticide nets
LPS	Low performing states
LSD	Lysergic acid diethylamide
MAP	Malaria Action Plan
MB	Multibacillary
MCH	Maternal & child health
MDA	Mass drug administration
MDGs	Millennium Development Goals
MDMP	Mid-day meal programme
MDR-TB	Multi-drug resistant tuberculosis
MDT	Multi-drug therapy
MDT	Multi-drugs therapy of tuberculosis
Mf	Microfilaria
MLEC	Modified leprosy elimination campaign
MMR	Maternal mortality ratio
MNP	Minimum needs programme
MO	Medical Officer
MOPHC	Medical Officer at primary health centre
MOU	Memorandum of understanding
MPO	Modified Plan of Operation
MPW	Multipurpose worker
MRFIT	Multiple risk factor intervention trial
MSM	Men having sex with men
MTCT	Mother to child transmission
MTP	Medical termination of pregnancy
MUFA	Monounsaturated fatty acids
MVA	Manual vaccum aspiration
NACO	National AIDS control organization
NAMP	National antimalaria programme
NBCC	Newborn care corner
NBSU	Newborn stabilization unit
NCCP	National cancer control programme
NCD	Non-communicable disease
NCDC	National centre for disease control
NCDs	Non-communicable diseases
NFCP	National Filaria Control Programme
NFHS	National family health survey
NGO	Non-government organization
NHP	National health policy
NID	National immunization day
NIMH	National Institute for Mentally Handicapped
NIMR	National Institute of Malaria Research
NLCP	National leprosy control programme
NLEP	National leprosy eradication programme
NMCP	National malaria control programme
NMEP	National malaria eradication programme
NMHP	National mental health programme
NNMR	Neonatal mortaliy rate
NNR	Net reproduction rate
NORAD	Norwegian agency for development cooperation
NPAC	National plan of action for children
NPSU	National polio surveillance unit
NPU	Net protein utilization
NRCS	Nutritional rehabilitation centres
NRHM	National rural health mission
NSI	The nutrition society of India
NTCP	National tuberculosis control programme
NTP	National tuberculosis programme
NVBDCP	National vector borne disease control programme
OPV	Oral polio vaccine
ORS	Oral rehydration salts
ORT	Oral rehydration therapy
PB	Paucibacillary
PCD	Passive case detection
PCV-7	Pneumococcal conjugate vaccine

PNDT	Prenatal diagnostic technique act
PPBS	Planning-programming-budgetting system
PPD	Purified protein derivative
PPP	Purchasing power parity
PPTCT	Prevention of parent to child transmission
PPV23	Pneumococcal polysaccharide-non-conjugate vaccine containing 23 serotypes
PRAI	Planning, Research and Action Institute, Lucknow
PTB	Pulmonary tuberculosis
PTCA	Percutaneous transluminal coronary angiography
PTCT	Parent-to-child transmission
PUFA	Polyunsaturated fatty acids
PWB	Patient-wise boxes
RBM	Roll back malaria
RCA	Research-cum-Action projects
RCH	Reproductive and child health
RCT	Randomized controlled trials
RDT	Rapid diagnostic test
RF	Rheumatic fever
RHME	Representative, re-sampled, routine household interveiw of mortality with medical evaluation
RLF	Retrolental fibroplasia
RMP	Rifampicin
RNTCP	Revised national tuberculosis control programme
RR	Relative risk
RTI	Reproductive Tract Infection
SAARC	South asian association for regional cooperation
SACS	State AIDS control society
SAPEL	Special action project for elimination of leprosy
SAR	Secondary attack rate
SARS	Severe acute respiratory syndrome
SC	Sub-centre
SEAR	South-East Asia Region
SEARO	South-East Asian Regional Office
SFD	Small for date baby
SIA	Supplemental immunization activities
SIDA	Swedish international development agency
SMR	Standard mortality ratio
SNCU	Special newborn care unit
SNID	Sub-national immunization day
SRS	Sample registration system
STDs	Sexually transmitted diseases
STI	Sexually transmitted infections
TB	Tuberculosis
TBA	Trained birth attendant
TFR	Total fertility rate
TG	Triglycerides
T-lymphocytes	Thymus-derived lymphocytes
TMFR	Total marital fertility rate
Torch agents	Toxoplasma gondii, rubella virus, ctyomegalovirus and herpes virus
TT	Tetanus toxoid
TU	Tuberculosis Unit
UCI	Universal child immunization
UHC	Urban health center
UIP	Universal immunization program
UN	United Nations
UNDP	United Nations Development Programme
UNESCO	United Nations Educational, Scientific and Cultural Organization
UNFPA	United Nations Fund for population activities
UNICEF	United Nations International Children's Emergency Fund
USAID	The United States Agency for International Development
UT	Union territory
VBDs	Vector borne diseases
VCTC	Voluntary Counselling and Testing Center
VDPV	Vaccine derived poliovirus
VHAI	Voluntary health association of India
VLDL	Very low density lipoproteins
VPD	Vaccine preventable disease
VVM	Vaccine vial monitor
WB	World Bank
WHO	World Health Organization
WPV1	Wild poliovirus type 1
WPV2	Wild poliovirus type 2
WPV3	Wild poliovirus type 3
WTO	World Trade Organization
XDR-TB	Extensively drug resistant tuberculosis
ZDV	Zudavudine

INDEX
